INTRODUCTION

Decades ago, Lewin (1931) criticized psychology for its overreliance on methodologies that were originally designed for studying closed, physical systems. These methods, he warned, were inappropriate for the study of complex, developmental processes. Over 70 years later, the same criticisms continue to be raised with increasing urgency. Specifically, leading theorists (Cicchetti & Cohen, 1995b; Ford & Lerner, 1992; Hinde, 1992; Kagan, 1992; Keating, 1990; Overton & Horowitz, 1991; Richters, 1997) suggest that there is a fundamental incompatibility between developmentalists' organismic, open systems models and the mechanistic research methods with which these models are tested. Developmental psychopathologists have been particularly concerned with their inherited mechanistic paradigm. Many of them have developed heuristically rich, complex models based on open systems concepts, but little headway has been made in finding alternative analytic tools appropriate for testing these models—a predicament Richters (1997) dubbed *the developmentalist's dilemma*.

In this chapter, we suggest that methods derived from dynamic systems (DS) theory may be useful for addressing this dilemma. There are three main objectives: (1) to outline key dynamic systems principles and highlight their commensurability with developmental psychopathologists' core conceptual concerns; (2) to provide a survey of research designs, methodological techniques, and measurement strategies currently being used and refined by developmental DS researchers; and (3) to elaborate on one specific DS method, state space grid analysis and provide several empirical examples using this method. The state space grid approach (Lewis, Lamey, & Douglas, 1999) was developed as a middle road between DS methods that are mathematically demanding on the one hand (and, thus, often inaccessible or inappropriate for developmental psychopathology) and purely descriptive on the other. We have included most DS methods currently available for developmentalists. The methodological techniques and specific examples we have selected were chosen because

An earlier, less detailed version of this chapter appeared in *Development and Psychopathology, 15* (2003). We gratefully acknowledge the financial support of Grant 1 R21 MH 67357 from the National Institute of Mental Health (to D. Pepler and I. Granic) and Grant 410-2003-1335 from the Social Sciences and Humanities Research Council of Canada (to the first author).

they seemed most appropriate for addressing the types of research questions developmental psychopathologists tend to pursue. In the end, however, our main purpose is to provide a clear enough picture of various DS methods to inspire developmental psychopathologists to expand their analytic repertoire and, thus, test their systems-based models more directly.

THE DEVELOPMENTALIST'S DILEMMA

Before proceeding to discuss DS theory and its methodological bag of tricks, we will review briefly the strong rationale for developing new methods for the field of developmental psychopathology (also see Cicchetti & Cohen, 1995b). Developmental psychopathologists have adopted an organismic, holistic, transactional framework for conceptualizing individual differences in normal and atypical development (e.g., Cicchetti, 1993; Cicchetti & Cohen, 1995a, 1995b; Cummings, Davies, & Campbell, 2000; Garmezy & Rutter, 1983; Sameroff, 1983, 1995; Sroufe & Rutter, 1984). These scholars often frame their models in terms of organizational principles and systems language. The systems theories that inform these models include General Systems Theory (Sameroff, 1983, 1995; von Bertalanffy, 1968); Developmental Systems Theory (Ford & Lerner, 1992); the ecological framework (Bronfenbrenner, 1979); contextualism (Dixon & Lerner, 1988); the transactional perspective (Dumas, LaFreniere, & Serketich, 1995); the organizational approach (Cicchetti & Schneider-Rosen, 1986; Erickson, Egeland, & Pianta, 1989; Garmezy, 1974; Sroufe, 1979, 1986; Sroufe & Rutter, 1984); the holistic-interactionistic view (Bergman & Magnusson, 1997); and the epigenetic view (Gottlieb, 1991, 1992). As a class of models, these approaches focus on process-level accounts of human behavior and on the context dependence and heterogeneity of developmental phenomena. They are concerned with the equi- and multifinality of development, the hierarchically embedded nature of intrapersonal (e.g., neurochemical activity, cognitive and emotional processes), interpersonal (e.g., parent–child relationships; peer networks), and higher order social systems (e.g., communities, cultures). They are also fundamentally concerned with the mechanisms that underlie change and novelty (as well as stability) in normal and clinically significant trajectories.

As a result of inadequate measurement techniques, however, the complex developmental models informed by the language of systems thinking remain largely untested (Richters, 1997). For example, in the field of childhood aggression, a number of leading scholars have become concerned with highlighting the heterogeneity of aggressive youth and advocating the development of causal models that recognize the equifinality of aggression (e.g., Cicchetti & Richters, 1993; Hinshaw & Zupan, 1997; Moffitt, 1993). But it remains difficult to test these models because most of our current research methods and analytic techniques (e.g., regression analysis, t-tests, path analysis) rely on strategies that aggregate overtly similar subjects into one group or another (e.g., aggressive and nonaggressive children) to conduct group-level statistical analyses. Thus, although we may know that aggressive children show the same behavioral pattern for very different reasons (e.g., abuse, permissive parenting, marital conflict, birth of a new sibling), this variability cannot be systematically addressed because multivariate analytic strategies carry an a priori assumption of within-group homogeneity. This is not just a niggling statistical detail. Several leading methodologists have argued that in most cases, these assumptions are completely unfounded and have likely led to serious misinterpretations of data (e.g., Hinshaw, 1999; Lykken, 1991; Meehl, 1978; Richters, 1997).

How did this gap between methods and models come about? Numerous past critics (e.g., Hinde, 1992; Meehl, 1978; Lykken, 1991; Overton & Horowitz, 1991; Richters, 1997) have pointed to psychology's original sin for an explanation: in an effort to gain credibility and align itself with the hard sciences, psychology appropriated the methods and analytic techniques of mechanistic, nineteenth-century physical sciences. This paradigm is inappropriate for the study of self-organizing, active, reactive, interactive, and adaptive organisms (i.e., the stuff of psychology). The irony is that psychology's embrace of this mechanistic paradigm came at the same time as the physical and biological sciences were advancing a radically new one—one based on open systems concepts (Overton & Horowitz, 1991; Richters, 1997).

For some domains of psychology, adopting techniques from statistical mechanics may not be as paralyzing as it has become for developmental psychology (Thelen & Smith, 1994, 1998; Thelen & Ulrich, 1991; van Geert, 1998a, 1998c). At the heart of developmental questions, however, is how things *change*. By what process do novel structures (e.g., formal operational thought) or skills (e.g., emotion regulation, walking, language) emerge? The pioneers of developmental science (i.e., Piaget, Vygotsky, Werner) concerned themselves with the pursuit of abstract laws or properties that govern development: the structural explanation of how development unfolds (Cicchetti, 1990; van Geert, 1998a, 1998c). As van Geert (1998a) argued, however, change and the emergence of novelty may no longer be the focus of contemporary developmental psychology. This state of affairs can be traced to the

"adoption of a statistics that was designed for different purposes, namely distinguishing populations characterized by some special feature . . . and estimating the linear association between the variance of some independent variable on the one hand and a dependent variable on the other" (p. 146). The adoption of such statistics seems to have missed the point of the original questions laid out by the founding scholars of developmental science (Thelen & Smith, 1994; van Geert, 1998a).

Developmental psychopathology, having grown in part from this tradition, inherited the same schism. But developmental psychopathology also grew from several other disciplines that were less hampered by this statistical baggage. Embryology (e.g., Kuo, 1967; Spemann, 1938) was one of these disciplines (for a review, see Cicchetti, 1990). In the pursuit of understanding normal embryological functioning, "early embryologists derived the principles of a dynamically active organism and of a hierarchically integrated system that were later used in investigations of the processes of abnormal development within the neurosciences, embryology, and experimental psychopathology" (Cicchetti, 1990, p. 4). These insights formed the basis for the organizational approach in developmental psychopathology. Another avenue of influence comes from the discipline of ethology, which views the organism as a comprehensive whole and advocates a "multidomain, multidiscipline approach to psychopathology," (Cicchetti, 1990, p. 19), an approach that is at the heart of developmental psychopathology (see also Hinde, 1983).

Interestingly, developmental psychopathology also shares its roots with the founders of child psychoanalysis (e.g., A. Freud, Klein, Winnicott, Bowlby, Erikson) who, like Piaget and Vygotsky, formalized theories based on detailed observations of children in their natural environments (Cicchetti, 1990; Cicchetti & Cohen, 1995b). These original, individual-based, ethnographic methods, however, are rarely applied in contemporary research (but see Cicchetti & Aber, 1998, for an exception). Yet it seems clear to us that these organismic, systems-oriented roots lend themselves well to DS principles and the methods they suggest.

As it stands now, the field of developmental psychopathology seems to be at an impasse. On one hand, some scholars have suggested that systems approaches to studying development have provided an interesting metaphor, but offer little more (Cox & Paley, 1997; Reis, Collins, & Bersheid, 2000; Vetere & Gale, 1987). Thus, one option is to give up the grail, abandon this well-intentioned enterprise, and build simpler, more linear models that can be tested with established statistical rigor. Another option is offered by Richters (1997): "Resolving the developmentalist's dilemma will require more than a recognition of the inadequacies of the existing paradigm. It will require intensive efforts to develop indigenous research strategies, methods, and standards with fidelity to the complexity of developmental phenomena" (p. 226). In the closing of his essay, Richters offered some general instructions for how this new generation of studies should proceed: (1) There should be intense focus placed on understanding individuals and the causal structures that underpin specific individuals' development, with particular attention paid to well-characterized exemplars (i.e., nonextreme) cases; (2) no single method should be held as superior or inferior (e.g., case based, variable based, cross sectional, longitudinal, historical, ethnographic), but instead methodological pluralism should be encouraged and may vary in degree depending on the phenomena investigated; (3) ritualized hypothesis testing should be generally abandoned for more exploratory, creative approaches that emphasize the discovery process; and (4) a narrow focus on explained variance and prediction should take a secondary role to explanatory power. These directions provide the springboard from which to consider the potential contributions dynamic systems methods can make to addressing systems-inspired models.

PRINCIPLES OF DYNAMIC SYSTEMS

Developmental psychopathologists will be familiar with most of the concepts in DS theory because of their long-standing familiarity with systems concepts in general. Nevertheless, for the sake of clarity and precision, we believe it is important to delineate this framework from the systems approaches mentioned previously (Lewis & Granic, 2000). Formally, a *dynamical system* is a set of mathematical equations that specify how a system changes over time. The various patterns and processes that emerge from this set of equations rely on a technical language originally developed in the fields of mathematics and physics. The concepts derived from this mathematical framework comprise the principles of dynamic systems approaches. The terms that are most commonly associated with this framework include attractors, repellors, state space, perturbations, bifurcations, catastrophe, chaos, hysteresis, complexity, nonlinearity, far from equilibrium, and so on. Thus, what we refer to as *dynamic systems* theory or *dynamic systems* principles is a *meta-theoretical* framework (Witherington, 2007) that encompasses a set of abstract principles that have been applied in different disciplines (e.g., physics, chemistry, biology, psychology)

and to various phenomena (e.g., lasers, ant colonies, brain dynamics) at vastly different scales of analysis (from cells to economic trends and from milliseconds to millennia).

Consistent with developmental DS theorists (e.g., Fogel, 1993; Lewis, 2000; Thelen & Smith, 1994, 1998), we use the term *dynamic systems* to refer to the systems themselves (not the equations) that change over time. DS principles provide a framework for describing how novel forms emerge and stabilize through a system's own internal feedback processes (Prigogine & Stengers, 1984). This process is known as *self-organization* and refers to the spontaneously generated (i.e., emergent) order in complex, adaptive systems. In fields as various as physics (e.g., Haken, 1977), chemistry (e.g., Prigogine & Stengers, 1984), biology (e.g., Kauffman, 1993), and neuroscience (Freeman, 1995), DS principles have proven essential for providing process-level accounts of the structure and organization of system behavior, and changes in that structure over time (Lewis & Granic, 2000).

DS principles resonate with most systems concepts in general. Dynamic systems approaches to development emphasize the multiple reciprocal interactions among system elements that are hierarchically nested and mutually influential. The context or ecology in which the system is embedded is critical for understanding a dynamic system's behavior (Hollenstein, 2012). Also consistent with various systems perspectives, development is conceptualized as movement toward greater levels of complexity through the interplay between positive and negative feedback cycles (Lewis & Granic, 1999b).

As will become clear from our selection of methods, we are most strongly influenced by the pioneering work of Esther Thelen, Linda Smith, Alan Fogel, Marc Lewis, and Paul van Geert—developmental psychologists who brought DS principles to the attention of the field at large. Because our focus is on methods specifically, a thorough theoretical discussion of DS concepts and their relevance to developmental science is precluded; thus, the reader is strongly encouraged to supplement the current theoretical introduction with reviews by Thelen & Smith (1994, 1998), Fogel (1993), and Lewis (2000; 2011). In the following discussion, we highlight some key principles and then move on to their methodological implications.

State Space, Attractors, and Dynamic Stability

Dynamic, self-organizing systems share several key properties, some of which have already been mentioned. One key feature of open systems is that, although theoretically they have the potential to exhibit an enormous number of behavioral patterns, they tend to stabilize in a limited range of these possibilities. Stable patterns emerge through feedback among many lower order (more basic) system elements; these emergent patterns are referred to as *attractors* in DS terminology. In real time, attractors may be understood as absorbing states that "pull" the system from other potential states. Behavior moves in a trajectory across the state space toward these attractors. Over developmental time, attractors represent recurrent patterns that have stabilized and are increasingly predictable. As noted by Thelen and Smith (1994), all developmental acquisitions can be described as attractor patterns that emerge over weeks, months, or years.

As recurring stable forms, attractors are often represented topographically as valleys on a dynamic landscape (Figure 16.1). The deeper and wider the attractor, the more likely it is that behavior falls into it and remains there, and the more resistant it is to small changes in the environment. *Repellors*, or states that the system tends to avoid or be repelled from, are represented as hills on this landscape—states in which the system cannot rest. As the system develops, a unique *state space*, defined as a model of all possible states a system can attain, is configured by several attractors and repellors. Critically, living systems are characterized by *multistability* (Kelso, 1995); that is, their state space (i.e., behavioral repertoire) includes several coexisting attractors. Contextual constraints probabilistically guide behavior toward a particular attractor at any given moment in time.

As we will see later, the concepts of state space, attractors and multistability have informed several research designs and methodologies in recent years. The operationalization of these principles, either graphically, mathematically, or heuristically, have helped DS researchers uncover previously undetected behavioral variability, as well as the processes by which this variability stabilizes into unpredicted, but nevertheless stable, attractor patterns.

Interrelations Between Time Scales

DS researchers are always fundamentally concerned with the interplay between different time scales. From a DS

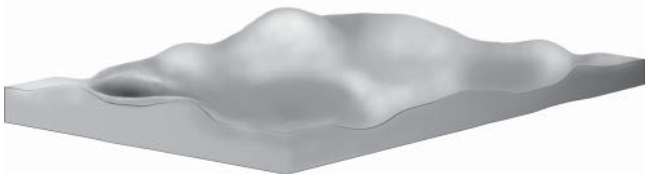

Figure 16.1 A state space with three attractors (the wells) and one repellor (the hill). *Source:* Hollenstein T. (2007). State space grids: Analyzing dynamics across development. *International Journal of Behavioral Development*, *31*, 384–396.

perspective, the same principles of change and stability can be applied at the moment-to-moment scale (real time) as they can to developmental time (weeks, months, years). The interplay between nested time scales is constant and reciprocal (Thelen & Smith, 1994, 1998). Self-organization at the real-time scale constrains self-organization at the developmental scale, which in turn constrains real-time behavior (van Gelder & Port, 1995). Thelen and Smith (1998) elaborated:

> . . . each behavioral act occurs *over time* . . . but every act changes the overall system and builds a history of acts over time . . . Habituation, memory, learning, adaptation, and development form one seamless web built on processes over time—activities in the real world. (p. 593)

Research designs based on DS principles almost always measure behavior on at least two time scales (Hollenstein, 2012; Hollenstein, Lichtwarck-Aschoff, & Potworowski, 2013). The manner and extent to which the two or more levels of analysis are related to each other is subsequently examined. Thus, DS-informed studies often involve collecting real-time, observational data over repeated sessions in a longitudinal design such that moment-to-moment behavioral patterns, and changes in those patterns, can be traced along a longitudinal trajectory (Lee & Karmiloff-Smith, 2002).

Hierarchically Embedded Levels of Organization

Dynamic systems are not only nested processes in time, they are also coupled hierarchically. Mechanisms in development may be defined at different levels of organization (e.g., physiological, emotional, behavioral, social) and these levels are thought to be embedded, linked by feedback processes, and mutually constraining. Importantly, DS theorists insist that no level of organization is any more "basic" or "primary" in terms of causality. Thus, for example, from a DS perspective, neural processes are accorded no higher causal privilege than psychological or social processes. Instead, "descriptions of change of many components are needed so that multilevel processes and their mutual interactions can be fully integrated . . . Moreover, explanations at every level must be consistent and ultimately reconcilable (Thelen & Smith, 1998, pp. 596–597). This view of causality contrasts with most approaches in psychology (but see Cicchetti & Dawson, 2002a).

Rather than simple linear relationships, DS researchers often understand relations among multiple levels in terms of *circular causality* (Hakens, 1977). Circular causality suggests that interactions among lower order elements provide the means by which higher order patterns emerge and these emergent attractors exert top-down influences to maintain the entrainment of lower level components. Developmental psychopathologists, particularly those in the neurosciences, have recently become interested in understanding how different levels of analysis can shed light on typical and atypical development (Calkins & Fox, 2002; Cicchetti & Dawson, 2002b; Nelson et al., 2002). The DS meta-theoretical framework, with concepts such as circular causality, may help researchers organize their findings and parsimoniously integrate the various theories about different levels into one coherent model. Indeed, it is likely that common dynamic principles of self-organization govern different levels of organization (e.g., neural, cardiac, emotional, behavioral, societal); if this is so, then synergistic DS methods that can be applied similarly at different levels of analysis will provide a powerful means by which integrative models can be developed and empirically supported. The extent to which real- and developmental-time scales are interrelated and hierarchical levels of organization are embedded is further clarified when considering perturbations and their relation to phase transitions.

Perturbations, Phase Transitions, and Nonlinear Change

Through the amplification properties of positive feedback, nonlinear changes in the organizational structure of a dynamic system can be observed. As shown in Figure 16.2, these abrupt changes are referred to as phase transitions and they occur at points of bifurcation, or junctures in the

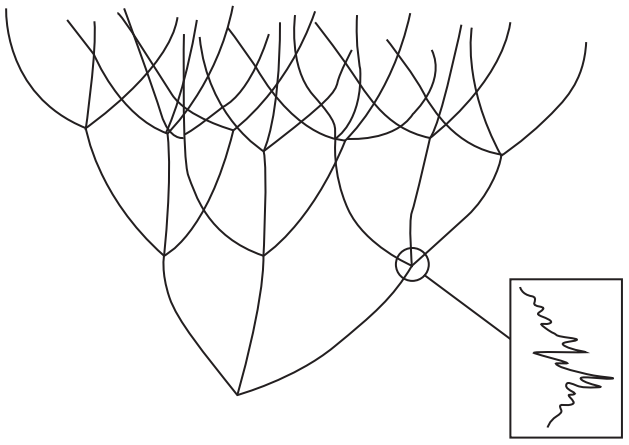

Figure 16.2 Alternative developmental trajectories. Phase transitions occur at regular junctures in development. Increased variability at phase transitions is shown in magnified segment. *Source:* From Lewis, M. D. & Douglas, L. (1998) A dynamic systems approach to cognition-emotion interactions in development (pp. 159–188), in *What Develops in Emotional Development?* M. F. Mascolo & S. Griffins (Eds.). New York: Plenum Press.

system's development. At these thresholds, small fluctuations have the potential to disproportionately affect the interactions of other elements leading to the emergence of new forms. Novelty does not have to originate from outside the system; it can emerge spontaneously through feedback within the system. During a phase transition, systems are extremely sensitive to perturbations. Between these points, however, self-organizing systems tend toward coherence and stability.

Phase transitions are characterized by interrelated changes in real and developmental time. In developmental time, periods of stability and relative predictability are followed by a period of disequilibrium in which established patterns are destabilized. After this period of flux, developmental systems restabilize and settle into new habits of interactions. Corresponding to this developmental profile, real-time behavior during a phase transition is more variable, flexible, and more sensitive to perturbations; behavior may change from one state to another frequently, and is less likely to settle in any one state for very long (Thelen & Ulrich, 1991). However, before and after the phase transition, real-time behavior is far less variable; only a small number of behavioral states are available to the system, and once the system settles into one of these stable patterns, it tends to remain there for an extended time period (e.g., Thelen & Smith, 1994; van Geert, 1998b; van der Maas & Molenaar, 1992).

DS researchers have used the concept of perturbations on a real-time scale as an empirical design innovation to test the relative stability of observed behavioral patterns. Perturbations have the potential to abruptly push the system from one stable pattern to another (Fogel, 1993; Thelen & Smith, 1994). But this is only a potential—whether and how a system becomes reorganized is determined by its underlying structure. A perturbation can be considered a focal aspect of environmental context, and sensitivity to perturbations (which typifies phase transitions) is a special case of the more general sensitivity of dynamic systems to their contexts—a sensitivity that changes with system development gradually or more suddenly. Thus, context-sensitivity for DS researchers is not just "a form of jargon for anything environmental, as if invoking the term suggests compliance with current scientific and conceptual canons" (Boyce et al., 1998, p. 145). DS researchers systematically observe changes in behavior, as it varies with contextual forces, to infer the underlying structure of the system (e.g., Fogel, 1993; Granic & Lamey, 2002; Lewis & Granic, 1999b, 2000; Thelen & Smith, 1994; Thelen & Ulrich, 1991).

On a developmental scale, principles of nonlinear change, phase transitions and perturbations have been most often used for the explicit purpose of studying the structural profile of developmental transitions (e.g., Fogel & Thelen, 1987; Granic, Hollenstein, Dishion, & Patterson, 2003; Lewis, 2000; Lewis & Granic, 2000; Thelen & Ulrich, 1991; van Geert, 1991, 1994). Neo-Piagetian scholars such as van der Maas and Molenaar (1992) have used a particular type of dynamic model, the cusp-catastrophe model, to represent the nonlinear nature of stage transitions. Borrowing from Gilmore (1981), they suggest a number of criteria or flags that can be used to operationalize a transition. Among the transition flags are: a sudden jump from one parameter value to another, evidence of hysteresis (i.e., when the same conditions elicit different behaviors, depending on the immediate prior history of the system), anomalous variance, and an increased sensitivity to perturbations. Transitions in motor, cognitive, linguistic, and socioemotional development have been successfully modeled by the application of variants of these flags (Case et al., 1996; Lewis et al., 1999, 2004; van der Maas & Molenaar, 1992; van Geert, 1991, 1994). Structural changes in parent–adolescent interactions at the early adolescent stage transition have also been shown to exhibit the properties of a phase transition (Granic, Dishion, & Hollenstein, 2003; Granic et al., 2003).

Many of the DS concepts described here are clearly resonant with other systems views. But as a point of distinction, we suggest that four principles central to the DS framework are either neglected or less emphasized in other approaches and hold great promise for new empirical directions in developmental psychopathology. First, DS theory is primarily concerned with the emergence of novelty through the process of self-organization, whereas, with some notable exceptions (Ford & Lerner, 1992), most of the emphasis in more general systems views is on mechanisms of stability (i.e., negative feedback processes, for examples see cybernetic models; Granic, 2000; Lewis & Granic, 1999a). Second, although systems views may acknowledge the nonlinear nature of change in developmental systems, this is the hallmark principle of DS approaches to development and it has led to the exploration of radical new strategies such as catastrophe theory (e.g., van der Maas & Molenaar, 1992), developmental growth curve modeling (van Geert, 1991, 1994), and the study of phase transitions (e.g., Thelen & Ulrich, 1991; Thelen & Smith, 1994). Third, variability represents critical information in DS research. Conventionally, variability in developmental data has been seen as the result of measurement error and, thus, a source of noise that should be minimized. DS theorists make a radical departure from this approach: variability is considered a rich source of information, indexing impending change and "the essential ground for exploration and selection" (van Geert & van Dijk, 2002, p. 342). Methods that

tap changes in variability are a mainstay of DS researchers (e.g., Thelen & Ulrich, 1991; van Geert & van Dijk, 2002). Finally, DS theorists are fundamentally concerned with the interrelations between time scales of development and put a great deal of emphasis on understanding the unfolding patterns of real-time behavior (Thelen & Smith, 1998). This final principle is critical in terms of its methodological implications, and it is most often ignored in other systems frameworks.

In the following sections, we describe a number of dynamic systems approaches to research designs and measurement strategies. To limit the scope of our review, we will not be discussing the exciting work emerging in the neurosciences (a field that has long embraced the principles of self-organization). This work is clearly relevant to developmental psychopathologists and the reader is referred to the neuroimaging methods detailed in the most recent volume of *Developmental Psychopathology,* 3rd edition. We also spend less time proportionally on the mathematical modeling techniques than the graphical, descriptive and statistical ones because we believe that the latter group of methodologies are generally more accessible and may ultimately prove more appropriate for the types of research questions put forward by developmental psychopathologists.

We first review some general DS-informed research design concepts and strategies put forth by Thelen and her colleagues (e.g., Thelen & Smith, 1994; Thelen & Ulrich, 1991). Next, we discuss the types of data most suitable for DS analyses. We follow by providing a list of graphical techniques and quantitative strategies appropriate for the analysis of real-time and developmental data; these descriptions are supplemented with actual or hypothetical examples relevant to developmental psychopathologists. We also highlight the limitations inherent in some of the techniques and argue that a newly developed DS methodology, state space grid analysis, may help address a number of these weaknesses. The last part of this paper provides a detailed description of the state space grid technique, which combines graphical methods with statistical analysis in a way that maintains fidelity to DS concepts. We provide several examples of programs of research and individual studies that have used variations of this approach.

RESEARCH DESIGN STRATEGIES INFORMED BY DS PRINCIPLES

Thelen and her colleagues have explicitly laid out a methodological strategy for developmental psychologists interested in dynamic analyses (Thelen & Smith, 1994, 1998; Thelen & Ulrich, 1991). Their strategy includes six steps:

1. *Identify the collective variable of interest*. A collective variable must be an observable phenomenon (not a construct or latent variable) that captures the coordination of the elements of a multidimensional system. Because Thelen and Ulrich (1991) were interested in motor development, they chose the phasing of alternating steps as the collective variable that condensed the many aspects of interlimb coordination. Changes in this collective variable can then be tracked over developmental time. This is the first challenging step—unlike physical systems, it is difficult to identify a collective variable in psychological systems. Extensive developmental observations and experiments are recommended as a first step toward this goal. An example relevant to developmental psychopathologists might be the observed intensity of a child's oppositional behavior—a collective variable that may capture the coordination of mood states, arousal level, appraisal processes, and so on (these processes themselves would need to be assessed in multiple contexts).
2. *Describe the attractors for that system*. This involves mapping the real-time trajectory of the collective variable in various contexts across different developmental periods and identifying its relative stability. Thus, the contexts in which a child's oppositional behavior is most stable can be identified (e.g., with a parent), as well as the contexts in which such behavior is less stable (i.e., more easily changed), is never observed, or is rarely observed. High stability indicates an attractor state.

   Attractor states may be tested by examining the variability of the collective variable given particular contexts (e.g., how often does the child become oppositional in response to a request to clean up at home versus at school). Additional features can help identify attractors as well. First, an attractor may be present if behavior takes a relatively short time to return back to the state once it has left it (latency to return to the attractor is short). Second, behavior tends to stay in an attractor for longer durations than other states. Third, it should take a much larger perturbation to move behavior out of a strong attractor state relative to weaker attractors or other regions of the state space. This last point is also a reminder that living systems exhibit multistability. The implication is that researchers should attempt to identify all or many of the attractors that are available to a particular system. Then the critical question becomes: what are the conditions under which behavior will gravitate toward one attractor versus another? Returning to

the oppositional child, most conventional approaches focus on describing and predicting the child's negative, destructive behavior. But a DS approach would map out not only the negative behavior attractors but also the interested/engaged states, the joyful and the neutral states, and, importantly, the pathways to and from these attractors. Although these latter states may be weaker attractors, the goal would be to track the contextual conditions under which the child moves from more positive to more negative attractors and vice versa to get a better picture of the underlying dynamics of this child's behavioral landscape.

3. *Map the individual developmental trajectories of the collective variable*. This step requires collecting observations at many time points in a longitudinal design (also see Fogel, 1993). The density of time samples depends on the developmental period in question (i.e., in infancy, weekly observations may be needed, whereas in late childhood data collected monthly might suffice; Fogel, 1993). Then, developmental profiles can be graphed on a case-by-case basis and the similarities and differences among profiles can be described. Stable (i.e., fixed or cycling) segments of the time series denote an attractor. At this stage, the multifinality and equifinality of developmental trajectories can be discovered. Some developmental profiles may start out looking similar and then, from very small differences that become amplified, trajectories may diverge. Other developmental profiles may show the opposite pattern of different initial conditions being "pulled" toward a particular attractor. The key at this stage is to create individual profiles rather than aggregate across subjects; otherwise, the variability inherent in developmental processes will be obscured. As described in more detail later, an alternative to averaging developmental profiles is to cluster individual trajectories into groups that share profile characteristics (Hollenstein, Granic, Stoolmiller, & Snyder, 2004). In developmental psychopathology, a similar point has been emphasized by researchers doing case-based, or person-oriented, analysis (e.g., Bergman & Magnusson, 1997).
4. *Identify phase transitions in development*. As described earlier, transitions in development are characterized by increased variability, a breakdown of stable patterns, and the emergence of new forms. The various catastrophe flags described earlier can help researchers identify points of transition. Transition periods are critical to mark because they allow researchers to access and manipulate mechanisms underlying change. This point is particularly relevant for developmental psychopathologists interested in clinical interventions. For instance, there may be normative stage transitions in children's development during which, as a result of normal maturational processes, the coordination among system elements begins to break down, previous attractors are destabilized, and there is an increased potential for new patterns to emerge (e.g., Granic, Hollenstein, Dishion, & Patterson, 2003; Lewis & Granic, 1999b; Lewis, Zimmerman, et al., 2004; Lewis et al., 1999). Clinical interventions may have their greatest impact if they are targeted at these sensitive periods.

   The idea of fluctuations at phase transitions is not new to developmental psychopathology, although it has rarely been pursued empirically. One fascinating example comes from a study conducted by Inhelder (1976), who found that some mentally retarded children's skill performance oscillated between various stage levels prior to reaching a new stage. Interpreting these findings, Cicchetti (1990) suggested two possibilities: the processes accounting for these children's development may simply be different from those of normal children, or, more intriguingly, "their oscillations are universal phenomena that become visible only in retarded children because of the slower nature of their development" (p. 16; see also Cicchetti & Sroufe, 1976).

   Bertenthal (1999) further emphasizes the importance of variability at phase transitions. He suggests that variability is not just an index of change, but actually helps *drive* change. According to Bertenthal, "variability offers flexibility, which drives development following Darwinian principles. Principles of variation and selection cause successful behaviors to be stored and repeated more frequently than the less successful" (van Geert & van Dijk, 2002, p. 343; Thelen & Smith, 1994). The theoretical implications for understanding intervention effects are compelling. Successful interventions may *induce* a phase transition during which behavioral, cognitive and affective variability increases, providing the fertile ground from which more positive, or less distressing patterns can be selected, repeated, and potentially stabilized. This possibility can be empirically verified by using simple descriptive statistics (e.g., looking for an increase in standard deviations and variance, a breakdown of correlations, and changes in entropy; additional measures of variance are described later) or more formal techniques (described in the section on state space grids).
5. *Identify control parameters*. In DS language, control parameters are the "agents of change." The purpose

of tracking the collective variable across different contexts and developmental transition points is to ultimately identify the mechanisms underlying processes of change. Control parameters are not simply independent variables (although they can be considered a special type). Usually, independent variables are static measures that are assumed to have a linear effect on outcomes. Control parameters are better understood as mediators with special properties; continuous and small changes in the values of these parameters can result in abrupt threshold effects on a collective variable. Moreover, these nonlinear changes occur at different values depending on whether the control parameter is increasing or decreasing. For example, through fine-grained longitudinal observations, Thelen and Ulrich (1991) were able to identify overall changes in muscle mass as the control parameter that was related to improvements in infants' treadmill stepping. In many areas of developmental psychopathology, however, this step is the most difficult, because psychological systems are incredibly complex and the problem of identifying and manipulating one or very few causal mechanisms is often insoluble. Moreover, a control parameter may not always be something that *can* be manipulated (e.g., temperament, parental depression). Nevertheless, DS researchers urge us to at least keep the concept in mind.

6. *Manipulate control parameters to experimentally generate phase transitions*. Despite its difficulty, this suggestion is a familiar one to many developmental psychopathologists. Simply put, once a causal factor has been inferred from careful descriptive analysis, it should be experimentally manipulated to examine whether it does indeed trigger the expected shift in behavior. In this respect, intervention studies are an exceptional avenue for testing the role of specific control parameters in developmental psychopathology (c.f. Dishion, Bullock, & Granic, 2002; Dishion & Patterson, 1999; Eddy & Chamberlain, 2000; Forgatch & DeGarmo, 1999). One of the best examples of following this proposed strategy comes from the work on the etiology and treatment of aggressive behavior. For instance, based on decades of microsocial observational studies with families, coercion has been identified as a mediating causal mechanism underlying the etiology of childhood aggression (e.g., Patterson, 1982; Patterson, Reid, & Dishion, 1992). To confirm this supposition experimentally, Forgatch and DeGarmo (1999) investigated the impact of a randomized control intervention that aimed to decrease the rate at which parents engaged in coercive interchanges. Results confirmed that, indeed, changes in coercion resulted in decreases in children's aggressive behavior. From a DS perspective, parental discipline strategies, for example, could have been the control parameter that was adjusted through the intervention (i.e., coercion decreased).

Despite the advantages of Thelen and colleagues' approach, many researchers are likely to experience some problems with implementing their general strategy. First, it requires collecting continuous time-series data (e.g., physiological data, behavioral observations coded in real time); this type of data is time-consuming and expensive to collect. More importantly, time-series data may not capture the type of information pertinent to many developmental psychopathologists. Second, and related, unlike motor or cognitive development in which some skill or task performance increases or decreases quantitatively over time, psychopathology may not involve such graded changes (Lewis & Granic, 1999b; Lewis et al., 2004). Instead, the development of psychopathology may better be characterized as emergent patterns of interconnected changes in different domains (e.g., biological, cognitive, emotional) that are nonlinearly related to one another and change qualitatively, as well as quantitatively (i.e., it is often categorical or ordinal). We will address this issue at greater length when we discuss state space grid analysis and the limitations it addresses in this regard.

SUITABLE DATA FOR DS ANALYSES

Developmental psychopathologists collect several types of data that are appropriate for DS analyses. Because a DS perspective is fundamentally about changes in time, the most important data characteristic is that there are multiple measurements over time. Thus, questionnaire data collected at one time point would be inappropriate for tapping dynamic processes (e.g., Cummings et al., 2000). Below, we list the four types of data that lend themselves most easily to DS analyses and name some examples of analytic techniques that can be conducted. These techniques are then explained in more detail in the following section. Table 16.1 lists the techniques, the appropriate data types for each, and provides some (non-exhaustive) examples of empirical papers that have applied the various DS methods.

1. *Observational data—continuous*. Includes data obtained in time units less than one second; these data are often composed of physiological measures. The density of

data points allows for the more sophisticated techniques adopted from the natural sciences, where this type of data is most common. These techniques are often based on time-series analysis and include the domain of elaborate mathematical models based on coupled equations and dynamical catastrophe models. Quantitative measures of chaos—Lyupanov exponents, entropy, correlational dimensions, and so on—can also be derived from such continuous data. Furthermore, all of the methods available to the other data types are available with this kind of data, either as time series or summaries of time series.

2. *Observational data—discrete*. Includes live and taped observational data that are converted to codes along

time units as small as one second. These codes can represent the sequence of behavior for one or more subjects and are typically inappropriate for time-series techniques unless they have a sufficiently large number of data points. By applying DS graphical techniques such as state space grids, Karnaugh maps, recurrence plots, and phase plots, the temporal patterns embedded in the temporal sequence can be uncovered. These data can be used to identify attractors, perturbations, phase transitions, and other DS patterns.

3. *Longitudinal data—short*. This type of data can include, for example, hourly/daily/weekly self-report measures (e.g., diary or beeper studies), repeated phone interviews, or repeated observational sessions (e.g., therapy sessions). The time points may be frequent enough to allow the use of some of the real-time techniques available to the first type of data or may be analyzed using techniques applicable to developmental-time data (type 4).
4. *Longitudinal data—long*. Includes any combination of the above data types collected at different time points that may span weeks, months, or years. The main distinction from data type 3 is the time span between first and last measurements. Data collected in three or more waves is often used to depict change, growth, or intervention effects and a variety of DS methods including state space grid analysis, dynamic growth modeling, developmental profile analysis, and catastrophe modeling can be applied. Developmental phase transitions are detectable through the application of these techniques.

DS METHODS

Real-Time Measures

As most teachers of research methods and statistics in general will insist, eyeballing your data is an important part of the analytic procedure. For DS researchers, graphical techniques provide the core of their analytic armament. Perhaps because dynamic systems theory is a descriptive framework and because it aims to describe phenomena in geometric terms (recall our discussion of behavioral trajectories on a state space), plotting data is the mainstay of DS researchers (Abraham, Abraham, & Shaw, 1992; Norton, 1995). A number of these real- and developmental-time graphical methods can be complemented with various quantitative tools. We have grouped the following methods under the rubric of real-time methods because that is how they have tended to be applied. But it is important to note that because the same principles of self-organization apply at different time scales, many of these techniques can be adapted easily to study phenomena in developmental time.

Case Studies

Perhaps the one common recommendation DS researchers offer is to start with fine-grained, real-time observations of the phenomenon of interest and follow this behavior across a significant developmental period. One of most basic first steps toward this end is the careful description of case studies. Fogel's (1990, 1993) research on mother–infant relationship processes is exemplary in this respect. His microgenetic research relies heavily on detailed descriptions of videotaped interactions, as they proceed in real time. He uses these case histories as a "means to seek patterns in sequences of action in a context, in both real and developmental time scales" (Fogel, 1990, p. 343). Metaphors based on DS principles serve as guides for identifying dynamically stable dyadic patterns (frames) and changes in those patterns across development. Although these narrative descriptions are rich in detail and provide ample fodder for generating hypotheses, they are intentionally not quantified at this stage. As such, this method does not address developmental psychopathologists' search for quantitative techniques to test their conceptual models. To quantify impressions from case studies and statistically test hypotheses, Fogel and his colleagues used a number of techniques (for a review, see Lavelli, Pantoja, Hsu, Messinger, & Fogel, 2005) including simple descriptive statistics, individual growth curve modeling (Fogel, 1995; Hsu & Fogel, 2001), conditional probabilities (Hsu & Fogel, 2003a), and event history analysis (Hsu & Fogel, 2003b) to measure the emergence, strength, and dissipation of parent–infant attractors. These methods are discussed in later sections of this chapter.

Time-Series Analysis

The group of methods that fall under time-series analysis offer some useful approaches to characterizing the real-time behavior of dynamic systems. The methods include visual representations as well as simple statistics that can be used to examine the qualities and predictive power of hypothesized attractor patterns. To illustrate the utility of this approach, we summarize the rationale, time-series procedures, and results from a study by Granic and Dishion (2003) using data from antisocial and normal friendship interactions.

Past research suggested that antisocial adolescents can be distinguished from their prosocial counterparts by the

extent to which they engage in reciprocal deviant talk (e.g., talk about stealing, lying; Dishion et al, 1995, 1996, 1997). Observational studies showed that antisocial peers had a higher mean duration of deviant talk (or "rule-break" talk) than prosocial peers. Central tendency measures, however, do not speak directly to the processes underlying these interactions. Moreover, they obscure potentially critical temporal patterns. To come closer to a process-level explanation, we began by conceptualizing deviant talk as an attractor for antisocial, but not prosocial peers (Granic & Dishion, 2003). Our interest was not in examining whether one group showed more deviant talk than another, but whether, over the course of an interaction, antisocial adolescents became stuck in an antisocial talk attractor. That is, did they become increasingly engrossed in topics organized around deviancy? One way to explore this hypothesis was to examine whether, as the interaction unfolded and antisocial dyads repeatedly returned to talking about deviant topics, they also spent increasingly more time in that deviant pattern. Time-series procedures were well suited for our purposes.

Deviant (or rule-break talk) and normative talk was coded continuously from videotaped interactions between best friends. Time-series plots were derived for each dyad, with the duration of each deviant talk bout on the y axis and each successive bout represented along the x axis (Figures 16.3 and 16.4). The slope of that time-series (i.e., the standardized beta) was then calculated using simple regression analysis. Slope is one parameter that can

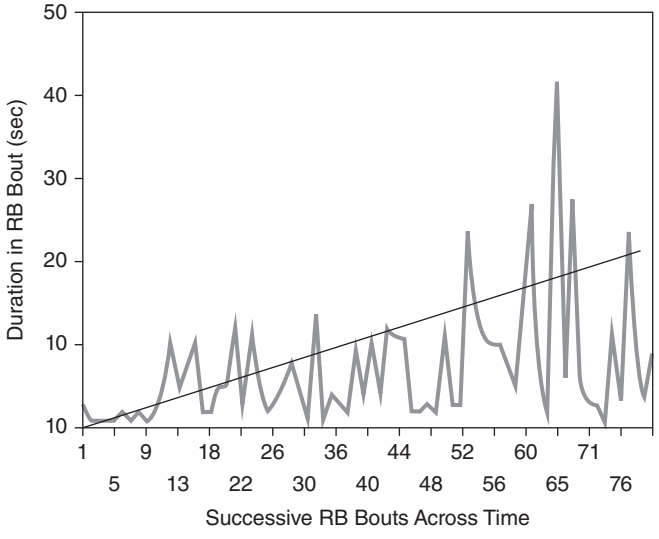

Figure 16.3 Example of a time-series for an antisocial youth with a positive rule-break bout slope. *Source:* From Granic, I., & Dishion, T. J. (2003). Deviant talk in adolescent friendships: A step toward measuring a pathogenic attractor process. *Social Development, 12*, 314–334.

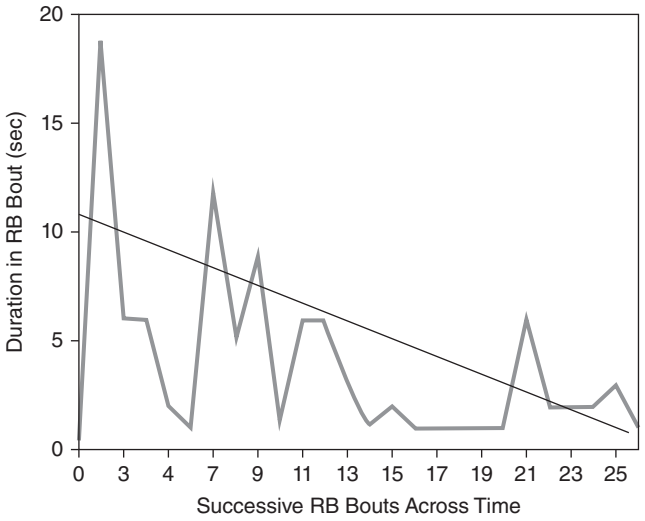

Figure 16.4 Example of a time-series for a normal adolescent with a negative rule-break bout slope. *Source:* From Granic, I., & Dishion, T. J. (2003). Deviant talk in adolescent friendships: A step toward measuring a pathogenic attractor process. *Social Development, 12*, 314–334.

be identified from a time series. Others include cyclicity (number of cycles in a series, length of cycles) and autocorrelation. We used the slope measure in a somewhat unique way to highlight a key DS principle. If deviant talk indeed functioned as an attractor for antisocial youth, then we expected to see a time-series that showed a positive slope, as exemplified in Figure 16.3. If it was not an attractor for a dyad, then we expected to see a time-series with either a flat or negative slope, as shown in Figure 16.4. Thus, each participant was assigned a deviant-talk slope value and these values were then used in regression analyses to predict antisocial outcomes 3 years later.

The results are summarized in Table 16.2. As hypothesized, the attractor index (the slope of deviant talk bouts) predicted serious authority conflict (e.g., number of arrests, school expulsion) and drug abuse three years later. These results were particularly strong because they remained statistically significant even after controlling for arguably the three most predictive risk factors in childhood: prior deviant behavior, family coercion, and deviant peer associations in childhood. We also showed that the mean duration of deviant talk bouts was not sufficient to predict these outcomes. Thus, these findings showed that reconceptualizing deviant talk as an attractor is not simply an exercise in relabeling; there are specific hypotheses that are engendered by applying this approach. From a DS perspective, although the frequency and amount of time spent talking about deviant topics are important, even more critical is the process by which dyadic behavior continues

TABLE 16.2 Regression Results Predicting Adolescent Authority Conflict and Substance Abuse in Midadolescence from the Strength of the Deviant Talk Attractor in Early Adolescence

	Antisocial behavior		Substance abuse	
Steps in regression	R^2 change	Total R^2	R^2 change	Total R^2
1. Child deviancy	.28[3]		.16[2]	
2. Child family coercion	.02	.30	.02	.18
3. Child deviant peer affiliation	.07[2]	.36	.06[1]	.24
4. Attractor strength (slope of deviant talk)	.05[2]	.41	.06[1]	.30

[3] $p < .001$.

to be drawn toward, and held, in this deviant pattern. Both antisocial and prosocial peers discussed deviant acts and breaking rules. It was the dynamic (time-based) characteristics of these conversations—as revealed by a simple time-series analysis–that differentiated antisocial and normal friendships.

Bakeman and Gottman (1997) used a similar analytic approach to analyze data from marital couples' interactions using this time-series technique, except they plotted the interevent interval between successive displays of negative affect (i.e., the time in between one negative affect and the next, across the interaction). They showed that, for distressed dyads, the time between each negative affect display became shorter and shorter over the course of the conversation (i.e., return time to the attractor became shorter over the interaction). Thus, negative affect was an absorbing state for distressed, but not happily married, couples.

Recurrence Quantification Analysis

Recurrence quantification analysis (RQA; Marwan, Carmen Romano, Thiel, & Kurths, 2007; Webber & Zbilut, 2005) is a nonlinear time series analysis technique that has found many applications across scientific disciplines (Webber, Marwan, Facchini, & Giuliani, 2009). We here discuss an adaptation of the RQA for categorical data because these are likely the kind of data that clinical researchers and developmental psychopathologists will use. In studies of behavior observation the data are usually time series that represent the occurrence of a particular type of behavior at a particular point in time. In that respect the data may be characterized as a temporal sequence of unordered behavioral responses, that is, as categorical time-serial data. RQA quantifies the temporal order in time series at each and all possible timescales or delays during the observation. RQA for categorical data is based on the dichotomous distance matrix, in which it is noted for all behaviors when each behavior that occurs at some instance in the time series also occurs at some other instance in that same time series, either earlier or later. Such a reoccurring value is called a recurrent point, which is the basic measure of RQA. A two-dimensional graphical representation of this matrix is called the recurrence plot. In a recurrence plot all the points are plotted that represent recurring values (Figure 16.5). When recurrent points occur in subsequent time steps in the time series, line or

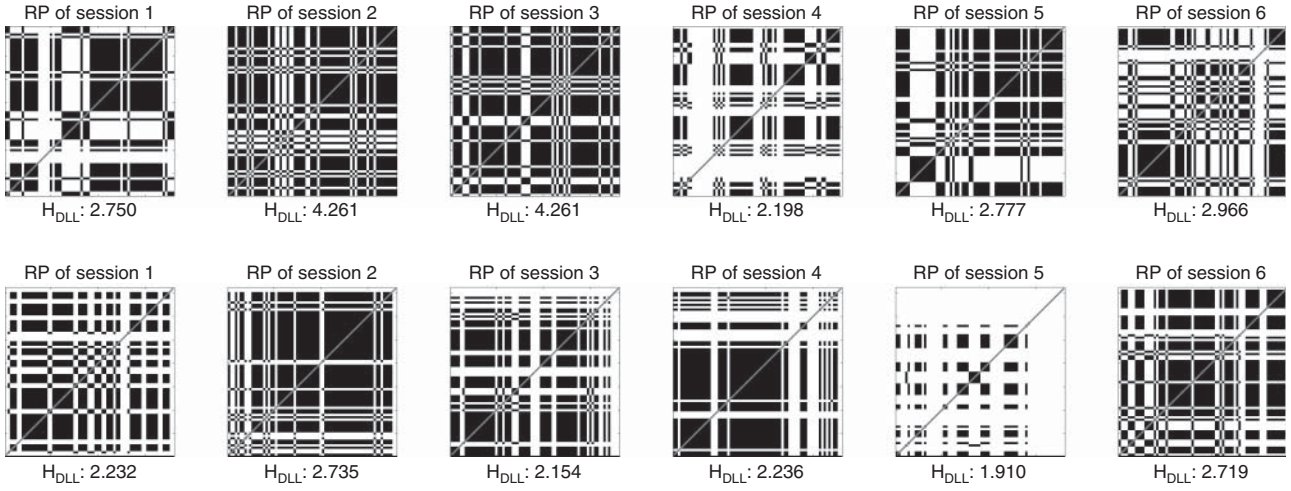

Figure 16.5 Recurrence plots of two exemplary dyads across observation sessions. Gray diagonal line represents the line of identity. Dyad in the upper row is showing the peak in entropy and dyad in the lower row does not show a peak in entropy. *Source:* With permission to reprint figure from Dr. David Pincus, Nonlinear Dynamics, Psychology, and Life Sciences (NDPLS) Permissions Editor. A characteristic destabilization profile in parent–child interactions associated with treatment efficacy for aggressive children. *Nonlinear Dynamics, Psychology, and Life Sciences*, *16*, 353–379.

block structures emerge in the recurrence plot. These structures reflect that certain sequences of values are repeatedly occurring (i.e., recurring) over time. One could say the dyad returns to a previously displayed pattern of behaviors. The (average) length of such structures indicates how stable (or prominent) this particular pattern of behavior is in the interaction. Note that various structures that are located at different regions in the recurrence plot may represent different behavioral patterns, not only in duration but also in terms of their particular constituent behaviors (i.e., content). As can be seen in Figure 16.5, the recurrence plots are symmetrical around the line of identity (see grey diagonal line). This line represents the time series as it was observed. Several different measures can be derived from those recurrence plots (e.g., determinism, predictability, entropy, trapping time, and divergence; for an elaborate discussion see Webber & Zbilut, 2005).

In a recent study Lichtwarck-Aschoff and colleagues (2012) applied RQA to examine changes in entropy to investigate whether successful treatment outcomes were associated with having gone through a phase transition. Repeated mother–child interactions of children being treated for aggression were analyzed over the course of a 12-week treatment period (treatment was a combined Cognitive Behavioral Therapy and Parent Management Training). Interventions can be seen as causing perturbations to a (mother–child) system. To be effective in eliciting a qualitative shift to a more healthy attractor state, treatment should trigger increasing levels of variability and disorganization up until the point that the system can no longer resist and is forced to give up the old maladaptive attractor state (see also Granic & Patterson, 2006). The temporary change in the natural variability of the system, the increased within-system variability, is functional in the sense that it allows the system to explore new patterns and configurations (De Weerth & Van Geert, 2002; Thelen & Smith, 1994; Van Geert & Van Dijk, 2002). After the destabilization phase, the system settles down again, organizing into a new (dynamically) stable regime of the system (Van Orden, Kloos, & Wallort, 2009). Thus, it was expected to find a change pattern, signaling an impeding phase transition that was characterized by a temporary increase in random fluctuations or breaking down of stable recurring patterns of dyadic behaviors following the start of the intervention.

The RQA measure that quantifies this particular aspect of the dynamics is the Shannon entropy of the distribution of diagonal line structures in the recurrence plot (see also Stephen et al., 2009; Stephen, Dixon, & Isenhower, 2009). A subsequent latent class growth curve analysis

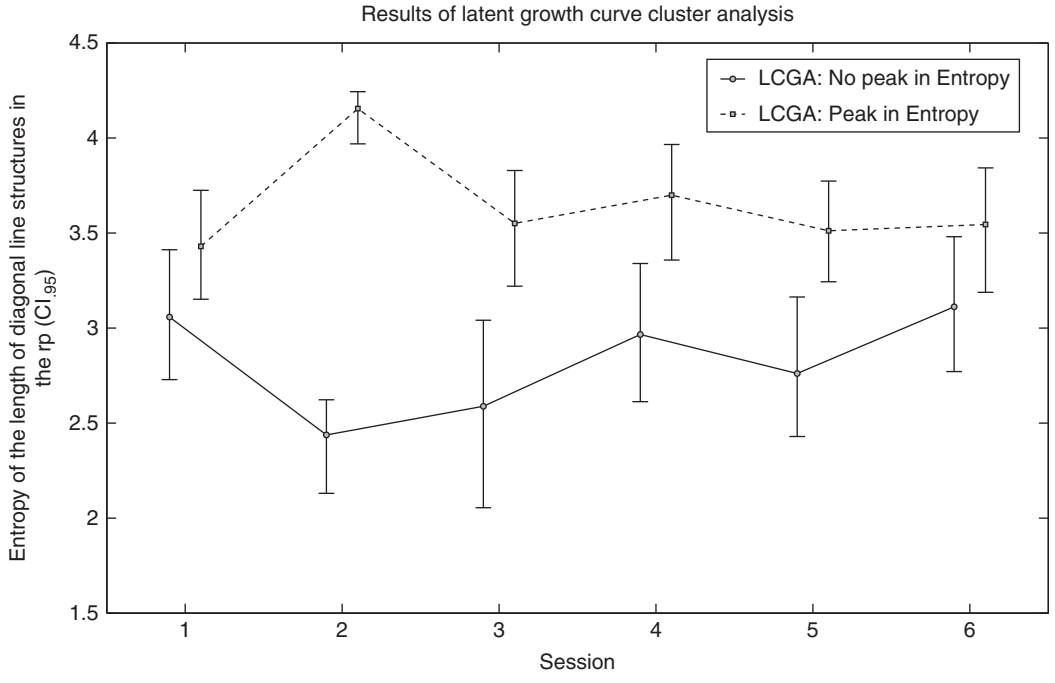

Figure 16.6 Result from the LCGA analysis of values for entropy of the diagonal line structures in the recurrence plots of each dyad across the six observation sessions (95% confidence intervals are based on 15,000 bootstrap replications). *Source:* With permission to reprint figure from Dr. David Pincus, Nonlinear Dynamics, Psychology, and Life Sciences (NDPLS) Permissions Editor. From Lichtwarck-Aschoff, A., Hasselman, F., Cox, R., Pepler, D., & Granic, I. (2012). A characteristic destabilization profile in parent–child interactions associated with treatment efficacy for aggressive children. *Nonlinear Dynamics, Psychology, and Life Sciences*, *16*, 353–379.

on the sequences of entropy values revealed two distinct classes of dyads, with one class showing a clear peak in entropy over the six measurement points (Figure 16.6). The latent class membership variables showed a significant systematic relationship with observed dyad improvement (as rated by clinicians). The class with the peak in entropy over the sessions consisted largely of treatment improvers (Figure 16.6). Further analysis revealed that improvers and nonimprovers could not be distinguished based on content-specific changes (e.g., more positivity or less negativity during the interaction). This study thus supports the DS view that treatment functions through creating the conditions that facilitate dynamic reorganization (Schiepek, 2009) rather than a linear input–output model in which a series of equally powerful weekly interventions force the system to a particular reaction or end state.

Event History Analysis

As can be seen with the previous examples, and others to follow, it is not always necessary to invent new methods to explore DS-inspired hypotheses. Another method that can help researchers explore the different characteristics of attractor processes is event history analysis. A variant of survival analysis and Cox regression models, hazard analysis calculates transition rates (also called hazard rate or latency to recurrence) of state changes in categorical time series (Allison, 1984; Blossfeld & Rohwer, 2002; Stoolmiller & Snyder, 2006). The rate of transition in and out of a behavioral state (e.g., tantrum, laugh) can be interpreted as an index of attractor strength. Several other measures including the frequency, duration, total time, and the time since the last occurrence of the behavior can be included in these models to determine the absorbing quality of a hypothesized attractor. Furthermore, time-invariant (e.g., gender, child's problem behavior, maternal depression) and time-varying (e.g., changes in context, affective behavior of the partner, time) covariates can be added to these models as predictors of the transition rate.

Figure 16.7 shows a schematic diagram of an interactive sequence. The bottom plot line represents the time line of events being modeled. In this case, there are only two states possible: in the proposed attractor or out of that state. This example illustrates a dichotomous response set, but it is not necessary for event streams to be binary for event history analyses; multiple states can be modeled as competing risks. The three episodes in this example correspond to the start and end times of the behavior of interest. The first episode lasts 14 seconds, the second episode lasts 18 seconds, and the third is 14 seconds long. With just this information it is possible to model the probability of transitions into the attractor as one instantaneous rate, and the duration since the last episode can be added into the model as a predictor.

Presumably, whatever behavior is being researched does not occur in a vacuum. There is the nature of the task at hand, the influence of other people and even factors unique to each individual that must be considered. Thus, as shown by the time-varying covariates (upper 2 lines) in Figure 16.7, more elaborate models can tease apart the relative contributions of various covariates to the recurrence of a particular behavior. In a series of studies Snyder,

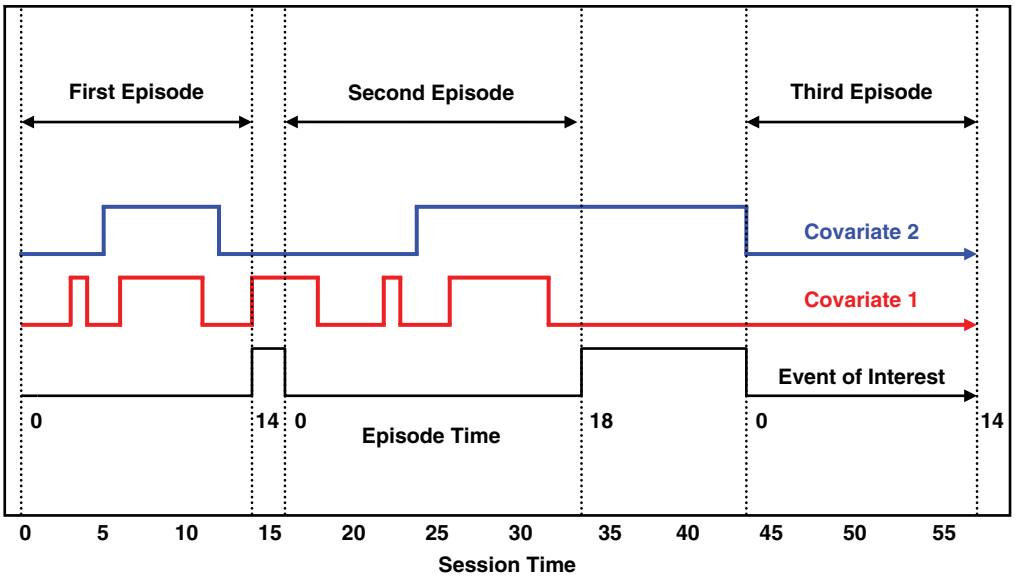

Figure 16.7 Schematic diagram of a behavioral interaction with some of the components that can be analyzed through event history analysis. See footnote 1. *Source:* Adapted from: Snyder, J., Stoolmiller, M., Wilson, M., & Yamamoto, M. (2003). Child anger regulation, parental responses to children's anger displays, and early child antisocial behavior. *Social Development, 12*, 335–360.

Stoolmiller, and colleagues have used hazard analyses to investigate a wide range of parameters of the state space for emotion response states in parent–child interactions (with clinical and control children), and the relationship of those parameters to time fixed and time-varying covariates. In the first study a repeated-events, competing-risks hazard analysis was used to estimate the return time for child anger displays using both time fixed and time-varying predictors (Snyder, Stoolmiller, Wilson, & Yamamoto, 2003). In state space terms, return time may be interpreted as an indication of the strength of the anger attractor state. Results showed that the longer it took a child to down regulate an anger display, the more quickly that anger display would reoccur. Further, the authors found that the speed of child's return time to an anger display (at time $t + 1$) was amplified by the cumulative frequency of parent negative responses (a cumulative time-varying covariate). Using a time-fixed covariate, poor parental discipline was also related to a faster return rate to anger. Individual differences in the hazard for return to anger displays were also associated with children's conduct problems (as rated by teachers and parents).

In a second study a complementary hazard analysis was applied to investigate the relationship of the child's hazard to move to an angry start state (given mom was aversive) to a neutral state to child overt and covert antisocial behavior (Dagne & Snyder, 2009). It was found that children high on overt antisocial behavior relative to the average child were slower to move to a neutral emotional state. Children high on covert antisocial behavior relative to the average child, in contrast, were faster to move to a neutral affective state. Additionally, maternal self-reported trait hostility (a time-fixed covariate) was associated with a reduced hazard for mothers to move from an aversive to a nonaversive state in the context of child anger displays, which indicates that hostile mothers are slower to cool down in negative encounters with their children.

In a third study Stoolmiller and Snyder (2006) examined the hazard of children's transition from a neutral state to positive, sad/fearful, or angry emotion states when their mothers initiated an aversive behavior. It appeared that on average, the hazard for children to move to a negative emotion state (either angry or sad/fearful) increased as mothers initiated an aversive behavior. Children high on antisocial behavior were significantly slower to move from neutral to sadness/fear, but there was no relationship between antisocial behavior and children's hazard to move from neutral to anger.

Finally, in a recent study Snyder, Bockman, and Stoolmiller (2012) investigated the hazard of down-regulating anger and sadness/fear relative to neutral in relation to children's antisocial behavior. The results showed that overt and covert antisocial behaviors were associated with an underutilization and rapid down regulation of sadness/fear relative to neutral. Further, children in overt antisocial behavior also showed an overutilization and slow down regulation of anger relative to neutral affect.

These studies demonstrate that hazard analysis is a sophisticated and flexible mathematical approach to model a system's behavior by capturing temporal and well as sequential shifts among various emotion states. These models can be run on individuals or pooled across an entire sample and it is possible to model the state space of emotion displays from a dyadic as well as an individual perspective (Stoolmiller & Snyder, 2006). It is not only the potential of identifying predictors of attractor strength that is the appeal for DS researchers but the fact that *time* itself can be used as a predictor. Probably the most difficult process of event history analysis is restructuring data into the appropriate format. Despite this difficulty, we expect that event history analysis will be used with increasing frequency as a method to model attractor dynamics.

Fourier analysis or *spectral decomposition* can be used for finding periodicities (i.e., cyclic patterns) in time-series data such as those used in phase plots. In general, this procedure treats a time-series as a conglomerate wave form, breaks it down into a collection of pure waves (each of uniform frequency), and identifies the most prominent waves (Schroeck, 1994). Newtson (1994, 1998) used this method to analyze the coupled dynamics of dyadic interactions. The relative amplitudes and temporal synchrony of these behavior waves were associated with the degree of mutuality or competition in interpersonal relationships. In other applications, different types of attractors including oscillating and periodic attractors can be identified. For behavioral scientists, however, this method has its limitations. Like all time-series procedures, it requires the researcher to collapse meaningful categorically coded observational data into one or very few continuous dimensions (e.g., Bakeman & Gottman, 1997). For example, most observational coding schemes used in developmental psychopathology (e.g., SPAFF—Gottman, McCoy, Coan, & Collier, 1996; FPC—Dishion, Gardner, Patterson, Reid, & Thibodeaux, 1983; MAX—Izard, 1979) code discrete behaviors like *contempt, argue, belligerence,* and *whining*. To conduct Fourier analysis, these codes would have to fall along a single dimension (i.e., intensity of negativity). This type of collapsing is often either conceptually unfeasible or it is unappealing because of its oversimplification.

Karnaugh Maps

Inspired by synergetics, a type of dynamics developed by Haken (1977), Dumas, Lemay, and Dauwalder (2001) adapted this technique from Boolean algebra to study parent–child interactions. Karnaugh maps depict all possible combinations of up to four binary variables in one table or grid. A simple two-variable Karnaugh map is basically a four-cell cross-tabulation of event frequencies with one dichotomous variable to each axis. Three- and four-variable maps are somewhat more complicated. Figure 16.8 shows a schematic four-variable Karnaugh map. Each variable (A, B, C, and D) can have a value of 0 or 1, and each is displayed on one side of the square table (bottom, left, top, and right). Each cell in the map can be represented as a unique combination of the binary values of the four variables. Thus, a Karnaugh map is a state space of all possible states of the system and represents the relative frequencies in each state. Dumas and colleagues extended the application of these maps by plotting the transitions between states to depict temporal patterns across the space.

In their study, Dumas et al. (2001) plotted every minute of six-hour home observations according to four parent and child dichotomous variables that included control, compliance, aversive and positive behavior. Each behavior was plotted according to the four-variable configuration and successive behaviors were connected by a trajectory. They were primarily interested in comparing the maps of clinically referred dyads with randomly selected controls. They analyzed the recurring transactions (i.e., attractors) that were found most frequently in each group and aggregated these findings graphically on one summary Karnaugh map. Their results showed differences in transactional patterns between the groups, mostly involving positive interactions and cycles of maternal control and child compliance.

In addition to the graphical depiction of interaction sequences, the authors computed a complexity index that was designed to quantify each map on a continuum from completely deterministic to completely random. They found that all maps, regardless of group assignment, were neither random nor deterministic but somewhere in between. While this approach was unique and interesting (particularly from a methodological standpoint), from a DS perspective there is no reason to think that social behavior, especially in dyads with a rich history, is ever random or ever completely determined. Nevertheless, the complexity measure has a great deal of potential. For example, it might be used to determine whether stable coercive parent–child interaction patterns become less determined (i.e., the old attractor patterns break down) during developmental transitions such as puberty.

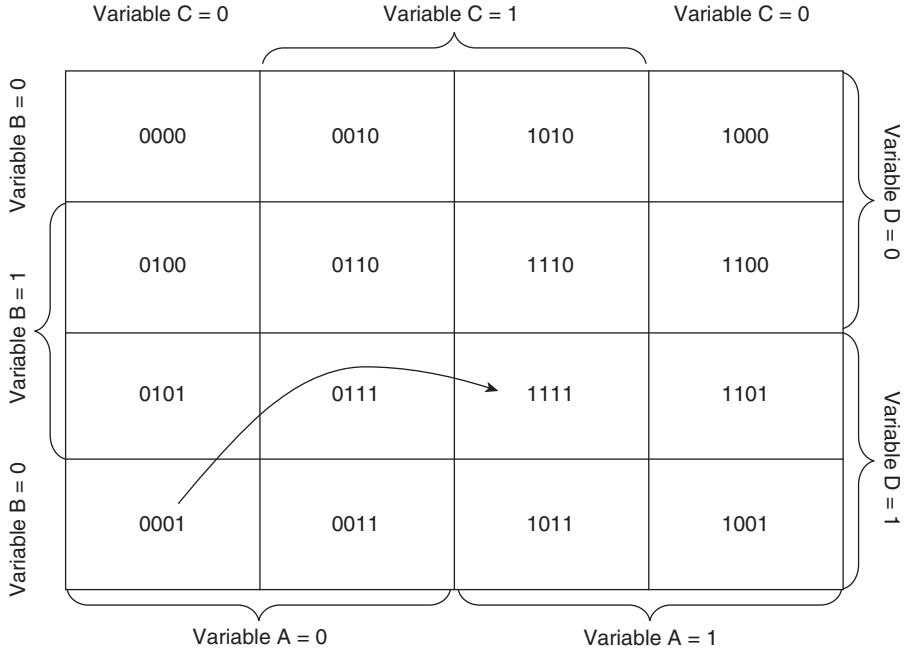

Figure 16.8 Schematic of a four-variable Karnaugh map. Each cell is a unique combination of four binary variables. The arrow shows a sample transition from one state, where only variable D is present (i.e., only D equals 1), to the next state in time, where all 4 variables are present (i.e., all equal 1).

A very similar approach has been applied in a study by Lichtwarck-Aschoff and colleagues (2009) to investigate intraindividual variability on a different time scale: diary entries of mother–daughter conflict episodes. Indices of the episode-to-episode variability in emotional states (i.e., composition of emotions) were used to assess whether girls in conflictual mother–daughter relationships would show signs of being stuck in a certain (emotional) conflict pattern. In line with research on real-time variability (Granic et al., 2007; Hollenstein & Lewis, 2006; Hollenstein et al., 2004) it was hypothesized that conflictual relationships would be characterized by a lack of variability across episodes. However, in contrast to real-time measures, which reflect changes from one emotion to another moment by moment, diary entries describe emotional states of entire conflict episodes that can be composed by several different emotions. Thus, changes in a multidimensional (emotional) space have to be assessed. (Note that this emotional space is therefore different from the state space grids developed by Lewis et al., 1999, described later in this chapter.)

To do so, measures based on symbol dynamics (Daw, Finney, & Tracy, 2003), which actually extends the Karnaugh maps in terms of the dimensions that can be included, were developed. The basic rationale behind this approach is the transformation of the system's trajectory or geographical movement in time into a sequence of specific symbols, corresponding to partitions within the state space (Dale & Spivey, 2005). First, the emotional state space for each girl was computed, which contained all her reported emotions across all her conflict episodes. Second, within each girl's state space all the emotional states that represented how a girl felt during a particular conflict were described. An emotional state could take the form of a single emotion or a combination of (many) different emotions. The mathematical representation of every state consisted of a particular string of ones (emotions being present) and zeros (emotions being absent). One way to assess the emotional variability was to count the number of different emotional states across all conflict episodes. Further, the Hamming distance (Hamming, 1950; Teşileanu & Meyer-Ortmanns, 2006) was used to compute additional variability measures. The Hamming distance calculates the distance (absolute difference) between two symbolic strings (here, two emotional states). The distance between the emotional states then indicates how much the emotional states differ from each other and in this sense represents the variation between the states (compare this with the intergrid distance used by Lewis et al., 1999). In this study a sequential and an overall Hamming distance was computed.

As expected the results revealed an inverse U-shaped relation between girls' emotional variability and the number of conflicts. Thus, the emotional variability decreased when relationships became highly conflictual. Moreover, girls who showed limited variability in emotional states across conflict episodes tended to attach the same emotional state to divergent conflict topics. For these girls, many different conflict contexts still induced the same emotional state. In other words, these girls felt the same, no matter what. Hence, the conflictual mother–daughter systems seemed to be stuck or frozen into a small number of emotional states and had lost their situational sensitivity (i.e., sensitivity and flexibility in response to different conflict topics).

Karnaugh maps and symbol dynamics hold considerable promise for several reasons. First, because these methods allow for the representation of behavior in multiple dimensions (including time), a great deal of the complexity in (interactional) behavior can be nicely captured. In case of the Karnaugh maps the temporal quality of dyadic behavior is also maintained and can be tracked easily through visual inspection. Moreover, the systemic properties of dyadic interactions are kept intact, in contrast to conventional methods that often require analyzing each dyad member separately. The approach described in the Lichtwarck-Aschoff et al. (2009) study offers the possibility to study changes and variability of multidimensional behavior which is especially relevant for studies on larger time scales where measures often reflect some aggregated unit of analysis (retrospective reports of conflict episodes rather than real-time presentations of emotions). However, some limitations need to be addressed before these techniques can be applied to a broad range of behavioral data. One problem is that data have to be collected or converted into dichotomous variables that occur concurrently. Developmental psychopathologists are often interested in data that cannot be meaningfully transformed into dichotomous values; continuous or categorical data cannot be adequately captured with these techniques. Also, these methods do not provide direct quantifiable tests of the strength of (dyadic) patterns, nor opportunities for comparing patterns. In this respect, the new developments in state space grid analysis may provide some promising avenues. Some of the quantitative measures that may be derived from state space grids may also be applicable to Karnaugh maps.

Coupled Equations

Most generally, this method refers to the use of paired equations derived from two synchronized time-series

that produce parameters that describe the underlying dynamics of a system. The use of coupled equations may involve mathematically demanding procedures and often require fine-grained time-series data or simulated data. One particularly successful application in the field has been the work of John Gottman and colleagues, who used coupled differential equations to model the dynamics of marital couples and to predict from those dynamics couples who will remain married or end up divorcing (Gottman, Coan, Carrere, & Swanson, 1998; Ryan, Gottman, Murray, Carrere, & Swanson, 2000). They also used this method to study how peer interactions influence the behavior of developmentally delayed versus normal children (Gottman, Guralnick, Wilson, Swanson, & Murray, 1997) and parent–infant interaction (Gottman, Murray, Swanson, Tyson, & Swanson, 2002).

Gottman and colleagues' modeling procedures, based on mathematical biology, are an attempt to mathematically formalize theoretical assertions made by general systems theorists such as von Bertalanffy (1968). Their model itself represents a theory about the mechanisms and dynamics of marriage. Their approach is to model maritial interactions using the mathematics of difference and differential equations. These equations express hypothesized mechanisms of change over time. Gottman and colleagues offered their model of marital interactions as a first attempt to create an explanatory theory of marriage; they recognize the value of cycling from theory development to modeling to experiments and back to theory development. As the authors comment, "The theory may be dead wrong, but it is precise" (Gottman et al., 2002, p. 67).

The modeling process is guided by posing two questions: (1) What are the steady states; and (2) which of these states are stable (i.e., the attractors) and which are unstable (i.e., repellors)? The first step is to set up the phase space such that each axis represents a variable corresponding to each participant. (This procedure is not the same as the one we described earlier in lag-1 phase plots.) The next step was to identify the steady states by graphing the null clines, curves in phase space for which variables stay constant. These curves help to determine the steady states by partitioning the phase space into regions where changes in each variable are increasing or decreasing.

Gottman et al.'s (2002)'s technique uses a time-series of coded observational data to create an equation for each person in the interaction. For this method, Gottman et al. uses variables that are codes or categories of codes that fall along a single continuous dimension from very negative to very positive with neutral in the middle. Equations are created to reflect the theoretical presumption that one person's behavior at time t is a function of his or her own behavior at time $t - 1$ as well as the other participant's behavior at time $t - 1$. Thus, there is an uninfluenced and an influenced factor in each equation that determines the behavior at each time t. The uninfluenced component is what each person brings to the interaction independent of the other. The uninfluenced set point can be thought of as a temperamental factor that is assumed to be the attractor a person, left on his or her own, will eventually approach. Mathematically, this is denoted by a parameter that represents the rate of change toward the uninfluenced set point, also called emotional inertia, plus a constant that is specific to the person. The influenced component is a mathematical function representing the other person's previous behavior. These functions can be used to plot curves that describe the degree of influence based on one assumption: positive behavior influences positively and negative behavior influences negatively. Thus, the equations for a husband, H, and wife, W, are

$$W_{t+1} = r_1 W_t + a + I(H_t)$$
$$H_{t+1} = r_2 H_t + b + I(W_t)$$

where r is the emotional inertia, a and b are constants specific to the individual, and I is the influence function. These equations are then manipulated to estimate the parameters and to determine the uninfluenced and influenced set points. Plotting both of the null clines (the curves for which the values of the variables remain constant) in phase space allows for the identification of stable steady states—the points where the two curves intersect.

Consider the example in Figure 16.9a, which shows a bilinear null clines for a husband and wife. There is one positive and one negative stable state, or attractor, for this couple (the circles at the intersection of the two null clines).

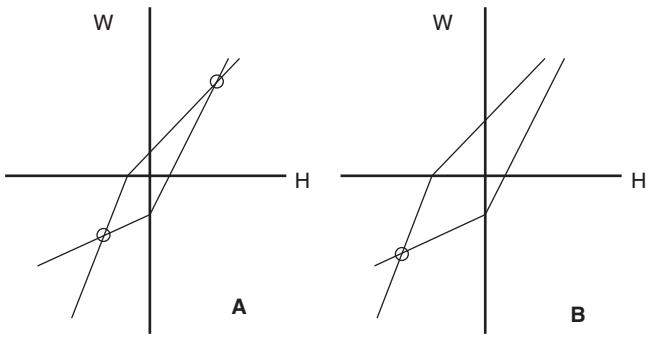

Figure 16.9 Null clines and the stability of steady states. Steady states are circled and represented by the point at which the null clines intersect. *Source:* Adapted from Gottman, J. M. (2002). *The mathematics of marriage: Dynamic nonlinear models*. London, UK: MIT Press.

Over the course of the interaction their behavior is drawn to one or the other of these attractors. One of the interesting uses of this modeling technique is its depiction of how a system exhibits sensitivity to initial conditions and how marriages can change over time. For example, situations at work may lead the husband to feel a lot of stress and he may begin to express this stress in his interactions with his wife. This would be reflected in a change in the parameter b in the model that corresponds to the husband's uninfluenced state, or what he brings to the interaction. A change in this constant shifts his influence function to the left (Figure 16.9b) to the point where the positive attractor no longer exists. Thus, this type of modeling can distinguish between superficial change (i.e., a move to different stable state) and deeper change (i.e., a fundamental change in the influence function that eliminates or adds a stable state to the marital couple's behavioral repertoire).

Gottman and colleagues (2002) have used this basic model and more elaborated versions to identify mechanisms related to specific types of marriages. Some couples only have one stable steady state, if it is positive the marriage is happy, if it is negative the marriage is unhappy. Typically, the situation is more complex. Happy couples also tend to have both positive and negative attractors. In fact, high influence and high inertia couples tend to have multiple steady states and thus will most likely have at least one negative attractor. It may be the relative strengths of these attractors that best distinguish distressed and nondistressed couples.

Gottman and colleagues' approach to mathematical modeling seems to hold exciting potential for developmental psychopathologists who are interested in understanding social processes of various kinds. For example, their model can be easily adjusted to simulate interactions that have different types of power imbalances: parent–child interactions, therapist–client sessions, sibling interactions, bully–victim relations, and so on. Developmental psychopathologists have constructed detailed theoretical models that hypothesize specific influence functions among social partners (e.g., coercion processes in families with aggressive children, authoritative parenting, and anxiety-disordered children). Gottman et al.'s approach challenges scholars in the field to translate these theories into mathematically specified mechanisms. This approach may be particularly rewarding if developmental principles can be formalized and included in these endeavors.

Nonlinear Dynamics

These methods are derived from mathematical procedures in physics and other sciences that aim to measure and model nonlinear phenomena (Abraham, Abraham, & Shaw, 1990; Heath, 2000; Norton, 1995). The simplest of these is nonlinear regression wherein the parameters are exponential functions or the predictive combinations are not simply additive. Other applications from this area are those related to chaos theory (Newell & Molenaar, 1998). One can use nonlinear dynamic techniques to find the embedding dimension, entropy, determinism, recurrence, or fractal dimension of any time series of sufficient length and sufficient precision. This class of techniques is typically applied to continuous time-series data (type 1), often physiological. For those developmental psychopathologists who are increasingly collecting this sort of data (e.g., heart rate, skin conductance, neural activity), this class of methods holds a great deal of promise, particularly if there are reasons to hypothesize nonlinearities. Moreover, there are many software packages available for free or at minimal cost that can calculate these measures for any appropriate time series. The challenge, therefore, lies not in the calculation but in the psychological interpretation of these measures.

There are a number of diverse applications of this class of techniques. One of the main reasons for using these methods is to determine the degree of orderliness, complexity, or predictability in the behavior of a given system. One example in developmental psychopathology comes from the work of Dishion, Nelson, Bullock, and Winter (2004). They applied a technique that calculated the degree of complexity of peer interactions, in the hopes of characterizing and differentiating prosocial versus antisocial peer interactions. The authors drew upon information theory and applied Shannon's entropy measure (Shannon & Weaver, 1949) as an index of the degree of disorganization, uncertainty, or information in a dyadic interaction. In information theory, uncertainty and information are related because "information about an unknown event is more useful as one knows less about the event" (Wickens, 1989, p. 231). For example, if 100% of a set of communications is of one type (e.g., deviant talk), there is total certainty and no information is conveyed from one communication to another. This is a case of low entropy. Conversely, if there are a variety of types of communications and all are equally probable, then there is total uncertainty and a maximal amount of information is gained by finding out which event occurred. This is an example of maximum entropy.

Shannon's entropy is typically used with contingency tables where the values in each cell represent the probability of a different two-event sequence. A simple way to think of entropy is the average number of dichotomous

decisions (yes–no) that need to be made to classify an event in that table (Wickens, 1989). Thus, in the previous example, the situation where only one event is observed would have a minimal entropy value of 1 because only one dichotomous decision is necessary to classify any event. Shannon's entropy is calculated as follows:

$$\text{Entropy} = H = \Sigma p_{ij}(\log_2(1/p_{ij}))$$

where p_{ij} is the conditional probability in the cell that is in row i and column j of a contingency table.

Dishion et al. (2004) used turn-taking observational data of boys interacting with their closest friend to calculate entropy. Their conversational turns were coded into five categories: negative engagement, directive, converse, positive engagement, and other. Thus, there was a 5×5 matrix of two-event sequences for each peer dyad. The frequencies in each cell of the matrix were used to calculate the conditional probabilities necessary for the entropy calculation. The findings from this study showed that all of the friendship dyads' interactions (regardless of whether or not they were antisocial) became more ordered (less entropic) over three time points, ages 14, 16, and 18 years old. This finding in itself is compelling. It supports the DS view that development is characterized by increasing orderliness—a crystallization of interaction patterns. As relationships of all kinds develop, they stabilize and, thus, become more predictable over time. When the authors compared early-onset antisocial boys with prosocial boys, they found that antisocial boys' interactions corresponded to higher entropy scores, suggesting a more disorganized pattern, and were characterized by more deviant talk than the typically developing boys. These results may suggest that antisocial boys are less skilled than prosocial boys at carrying on a fluid, appropriately contingent conversation.

Some other potentially useful applications of this approach are found in clinical therapy research (e.g., Badalamenti & Langs, 1992; Burlingame, Fuhriman, & Barnum, 1995; Butz, Chamberlain, & McCown, 1997; Lichtenberg & Heck, 1986; Pincus, 2001; Tschacher, Scheier, & Grawe, 1998). Lichtenberg and Heck (1986) examined the "Gloria" psychotherapy tapes and compared the results of Shannon's entropy measure, Markov chain analysis, and sequential analysis. Each of these approaches showed some merit and each had associated limitations. In terms of therapeutic process and outcome, two therapy studies have applied Shannon's entropy measure with somewhat contradictory results: one found that, over the course of intervention, verbal utterances became increasingly complex (Badalamenti & Langs, 1992) while the other found that client and therapist measures of therapy sessions became increasingly coherent (i.e., less complex, according to the entropy measure) and this tendency was related to treatment success (Tschacher et al., 1998).

Finally, a study conducted by Pincus (2001) set out to demonstrate that when treatment works, therapy sessions become both more complex and more coherent. This study may be particularly relevant to developmental psychopathologists because it was based on assumptions from family systems theory (Minuchin, 1974). Pincus was interested in empirically testing one of the basic assumptions of family systems therapy: that families maintain a state of equilibrium through negative feedback processes which dampen deviations. These deviations (e.g., depressive withdrawal, angry outbursts) manifest as symptoms for a particular family member, but also serve to maintain homeostasis in the family (e.g., Minuchin, 1974; Minuchin & Fishman, 1974). For example, a child may become oppositional to (consciously or unconsciously) distract the family from the real problem: intense marital discord. When the child acts out, the parents join forces and attend to the disruptive behavior, which precludes escalation of the marital conflict (dampening process); thus, the family maintains a state of equilibrium, however dysfunctional it may be. The goal of family therapy is twofold: "to disrupt or block these negative feedback processes, promoting family disequilibrium and reorganization" and to "capitalize on natural deviation-amplifying processes within family systems in order to bring about systemic change" (positive feedback; Pincus, 2001, p. 145). In short, the goal of therapy is to induce a phase transition in the family system.

As a first step toward validating these assumptions, Pincus conducted a pilot study in which he analyzed the conversations of one family undergoing therapy. He used an analytic technique called *orbital decomposition* (OD; Guastello, Hyde, & Odak, 1998), which combined Shannon's entropy and measures of Lyapunov dimensionality, as well as others, to identify hierarchical patterns, the extent of randomness in a time series, and the optimal level of analysis for any particular series (i.e., the number of units in a string that best captures the information for a time series). The results confirmed that, indeed, the family exhibited evidence of both coherence and complexity across treatment sessions. Because this was a pilot study, we are hesitant to make too much of these findings. But OD may hold particular promise for developmental psychopathologists because it was developed for analyzing *categorical* time series data, instead of the usual continuous series. As such, it addresses a major limitation that has

been repeatedly raised with the other time series techniques reviewed here.

The methods for analyzing nonlinear dynamics described in this section have been applied to single time series. These are appropriate for some biological measures with high temporal resolution (e.g., heart rate) but another form of continuous data, electrical activity in the brain, presents a more complex challenge. There are increasingly more developmental psychopathologists who are integrating brain activity measures in their research programs (e.g., Calkins & Fox, 2002; Cicchetti & Dawson, 2002a; Nelson et al., 2002). Although there is clearly not enough space to discuss the various brain imaging methods in the current review, a word on these techniques is warranted. Ongoing electrical activity in the brain, measured by electroencephalogram (EEG), can involve as many as 256 separate time series, one per electrode. Methods that analyze these kinds of complex data are designed to find relations and patterns among and across these various time series. For example, developmental neuroscientists interested in the self-organization of brain dynamics have found real-time synchronization across distal cortical areas to be correlated with attentional states or focused perception (Lewis, 2005). Transient, organized activity in different regions oscillating in phase (phase synchrony) and cortical coherence (a similar measure that incorporates both amplitude and phase) are detected through various temporal correlation methods and have been found to correspond with attentional (e.g., Engels, Fries, & Singer, 2001) and emotional (Paré & Collins, 2000) events.

We close this section with a cautionary note that applies to any dynamical mathematical technique—because these techniques are derived from other fields, oftentimes it may be easier to input numbers into the equations than to sensibly interpret the results of the computations. A number of DS researchers have been criticized for interpreting their mathematical functions too literally, either the data inserted into the equations do not conform to the mathematical assumptions or, perhaps more seriously, they are potentially arbitrary in terms of their psychological meaning. These methods hold a great deal of promise, but a great deal of theoretical and empirical work remains to be done before the psychological meaning of nonlinear dynamic techniques is clearly understood.

Developmental-Time Measures

Descriptive Developmental Profile Analysis

The empirical work by Thelen and colleagues (e.g., Thelen & Smith, 1994; Thelen & Ulrich, 1991) has been characterized as descriptive in that it is nonparametric, uses descriptive statistics, and often relies heavily on displaying individual developmental profiles graphically. These researchers most often collect continuous time-series data (e.g., number of alternating steps, degree of displacement of foot, proportion of stepping cycle) over repeated occasions across a significant developmental period. They create developmental profiles on a case-by-case basis and describe the similarities and differences among these profiles. A core concern in this type of analysis is to identify periods of transition during which variability dramatically increases and old behavioral habits dissolve, giving rise to new ones (i.e., from crawling to walking).

The most straightforward way to graph developmental growth profiles is to simply plot scores for the collective variable (e.g., alternate stepping) on the y axis across several developmental time points on the x axis, and to do so for each case individually. Van Geert and van Dijk (2002) offered a number of additional methods for visualizing and describing intraindividual time-series data over repeated observations. These methods were specifically created for measuring changes in variability across developmental time and they are well suited for one-dimensional continuous longitudinal data. In addition, with any individual developmental profile plot, several trajectories can be grouped into clusters that show similar profiles by using variations of a cluster analytic procedure (e.g., Hollenstein, Granic, Stoolmiller, & Snyder, 2004).

One simple but elegant plotting technique is referred to as the *moving min-max graph* (van Geert & van Dijk, 2002). This graph represents the developmental trend line but also the variability around this trend line in a bandwidth of observed scores. A moving window is used—that is, a time frame selected by the researcher (e.g., 2 weeks, 3 months) is moved over one position all the way across the time series such that each window partly overlaps with the previous window. There is no absolute window length that is required, but van Geert and van Dijk (2002) suggest that the window size should be about one-tenth the size of the entire data set and no less than five data points. The maximum and minimum score at each time window is plotted and then the bandwidth of these scores can be examined in terms of its stability and change. In addition, a moving average that corresponds to the moving min-max window can be computed and displayed along the middle of the bandwidth. Figure 16.10 shows a graph taken from van Geert and van Dijk (2002) in which they showed the developmental trend for one child's acquisition of spatial prepositions. They used a time window of 18 days across a 10-month period. The graph shows that there is a moderate sized bandwidth in the beginning of the trajectory and then, after a couple of oscillations, a

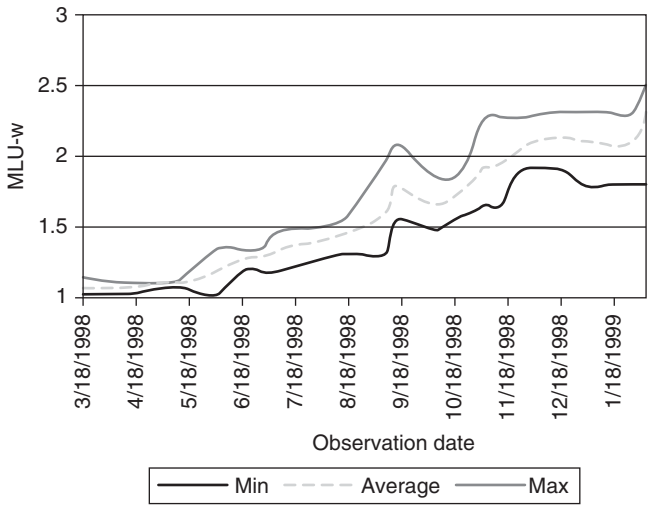

Figure 16.10 Moving min-max graph representing one child's acquisition of spatial prepositions (time window of 18 days, last window, 15 days) From van Geert, P., & van Dijk, M. 2002). Focus on variability: New tools to study intra-individual variability in developmental data. *Infant Behavior and Development, 25*, 340–370.

large increase in the bandwidth is maintained until the end of the observation period. The authors interpreted this plot as suggesting a developmental transition (one that showed the characteristics of a phase transition) in the use of spatial prepositions. For a more detailed examination of the values within the bandwidth, the authors also propose using an "altitude line graph," which simply depicts intermediate values as well (e.g., the second highest and second lowest values, percentiles) with a line connecting these values. The result is a plot that resembles the contour lines in a geographical relief map. A number of other variations of these variability charts can be found in van Geert and van Dijk (2002).

To explore developmental trends in individual or group data, developmentalists commonly plot idealized or processed estimations of a data series (e.g., regression models, smoothing techniques) that obscure information on variability (this is what they are designed to do: smooth out fluctuations). In general, developmentalists constrain themselves to a very small repertoire of smoothing techniques and, thus, lose potentially critical information about the characteristics of transitions and the idiosyncratic nature of development (van Geert & van Dijk, 2002). Van Geert and van Dijk (2002) argued for the application of more sophisticated smoothing models "which follow the actual rise and fall of the data as faithfully as one wishes" (p. 351). They provide alternatives, many of which are options available in commonly used statistical packages including SPSS. Some of these techniques include spline models and local polynomial regression models, or loess smoothers, which allow researchers to detect fluctuations and nonlinear trends in their data sets (Simonoff, 1996; van Geert & van Dijk, 2002).

To complement the impressions gained from the graphical developmental profiles, DS researchers may use simple statistics such as within-subject measures of variance (e.g., standard deviations) and correlations to track increases in variability across developmental transition points. The well-known standard deviation (SD) measure is sometimes problematic, however, because of its sensitivity to the mean (i.e., if distributions are censored at a low score, the SD tends to increase when the mean increases), making SDs difficult to compare across individual subjects or samples. To address this limitation, another less common measure of variability can be used: the coefficient of variation (CV; van Geert & van Dijk, 2002). The CV is simply the SD divided by the mean and, although it too has limitations, it can be used as an alternative to the SD.

Skewness is another easily calculated measure that provides a great deal of information about the pattern of variability in a given trajectory (van Geert & van Dijk, 2002). A skewed distribution is one potential indicator of bimodality, one of the catastrophe flags previously mentioned. In DS terms, bimodality can provide information about the extent to which a particular skill has been acquired or a pattern has been consolidated. For example, in the context of acquiring theory of mind (ToM), a 3.5-year-old child who is just beginning to understand that others may hold false beliefs about the child will likely show very few correct responses to ToM tests over several weeks of repeated testing; these will show up as positive outliers. In general, the child will still be responding "incorrectly," as if she has no false belief understanding; thus, the distribution will be positively skewed. At the age of 4, however, this child will likely show a negatively skewed distribution of responses—her ToM skills will have consolidated and now only very rarely will she respond as if she did not understand that others' can hold false beliefs.

A similar example might be used for thinking about children in treatment. For instance, at first, a child undergoing cognitive-behavioral therapy for problems with anxiety may respond to frightening or challenging situations with predominantly avoidant strategies and very few proactive, assertive behaviors (i.e., the distribution will be positively skewed, with most behaviors falling toward the avoidant end of the continuum and a few outliers falling toward the assertive end). But if treatment is successful, this child may end therapy showing a pattern of responses that is negatively skewed. The point at which the distribution shifts from being positively to negatively skewed may provide key information about the timing and profile of change

across treatment. From a DS perspective, it is likely that this child's distribution of avoidant-assertive scores from pre- to posttreatment will shift from positively skewed to bimodal to negatively skewed—that is, at no point will he exhibit responses that show a normal distribution. This pattern would suggest an abrupt shift (a phase transition) in response styles may be related to treatment success. The main point here is that instead of trying to normalize distributions at any stage, information about skewness and variability can provide insights about the nature of transitions and developmental change.

Standard statistical packages (e.g., SPSS, SAS) provide tests for assessing skewness. A Kolmogorow-Smirnov test provides a statistic for sample sizes (or number of observations) greater than 50 and the Shapiro-Wild test for sample sizes less than 50 (van Geert & van Dijk, 2002). In addition, van Geert and van Dijk (2002) described bootstrapping methods that provide researchers a random sample with which to compare statistically significant differences in skewness values across a given developmental trajectory.

Finally, individual growth curve modeling procedures can be applied to examine different profiles of change on both the individual and group level. This method is familiar to many developmentalists; it has been applied to examine different trajectories of antisocial behavior (e.g., Nagin & Tremblay, 1999), infant vocal development (Hsu & Fogel, 2001), infant-mother interactions (vanden Boom & Hoeksma, 1994), as well as many other domains. Several easily accessible computer programs are available to run these modeling procedures including multilevel analysis and hierarchical linear modeling (HLM; Willett, 1997).

Latent Class Analysis

Descriptive developmental profile analyses, as we have described them, are generally restricted to continuous one-dimensional data. Categorical and nominal data are difficult to use with these approaches (without somehow transforming them into continuous data). In this regard, combining different types of developmental profile analyses with methods that can capture content-specific changes in categorical or ordinal variables may be important. Another elegant option for investigating the bimodal properties of a distribution is offered by van der Maas (1998): latent class analysis (LCA). This technique is appropriate for analyzing categorical data. A number of developmental psychopathologists familiar with modeling procedures such as structural equation modeling (SEM) and HLM may also be aware of this method. LCA is conceptually similar to cluster analytic procedures in that it identifies subgroups or types. But it has additional power because it also provides a maximum likelihood estimation and is adaptable to different data structures with no a priori assumptions about the distributions.

As a cognitive developmentalist, van der Maas (1998) was particularly interested in this method for modeling the bimodal response distributions identified on various cognitive tasks at developmental transiton points or across various contexts (Quinlan, van der Maas, Jansen, Booij, & Rendell, 2007; van Rijn, Someren, & van der Maas, 2003). He argued that cognitive strategies can be best understood as attractors that are more or less available at different ages and in different contexts. In his approach, response patterns to multiple tasks are analyzed in terms of a cusp catastrophe model and multistable states (bimodality) are identified through LCA procedures. By presenting several examples of the application of rule and strategy detection in multiple domains, van der Maas (1998) showed that LCA may be one of the more promising psychometric models for identifying attractors and multistable states with categorical data.

Dynamic Growth Modeling

A group of scholars from the Netherlands can be credited for having pioneered the use of dynamic growth models in the study of cognitive developmental transitions (e.g., van der Maas, 1998; van der Maas & Molenaar, 1992; van Geert, 1994, 1995ab, 1997). The class of techniques advocated by these researchers is often grouped under the heading *nonlinear dynamics*, in reference to the modeling techniques and equations that are associated with this branch of mathematics. Although the techniques have often been applied to real-time data, these scholars explore various applications to developmental modeling instead.

Dynamic growth modeling was developed to simulate change over time (or growth) using logistic difference equations. Van Geert (1994) has used this procedure to model the processes underlying stage-like transitions in the growth of syntactic forms. The basic DS premise of van Geert's technique is that development of cognitive capacities is much like the self-organized proliferation of multiple species over the course of evolution. Van Geert models cognitive growers that constitute a complex system of intraindividual and environmental relations. Like the real-time coupled equations described earlier in reference to Gottman's work, the modeling procedure is realized with iterative equations in which behavioral states are updated by the amplifying and dampening forces inherent in the system's (i.e., the child's) experiential history combined with current external (contextual) resources and limitations. The

growth models depict the kinds of nonlinear developmental profiles predicted by stage theorists (e.g., Piaget and Vygotsky). They also emphasize the use of graphical procedures to plot empirical data from longitudinal studies of children's cognitive skill acquisition to match these empirical profiles to the data from simulations derived from the equations. The mathematical formulations used in these models are common in other disciplines; what makes these models unique is the application of both psychological and DS concepts to identify the mechanisms of growth that model observed developmental profiles. Another critical strength of this approach is that the process of developing simulations forces the researcher to specify the null hypothesis explicitly. The conventional a priori comparison between the hypothesized result and a lack of any effect is replaced by a specific null hypothesis of an alternative pattern of results.

More recently van Geert and his colleagues have broadened their cognitive developmental focus and have become interested in modeling children's peer play interactions (Steenbeek & van Geert, 2005, 2007, 2008). This new modeling endeavor may be more relevant to developmental psychopathologists because of its content (i.e., peer interactions), but more importantly, it may prove more generalizable to a large body of social interaction problems that developmental psychopathologists are interested in tackling.

Similar to previous endeavors, the procedure begins with a theoretical model. In this case, Steenbeek and van Geert (2005, 2007) developed a theoretical model that stipulated that differences in peer interactions with rejected versus popular children can be understood as a function of the following reciprocally interacting factors: each child's goals (autonomy and involvement), the drive that results from the extent to which these goals are met, the emotional appraisal at each given moment, and the resulting emotional expression and behavior. These theoretical factors are then formalized into a mathematical model that stipulates the mechanism differentiating rejected and popular children's dyadic interactions. Because this is a DS-based model, the mathematical formulation necessarily includes reciprocal, iterative processes and feedback cycles within and across occasions, as well as sensitivity to random or chance variations, and the potential for nonlinear results. Next, the simulation is run repeatedly and the results of the simulation are compared to theoretical expectations. Finally, the results of the simulation are compared to empirical data from real dyadic interactions.

The model includes a number of input parameters that can be set at the outset. These values can be start values for a particular variable or the strength of the connection between two variables. Rejected and popular children, for example, are assigned different preference values according to the original theoretical model. Figure 16.11 is a representation of the simulation model with all of the reciprocal and iterative processes depicted by arrows. Table 16.3 shows the different parameters and what values can be manipulated at the outset. The table also shows the parameter

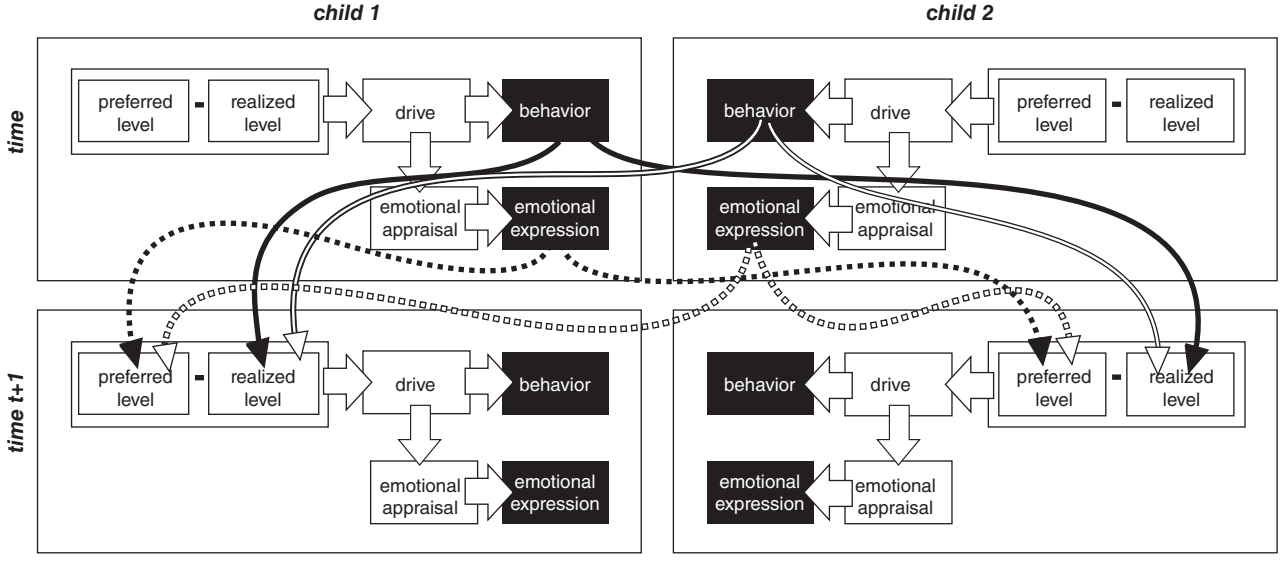

Figure 16.11 Steenbeek and van Geert's (2005) peer interaction simulation model. The first row of boxes represents the first moment in time, *t*, and the second row represents the second moment, $t + 1$. Thin arrows represent the iterative feedback components (the output of one iteration is the input for the next). *Source:* Steenbeek, H., and van Geert, P., 2005. A Dynamic Systems Model of Dyadic Interaction during Play of Two Children. *European Journal of Developmental Psychology*, *2*(2), 105–145.

TABLE 16.3 Parameter profiles for various types of dyads

Type of dyad	*Rejected dyad*		*Average dyad*		*Popular dyad*	
Status of child	*Rejected*		*Average*		*Popular*	
Status of play partner		*Average*		*Average*		*Average*
1 Concerns	I *much stronger* than A	I *little bit stronger* than A	I *stronger than* A	I *stronger than* A	I *little bit stronger* than A	I *much stronger* than A
2 Influence of behaviour on realization of concerns	I = average A = *high*	I = *high* A = average	I = average A = average	I = average A = average	I = *high* A = average	I = average A = *high*
3 Relation between emotional appraisal and emotional expression	Positive = moderate Negative = *difficult*	Positive = moderate Negative = moderate	Positive = moderate Negative = moderate	Positive = moderate Negative = moderate	Positive = moderate Negative = moderate	Positive = moderate Negative = *difficult*
4 Influence of emotional expression on preference of concerns	Positive = *big* Negative = *big*	Positive = average Negative = average	Positive = average Negative = average	Positive = average Negative = average	Positive = average Negative = average	Positive = *big* Negative = *big*
5 Nonintentional principles of behaviour	Continuity = average Symmetry = *high*	Continuity = average Symmetry = *low*	Continuity = average Symmetry = average	Continuity = average Symmetry = average	Continuity = average Symmetry = *low*	Continuity = average Symmetry = *high*

Notes: [a]The table can be read as follows: a child with a rejected status that plays with a play partner with an average status (rejected dyad; upper left of the table) has as setting for the first input parameter group concerns that his/her concern involvement is much stronger than his/her concern autonomy, which is expressed as "I *much stronger than* A". [b]I = concern involvement, A = concern autonomy. The average dyad has standard settings (average, moderate), Everything that differs from these standard settings is printed *in italics (high, low, difficult, big)*. [c]Information about the corresponding ranges of numerical values of these settings of input-parameter groups for children of different statuses in the context of playing with a play partner with a different status can be found in Appendix 2.

profiles for each type of dyad (the various combinations with rejected, popular, and average children). The model is run, for example, 1,000 times with the particular inputs specified in Table 16.3 for children with different sociometric status.

One of the unexpected results that emerged from running the simulations was that, contrary to what previous literature suggested, the data representing rejected children playing with normal-status children showed more positive emotional expressions than that for popular children with normal-status children (Steenbeek & van Geert, 2005, 2008). When these simulation results were compared to actual empirical data, the results matched (statistical tests described by the authors in detail were run to compare the simulated and empirical results). The authors concluded that, because rejected children seldom had a chance to play with other children in general, the new experience of playing with someone else led to the expression of more happy emotions than expected. The popular children, on the other hand, were not as pleased with the experience because they were not playing with their regular friends and had plenty of opportunities to play with other children.

The authors suggest that the modeling results are consistent with contextualist, functionalist, and dynamic systems perspectives. Indeed, their models remain true to fundamental DS assumptions. Broadly, the simulation technique demonstrated that emotions and behavior:

> . . . Are not a function of] personality characteristics that are relatively independent of the contexts and of the local and temporal realization of the concerns . . . [instead, the findings] emphasize the importance of iterative and interacting processes that take place in real time. It overthrows the classical distinction between independent and dependent variables in favor of a process of mutually interacting and simultaneous processes. (Steenbeek & van Geert, 2005)

Van Geert (1998) emphasized the critical role mathematical modeling plays in developmental research: "In order to find out the implications of theories, they have to be transformed into mathematical models that capture the major dynamic principles of such models and that can be used to explore the range of developmental trajectories under all possible or likely parameter conditions" (p. 155; also see Newtson, 1994; van Geert, 1994). But despite van Geert's concerted efforts to make his approach accessible, its impact on developmental psychology and developmental psychopathology may be limited because of its use of mathematical procedures that are daunting to most psychologists. More importantly, a great deal of the developmental phenomena that researchers are interested in examining are not conducive to this sort of modeling because they are not easily quantified as continuous variables. Also, regardless of the domain in which this method is applied, and as with all simulation techniques, the correspondence of the parameters in the model with genuine psychological mechanisms is often difficult to evaluate and runs the risk of seeming arbitrary. Nevertheless, this modeling technique and others may prove useful for developmental psychopathologists who have very precise hypotheses that can be faithfully translated into mathematical functions that specify mechanisms of change, influence, and interaction.

Connectionist Modeling

Connectionist and dynamic systems theories have separate histories, but share a great deal of commonalities (Spencer & Thelen, 2003). Although it is not quite accurate to characterize connectionism as a dynamic systems methodology, we would be missing an important contribution if we were not to include this modeling approach. Many (but not all) connectionist models are indeed dynamic systems and researchers working with these models often turn to concepts such as attractors, bifurcations, and chaos to understand their properties (Smith & Samuelson, 2003).

Connectionism is often characterized as a framework for simulating idealized brain-like, or neural network, processing. This is because connectionist modeling starts with the propagation of activation across a network of abstract units that can be hypothetically likened to networks of neurons that fire or do not, depending on the context. Knowledge, representation, or meaning is understood as being stored not in one or two units, but in connection weights between processing units. Learning and development is evidenced by changes in connections between these units. These changes result from statistical regularities in the input to the network and these regularities are governed by the Hebbian learning principle: units that fire together, wire together. Thus, "the connection weights between layers [of units]—the response of the network to a specific input—depend on the statistical regularities in the network's *history* of experiences" (Thelen & Smith, 1998, p. 580). Through their own real-time activity, without any additional intervention, connectionist networks change their own connections and, thus, teach themselves. One of the best-known examples of a connectionist model is Rumelhart and McClelland's (1986) demonstration of a network that acquired irregular and regular forms of past-tense, and overgeneralized (like real children were thought to do) the irregular forms. Their breakthrough was to show that a network could behave as if it was

governed by higher order rules with no such rules having been prespecified.

In most connectionist models, activation among units is a continuous temporal process. Differential equations are used to simulate this continuous activation process such that weighted connections link the rate of change in one variable to the inputs received from the other units (e.g., Munakata & McClelland, 2003). In many recent models, the activation process is assumed to be nonlinear. A simple example is provided by a nonlinear adjustment to McClelland's (1979) cascade model:

$$\frac{dneta_i}{dt} = k(\Sigma a_j w_{ij} - a_i)$$
$$a_i = f(net_i)$$

where a represents the activation of receiving unit i, a_j is the activation of sending unit j, w_{ij} represents the connection weight from unit j to unit i, and k is a time constant that sets the rate of change. $neta_i$ refers to the net input to unit i, and f is a nonlinear function (Munakata & McClelland, 2003).

In terms of development, connectionist simulations based on variations of the nonlinear differential equation have been developed to understand category and word learning (Plunkett, 1993; Smith, 1993, 1995), children's knowledge of dimension words and their selective attention to each dimension (Gasser & Smith, 1996; Smith, 1993), the development of face recognition (Johnson & Morton, 1991), and the A-not-B error (Munakata, 1998), among others. In terms of the A-not-B error, Thelen and colleagues (Thelen, Schoener, Scheier, & Smith, 2001; Smith & Thelen, 2003) extended past connectionist models by applying the dynamic systems principles of multicausality and nested time scales and developed a dynamic field model. They incorporated the idea that instabilities in network activities (i.e., variability) index qualitative changes in systemic behavior. Spencer and Schoner (2003) summarize this dynamic connectionist model: "Instabilities disrupt the one-to-one input–output mapping and make dynamic fields nonstandard neural networks" (p. 406).

Connectionist modeling, like other dynamical modeling techniques listed, requires either a great deal of technical expertise or collaboration among researchers with varying talents (e.g., computer programming, mathematics, developmental theory). We are aware of very few efforts in developmental psychopathology to apply this type of simulation procedure, but there may be a number of phenomena in the field that could benefit from such an approach. For example, different types of friendship formations on the playground may be modeled through connectionist procedures. Children seem to self-organize into coalitions or cliques very quickly at the beginning of a school year. These emergent groupings may be modeled as networks of units that become strengthened over time. Different types of coalitions (e.g., bullies and victims versus supportive friendship relationships) may exhibit unique properties (e.g., bullies/victims may be less stable, more perturbable, and they may be less likely to include new members than other types of friendships). These unique properties may suggest adjustments to existing theoretical models of friendship formation and even have the potential to suggest change mechanisms that may be targeted through intervention.

Readers interested in applying connectionist modeling are directed to *Rethinking Innateness: A Connectionist Perspective on Development* (Elman et al., 1996) and the companion book *Exercises in Rethinking Innateness: A Handbook for Connectionist Simulations* (Plunkett & Elman, 1997). These volumes provide a thorough primer in connectionist modeling and give novices an opportunity for hands-on practice. The authors make important distinctions between mechanisms of change and development and the content of those changes. Of special concern is the attempt to understand emergence and nested interactions at multiple time scales. The exercise book is a practical step-by-step manual that includes computer software and several example simulations that model, for example, stage-wise development and how children learn the past tense.

Catastrophe Modeling

This is a mathematical procedure wherein several control parameters can be used to account for discontinuous change in one of seven topological forms (catastrophe models; Thom, 1975; Guastello, 1995). As such, it has some appeal for developmental psychopathologists interested in incorporating insights from developmental stage theories or modeling nonlinear changes in behavior due to treatment or trauma. These models show how each of the possible combinations of control parameters result in different values of a dependent variable. The potential values of the dependent variable are represented on a plane, much like a state space. Nonlinear shifts can be depicted as a fold or curl in the plane showing where behavior changes suddenly rather than continuously.

The simplest and most commonly used catastrophe model is a cusp catastrophe, as depicted in Figure 16.12. The top surface of this three-dimensional figure is the

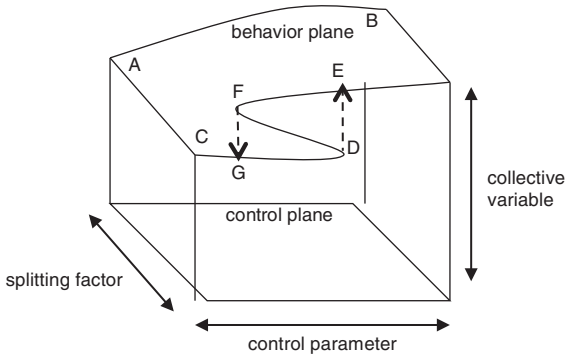

Figure 16.12 Basic cusp catastrophe model.

behavior plane, which is made up of all the possible values of the response variable (i.e., collective variable). The location of a point in the behavior plane is predicted by the values of the control parameter and the splitting factor (the axes on the bottom plane called the control plane), which are equivalent to independent variables in these models. The top left position on the behavior plane (point A), for instance, is a combination of a low value of the control parameter and a low value of the splitting factor. Keeping the splitting factor constant for the moment, follow the movement from point A to point B. Here we see that there is a linear response in behavior as the control parameter increases continuously. However, when the values of the splitting factor are high, there are some values of the control parameter that result in two possible locations on the behavior plane (points D and E or F and G). This cusp fold in the behavior plane is the region that describes the nonlinear response dynamics of the system. As the control parameter increases from the lowest value at point C, the behavior increases through points G and D. However, at point D the collective variable value suddenly jumps to point E on the plane. When the control parameter decreases from its maximum value, behavior passes through point E to point F in a linear response. Now at point F, behavior suddenly jumps down to point G, a much lower value for the collective variable. This difference in response depending on whether the control parameter is increasing or decreasing is one of the unique features represented by cusp models and exemplifies the process of hysteresis.

For example, consider the relationship between frustration and anger. The first step in catastrophe modeling is to identify that a catastrophe exists. The catastrophe flags mentioned earlier are used for this purpose. Presence of hysteresis, divergence from linear response, sudden jumps, bimodality, anomalous variance, and critical slowing down can all serve as flags. For the current example, suppose that through experimentation a researcher discovers a bimodality in the distribution of anger responses to frustration. In cases where frustration is moderate, anger is either high or low but never in between. This would be an indication that a cusp catastrophe could be an appropriate model. Moreover, suppose this bimodality only occurs in high reward contexts, and that frustration and anger have a positive linear relationship in low reward contexts. Thus, for this example, anger is the collective variable of interest, frustration is the control parameter, and amount of reward in the context is the splitting factor (Figure 16.13). In a low-reward task (e.g., no motivational incentive other than following instructions), as frustration increases, the anger response would increase gradually (path A to B in Figure 16.13). In a high-reward task (e.g., in a gambling context), as frustration increases, the anger response would break from linearity at point D. Anger would suddenly jump to a higher level at point E. If frustration continues to increase, there would again be a linear increase in anger. However, frustration would have to subside well below the levels at which the previous jump occurred (point F) before anger decreased nonlinearly to its former level.

The next step of the modeling procedure is to fit the model to empirical data, much like linear regressions are fit to data. Catastrophe models have been used to model diverse developmental transitions such as conservation of liquid (van der Maas & Molenaar, 1992); acquisition of syntax (Ruhland, & van Geert, 1998); infant reaching with grasping (Wimmers, Savelsbergh, van der Kamp, & Hartelman, 1998); dating (Tesser & Achee, 1994); blame responses of victims of assault (Lanza, 1999); adolescent smoking (Byrne, Mazanov, & Gregson, 2001); alcohol use (Clair, 1998); and anxiety in preuniversity students (Haslett, Smyrnios, & Osbourne, 1998). These and other

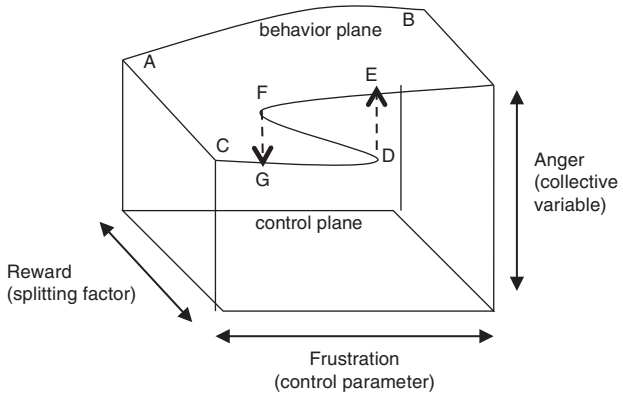

Figure 16.13 Cusp catastrophe model representing the relation between anger and frustration in different contexts.

examples indicate that, despite the difficulty in specifying or measuring control parameters, as discussed earlier, important insights about the profiles and mechanisms of change can be gained. Catastrophe theory and models will likely become more applicable as more researchers address the nonlinearities in their data and work to measure hypothesized control parameters.

STATE SPACE GRID ANALYSIS: A GRAPHICAL AND STATISTICAL MIDDLE ROAD

The various DS techniques introduced thus far have considerable potential for addressing some of the analytic challenges faced by developmental psychopathologists. However, we have also pointed out some obstacles for implementing these techniques. In general, most techniques require continuous data, whereas ordinal and categorical variables are more common in developmental psychopathology, especially in observational studies. In addition, many of the techniques are either solely descriptive, preventing researchers from testing the strength and reliability of their findings, or require complex mathematical procedures that may be inaccessible or irrelevant to most developmental psychopathologists. Recently, hybrid strategies have been developed, providing a middle ground by combining graphical techniques that capture the descriptive richness of DS concepts with simple statistical procedures that stay true to systems assumptions (Hollenstein, 2007, 2012, 2013; Lamey et al., 2004; Lewis et al., 1999). The state space grid method is a graphical and statistical strategy that links the analysis of real- and developmental time patterns and allows for the identification of individual and group differences. Thus, the flexibility of this methodology has proven valuable for developmental psychopathologists. We begin by describing this technique and the various measures that can be derived for statistical analysis.

State Space Grids

Recall that DS theorists use the concept of a *state space* to represent the range of behavioral habits, or attractors, for a given system. In real time, behavior is conceptualized as moving along a trajectory on this hypothetical landscape, being pulled toward certain attractors and freed from others (Figure 16.1). Based on these abstract formalizations, Lewis, Lamey, and Douglas (1999) developed a graphical approach that utilizes categorical time series structured as two ordinal variables that define the state space for any particular system. Though these state variables can represent two measures of one individual's behavior (e.g., Lewis et al., 1999, Lewis et al., 2004) so far the most frequent use of state space grids has been the analysis of dyadic interactions (Branje, 2008; Cerezo, Trenado, & Pons-Salvador, 2012; Connell, Hughes-Scalise, Klostermann, & Azem, 2011; Dishion et al., 2004; Gardner & Wampler, 2008; Granic, Dishion, & Hollenstein, 2003; Granic & Lamey, 2002; Granic et al., 2003, 2007; Granic et al., 2012; Hollenstein, 2007; Hollenstein & Lewis, 2006; Hollenstein et al., 2004; Lunkenheimer, Albrecht, & Kemp, 2012; Lunkenheimer et al., 2001, 2012; Mainhard, Pennings, Wubbels, & Brekelmans, 2012; Moore et al., 2012; Ribeiro, Bento, Salgado, Stiles, & Gonçalves, 2011; Sravish, Tronick, Hollenstein, & Beeghly, 2013; van Dijk, Hunnius, & van Geert, 2012; van der Giessen, Branje, Frijns, & Meeus, 2013; van der Giessen et al., 2015). With this application, a dyad's trajectory (i.e., the sequence of behavioral states) is plotted as it proceeds in real time on a grid representing all possible behavioral combinations. Categories of one dyad member's (e.g., parent) behavior forms the columns on the x axis and the other member's (e.g., child) behavior forms the rows on the y axis. Each cell of the grid is the joint x–y state (e.g., parent–child) and plot points in these cells represent the occurrences of these joint states, and their durations if applicable. Moreover, a trajectory is drawn through the successive dyadic points in the temporal sequence they were observed. Any time the behavior changes a line is drawn connecting the new point and the previous point. For example, a hypothetical trajectory representing 15 seconds of coded behavior is presented in Figure 16.14. With the duration of each joint state represented by the size of the plot point and the direction of each transition indicated by an arrow, this sequence begins with the parent and child in conflict (shared negativity/hostility, bottom left cells) and ends in repair (shared positivity, top right cell).

The SSG methodology can tap both the content of interactions (e.g., mutual hostility, permissive parenting) and the structure of these interactions. When we refer to structure, we mean the patterning of behavior, regardless of content, such as the relative flexibility versus rigidity of interaction patterns (Hollenstein, Lichtwarck-Aschoff, & Potworowski, in press). With SSGs, we are able to examine whether behavior clusters in very few or many states (i.e., cells), or regions (i.e., a subset of cells) of the state space. We can also track how long the trajectory remains in some cells but not others, and how quickly it returns to particular cells. If a dyadic trajectory remains in a small number of cells, and makes very few transitions between cells, this system may be thought of as rigid, inflexible, or stuck. In contrast, a trajectory that moves around to many cells in the state space grid and makes frequent changes between

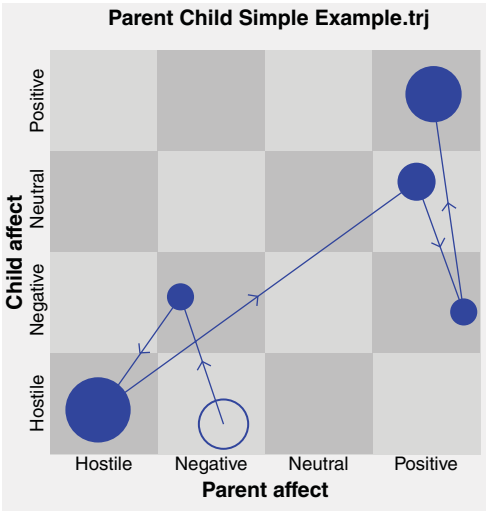

Figure 16.14 Example of a state space grid with a hypothetical trajectory representing 10 seconds of coded behavior, one arrow head per second. Plotting begins in the lower left part of the cell and moves in a diagonal as each second is plotted, ending in the upper right. See footnote 1.

these cells may indicate a highly flexible, or variable, system. We can identify attractors as those cells to which behavior is drawn repeatedly, in which it rests over extended periods, and/or to which it returns quickly. Moreover, as discussed in the following sections, a range of variables that capture the relative stability of particular attractors may be derived from SSGs and these values can be tested statistically for changes in real and developmental time.

A major advantage of SSGs is that they provide an intuitively appealing way to view complex, interactional behavior; thus they are first and foremost a useful tool for exploratory analysis. An examination of the heterogeneity of family interactions with aggressive children may help illustrate this point (Granic & Lamey, 2002). SSGs were used to explore differences in the parent–child interactions of "pure" externalizing children (EXT) and children comorbid (MIXED) for externalizing and internalizing problems. This study is useful not only for demonstrating how the grids work, but also to demonstrate design innovations based on DS principles that are useful with or without SSGs, in this case, a systematic perturbation.

Parents and clinically referred children discussed a problem for four minutes and then tried to "wrap up and end on a good note" in response to a signal (the perturbation) within the next two minutes. The perturbation was intended to increase the emotional pressure on the dyad, triggering a reorganization of their behavioral system. We hypothesized that, as a function of differences in the underlying structure of their relationships, EXT and MIXED dyads would be differentially sensitive to the perturbation and would reorganize to different parts of the state space. Prior to the perturbation, however, we expected dyads' interactions to look relatively similar. Separate grids were constructed for the pre- and postperturbation interaction sessions. For this study, the lines (trajectories) are less important to notice than the points that show clustering in particular cells. Figure 16.15 shows an example of an

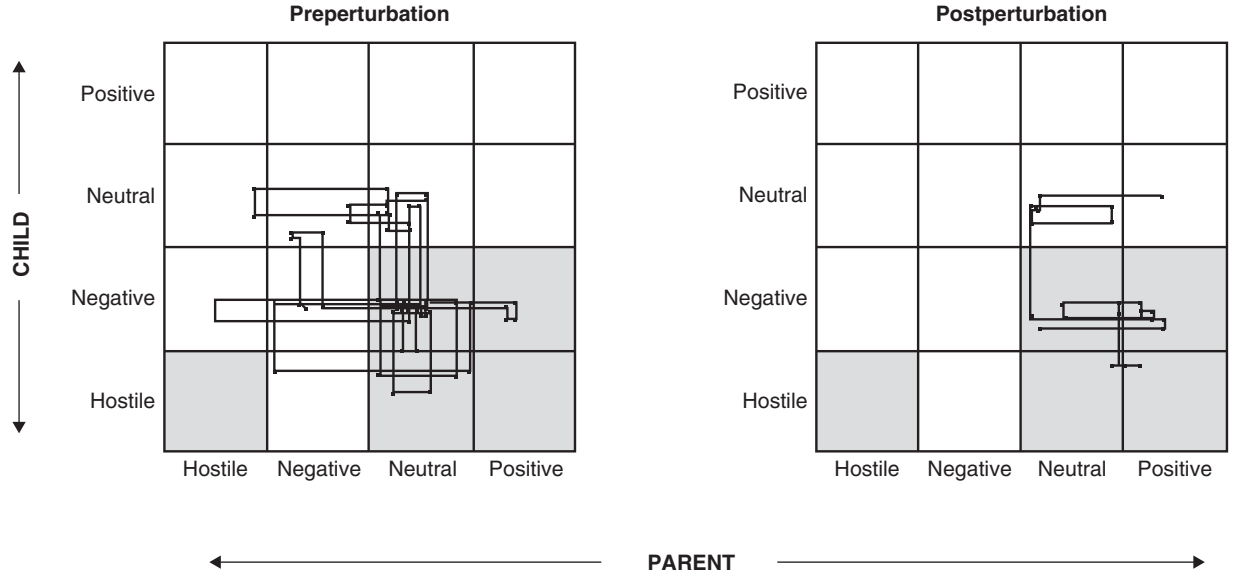

Figure 16.15 Pre- and postperturbation state space grids for an EXT dyad. *Source:* From Granic, I., & Lamey, A. V. (2002). Combining dynamic-systems and multivariate analyses to compare the mother–child interactions of externalizing subtypes. *Journal of Abnormal Child Psychology*, *30*, 265–283.

interaction between a pure externalizing child and his parent, pre- and postperturbation. As exemplified in these grids, EXT dyads tended to go to the permissive region (child hostile–parent neutral/positive) of the state space grid, as well as other regions (i.e., mutual neutrality and negativity), before the perturbation. After the perturbation, EXT dyads tended to remain and stabilize in the permissive region. Figure 16.16 represents the interaction of a MIXED dyad. Similar to EXT dyads, the MIXED dyads occupied the permissive region, as well as other areas, before the perturbation. But in contrast with the EXT group, MIXED dyads tended to move toward the mutual hostility, or mutual negativity, region of the state space grid after the perturbation. Granic and Lamey (2002) concluded that the perturbation was a critical design innovation that provided the means by which clinical subtypes could be differentiated.

Another contribution of this study was a more general one—the use of SSGs, with their rich case-by-case temporal narratives, provided a technique to further parse interaction processes that have been previously assumed to represent one coherent pattern. In this case, the coercive process (Patterson, 1982; Patterson, Reid, & Dishion, 1992; Snyder et al., 1994) was shown to constitute two separate microsocial patterns—two separate attractors on a state space (Granic & Patterson, 2006). Moreover, the conditions under which dyads would be drawn toward one region or the other were found to differ for subtypes. The use of SSGs to uncover heterogeneous processes may be relevant to a variety of phenomena in developmental psychopathology including variability in the real-time unfolding of attachment patterns (Coleman & Watson, 2000), in bullying interactions on the playground (Pepler, Craig, & O'Connell, 1999) and in parent–adolescent interactions during puberty (Granic, Dishion, et al., 2003; Granic, Hollenstein, et al., 2003).

State Space Grid Analysis: Within Grids

In general, there are two ways to use SSGs for analysis: deriving measures from one specific state space arrangement (within-grid analysis) and analyzing similarities and differences between grids, such as with longitudinal designs (between-grid analysis). Within a given SSG, patterns can be quantified and used as variables for statistical analyses. Measures that capture the temporal and spatial patterning of behavior have been developed for time-based (e.g., second-by-second coding, daily diary entries) as well as event-based (e.g., conversational turns) data (Hollenstein, 2013). These variables can all be obtained via the SSG software program, GridWare (Lamey et al., 2004), available for free on the Internet (www.statespacegrids.org) and may be used to map intra- or interpersonal behavioral trajectories. Here, we highlight two within-grid analysis approaches relevant to the development of psychopathology (for a comprehensive review, see Hollenstein, 2013): attractor (or content) analysis and whole-grid (or structural) analysis. In general, long durations or frequent recurrences of

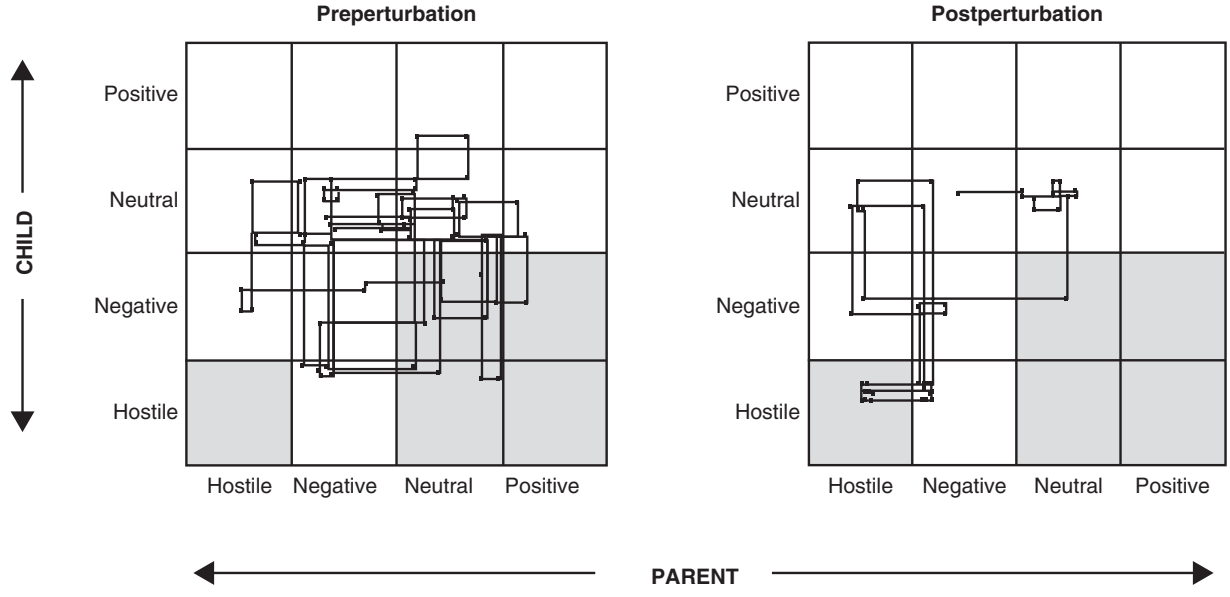

Figure 16.16 Pre- and postperturbation state space grids for a MIXED dyad. *Source:* From Granic, I., & Lamey, A. V. (2002). Combining dynamic-systems and multivariate analyses to compare the mother–child interactions of externalizing subtypes. *Journal of Abnormal Child Psychology*, *30*, 265–283.

behavior in a particular cell or region suggest an attractor on the state space, and these hypothetical attractors can be compared and tested within individuals across development as well as between individuals.

Attractor analysis can be theoretically driven (expected attractor states are compared across subjects; e.g., Granic & Lamey, 2002) or empirically derived for each case (e.g., Lewis et al., 1999). Lewis et al. (1999) is still the best example of empirically derived attractors for analysis. First, attractor cells or regions were identified via a winnowing technique that used the individual cell durations. Through iterations removing one cell at a time, the number of possible attractor states was winnowed down to only those cells in which durations exceeded chance. Each trajectory was found to have at least one cell—and sometimes two cells—that qualified as attractors. Once identified, analytical options for theoretically and empirically derived attractors are the same. For within-grid analyses, this primarily consists of determining the *strength* or relative pull of the attractor on the system's trajectory. On top of relatively straightforward attractor indices such as cumulative, proportional, mean, or maximum durations in cells or groups of cells (i.e., regions) of interest, attractor strength can be measured via return time. Return time is the latency to return to a cell or region following an event in that cell or region. This can be measured in units of time, number of events, or number of unique cells visited en route. For example, Figure 16.17 shows three grids with attractor regions shaded in gray. Grid B shows a duration in cells 2/2 (cell labels follow the x/–y convention) and 2/3 and a very low duration in cell 1/3. In grid C, cell 3/1 shows a high mean duration (each time behavior goes to that cell, it tends to stay there for some time) whereas cell 1/1 in that same grid shows a low perseverance value. Finally, grid B shows a very low return time for cell 2/2 (every time behavior leaves that cell, it returns in approximately one turn), but a high return time for grid A, cell 1/0. Thus, multiple attractor strength indices can be used for subsequent statistical analyses.

Whole-grid analysis can be used to derive measures of the overall variability or structure of trajectories on the SSG. There are two classes of overall variability measures: dispersion-based and transition-based. Measures of dispersion capture the overall spread of the trajectory based on the number of unique cells visited. With duration-based data, this dispersion can also be calculated controlling for the relative durations in each cell—cells with longer duration count more in the index than cells with low durations. Thus, high levels of dispersion indicate a more even distribution of behavior across the entire state space. Transitions are somewhat independent of dispersion. A trajectory can have a high number of transitions (i.e., the number of lines in the trajectory on an SSG plot) among many cells or only a few. Thus, a simple count of the number of transitions (or transitions-per-minute for studies with trajectories of unequal length) can indicate the dynamic flexibility of the system, as complementary information to dispersion. As discussed earlier, another transition-based measure is entropy, which is based on the lag 1 event sequences—higher entropy indicates less predictability. Both dispersion and transition measures of dyadic variability have been shown to correlate with children's mood and behavior problems. Low variability, interpreted as low flexibility or high rigidity, in parent–child interactions has been associated with externalizing and internalizing problems in early childhood (Hollenstein et al., 2004), lack of response to treatment for externalizing problems (Granic et al., 2007), and maternal depression (Lunkenheimer et al., 2012). Returning to Figure 16.17, grids A and C show high dispersion, compared with grid B, and grid A shows a low stability 1 value, compared with grid B.

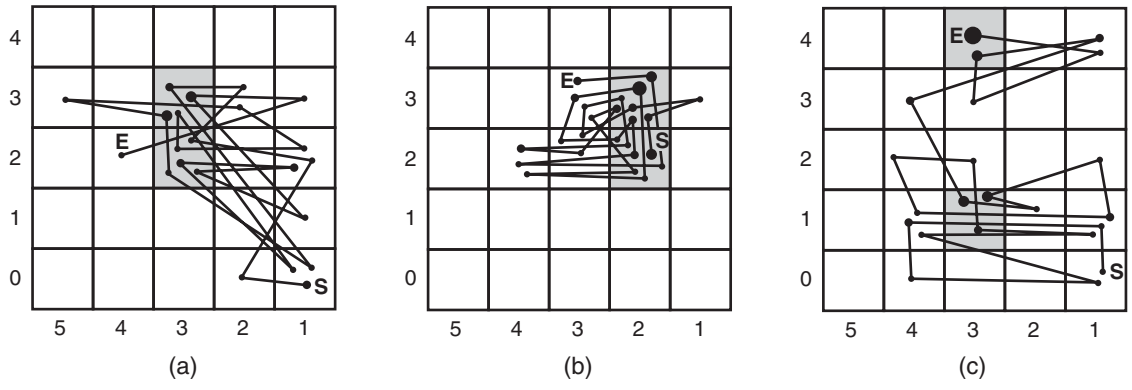

Figure 16.17 Examples of three state space grids from Lewis, Lamey, and Douglas (1999). *Source:* From Lewis, M. D., Lamey, A. V., & Douglas, L. (1999). A new dynamic systems method for the analysis of early socioemotional development. *Developmental Science*, *2*, 457–475.

State Space Grid Analysis: Between-Grid Analysis

After computing the within-grid parameters that are most relevant for a particular research question, longitudinal statistical techniques (most of which are quite familiar to developmental psychopathologists) may be applied. We recommend using these statistical procedures in such a way that maintains the integrity of the individual (or dyadic) case (e.g., growth clusters). However, multivariate analyses including one-way analyses of variance (ANOVAs), regressions, and SEM can just as easily be run on the grid variables. For example, we have shown over the course of five longitudinal observations that parent–boy variability (dispersion and transitions) peaked when the son was 13–14, consistent with the hypothesis that adolescence is a developmental phase transition of temporarily heightened variability in interpersonal interactions. The use of within-grid measures of repeated observations in this way is statistically relatively straightforward, thus we will not elaborate further here However, two between-grid techniques enable the kind of person-centered analyses of interest to system-minded researchers.

Lewis et al. (2004) developed two techniques to depict month-to-month stability and change in toddler's socioemotional habits. Observed once a month for 11 months (ages 14–24 months), each subject had 11 SSGs of the behavioral trajectories. The study was designed to test the hypothesis that the 18–20-month transition was a developmental phase transition—a temporary period of instability and fluctuation as the children developed from one stable behavioral pattern to another. Thus, the authors derived two indices from SSGs to see if the lowest month-to-month stability (i.e., greater change) occurred at 18–20 months. The first technique they used was to calculate the *inter-grid distance* score (IDS). Grid-to-grid Euclidian distance scores yield a global metric of the difference in behavioral landscapes from month to month, based on the sum of squared differences across all cell pairs. For each grid cell pair, the difference in duration values over two consecutive months is calculated, then squared, and then these values are summed for all cells. Next, the square root of this sum is taken as the distance score between the two grids. The second technique was to put all SSG cell variables for all participants at every month into one cluster analysis. Each SSG was then identified as a member of a homogenous cluster. Then, returning back to a case-by-case computation, a cluster change score was calculated: a value of zero was assigned if the cluster membership of one month was the same as the subsequent month and a value of 1 was assigned if the cluster membership changed from one month to the next. Thus, from 11 SSGs, 10 cluster change scores were calculated for each case. Both the IDS and cluster change score were highest during the 18–20-month period as hypothesized. Thus, SSG-to-SSG change can reveal patterns of development that go beyond using within-grid measures in standard statistical analysis.

Although the SSG method is clearly still in its early stages of development, we are encouraged by its potential. One of the important advantages to this technique is its inherent flexibility. At the very least, it is a visual, exploratory tool to develop and refine hypotheses. At best, this methodology provides a source from which novel, temporal-based, process-level predictors may be tapped and used to strengthen current models of normal and atypical development. Researchers are not limited to using continuous time-series, as is the case with many other DS methods. Categorical and ordinal data are also appropriate for this type of analysis. Also, the grids are malleable in that they can represent systemic behavior on the individual as well as dyadic level. In addition to the aforementioned examples, changes in peer, romantic couples, and sibling interactions, for example, can easily be tracked using SSGs. In fact, apart from the difficulties in visually representing the data, the variables derived from the grids can be extended past the two dimensions on which we have focused. For instance, SSGs have been used to analyze triadic (Lavictoire et al., 2012) and group (Martin et al., 2005) interactions.

Another benefit of this approach is the extent to which it remains user-friendly and does not require expertise in mathematical modeling. In addition, we have developed a SSG software program that will output grids, compute all the grid parameters mentioned previously, and export these measures for statistical analyses on these parameters: GridWare (Lamey et al., 2004), available for free on the Internet (www.statespacegrids.org).

FUTURE DIRECTIONS: IMPLICATIONS FOR CLINICAL RESEARCH

There are no limits to the diverse topics and varied problems that can potentially be addressed with the application of DS methods; clearly listing all of them here would be impossible. In this final section, we have chosen to limit our discussion to the implications for clinical research, an area in which many developmental psychopathologists share an interest. Because DS methods are specifically designed to capture change processes, and because the study of psychopathology often breaks down into the study of individual patterning, one of the most exciting potential

applications of DS methods may be in treatment research. Although randomized controlled trials have helped to identify the most effective interventions for a variety of childhood mental health problems, there remains variability in outcomes (e.g., Eyberg, Nelson, & Boggs, 2008; In-Albon & Schneider, 2007) and almost no understanding about the underlying processes and mechanisms of change (Hinshaw 2002; Kazdin, 2000, 2001, 2002, 2009). This problem highlights our lack of understanding of the change process itself. Information about the mechanisms responsible for the success of interventions is critical for guiding clinicians in making informed decisions about how to tailor interventions to different contexts and for unique individuals and families. Also, identifying mechanisms of change is a crucial step toward more effective program dissemination in community settings (Kazdin, 2000).

DS principles and methods should be able to provide a microsocial, process-level account of how family and peer relationships change over the course of treatment and why some may fail to do so (Gardner & Wampler, 2008; Granic et al., 2007; Lichtwarck-Aschoff et al., 2012). In the following, we present three hypotheses that can be generalized to any evidence-based intervention.

First, phase transitions in normative development may be critical to mark because they allow clinicians and researchers to more efficiently, and perhaps more successfully, access and manipulate mechanisms of change. There may be normative stage transitions in children's development (e.g., early childhood 3–5 years, early adolescence 11–14 years), as well as idiosyncratic transition periods (e.g., divorce or birth of a sibling) during which, the coordination among system elements begins to break down, previous attractors are destabilized, and new patterns have the potential to emerge (e.g., Lewis et al., 1999). During phase transitions, the system is much more open to environmental shifts, and seemingly small changes have the potential to radically alter the trajectory of relationships and individuals. As a result, prevention and intervention efforts that target youth mental health problems may have their maximal effect during these periods. Thus, based on DS ideas we would expect that clinical interventions and prevention efforts will be most effective if they are targeted at these sensitive periods. The same intervention targeted before or after a phase transition is hypothesized to be less successful. To test this hypothesis rigorously, it would be important to design treatment studies that examine the differential impact of the same evidence based intervention before, during, and after a recognized transition period.

Second, psychotherapy researchers suggest that, for improvements to be made, treatment must trigger a reorganization of affective, cognitive, and behavioral systems (e.g., Caspar, Rothenfluh, & Segal, 1992; Greenberg, Rice, & Elliott, 1996; Mahoney, 1991). To induce a major reorganization, "old patterns must be shaken loose or destabilized to allow for new configurations to emerge or to be discovered" (Hayes & Strauss, 1998, p. 940). Thus, "destabilization is viewed as a necessary and natural process that allows for growth and change" (p. 940). Although this destabilization period has been theoretically proposed, very few empirical studies have investigated this profile of change in therapeutic contexts partly because, until recently, we lacked the appropriate methodological tools for doing so (Cicchetti & Cohen, 1995). The study by Lichtwarck-Aschoff et al. (2012) discussed earlier explicitly investigated the destabilization profile in aggression treatment and found that children who improved through treatment showed characteristics of a reorganization in the parent–child dyad. In line with that study we expect that treatment gains—across a wide range of psychopathologies and interventions—will be evident only after a phase transition, operationalized as a significant increase in the variability of behavioral patterns. Without evidence of a destabilization period, treatment is expected to be less successful.

It is important to keep in mind that system destabilization, or a lack thereof, is part of a process description, revealing potential forms of treatment progressions. They are never the cause of success or failure of the treatment itself. Therefore, it is important that future efforts are targeted on unraveling the underlying causes of the reorganization that are triggered by the treatment perturbation. One way to do this would involve a model building and simulation approach (discussed in this chapter; e.g., Gottman, Murray, Swanson, Tyson, & Swanson, 2002; Van Geert, 1994; Van Geert & Lichtwarck-Aschoff, 2005), emphasizing the client's internal dynamics, together with the interaction with external influences such as treatment. A second way of understanding the causal mechanisms in terms of change processes is the investigation of (changes in) control parameters (Van Orden et al., 2009). A prime candidate for a control parameter within the context of treatment is motivation to change (Guastello, 1995, 2002; Hayes & Strauss, 1998; Kowalik, Schiepek, Kumpf, Roberts, & Elbert, 1997; Mahoney, 1991; Schiepek, 2009). Regarding organizational change, Guastello (1995, 2002) described pressure for change and resistance to change as two orthogonal control parameters. When resistance is low, even minor pressures to change (i.e., intervention efforts) may lead to gradual and small changes in behavior. When resistance is high, old patterns of behavior will not

change if pressure to change is low. However, when both resistance and pressure to change are high, radical, nonlinear change is likely to occur. This conception is in line with the struggle-and-work-through hypothesis (Chamberlain et al., 1984; Stoolmiller et al., 1993) where it has been demonstrated that families that show low resistance from baseline to termination are unlikely to show significant change and benefit from treatment (Stoolmiller at al., 1993). Hence, the time-serial investigation of changes in control parameters (e.g., motivation to change) in relation to structural changes in real-time behavior is needed to enhance our understanding of causal mechanisms producing successful treatment outcomes.

Finally, an implicit, if not explicit, assumption made by most clinicians and clinical researchers is that, when treatment works, family interactions change from being emotionally negative or angry to positive or supportive. But according to emotion theorists (e.g., Izard 1977; Magai & McFadden 1995; Tomkins 1963), the expression of anger or any other negative emotion is not pathogenic; all emotions are adaptive and important to express in appropriate contexts. It is the effective—flexible—regulation of these emotions that is critical for healthy development (e.g., Bonanno, Papa, Lalande, Westphal, & Coifman, 2004). Being emotionally flexible is the hallmark of healthy functioning at any age (Kashdan & Rottenberg, 2010). Being locked into any one emotional state is often the definition of certain psychopathologies: perseveration of fearful vigilance is the mark of anxiety, unyielding sadness is diagnostic of depression, and long-lasting elation is mania. Developmentalists agree that, in general, regulation skills are learned and practiced in the context of parent–child interactions. We go on to propose that flexibility in these interactions (i.e., the ability to shift from one emotional state to another, according to contextual demands) may be more important for healthy development than the complete avoidance of negative affect (see also Gottman & Notarius, 2000, for a similar suggestion for marital relationships). Indeed the study by Granic and colleagues (2007) discussed earlier showed that children that improved through treatment could be distinguished from the ones that did not based on the flexibility of their parent–child interactions. The improvers had changed their rigid interactions into emotionally flexible and reparative ones not simply into positive interactions. But flexibility can also be assessed on different levels. As an illustration, we are currently investigating whether flexibility is associated with positive treatment outcomes in an anxiety treatment for children on the basis of changes in the coordination of body movements in parent–child interactions (see for a similar approach Ramseyer & Tschacher, 2011). Here we expect that improver dyads show a more balanced body synchronization in contrast to a parent dominated coordination. In sum, parent–child and peer interactions are predicted to become more flexible as a function of successful treatment. Rigidity in parent–child and peer interactions on the other hand gives rise to a variety of cascading constraints that contribute to the emergence and maintenance of problem behavior.

These three hypotheses provide an illustration of how DS ideas and methodologies can promote the study of change processes in clinical research. Providing a finer degree of resolution than pre-post designs and thereby revealing predictors, moderators, mediators, and mechanisms of change (Hayes et al., 2007). The evidence-based treatment movement has set out to identify what works for whom by implementing randomized clinical trials. The ideas and methodologies described in this chapter offer the possibility of enriching this work to better understand the when, how, and why of change.

CONCLUSION

From the beginning of its establishment as a discipline, one of the core priorities in developmental psychopathology has been methodological diversity (e.g., Cicchetti & Cohen, 1995b; Cummings et al., 2000; Richters, 1997). One reason for encouraging this analytic pluralism is the recognition of the disparity between systems-based models of developmental psychopathology and the inadequate methodological tools that are available to test them (Richters, 1997). We have argued that DS approaches to development offer research methods that show greater fidelity to the complex, heterogeneous, temporal nature of developmental phenomena. Clearly no set of analytic methods can address the mismatch of methods and models entirely; thus, we are not arguing for the complete abandonment of well-established techniques. Instead, our purpose in providing a survey of DS methods is to encourage developmental psychopathologists to begin examining empirically questions that may have previously seemed out of analytic reach.

CHAPTER 17

Missing Data

TODD D. LITTLE, KYLE M. LANG, WEI WU, and MIJKE RHEMTULLA

STATISTICAL ISSUES: WHAT HAPPENS WHEN DATA GO MISSING? 761
Bias 761
Type I Error 761
Type II Error/Power 761
MECHANISMS OF MISSINGNESS 763
Missing Completely at Random 764
Missing at Random 766
Missing Not at Random 766
MODERN MISSING DATA METHODS 767
FULL INFORMATION MAXIMUM LIKELIHOOD 767
Multiple Imputation 768
PRACTICAL CONSIDERATIONS 774
Assumptions 775
Auxiliary Variables 776
Fraction of Missing Information 777
Assessing Model Fit with Missing Data 777
Mediation Analysis 780
When to Use FIML Versus MI 782
REVIEW OF MISSING DATA PRACTICES IN PSYCHOLOGICAL RESEARCH 782
WHY CHANGE? 784
PLANNED MISSING DATA DESIGNS 784
Multiform Planned Missing Protocols 785
Two-Method Planned Missing Design 787
Wave-Missing Designs 789
CONCLUSIONS 790
REFERENCES 791

Missing data are ubiquitous in most human science data, and many prominent social scientists and statisticians have written on the subject of addressing nonresponse in social science studies (e.g., Enders, 2013; Graham, Cumsille, & Shevock, 2012; Graham, Hofer, Donaldson, MacKinnon, & Schafer, 1997; Graham, Hofer, & Piccinin, 1994; Hofer & Hoffman, 2007; Little & Schenker, 1995; Nakagawa & Freckleton, 2010; Sinharay, Stern, & Russell, 2001). The treatments for missing data vary considerably across the disciplines covered under the human sciences umbrella. Unfortunately, the traditional procedures that have been in common use through the last century are prone to bias except in very circumscribed conditions. Fortunately, recent advances in the capabilities of computer hardware and software have made a new breed of contemporary approaches both accessible and easy to implement. These contemporary treatments are versatile and powerful in the ways that unplanned missing data can be handled. And, as we will describe in detail, the power of the modern missing data approaches can be leveraged to allow remarkable uses in the form of planned missing data designs. The goal of this chapter is to supplement, in an accessible manner, the burgeoning literature on modern missing data treatments, with a particular focus on planned missing data designs. Later in this chapter, we will describe in some detail the two contemporary approaches: full information maximum likelihood (FIML) estimation and multiple imputation (MI). For book-length treatments of these contemporary approaches to addressing missing data, see Allison (2002), Enders (2010), Graham (2012), Little and Rubin (2002), and van Buuren (2012).

Our discussions around the topic of missing data will focus on examples derived from clinical research in the area of developmental psychopathology (see also Little, Jorgensen, Lang, & Moore, 2014). Our goal is to fuel the movement toward a data-collection paradigm shift

Partial support for this project was provided by grant NSF 1053160 to the first and third authors, a Banting postdoctoral fellowship from the Social Sciences and Humanities Research Council of Canada to the fourth author, and the Center for Research Methods and Data Analysis at the University of Kansas (when it was under the direction of Todd D. Little). Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the funding agencies. We would like to thank Richard Kinai for assisting with creating Table 17.2.

that embraces planned missing data designs and improves study protocols to better address the inevitable unplanned missing data that will arise. In this regard, missing data are not a bane in the research process, but rather appropriate application of modern methods provide solace for the unplanned missing values and dramatic opportunities in the context of planned missing data designs.

STATISTICAL ISSUES: WHAT HAPPENS WHEN DATA GO MISSING?

Regardless of the reasons for missing data, the problem cannot simply be ignored (Allison, Goodson, & Neilands, 2008; Raghunathan, 2004), and the presence of nonresponse necessarily complicates the statistical analysis (Brown, 1994; Cheung, 2007; Finkbeiner, 1979; Gleason & Staelin, 1975; Haitovsky, 1968; Harel, Hofer, Hoffman, Pedersen, & Johansson, 2007; Kim & Bentler, 2002; Lee, 1986; Little, Howard, McConnell, & Stump, 2011; Little, Schnabel, & Baumert, 2000; Longford, 2005; McArdle, 1994; McArdle & Hamagami, 1992; McArdle & Hamagami, 2001; Rovine, 1994; Song & Lee, 2002; Wothke, 2000). More specifically, three statistical issues emerge when data have gone astray: bias, type I error, and type II error (i.e., power).

Bias

The first key issue is bias. Is there anything systematic about why the data are missing? If so, then the remaining data for the selected sample are no longer representative of the population from which the sample was drawn. Any parameter estimates derived from the remaining data will no longer generalize to the population and any conclusions will be, to some degree, invalid (Little & Rubin, 2002; Schafer, 1997). As we will illustrate in more detail below, the classical, or *ad hoc*, treatments for missing data (e.g., listwise or pairwise deletion) do nothing to correct for potential bias, whereas the modern, or *principled*, treatments attempt to correct for any biasing influences (Little & Rubin, 2002; Rubin, 1987).

Modern missing data treatments address the bias induced by a systematic influence associated with the missing data by adjusting the parameter estimates to reflect, as closely as possible, what they would have been had there been no missing data (Rubin, 1996). The extent to which this is possible depends on the causes of missing data, and whether those causes are represented in the data (i.e., the missing data mechanism; more on this later). In other words, when data go missing we lose information both in the statistical sense of lower power and in the substantive sense that we know less than what we should know.

Type I Error

The second issue to contend with in the face of missing data is type I error. Many traditional methods for dealing with missing data (e.g., any single-imputation technique) result in standard errors that are smaller than they should be, given that the data are not complete. The problem here is similar to what would happen if one collected data from 20 people but computed a standard error using $N = 200$. The standard error is based on an assumption that the data contain more statistical precision than they really do, so the estimated standard error is too small. Too-small standard errors translate to a higher-than-nominal probability of finding a significant result when there is no effect in the population.

Type II Error/Power

The third issue when data go missing is power loss (i.e., higher type II error rates). As implied in the previous paragraph, missing data means less statistical precision, so it will always result in less powerful analyses than a complete data set (unless the missing values were completely redundant with the nonmissing values; Davey & Savla, 2010; Graham, Olchowski, & Gilreath, 2007; Savalei & Rhemtulla, 2012). Listwise deletion leads to the greatest loss in power of all missing data methods (Enders, 2010; Little & Rubin, 2002; Schafer & Graham, 2002). Single imputation methods, such as mean substitution or regression imputation, will lead to greater power; however, these methods rarely lead to unbiased estimates and are associated with increased type I error rates (Enders, 2010; Rubin, 1987, 1996; Schafer & Graham, 2002). Modern treatments to missing data are *efficient*, which means they result in the most powerful analysis possible, while also eliminating much of the bias due to selective missingness (Graham et al., 2007).

Table 17.1 presents a list of missing data treatments along with descriptions of how each treatment deals with (or fails to deal with) bias and type I and II error. As is plain from this table, the conditions under which the traditional ad hoc methods will be valid are quite limited and often unrealistic in contemporary studies across the human sciences. To fully understand the reasons for the poor performance of classical methods, we need to define the three mechanisms for missing data.

TABLE 17.1 Methods of Treating Missing Data

Method Deletion	Bias/power/error	Description
Listwise deletion/complete case analysis	Bias under MAR & MNAR Loss of power under MCAR, MAR, & MNAR	All cases with any missing values are deleted. Analyses are done on the remaining cases. Under MCAR, this technique produces unbiased parameter estimates. Standard errors (and thus confidence intervals and *p*-values) are larger, reflecting the loss of data. As the proportion of missing data increases, power can decrease substantially. Under MAR/MNAR, the sample after deletion is not representative of the complete data set, resulting in biased parameter estimates (e.g., means, correlations, regression coefficients). Bias increases as the complete case sample grows more different from the complete sample, and as the proportion of missing data increases.
Pairwise deletion/available case analysis	Bias under MAR & MNAR Loss of power under MCAR, MAR, & MNAR	Each statistic is computed using cases that have complete data available for that statistic. A case with missing data on V3 is not used to find the correlation between V2 and V3, but is used to find the correlation between V1 and V2. Power loss is less than with listwise deletion but still a problem. Estimates are biased under MAR and MNAR. Every statistic is based on a different sample size, which may result in an impossible correlation matrix, which can cause serious estimation problems. As sample size is a key element in calculating standard errors, lack of a constant N results in some software packages using the average sample size per variable for these computations. This has the potential of underestimating/overestimating the standard error for some variables. Lack of a single value for a sample size affects the accuracy of the standard error and the testing of model fit.
Single imputation		Single-imputation techniques address prediction error but not error of estimation, leading to deflated standard error estimates. This leads to inflated type I error rates. When variance is underestimated, correlations suffer and significance testing tends to result in more type II errors.
Mean substitution	Bias under MCAR, MAR, & MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	Each missing value is replaced with that variable's mean. The imputed values have zero variance because they all take on the same value. As such, estimates of the variable's variance and relations with other variables (e.g., covariances, correlations, regression coefficients) are underestimated. This problem exists regardless of the missingness mechanism and gets worse as the proportion of missing data increases.
Regression imputation	Bias under MCAR, MAR, & MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	Each missing value is replaced with its predicted value based on a regression equation using all other variables as predictors. Information from the complete variables is used to fill in the incomplete variables. The imputed values are perfectly predicted by the other variables in the data set, with no error added. Variances will be underestimated (because error variance is lacking), and variable relations (correlations, covariances, regressions) will be overestimated. This problem exists regardless of the missingness mechanism, and gets worse as the proportion of missing data increases.
Stochastic regression imputation	Bias under MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	As with regression imputation, each missing value is replaced with its predicted value, but it has a normally distributed residual error term added to the imputed predicted score. The added residual variance adds variability to the imputed variable and adds noise to the estimated relations between variables. Thus, under MCAR and MAR, parameter estimates are unbiased. Under MNAR, the required information to achieve accurate estimates is missing, so bias persists under MNAR. As with every single-imputation technique, the imputed data are treated like complete data, so standard errors will resemble what they would have looked like with complete data. In other words, the information lost due to missing data is not accounted for, so standard errors will be too small. Inflated type I error rates (under every mechanism) result.
Expectation-maximization (EM) imputation	Bias under MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	The EM algorithm produces maximum likelihood (ML) estimates of the covariance matrix $\boldsymbol{\Sigma}$ and mean vector $\boldsymbol{\mu}$ from incomplete data. The algorithm iterates through two steps. In the expectation (E) step, the missing values are filled in with their expected values after conditioning on the observed data (similar to stochastic regression imputation). The subsequent maximization (M) step applies complete data ML estimation to the imputed data from the E-step to derive updated estimates of the covariances and the means. These updated estimates are used by the next E-step to build the regression equations used to fill in the missing data. The algorithm repeatedly iterates between the E- and M-steps until the difference in the maximized likelihood values from adjacent M-steps falls below a specified criterion. The imputed values from the last E-step may be saved as a single imputed data set. EM is an important building block of more complex missing data methods (e.g., Enders, 2003; 2004; Enders & Peugh, 2004; Lauritzen, 1995; Savalei & Bentler, 2009). The estimated $\boldsymbol{\Sigma}$ and $\boldsymbol{\mu}$ are the same as those produced by FIML. However, a single EM imputation has the same problem as any other single imputation, which is that uncertainty cannot be accounted for in a single-imputed data set. Type I error rates will be inflated.

(*continued*)

TABLE 17.1 *(Continued)*

Method Deletion	Bias/power/error	Description
Hot deck imputation	Bias under MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	Both hot and cold deck imputation techniques are common in survey research. Hot deck imputation works by finding participants who match the case with missing data on other variables. For example, missing scores on job performance are replaced by randomly sampling job performance scores from cases with identical age and gender. Depending on how the imputation is actually performed, this method might or might not preserve the correlations among variables. This method is nonparametric and less sensitive to model misspecification. It is not good for small sample sizes.
Cold deck imputation	Bias under MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	In cold deck imputation, information from external sources is used to determine the matching variables. An external source could be another available data set from which to impute missing values. This technique results in small standard errors (as missing information is not taken into account) and adjusted R^2, denoting decreased variability in the data used for these analyses.
Averaging available items (person-mean imputation / prorated scale score)	Bias under MCAR, MAR, & MNAR Error inflation under MCAR, MAR, & MNAR	A technique used on multiple item scale data with item-level missing data. A scale score is computed by averaging the available items for each case. This technique is equivalent to replacing the missing values for each case with the mean of that case's values. This technique only works for MCAR assuming *parallel items*: all items have same mean, same true-score variance, and the same error variance—this is rarely the case. When this assumption is violated, estimates will be biased even when data are MCAR. More specifically, coefficient alpha estimates will be biased, as will measures of association and variance.
Last observation carried forward	Bias under MCAR, MAR, & MNAR Error inflation (type I error) under MCAR, MAR, & MNAR	Missing values in longitudinal data are replaced with the latest previous observation. A key assumption here is that the most recent observation is the best guess for subsequent missing values. The implication is that scores remain constant after the last observed measurement, an assumption that is not reasonable in longitudinal data. Parameter estimates will be biased in unpredictable directions, depending on the particular features of the data. The magnitude of bias is not predictable. Treatment group differences can be attenuated. Type I error rates are inflated through failure to account for the effect of missing information.
Modern methods		
Multiple imputation (MI)	Bias under MNAR only Power is maximized and error rates are correct for MCAR and MAR	In MI, multiple values for each missing data-point are imputed. The information lost due to missing data in estimating model parameters is quantified using the variability in parameter estimates between imputed data sets. As such, standard error estimates are unbiased, resulting in accurate type I error rates. Imputation uses all the information in the data set, resulting in unbiased parameter estimates under MCAR and MAR. MI commonly assumes multivariate normal data, but imputation algorithms for other distributions are possible. With the correct assumptions on data distributions and missing data mechanism and a large number of imputations, MI is asymptotically unbiased and efficient.
Full information maximum likelihood (FIML)	Bias under MNAR only Power is maximized and error rates are correct for MCAR and MAR	FIML estimates model parameters and standard errors directly using all the available data. FIML aims at identifying the population parameters that are most likely to have generated the observed data (i.e., maximize the likelihood of observing sample data). FIML is a model-based missing data solution, which means that its accuracy depends on the accuracy of the model being estimated. Typically multivariate normality is assumed, though it is possible (but computationally intensive) to use FIML with binary and other distributions. When the assumptions are met, FIML leads to asymptotically unbiased and efficient estimates.

MECHANISMS OF MISSINGNESS

Missing data can occur because a specific datum for given person is not present (e.g., a participant skipped an item due to an error or not wanting to answer) or because data on all variables at a specific measurement occasion for a specific person is not present (e.g., a participant dropped out of a longitudinal study after the second wave of data collection). The first type of missing data is often referred to as item missing. The second type of missing data is often called wave missing, or if the wave missingness occurs because of participants permanently dropping out of a study, attrition. Terms like attrition, wave missing, and item missing are general descriptors of the types of missing data that occur because a desired response was not obtained (Enders, 2010; Rubin, 1987; Shafer & Graham, 2002). This type of missing data should be distinguished from structural missingness. Structural missingness refers

to elements of a data matrix that are not possible to collect (e.g., items that ask about pregnancy for participants who are not or cannot become pregnant, empty cells following a negative response to a "gatekeeper" item, or data for participants after they are deceased). The various descriptors of the types of nonresponse that can occur should not be confused with the mechanisms of missing data. A mechanism of missing data is the causal process associated with whether a data point is missing or not but not necessarily what the value of the missing information would have been.[1]

Missingness mechanisms distinguish the causes of missingness. The pattern of missing data can be described using a missingness matrix, R, which has the same dimensions as the data matrix but contains 0 whenever a datum is observed and 1 whenever it is missing. The key question in establishing the missingness mechanism is: what predicts R? There are three potential sources of prediction, which are the three missingness mechanisms (Rubin, 1976). These causes together account for all missing data. In describing these mechanisms, we will refer to Table 17.2, which provides their definitions in terms of the formal probability distributions of the missing data patterns as originally described by Rubin (1976). Figure 17.1 provides a graphic schematic of the mechanisms of missing data.

By way of a running example, we will describe a hypothetical study of the relationship between parental involvement (a scale administered as part of a larger parent protocol) and child school adjustment (a scale administered as part of a larger teacher protocol). As a purely hypothetical point of discussion, we will pick an arbitrary true correlation of .5 between these two constructs. This correlation of .5 exists in the population and in the hypothetical sample that is drawn from the population; that is, sampling error is held constant so we can focus on the influence of the missing data mechanisms.

Missing Completely at Random

The first mechanism of missing data is termed missing completely at random (MCAR). When the data are MCAR it means that the missing data patterns have zero associations with any variables included in the data set or with any unmeasured variables that are associated with the missing values themselves.[2] This lack of association does not mean that a datum is not missing for a reason—under MCAR, the reasons are essentially random. In this regard, the label for this mechanism clearly communicates, even to naïve readers, the reason for the missingness. In this regard, MCAR can be a truly random process or a process that happens to have a zero association with all variables in an investigation. Unfortunately, MCAR data are not as common as we would hope. As indicated in Table 17.1,

[1]Strictly speaking, the missingness mechanism can't provide any information about what the missing value may have been. It is only a way to describe the process that gave rise to the nonresponse. From the perspective of Rubin (1976), every cell in a data set is associated with two values: an actual data value Y_{ij} (which may or may not be observed); and a missingness indicator R_{ij} (which takes a value of 1 when the corresponding Y_{ij} is missing and 0 if it is observed). The missingness mechanisms, as they are traditionally conceptualized, are concerned only with describing the process by which R_{ij} takes a value of 1 or 0 (i.e., whether or not Y_{ij} is missing or observed), but they do not address what the correct value for any missing Y_{ij} might be. This is an important distinction. Knowing what the missing values would have been implies knowledge of the sampling distribution of the missing values. Knowing the missingness mechanism, on the other hand, is a weaker form of information that implies only knowledge of the more general process by which a value is or is not observed (but not anything about what that value may look like). Rubin (1987, p. 17) overtly distinguishes between these two types of information when he says: "In general, it is impossible to estimate a population quantity such as the mean without making assumptions about either the distribution of values for nonrespondents or the process that creates nonresponse."

[2]Every incident of nonresponse, as with any natural occurrence, has some cause. If MCAR missing had no relationship to any variable at all, then it would not exist. In other words, if there is no reason for a value to go missing, it will be observed. This claim can lead to confusion if we describe MNAR as the probability of missingness being predictable by some set of unmeasured variables. This misunderstanding can be largely remedied if we recognize that this definition of MNAR is what Enders (2010) called *indirect MNAR*. The issue can be illuminated by expanding the description of indirect MNAR slightly. Indirect MNAR is only problematic because the unobserved variables that predict R are also related to the Y_{mis}. This mutual association induces a spurious correlation between Y_{mis} and R. This is one reason that the original Rubin (1976) definitions for the missingness mechanisms are given only in terms of the statistical patterns in the data set. In practice, whether the MNAR is direct or indirect, the observed pattern of relationships in the data will be the same. Namely, there will be an apparent relationship between Y_{mis} and R, even after controlling for the relationship between Y_{obs} and R. As discussed above, the probability of MCAR missing is necessarily predictable by some set of unmeasured variables (otherwise the data wouldn't be missing). However, unlike the indirect MNAR case, those unmeasured variables are *not* associated with the missing values. Therefore, in the MCAR case, there is no spurious correlation induced between Y_{mis} and R, and there is no apparent connection between Y_{mis} and R in the data set.

TABLE 17.2 Missing Data Mechanisms

Mechanism	Mathematical definition[1]	Verbal definition
Missing completely at random (MCAR)	$P(R\|Y_{Obs}, Y_{Mis}) = P(R)$	Missingness on Y is unrelated to any of the variables of interest. The missing data are a pure random sample of the complete data.
Missing at random (MAR)	$P(R\|Y_{Obs}, Y_{Mis}) = P(R\|Y_{Obs})$	Missingness on Y is related to the observed data and not Y itself. The missing data are a random sample of the complete data, after conditioning on the observed data.
Missing not at random (MNAR)	$P(R\|Y_{Obs}, Y_{Mis}) = P(R\|Y_{Obs}, Y_{Mis})$	The missingness on Y is dependent on the missing values themselves. The distribution of the missing values is unrecoverable because the predictors of nonresponse are missing.

[1] R represents the missing data pattern (i.e., 1 if the value is missing, 0 if the value is observed). Y_{Mis} is the notation for the values of the missing data; Y_{Obs} represents the values of the observed scores.

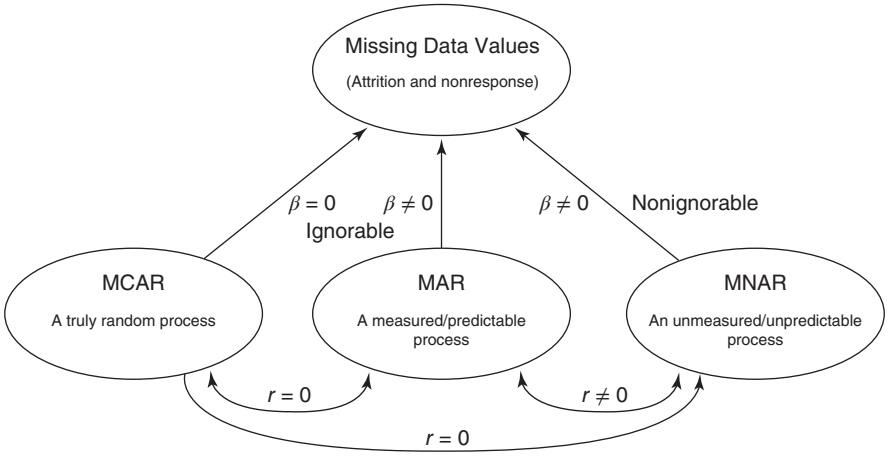

Figure 17.1 The mechanisms of missing data and their potential associations with the missing data and the missing values. (*Note:* The MCAR variables are necessarily uncorrelated with MAR variables and MNAR variables. MAR and MNAR variables can have varying overlap and the higher the overlap the less the influence of the MNAR process can be. The regression betas reflect the implied strength of the multiple linear prediction of the missing values from the set of possible variables that are classified as either in MCAR, MAR, or MNAR set.) *Source:* Little (2013). Used with permission of Todd D. Little.

many classic methods for treating missing data assume that all missing data are due to the MCAR mechanism (Little & Rubin, 2002). When the data are MCAR it means that every missing data treatment, except for single imputation techniques, will produce unbiased parameter estimates. When the pairwise deletion method is used with MCAR missing data, for example, estimates will be perfectly accurate. Here, the problem is that the missing data have undermined the power of the statistical model and type II errors are now likely to arise (i.e., failing to detect a true effect as being significant; Schafer & Graham, 2002).

Figure 17.1 shows the lack of association between the MCAR mechanism and the missing data as a predictive relationship that is necessarily zero and the correlation of the MCAR mechanism with the other two mechanisms is also necessarily zero. Table 17.2 shows that the conditional probability of the missingness, R, is not associated with the values of the missing variables (Y_{Mis}) or with the values of the observed variables (Y_{Obs}), and thus conditional independence holds and the missingness can be ignored.

Using the hypothetical example above, some children are missing the teacher-rated adjustment score because one teacher had recently moved, one teacher had the flu, one teacher refused because the child had just arrived in his classroom, one teacher lost the protocol, one teacher was distracted by a health issue, and so on. In each of these cases, a unique reason for each missing data point is to blame—the missing data are due to the whims of truly chance events, none of which are related to any of the variables under examination. Similarly, if a random subset of the completed adjustment protocols were accidentally shredded, this would also constitute an MCAR mechanism. In these scenarios, a principled missing data tools will, on average, reproduce the .5 correlation that exists in the population. In other words, the truly chance events have not introduced bias in the estimated correlation. The

only problem in this scenario is the loss in power that the lost data have caused. In this scenario the cause of missingness is "ignorable" because it does not need to be explicitly accounted for in the imputation or analysis models (as opposed to the missing not at random mechanism; Rubin, 1976). In other words, when using principled missing data tools, the MCAR mechanism will not have an impact on the estimated parameters of an analysis model (Figure 17.1).

Missing at Random

The second mechanism of missing data is labeled, confusingly, missing at random (MAR). When data are MAR it means that the causes of the missing data are in the observed data. Here, the values of the missing data can be regarded as a random effect that can be predicted by other variables in the data set. The MAR mechanism, therefore, is also an ignorable mechanism in so far as values of the missing data can be accurately recovered using a modern missing data model. In this regard, therefore, both MCAR and MAR are considered ignorable because the consequences for conclusions are negligible; that is, when employing modern, principled missing data tools, the parameter estimates of any statistical model fit to the data will be unbiased when either or both of these mechanisms are involved. As seen in Table 17.2, under the MAR mechanism, the only predictors of the missing data pattern (R) are contained in the observed data (Y_{obs}). So the missing values (Y_{mis}) can be considered a purely random sample of the complete data (Y), after accounting for the values of the observed data (Y_{obs}).

Using the hypothetical example above, some children are missing the parental involvement scores because a large percentage of primary care givers failed to fill out portions of the parental protocol. The reason these primary care providers did not complete the protocol is because they are consumed with the responsibilities and demands of care providing. The questionnaire protocol contains variables that record important characteristics of these care providers that were collected during the intake assessment by a trained interviewer. The variables include the person's role as a primary care provider or not, the number of hours per day spent providing care, employment status, the number of hours spent working per week, and the like. These variables are strong predictors of the reason for the missing responses. Using these variables in a modern treatment procedure would recover the lost information and would provide unbiased parameter estimates from a given statistical model.

The MAR assumption is often tested by predicting the missing data pattern from variables that are on the data set (e.g., by using the Little, 1988, test for MCAR or logistic regression). If the results of these tests are nonsignificant, then one of two reasons is possible: either the data are MCAR, or they are MNAR. Unfortunately, the ability to differentiate between these two mechanisms is challenging. In many ways, finding evidence of predictive links would be a preferred outcome of a missing data screening because it would indicate evidence of an ignorable MAR process.

Missing Not at Random

The third mechanism of missing data is the nefarious one. Here, the data are missing for a systematic reason but this systematic reason for the missingness is not accessible to the researcher. In this situation, data are MNAR. That is, there is not a predictor of the missingness that a researcher can use. In our example, parents who have low involvement in their children's education may be the least likely to turn in the survey for all the same reasons that they have low involvement to begin with (e.g., being overly busy). This selective responding results in a situation where the lowest values on parental involvement are missing, and the variable that predicts missingness is parental involvement itself.

In situations like these, the variable needed to predict the missingness is, itself, missing. Another way to describe this mechanism is that the data are missing for a reason, but the variable representing the reason is not on the observed data set (i.e., because it is part of Y_{Mis} in Table 17.2). Under the MNAR mechanism, the equation for predicting the missingness (R) does not simplify—unlike MCAR and MAR, the missing values themselves (Y_{Mis}) predict unique information in R. This means that the information that is available in the data set is not sufficient to recover the relations among variables. The MNAR circumstance is a non-ignorable situation because it will have consequences on the validity of any conclusions. The information needed to correct the data for the reasons is simply not available because it is missing. Because the observed data cannot predict the missing values, if these missing values were imputed, the imputations would be constructed as though the missingness mechanism were MCAR. However, the results would be biased because the reason for the missingness is unrecoverable.

Models that are designed to recover missing information when the data are MNAR are beyond the scope of our discussion because (1) the methods for preventing bias are complex models that require making strong untestable assumptions (see Enders, 2010, 2011; Muthen, Kaplan, &

Hollis, 1987); and (2) with planning, an MNAR mechanism can be converted to a MAR mechanism (Collins, Schafer, & Kam, 2001; Schafer & Graham, 2002; Yoo, 2009; Yuan, 2009a). For example, a classic example of an MNAR mechanism applies to income reported in net or gross annual salary. Very rich participants are more likely to leave this information missing than are the less wealthy participants. In this case the cause of the missingness is itself missing. There is no variable on the data set that would predict it and, therefore, it would not be recoverable. On the other hand, the research protocol could include variables that are known correlates of income. For example, job title, years of education, square-footage of the primary home, make and model of the primary automobile, and political affiliation. Variables such as these will, in a multivariate combination, provide information that now correlates with the pattern of missingness on income. Variables such as these are proxies of the missing information. A well-planned protocol would strive to have such proxies of important information that might be missing as an MNAR process. In the developmental psychopathology literature, sensitive variables such as physical, emotional, and sexual abuse might be missing because the person has been abused in some way. If the protocol contains variables that are expected to predict abuse the process would fall under the MAR mechanism because these variables predict missingness.

MODERN MISSING DATA METHODS

Table 17.1 reviews a range of classic techniques for dealing with missing data, from the simplest (e.g., listwise deletion, mean imputation) to more complex (e.g., stochastic regression imputation, hot deck imputation). As described there, none of these methods produce ideal results. At best, some of these methods can produce unbiased parameter estimates when the missingness is MCAR (e.g., listwise or pairwise deletion) or when it is MAR (e.g., stochastic regression imputation). At worst, some of the methods produce biased results even under MCAR (e.g., mean imputation, regression imputation). In addition, all of these methods either lack power (i.e., any deletion method) or result in inflated type I error rates (i.e., any single imputation method). Though it can be justifiable to use one of these methods when there is only a very small amount of missingness, using any of these techniques to deal with a substantial amount of missing data risks biased estimates, low power, or inflated type I error. In contrast to all of these methods, multiple imputation and full information maximum likelihood produce unbiased and fully efficient (i.e., powerful) parameter estimates when their assumptions are met. In the next sections, we describe these two methods in detail.

FULL INFORMATION MAXIMUM LIKELIHOOD

Full information maximum likelihood (FIML) is a state-of-the-art missing data tool that represents the culmination of an extensive history of research into maximum likelihood solutions to the missing data problem (e.g., Beale & Little, 1975; M. B. Brown, 1974; C. H. Brown, 1983; Carter & Meyers, 1973; Chen & Fienberg, 1976; Dempster, Laird, & Rubin, 1977; Enders, 2001b; Enders & Bandalos, 2001; Gold & Bentler, 2000; Hartley, 1958; Hartley & Hocking, 1971; Healy & Westmacott, 1956; Jamshidian & Bentler, 1999; Kenward, Lesaffre, & Molenberghs, 1994; Kenward & Molenberghs, 1998; Little & Rubin, 1989; Orchard & Woodbury, 1972; Rubin, 1991). The framework for FIML was formalized by Anderson (1957) as a way to derive ML estimates directly from incomplete data. Through clever manipulation of the likelihood function, FIML can hide any missingness from the estimator and allow one to fit a statistical model directly in the presence of incomplete data, without any need to estimate values for the missing data (Arbuckle, 1996). This approach has a distinct advantage over EM and imputation-based missing data tools. Because there is no estimation of values for the missing data, there is also no artificial certainty introduced into the treated data (as opposed to EM and single imputation techniques) nor is there any need to quantify the uncertainty in the accuracy of the imputed values (as must be done with multiple imputation).

To get a conceptual idea of how FIML operates, consider your computer's monitor. The image on this monitor is made up of many rows of pixels, just as a data set is made up of many rows of responses. If a pixel dies in your monitor, you are still able to understand the image on the screen because you can use the information from surrounding pixels to infer the whole image, passing over the damaged one. This principle will hold true even if a relatively large proportion of the pixels in your monitor were to fail, so long as there are enough pixels remaining for you to connect the dots and extrapolate the implied complete image from the partial image on your screen. Similarly, the FIML log likelihood function (equation 17.2) achieves an analogous effect when used to fit a statistical model to incomplete data. By using only what is known from the observed data, FIML can estimate around the missing data and infer what the whole model should look

like without needing to know what the missing responses would truly be. In this way, just as you can look at a damaged computer monitor and still understand how the complete image would appear, FIML can be applied to an incomplete data set to produce estimates that correctly describe the entire sample.

While the underlying mathematics can get complicated, the overarching principles guiding FIML estimation are relatively simple. First we must consider how a maximum likelihood estimator transforms the information contained in the observed data into a set of parameter estimates. Since FIML is based on normal-theory ML estimation, the multivariate normal loglikelihood function is a natural starting point for this discussion. Equation 17.1 gives the multivariate normal loglikelihood function:

$$\ell(\boldsymbol{\mu}, \boldsymbol{\Sigma}|\mathbf{Y}) = \sum_{i=1}^{N}\left[-\frac{k}{2}\ln(2\pi) - \frac{1}{2}\ln|\Sigma| - \frac{1}{2}(\mathbf{Y}_i - \boldsymbol{\mu})^T\Sigma^{-1}(\mathbf{Y}_i - \boldsymbol{\mu})\right], \tag{17.1}$$

where $\mathbf{Y}$ is a $N \times k$ matrix of incomplete data, $\boldsymbol{\mu}$ is the k-variate vector of unknown, population-level means of the variables in $\mathbf{Y}$, and $\boldsymbol{\Sigma}$ is the $k \times k$, unknown, population-level covariance matrix of the variables in $\mathbf{Y}$. The derivation of this equation falls beyond the scope of this chapter. However, for the sake of the current discussion, the reader need only recognize that equation 17.1 represents a reformulation of the multivariate normal distribution that provides a more computationally efficient way to compute ML estimates of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$.

The beauty of FIML estimation is that it accomplishes its objective with only a small modification to equation 17.1. In the presence of missing data, equation 17.1 becomes the following:

$$\ell_{FIML}(\boldsymbol{\mu}, \boldsymbol{\Sigma}|\mathbf{Y}) = \sum_{i=1}^{N}\left[-\frac{k}{2}\ln(2\pi) - \frac{1}{2}\ln|\Sigma_i| - \frac{1}{2}(\mathbf{Y}_i - \boldsymbol{\mu}_i)^T\Sigma_i^{-1}(\mathbf{Y}_i - \boldsymbol{\mu}_i)\right]. \tag{17.2}$$

The only difference between equations 17.1 and 17.2 is that equation 17.2 includes subscripted versions of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. This subtle distinction allows each row in $\mathbf{Y}$ to have unique versions of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$, which allows the dimensions of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ to differ between observations. When the dimensions of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ can differ across observations, it is possible for the final aggregated estimates of those parameters to be based on only the observed data, thereby hiding the nonresponse from the estimator and removing the need to delete any data or fill in any values for the missing data. This small change to the likelihood function is the mathematical procedure that allows FIML to estimate around the missing data and infer a complete set of parameter estimates from incomplete input. As long as there is sufficient overlap in the questions with observed responses (i.e., the *coverage* is adequate), FIML estimation can borrow enough information across observations to effectively remove any need to consider what the true values of the missing data would have been.

In practice, FIML estimation is quite convenient because it works behind the scenes to produce accurate parameter estimates without requiring the user to give much thought to the missing data (Enders, 2006, 2010; Muthen & Muthen, 2012). Consider the case of many participants filling out the same survey (i.e., a standard cross-sectional design). Even if some of those subjects do not complete the survey, we would still like to fit a model that will allow us to draw accurate conclusions about the entire sample, but we may not wish to go through the process of filling in values for the missing data. FIML estimation can help us accomplish this by using the observed responses to supplement the loss of information due to the missing responses (Enders, Dietz, Montague, & Dixon, 2006). In the end, FIML will produce unbiased and efficient estimates of the model parameters that we're actually interested in, without ever requiring us to consider the true values of the missing data.

While FIML is often the preferred method of addressing nonresponse in psychological studies, there are certain situations in which maximum likelihood methods are not applicable. For example, if a researcher wishes to calculate scale scores or parcels from incomplete data, they will find that there is no way to apply FIML estimation to those analyses without an additional loss of information (Enders, 2010). In such circumstances, it is beneficial to begin the substantive analysis with a complete data set. Thus, the analyst will be better served by a technique that fills in the missing values through imputation (Rubin, 1996).

Multiple Imputation

Single-imputation techniques all use some prediction mechanism (some better than others) to fill in the missing value with a plausible value. Once the missing data are thus filled in, the analysis of interest is run on the completed data set. A fundamental problem with this approach is that there is no way to quantify the additional uncertainty that results from the missingness (Rubin, 1987; Schafer, 1997). For example, a data set with 200 cases and 5% missing data

contains much more information than the same data set with 75% missing data. With a single-imputation approach, both situations will result in statistics that have similarly sized standard errors and confidence intervals. Intuitively, we can see that this should not be the case—statistics based on data with 75% missingness should have more uncertainty than those based on data with 5% missingness. This is where single imputation fails.

Multiple imputation overcomes this problem through introducing a second source of variation by repeating the imputation process multiple times. In MI, a modified single imputation technique (usually some form of regression imputation) is repeated to simulate multiple plausible values for each missing data point. Because there are small differences in the values chosen to replace the missingness from one iteration of the MI algorithm to the next, the final answer is a plausible *distribution* for each missing value, rather than an arbitrarily chosen single value that replaces each missing datum (Rubin, 1987; Schafer, 1997).

With more than one imputation (traditionally three to five, but these days more often 20 or even 100), the amount of information loss can be measured by looking at how different the imputed data sets are (Harel, 2007). If very little information is lost (e.g., if only a few values are missing, or if the missing values are highly redundant with complete values), then the imputed data sets will be highly similar to each other; that is, there will be low "between-imputation" variability. If a lot of information is lost (e.g., if a high proportion of data are missing, or if the missing values contain a lot of unique information), then the imputed data sets will differ a lot, and there will be high between-imputation variability. When doing an analysis on imputed data sets, the standard errors of the produced statistics are adjusted using the between-imputation variability—the greater the between-imputation variability, the larger the standard error becomes, to reflect the missing information. In this way, multiple imputation produces both unbiased estimates and correct standard errors.

If we think of the missing data as random variables with a distribution of possible values—of which the imputed values are just one possibility from an infinitely large pool—it is natural to compare the rationale for the multiplicity of MI to the rationale for collecting large samples, in general (Rubin, 1987). For most substantive research, gathering larger samples is advisable because basing your inferences upon a larger pool of observations gives you more certainty in the veracity of your conclusions. The exact same reasoning can be applied to the repeated imputations of MI.

For the sake of argument, consider the following extreme example. Say you wish to examine the prevalence of claustrophobia among elementary school students. You could go to a local elementary school and ask a single student to rate his or her fear of confined spaces on a scale from 1 to 10. If that student gives a response of 9, and you don't question any other children, then you are limited to the information carried by that student's data when constructing your inference. In this situation, your only option would be to conclude that elementary school students universally suffer from severe claustrophobia. This approach is plainly ridiculous, and it is clear that sampling more students would likely alter your finding.

While most researchers are naturally skeptical of statistical inferences based on very small samples, they may not automatically apply this same reasoning to missing data analysis. However, just as relying on only one child's data to model the severity of childhood claustrophobia can lead to highly erroneous findings, so too can blindly trusting the single set of imputed values produced by a single-imputation technique (Schafer, 1997). In the preceding example, it would be advisable to sample many children and use that large sample to derive a probability distribution that describes the levels of claustrophobia among elementary school students. The same is true of imputation. It is bad practice to impute a single value and trust it without question. A much more trustworthy answer can be achieved by simulating many different values for the missing data (i.e., create multiple imputations) so that we can derive a distribution to describe the plausible values that the missing data may take in the population. This distribution of plausible values helps us understand the degree of uncertainty associated with any of the parameter estimates of a given model.

At a conceptual level, the MI approach is relatively straightforward. An MI analysis is a piecemeal endeavor that is broken into three phases: the imputation phase, the analysis phase, and the pooling phase (Enders, 2010). Suppose you wish to analyze an incomplete data set $Y = \{Y_{obs}, Y_{mis}\}$, where Y_{obs} is the observed portion of the data and Y_{mis} is the missing portion. In the imputation phase, you must fill in Y_{mis} with M different sets of plausible values (i.e., you must create M imputations). This process will result in M imputed data sets $Y^{(1)} = \{Y_{obs}, Y_{imp}^{(1)}\}$, $Y^{(2)} = \{Y_{obs}, Y_{imp}^{(2)}\}$, …, $Y^{(M)} = \{Y_{obs}, Y_{imp}^{(M)}\}$ in which the original missing values of Y are replaced by the M sets of imputations. In the analysis phase, you will use these imputed data sets to fit M replicates of your statistical model. This step will result in M distinct sets of model parameter estimates $\widehat{Q}^{(1)}$, $\widehat{Q}^{(2)}$, …, $\widehat{Q}^{(M)}$

(these could be fitted regression coefficients, for example). Finally, in the pooling phase, you will combine these M sets of estimates into a single pooled set of estimates from which you will draw your conclusions. This final pooling is most commonly accomplished by applying Rubin's Rules (Rubin, 1987).

The original framework for MI was proposed by Rubin (1978) and greatly expanded by Rubin (1987), but the flexibility of the underlying concept has left the door open for the development of many different algorithms with which the imputations themselves can actually be created. Table 17.3 shows a list of currently popular software packages that can implement MI. Although there are seven distinct software packages listed in Table 17.3, the estimation methods they use to produce the imputations can be broken into three basic classes, namely: Bayesian data augmentation (or Bayesian MCMC), multiple imputation with chained equations (or sequential regression imputation), and bootstrapped EM imputation. These three approaches can be further categorized into joint modeling and fully conditional specification techniques. The joint modeling techniques (data augmentation and bootstrapped EM imputation) treat all missing data simultaneously by applying a single parametric model that describes the joint distribution of all the missing values. Fully conditional specification techniques (multiple imputation with chained equations), on the other hand, treat each individual variable sequentially and model the conditional distribution of each individual variable's missing data separately (van Buuren & Groothuis-Oudshoorn, 2011).

We will begin by discussing joint modeling techniques because they were the first to become widely available (Schafer, 1997; Schafer & Olsen, 1998), and fully conditional specification techniques can be discussed as special cases of the joint modeling approach.

Data Augmentation

Data augmentation was one of the first algorithms to become popular for use in creating multiple imputations. Data augmentation is a special application of Gibbs sampling that was proposed by Tanner and Wong (1987) as a method of estimating a Bayesian posterior distribution of model parameters when the underlying data are incomplete. These parameters can then be used to construct the multivariate regression equations needed to impute the missing data. The process is iterative, and accomplished in two steps. The first step, or imputation (I) step, is basically a multivariate stochastic regression imputation. During the I-step, the most up-to-date values for the mean vector $\boldsymbol{\mu}$ and the covariance matrix $\boldsymbol{\Sigma}$ (user specified starting values are used in the first I-step) are used to construct the coefficients of a series of multivariate regression equations (one for each distinct pattern of missingness). A randomly drawn, multivariate normally distributed vector of residual terms is then added to each of the predicted values from these equations and the resulting quantities are used to replace the missing values. Thus, after each I-step, all missing data are filled in, and the data set contains no missingness. From the Bayesian perspective, this is equivalent to creating the imputations by randomly sampling from a *posterior predictive distribution* of the missing data (Enders, 2010).

The second step, or posterior (P) step, uses the imputed data set from the preceding I-step to calculate updated values for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. These new values for $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are then used to construct the Bayesian posterior distributions for the mean vector $P(\boldsymbol{\mu}|\mathbf{Y}, \boldsymbol{\Sigma})$ and covariance matrix $P(\boldsymbol{\Sigma}|\mathbf{Y}, \boldsymbol{\mu})$. Finally, MCMC simulation techniques are used to randomly draw simulated values for the mean vector $\boldsymbol{\mu}^*$ and the covariance matrix $\boldsymbol{\Sigma}^*$ from these posterior distributions. These simulated values are then passed on to the next I-step, where they are used to construct updated regression coefficients for use in the next round of stochastic regression imputation.

This process is repeated a large number of times (e.g., 5000 I and P step pairs) and every n-th imputed data set produced by the I-step is saved. It is important to ensure that the number of imputed data sets to discard ($n - 1$) is large enough that the imputed values in subsequently saved data sets are statistically independent of each other (Baraldi & Enders, 2010). When M data sets have been saved, the algorithm terminates and these saved data sets make up the final collection of multiply imputed data sets.

Bootstrapped EM

Another popular joint modeling technique is the bootstrapped EM algorithm that was developed by Honaker and King (2010) and implemented in the R (R Core Team, 2012) package Amelia II (Honaker, King, & Blackwell, 2011) as a way to address the computational inefficiency of traditional data augmentation approaches. The bootstrapped EM algorithm is very simple at a conceptual level. First, standard bootstrapping procedures are applied and the incomplete data are resampled with replacement to create M incomplete bootstrapped samples of the same dimension as the original data set. Next, the EM algorithm is applied to each of these M samples to create M ML estimates of the mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$

TABLE 17.3 Software Packages That Implement Multiple Imputation

Software (citation)	Estimation technique	Pros	Cons
Amelia II (Honaker, King, & Blackwell, 2011)	Bootstrapped EM Algorithm	Robust convergence Models time when imputing longitudinal data Freeware/Open Source	Only supports MVN imputation models Applies the same imputation model to all variables
mice (van Buuren & Groothuis-Oudshoorn, 2011)	Chained Equations	Accommodates mixed variable types Applies the correct imputation model to categorical and count variables Maintains factor labels for imputed values Offers numerous elemental methods Allows unique imputation models for each variable Freeware/Open Source Imputes multilevel data	Imputed values can be sensitive to the order that the variables are visited
mi (Su, Gelman, Hill, & Yajima, 2011)	Chained equations	Accommodates mixed variable types Applies the correct imputation model to categorical and count variables Allows unique imputation models for each variable Freeware/Open Source Includes many imputation diagnostics	Imputed values can be sensitive to the order that the variables are visited
Mplus (Muthen & Muthen, 2012)	Bayesian MCMC	Accommodates many different imputation models Imputes multilevel data Allows user-specified imputation models Categorical variables are imputed using probit models	Unrestricted models can exhibit poor convergence for large imputation models Applies the same imputation model to all variables Does not implement the full flexibility of the MICE approach
	Chained equations	Accommodates mixed variable types Allows unique imputation models for each variable	Imputed values can be sensitive to the order that the variables are visited Does not implement the full flexibility of the MICE approach Limited elemental methods
SAS 9.3: Proc MI (SAS Institute, 2011)	Data augmentation	Uses one of the best studied MCMC algorithms available	Only supports MVN imputation models Applies the same imputation model to all variables
	Chained equations	Accommodates mixed variable types Applies the correct imputation model to categorical variables Allows unique imputation models for each variable	Does not implement the full flexibility of the MICE approach Imputed values can be sensitive to the order that the variables are visited
SPSS: Missing Values (IBM Corp, 2012)	Chained equations	Accommodates mixed variable types Applies the correct imputation model to categorical variables Allows unique imputation models for each variable	Imputed values can be sensitive to the order that the variables are visited Does not implement the full flexibility of the MICE approach
Stata: mi (StataCorp, 2013)	Chained equations	Accommodates mixed variable types Applies the correct imputation model to categorical variables Allows unique imputation models for each variable	Imputed values can be sensitive to the order that the variables are visited
	Data augmentation	Uses one of the best studied MCMC algorithms available	Only supports MVN imputation models Applies the same imputation model to all variables

(Table 17.1). Finally, the M estimates of $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are used to carry out M multivariate stochastic regression imputations which are applied to the original incomplete data, just as in the I-step of traditional data augmentation. This process results in M replicates of the original data, each of which contain a different set of imputed values, in other words, M multiply imputed data sets.

Multiple Imputation with Chained Equations

Multiple imputation with chained equations (MICE) has been gaining in popularity over recent years. It is unique among the algorithms discussed here because it is a fully conditional specification technique rather than a joint modeling technique. Therefore, MICE does not seek to treat all variables simultaneously; rather, the MICE

approach sequentially addresses each variable individually (van Buuren, 2012). While this is an important distinction, with considerable implications for the usage of the MICE approach, the estimation process underlying MICE is essentially identical to data augmentation. The only meaningful difference is that joint modeling techniques treat the imputation as a large multidimensional problem, in which the I-step performs a multivariate stochastic regression imputation and the P-step draws a k-variate $\boldsymbol{\mu}^*$ and $k \times k$ $\boldsymbol{\Sigma}^*$ from the joint posterior distributions $P(\boldsymbol{\mu}|\mathbf{Y}, \boldsymbol{\Sigma})$ and $P(\boldsymbol{\Sigma}|\mathbf{Y}, \boldsymbol{\mu})$. The MICE I- and P-steps, on the other hand, reduce to repeatedly solving k univariate analogues of the data augmentation I- and P-steps, where k is the number of incomplete variables to be imputed. In other words, the MICE I-step imputes the missing portion of only a single variable at a time, and the MICE P-step simulates only the univariate mean μ^* and variance σ^{2*} of that focal item.

This approach affords a great deal of flexibility to the analyst because each variable's imputations can be created from its own distinct regression equation (van Buuren & Groothuis-Oudshoorn, 2011). This approach also allows specification of appropriate posterior distributions for the parameters simulated in the P-step even in cases where the joint distribution of all of these parameters may not have a well-defined form (van Buuren, 2012). For example, suppose you have collected data from middle school students and you wish to analyze three variables: age, gender, and a count of aggressive outbursts in class. If there is missingness on these variables, you will be limited in your ability to treat that missingness with data augmentation or bootstrapped EM, since both techniques are based on the assumption that the incomplete data are jointly multivariate normally distributed. However, MICE allows an imputation model where age is imputed with a normal-theory regression model, gender with a logistic regression model, and the count of aggressive outbursts with a Poisson regression model. Thus, the MICE approach will produce correctly distributed imputed values for each special variable type while only requiring the user to run a single instance of the multiple imputation procedure.

Rubin's Rules

Rubin's rules are a simple set of formulae given by Rubin (1987) that allow pooling of the M distinct sets of parameter estimates derived from the analysis phase of an MI analysis. Recall that the product of the MI analysis phase is a set of M parameter estimates $\widehat{Q}^{(1)}, \widehat{Q}^{(2)}, \ldots, \widehat{Q}^{(M)}$. The *multiple imputation point estimate* is simply the arithmetic mean of these M individual parameter estimates:

$$\overline{Q} = \frac{1}{M}\sum_{m=1}^{M} \widehat{Q}^{(m)}, \tag{17.3}$$

where $\overline{Q}$ is the pooled point estimate, $\widehat{Q}^{(m)}$ is the parameter estimate from the m-th imputation, and M is the number of imputations.

Pooling the variance components is a little more involved than pooling the point estimates and requires three distinct steps. The pooled within-imputation variance is simply the arithmetic mean of the M parameters' sampling variances:

$$\overline{U} = \frac{1}{M}\sum_{m=1}^{M} SE^2_{\widehat{Q}(m)}, \tag{17.4}$$

where $\overline{U}$ is the pooled within-imputation variance, $SE^2_{\widehat{Q}(m)}$ is the squared standard error for the parameter estimate from the m-th imputation, and M is the number of imputations. The next step is calculating the between-imputation variance. The between-imputation variance simply captures the dispersion in the imputed values across all M imputations. It is calculated via the following formula:

$$B = \frac{1}{M-1}\sum_{m=1}^{M} \left(\widehat{Q}^{(m)} - \overline{Q}\right)^2, \tag{17.5}$$

where B is the between-imputation variance, $\widehat{Q}^{(m)}$ is the parameter estimate from the m-th imputation, $\overline{Q}$ is the multiple imputation point estimate, and M is the number of imputations. Finally, these two sources of variance must be combined into the *total sampling variance*. The total sampling variance is simply a weighted sum of the within and between-imputation variances:

$$T = \overline{U} + (1 + M^{-1})B, \tag{17.6}$$

where T is the total sampling variance, $\overline{U}$ is the pooled within-imputation variance, B is the between-imputation variance, and M is the number of imputations. With a large number of imputations, the influence of the weighting term in equation 17.66 becomes negligible and the total sampling variance reduces to a simple sum of the within and between-imputation variance.

Once the multiple imputation point estimate and total sampling variance have been calculated, they can be

combined into familiar test statistics. The MI Wald statistic is produced by combining the pooled components in the natural way:

$$t(v)_{MI} = \frac{\overline{Q} - Q'}{\sqrt{T}}, \tag{17.7}$$

where $\overline{Q}$ is the multiple imputation point estimate, Q' is the null hypothesized value of the parameter estimate, and T is the total sampling variance. This test statistic can be compared with a student's t distribution with degrees of freedom given by the following:

$$v = (M-1)\left[1 + \frac{\overline{U}}{\left(1 + M^{-1}\right)B}\right]^2, \tag{17.8}$$

where v is the degrees of freedom, $\overline{U}$ is the pooled within-imputation variance, B is the between-imputation variance, and M is the number of imputations. These components can also be combined into the following confidence interval for the multiple imputation point estimate:

$$(1-\alpha)\%CI_{MI} = \overline{Q} \pm t_{v,1-\alpha/2}\sqrt{T}, \tag{17.9}$$

where α is the probability of a type I error (i.e., significance level), $\overline{Q}$ is the multiple imputation point estimate, $t_{v,1-\alpha/2}$ is the cutoff value on the student's t distribution corresponding to the desired significance level and the degrees of freedom calculated via equation 17.8, and T is the total sampling variance.

Convergence

To ensure the quality of the imputed data sets when MCMC is used to impute data, convergence of MCMC needs to be carefully monitored. An MCMC procedure is deemed converged if the posterior distribution of the parameters in the imputation model reaches a stationary point. The convergence of MCMC ensures that the imputed data are drawn from the right posterior distribution. The iterations prior to convergence, termed burn-in iterations, need to be disregarded. Depending on the specific program one chooses, the number of burn-in iterations of MCMC is either decided by the program automatically or needs to be specified by researchers themselves. In Mplus, convergence of MCMC is monitored using a criterion termed potential scale reduction (PSR; Gelman & Rubin, 1992). The number of burn-in iterations is then specified based on this criterion. Detailed explanation of the PSR is beyond the scope of the chapter. What applied researchers need to know is that there will be one PSR for each parameter in the imputation model at each iteration of MCMC. According to Asparouhov and Muthén (2012), MCMC is deemed as converged if the worst PSR becomes less than 1.05 or 1.1 (Asparouhov & Muthén, 2012). In addition, graphical tools such as trace plots and autocorrelation plots can be very useful in assessing MCMC convergence. Trace plots display the change of simulation draws of each of the imputation parameters over iterations. When MCMC converges, the simulation draws should show random fluctuations over iterations. Autocorrelation plots are plots of autocorrelations between the simulated draws for each of the imputation parameters against lag. The autocorrelations usually decrease to zero after a certain number of lags. The faster the autocorrelations decrease to zero, the faster an MCMC procedure converges.

Due to their autocorrelations, the imputed values from successive iterations are also correlated. Because the imputed data sets need to be independent to produce correct standard error estimates, it is necessary to allow a number of iterations to lapse every time before saving an imputed data set. This strategy is termed *thinning* and the number of iterations between imputed data sets are termed *between-imputation iterations*. Usually 100 between-imputation iterations would be sufficient for most of cases. However, if one has a difficult data set with a large fraction of missing information, a larger value should be specified for the thinning interval. The autocorrelation plots can inform researchers of the appropriate number of between-imputation iterations.

There are also many things researchers can do to facilitate the convergence of MCMC (Asparouhov & Muthén, 2012). First, researchers need to make sure that there are no variables in the imputation model that are highly correlated with one another. Second, try not to include variables that do not predict the missing values in the imputation model (e.g., ID). Although, including them has no harm on the parameter estimates (Collins, Schafer, & Kam, 2001), they might cause convergence problems. Third, if there are missing data indicators (binary variables created to indicate whether a score is missing or not), they should not be included in the imputation model as their correlations with the variables having missing data are not identified. Fourth, the imputation model has to be identified. For single-level data, the number of observations on each of the variables

should be no less than the number of variables included in the imputation model. For example, if the variable with most of the missing data has 50 observations, then including more than 50 variables in the imputation model would create convergence problem. Finally, If MI does not converge and you don't know which variable causes the problem, try to include a subset of variables and add variables sequentially into the model.

Number of Imputations

The number of imputations that are needed for MI to give accurate and efficient standard errors depends on the amount of missing information (Bodner, 2008; Graham et al., 2007). Although MI standard errors are less efficient than those of FIML as long as the number of imputations is finite, practically speaking the incremental gain in efficiency from more imputations drops off very quickly (von Hippel, 2005). Until recently, five imputations was considered a sufficient number of imputations to yield standard errors virtually as efficient as FIML (Rubin, 1987). More recently, 20 imputations has emerged as the new minimum and many analysts recommend producing 100 imputed data sets to ensure comparability to FIML estimates (Bodner, 2008; Enders, 2010; Graham et al., 2007; Little, 2013).

A key consideration in deciding the number of imputations is the amount of missing information, which can be quantified in the *fraction of missing information* (FMI) statistic (Bodner, 2008; Graham et al., 2007; Savalei & Rhemtulla, 2011). Recall that when more information is missing, there is greater variability between imputations. As such, each individual imputed data set is less reliable. A lower FMI means that the missing data are highly predictable (or there are very few missing data) and thus fewer imputations are needed to produce a reliable result, whereas a high FMI indicates that more imputations are needed due to the uncertainty of the missing values (Fraley, 1999; Rubin, 1987). White, Royston, and Wood (2011) suggested a rule of thumb that the number of imputations should be at least the fraction of missing information multiplied by 1000. That is, if 50% of the information is missing (FMI = .5), then the minimum number of imputations should be 50. Unfortunately, estimates of the FMI itself can fluctuate dramatically when few imputations are used. To get a reliable estimate of the fraction of missing information from MI, several hundred imputations are needed. As such, with advances in computing making it relatively quick and easy to do many imputations and combine the results across them using automated software, we recommend using 100 imputations whenever possible.

Above, we mentioned a type of missing data that we called structural missing such as items on a questionnaire that would not be asked of certain individuals because the items do not pertain to the person (e.g., asking boys about their menstruations). Multiple imputation procedures are unable to distinguish between structural missing and the nonresponse forms of missingness that we desire to recover. In these situations, we recommend creating a flag variable to indicate true missing from structural missing. The imputed values for the structural missing can then be reset to missing by using the flag variable.

PRACTICAL CONSIDERATIONS

Keep in mind that the primary goal of a modern missing data procedure is to reproduce the summary parameter estimates (Rubin, 1996). In the case of FIML estimation, the goal is to provide unbiased values of the parameter estimates from the statistical model being fit to the data (Arbuckle, 1996; Enders, 2010). As mentioned previously, all observations are used to inform the model's parameter estimates. With MI, the goal is to produce sufficient statistics that are unbiased (Rubin, 1987; 1996) and accurately reflect the statistical precision in the data. The sufficient statistics are the means, variances, and covariances among the variables (note that the range is not a sufficient statistic). The statistical model is fit at the level of the sufficient statistics and it produces unbiased parameter estimates that are equivalent to those of FIML (all other things being equal; Graham, et al., 2007). With MI, the person-level information is not part of the imputation objective (Rubin, 1996; Schafer & Graham, 2002). The imputation model does use plausible values for the cells that are missing but these values are not treated as scores for the person because many different plausible values can be used to optimize recovery of the unbiased sufficient statistics. The value assigned to a cell is more of a temporary place holder that is used to infer the population sufficient statistics. When a statistical model is fit to the aggregate data, the parameter estimates of this model will be unbiased. Imputed values for a given person, therefore, should be treated with caution. The distribution of the imputed values for a given person can be quite variable and any one imputation would not be a trustworthy estimate for that person (Schafer, 1997). It would be possible to produce an estimated value from the imputed scores that would be the mean of the imputed values with a confidence interval around this value to be used for assessment purposes, for example.

A second important objective of missing data analysis is accurate quantification of the information inherent in the

incomplete data (Harel, 2007). The missing information principle of Orchard and Woodbury (1972) states that the information of an incomplete data set can be partitioned into two quantities: the observed information and the missing information. Modern missing data tools allow us to differentiate between these two types of information and accurately estimate their values (Savalei & Rehemtulla, 2012). While both MI and FIML quantify the data's information, they address the problem in two different ways. MI quantifies the missing information as a function of the between-imputation variance (Rubin, 1987; Schafer, 1997). As suggested above, this way of quantifying is another reason that it is advantageous to construct a large number of imputations—doing so will produce a more accurate estimate of the missing information. FIML, on the other hand, implicitly derives a corrected estimate of the observed information by ascribing more certainty to those parameter estimates that are derived from a larger number of observed responses (Enders, 2010).

Assumptions

Both FIML and MI are model based in the sense that the accuracy of their results rely on the assumptions underlying their respective models. For FIML, the missing data model is the analysis model (e.g., a structural equation model or regression model). For MI, the missing data model is the imputation model, which is specified separately. In both cases, to the extent that the model is false, the results of the procedure will suffer (Little & Rubin, 2002; Schafer & Olsen, 1998).

One common assumption is that the associations between variables, including the associations that account for missingness, are linear (Honaker & King, 2010). If the missingness is actually due to an interaction between two variables, for example, and that interaction term is omitted from the missing data model, the missingness will not be accounted for. In MI, new variables such as powered polynomials and product terms can be inserted into the imputation model to represent potential nonlinear effects of missingness. For example, socioeconomic status (SES) is a common linear correlate of dropout in longitudinal studies. If the rate of dropout increased in a nonlinear fashion at lower levels of SES, the squared powered term of SES (SES^2) can be included in the imputation model to recover the nonlinearity of the MAR process (Graham, 2009; von Hippel, 2009). In FIML, these nonlinear variables may be used as auxiliary variables (see next section).

Another common assumption is that of independence, which is violated when data are nested. Nested data are common in longitudinal data and samples collected from schools, where data points are nested within individuals, within classrooms, or within schools. In these cases, if the missing data model does not take into account the nested structure of the data, the complex relations between variables within and across clusters can be obscured, resulting in incorrect estimates of between- and within-cluster variability and incorrect standard errors (Beunckens, Molenberghs, Thij, & Verbeke, 2007). When dealing with nested data and using FIML, if the nested structure is accounted for in the model (e.g., by using a multilevel model or multilevel structural equation model; Muthén & Asparouhov, 2009) maximum likelihood estimation of the model will successfully recover the relations among the variables at the levels included in the model.

When using MI, it is important to remember to incorporate the nesting structure into the imputation model as well as the analysis model. If the imputation model does not account for nesting, the imputed values will underestimate the amount of variance at the individual level, leading to too-small standard errors, even if a correct multilevel model is used as the analysis model (Schafer, 1997). When more than one level of analysis is of interest, for example, if a researcher is interested in both the effects of student-level predictors such as student motivation as well as teacher-level predictors such as teacher experience, the former effects will be overestimated and the latter effects will be underestimated if the nesting is not properly modeled during multiple imputation (Reiter, Raghunathan, & Kinney, 2006). Several methods have recently been implemented in software to account for nesting in multiple imputation (e.g., mice—van Buuren & Groothuis-Oudshoorn, 2011; Pan—Schafer &Yucel, 2002; SHRIMP—Yucel & Raghunathan, 2006).

Another assumption of many modern missing data treatments is that the variables are multivariate normally distributed (Allison, 2006; Demirtas, Freels, & Yucel, 2008; Enders, 2001a; Gold, Bentler, & Kim, 2003; Honaker & King, 2010; Savalei, 2010a). Only a few studies have been done on the degree to which MI and FIML are robust to violations of this assumption and whether some modern procedures are better than others when the normality assumption is violated (e.g., Savalei & Bentler, 2005; Shin, Davidson, & Long, 2010). Although some work suggests that both normal-theory MI and FIML are robust to violations of normality (Demirtas et al., 2008; Enders, 2001a; Graham & Schafer, 1999; Yuan, 2009b), further research in this area is needed. We still recommend a modern imputation approach even when the assumptions are violated because the consequences of using another method

are graver than the lack of precision that nonnormal data might introduce (Graham, 2009; Schafer & Graham, 2002).

Auxiliary Variables

Auxiliary variables are those that are associated with the missing data pattern or the values of the missing responses, but are not substantively interesting to the researchers (Collins et al., 2001; Enders & Gottschall, 2011). That is, they are variables that capture a MAR missing data process. Recall that FIML and MI only result in unbiased estimates when the causes of missingness are included in the model (FIML) or the imputation model (MI).

When FIML estimation is used, auxiliary variables must be included in the analysis model. Graham (2003) described a method for including auxiliary variables in any structural equation model without changing the interpretation of the substantively interesting model parameters, called the "saturated correlates" approach. In a nutshell, this approach introduces auxiliary variables into the model by allowing them to correlate with other exogenous variables (e.g., predictors) in the model, without allowing them to predict unique variance in any dependent variables. In this way, the paths of interest are not affected, but the auxiliary variables are nonetheless part of the model. Once they are part of the model, the influence of auxiliary variables on missingness is taken into account. If auxiliary variables are not used when FIML estimation is employed, the MAR process is not likely to be represented (unless the MAR-associated variables just happen to be part of the desired analysis model; Enders, 2008, 2010; Graham, 2003).

Auxiliary variables are easier to deal with in MI. Here, auxiliary variables are just included in the imputation model, which typically contains the complete data set (Collins, et al., 2001; Schafer, 1997). In MI, there is no need to explicitly distinguish auxiliary variables from analysis variables—auxiliary variables can be any variables in the imputation model, whereas analysis variables are whichever variables are chosen, post-imputation, for use in the analysis. Once imputation is complete, there is no further need for auxiliary variables.

Two general strategies for including auxiliary variables are recommended. The first is the *inclusive strategy* (Collins et al., 2001). Here, all variables on a data set that are not part of the analysis model are included in the analysis as auxiliary variables. This strategy ensures that if a MAR association is contained among the set of auxiliary variables, its impact will be represented (Collins et al., 2001; Kreuter & Olson, 2011; Yoo, 2009). The inclusive strategy will generally become intractable when too many variables are included, particularly because the auxiliary variables themselves will often contain missing values (Enders, 2008; 2010). The large number of variables coupled with the variety of missing data patterns that occurs can lead to an insurmountable estimation problem—the software simply will not converge on a solution (Honaker & King, 2010).

The *restrictive strategy* is an alternative approach that entails selecting variables that have an observable relationship with the missing data patterns, that is, those variables with a significant unique predictive association to be included as auxiliary variables (Enders, 2010). Van Buuren (2012) suggested including all variables that appear in the analysis model, the variables that are related to the variables having missing data, and the variables that are highly correlated with the target variables. In addition, including an incomplete auxiliary variable is beneficial, even if that variable contains MNAR missingness. However, variables that have too many missing data might introduce estimation problems, and should not be included in an imputation model. In general, the restrictive strategy tends to be less effective than the inclusive strategy (Collins et al., 2001). However, it is sometimes necessary to reduce convergence problems.

Both the inclusive strategy and the restrictive strategy often ignore potential nonlinearity in the MAR association of the variables on the data set (Collins et al., 2001). To allow an effective use of the inclusive strategy and to encourage broader representation of the potential MAR process, Howard, Rhemtulla, and Little (2015) introduced the use of principal components scores as auxiliary variables. The principal components strategy relies on the characteristic of component scores as distilled sources of much of the variance contained in a set of variables.

The basic strategy involves (1) doing a single imputation of the missing values using a stochastic regression imputation or EM imputation, (2) computing nonlinear variables including powered and interaction terms, and (3) reducing the resulting very large data set down to a handful of meaningful component scores. The first step uses precise predicted values as temporary substitutes for the values that are missing. The uncertainty issues for statistical inference are not a concern in this step because the predicted values are simply estimates for the calculation of the component scores. In the second step, when nonlinear terms are calculated, the strategy is to be very broad. For example, each variable could be squared and all possible two-way interaction terms among the set of variables could conceivably be calculated.

Ongoing simulation work and comparative analysis on existing data sets indicates that using around 10 component scores is sufficient to capture the missing data relevant

information that is contained on many practical data sets (Garnier-Villarreal et al., 2013). These 10 component scores are included as the auxiliary variables in an FIML or MI analysis model.

Fraction of Missing Information

As suggested earlier, fraction of missing information (FMI) is probably the most useful value for quantifying the effect that missing data has on a statistical analysis. Allison (2002) gave a conceptual definition of FMI as "how much information is lost about each coefficient because of missing data" (p. 48). FMI can also be interpreted as the proportion of the total sampling variance of a focal parameter Q_j that is attributable to the missing data (Rubin, 1987), in this sense it is much like an R^2 statistic of the missing data (Enders, 2010). Alternatively, the FMI shows how much more variable a given parameter estimate is with missing data than it would have been had all of the data been fully observed, thereby conveying information about the statistical efficiency lost to nonresponse (Harel, 2007; Savalei & Rhemtulla, 2012). FMI has a fundamental place in any missing data analysis because it is intimately tied to many aspects of the missing data problem. The FMI directly impacts power loss due to missingness (Savalei & Rhemtulla, 2012), rates of convergence for missing data algorithms (Fraley, 1999; Harel, 2007; Schafer, 1997), and the number of imputations required for MI (Bodner, 2008; Graham et al., 2007).

Although it seems natural to quantify the scope of a missing data problem by the raw percentage of cells in the data set that are missing (i.e., percent missing [PM]), FMI is actually the more appropriate metric from which to draw guidance (Harel, 2007). FMI can be viewed as showing the impact of the raw PM after accounting for the strength of the item interrelations in the observed data (Enders, 2010; Rubin, 1987). Consequently, FMI will often be lower than the simple PM because high variable correlations may mean that there is less missing information than missing data. On the other hand, particularly when the missing data mechanism is MAR, FMI can be much higher than the raw percentage of missing values (Rhemtulla, Savalei, & Little, 2014; Savalei & Rhemtulla, 2011).

The formula for FMI is usually given in terms of the variance components of an MI analysis. Schafer and Graham (2002) gave the following formula for a sample estimate of the FMI for a focal model parameter Q_j:

$$FMI_{j,\mathrm{MI}} = \frac{(1 + M^{-1})B_j}{\overline{U}_j + (1 + M^{-1})B_j} \approx \frac{B_j}{\overline{U}_j + B_j}, \qquad (17.10)$$

where B_j is the between-imputation variance of the focal parameter, $\overline{U}_j$ is the average within-imputation variance for the focal parameter, and M is the number of imputations. With a large number of imputations the formula for FMI reduces to the approximation shown rightmost in equation 17.10 (Savalei & Rhemtulla, 2012). This approximation makes clear the conceptual parallel of FMI and the R^2 statistic. Replacing B_j with between-subject variance and $\overline{U}_j$ with within-subject variance gives the familiar R^2 statistic from ANOVA.

FMI is often discussed in the literature as a natural consequence of MI that is not easily derived from ML-based missing data tools (e.g., McKnight, McKnight, Sidani, & Figueredo, 2007; Schafer, 2001), but Savalei and Rhemtulla (2012) appealed to the missing information principle of Orchard and Woodbury (1972) to give a simple method for estimating FMI in the course of a FIML-based analysis. The computational formula given by Savalei and Rhemtulla (2012) is the following:

$$FMI_{j,FIML} = 1 - \frac{SE^2_{j,Comp}}{SE^2_{j,FIML}}. \qquad (17.11)$$

where $SE^2_{j,Comp}$ is the squared standard error of the focal parameter $\widehat{Q}_{j,Comp}$ derived from complete-data ML estimation and $SE^2_{j,FIML}$ is the squared standard error of the focal parameter $\widehat{Q}_{j,FIML}$ derived from a FIML analysis.

The natural stumbling block of this approach is the apparent inability to estimate $\widehat{Q}_{j,Comp}$ from incomplete data, but an asymptotic approximation is readily available. The method described by Savalei and Rhemtulla (2012) involves breaking the analysis into two phases. Phase 1 consists of estimating $\widehat{Q}_{j,FIML}$ by applying FIML to the incomplete data. Phase 2 consists of using ordinary ML estimation to fit an identical model to the model implied mean vector and covariance matrix produced by Phase 1. Because FIML produces model implied moments that are asymptotically equal to their complete-data analogues, the estimates derived from the Phase 2 model are asymptotically equal to the complete data ML estimates $\widehat{Q}_{j,Comp}$. Furthermore, because $SE^2_{j,Comp}$ and $SE^2_{j,FIML}$ are natural byproducts of estimating $\widehat{Q}_{j,Comp}$ and $\widehat{Q}_{j,FIML}$, these two models produce all the necessary components of equation 17.11, and FMI is easily calculated.

Assessing Model Fit with Missing Data

In many popular modeling paradigms assessing how well an estimated model recreates the relationships observed in

the sample data (i.e., the *model fit*) is an integral component of the research process (Davey, Savla, & Luo, 2005). Latent variable modeling techniques, in particular, have been developed hand-in-hand with ever more sophisticated model fit indices. Consequently, the consumers of research that employs latent variable models have come to expect a complement of fit indices to be reported alongside parameter estimates and test statistics. The ability to accurately assess model fit, therefore, is of paramount importance to any researcher seeking to employ a latent variable model. Unfortunately, missing data complicate this issue.

As with any other statistic we may wish to estimate, fit indices were developed under the assumption of completely observed data, and special consideration must be given to their calculation when they are derived from models fit to incomplete data (Davey et al., 2005; Savalei, 2010b). The assessment of model fit is problematic whether employing FIML or MI, but the issues inherent in the two approaches are unique, so we will address them separately below.

If using FIML estimation, one of the biggest issues arises from the unique form of the likelihood function that FIML maximizes to derive its parameter estimates. Traditional, complete-data, ML estimation is customarily accomplished by minimizing the discrepancy between the observed data moments and the model implied moments via the discrepancy function given by Joreskog (1967):

$$F_{ML} = \ln|\Sigma| + \text{tr}\left(S\Sigma^{-1}\right) - \ln|S| - p \tag{17.12}$$

where Σ is the model implied covariance matrix, S is the covariance matrix of the observed data, p is the total number of manifest variables, $|\cdot|$ represents the determinant of a matrix, and tr(.) is the trace of a matrix. Once F_{ML} is calculated, it can be used to compute the likelihood ratio (chi-squared) statistic in the following way:

$$\chi^2_{ML} = (N-1)F_{ML}, \tag{17.13}$$

where F_{ML} is the minimized discrepancy function from equation 17.12, and N is the total sample size. However, as described previously, FIML maximizes the joint case-wise loglikelihoods given by equation 17.2. Unfortunately, the FIML χ^2 cannot be calculated by simply replacing F_{ML} in equation 17.13 with ℓ_{FIML} from equation 17.2 (even though they are analogous quantities; Enders, 2001c).

Fortunately, the FIML χ^2 can be computed without a great deal of additional effort on the part of the researcher. Rather than naively replacing terms in equation 17.13, the FIML χ^2 is calculated by taking the difference between the maximized loglikelihood functions associated with the researcher's hypothesized model and a fully saturated model:

$$\chi^2_{FIML} = -2\left[\ell_{FIML}\left(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1|\mathbf{Y}\right) - \ell_{FIML}\left(\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0|\mathbf{Y}\right)\right] \tag{17.14}$$

where $\ell_{FIML}\left(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1|\mathbf{Y}\right)$ represents the loglikelihood function from equation 17.2 fit to the mean vector $\boldsymbol{\mu}_1$ and covariance matrix $\boldsymbol{\Sigma}_1$ implied by the researcher's hypothesized model, and $\ell_{FIML}\left(\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0|\mathbf{Y}\right)$ represents this same loglikelihood function fit to a fully saturated mean vector $\boldsymbol{\mu}_0$ and covariance matrix $\boldsymbol{\Sigma}_0$. The fit of the hypothesized model can then be assessed by comparing χ^2_{FIML} with a central χ^2 distribution with degrees of freedom equal to the difference in the number of free parameters in the hypothesized and fully saturated models. Model fit can also be judged by computing derived fit indices (e.g., CFI, TLI, RMSEA) by substituting χ^2_{FIML} for χ^2_{ML} in their standard formulae (Wu, West, & Taylor, 2009).

The formulation of equation 17.14 may not map intuitively back to the two step procedure illustrated by equations 17.12 and 17.13, but the underlying rationale becomes more clear if we consider $\ell_{FIML}\left(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1|\mathbf{Y}\right)$ to carry roughly the same information as the model-implied components of equation 17.12 and we think of $\ell_{FIML}\left(\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0|\mathbf{Y}\right)$ as carrying the same information as the observed data components of equation 17.12.

An additional concern arises when using incremental fit indices (i.e., CFI, TLI) to assess the fit of FIML-based models that employ the saturated correlates approach to include auxiliary variables (Enders, 2010; Graham, 2003). The saturated correlates approach necessarily adds extraneous variables to the model, but the software may not recognize the unique status of the new variables. Therefore, relying on the default independence model when calculating incremental fit indices will lead to incorrectly calculated degrees of freedom and fit indices that suggest better fit than they should. Interested readers can find a more detailed discussion of this issue and a description of the procedure for correct specification of the null model in Enders (2010, pp. 137–140). Although this issue still holds, in general, several software packages have implemented the ability to compute the correct null model when employing the saturated correlates approach. If the auxiliary variables are correctly entered into the model, the Mplus software (Muthén & Muthén, 2012) will calculate the correct null model (Asparouhov & Muthén, 2008). By using the R package semTools (Pornprasertmanit, Miller, Schoemann, & Rosseel, 2013) to introduce the auxiliary variables, the incremental fit indices from models fit with the R package

lavaan (Rosseel, 2012) are also calculated from the correct null model.

The biggest issue facing researchers who wish to assess model fit when employing MI is not calculating the χ^2 statistic, but correctly pooling the inevitable replicates of the χ^2. As with any implementation of MI, the analysis phase of an MI-based latent variable modeling enterprise will result in M distinct replicates of the χ^2 statistic. Unfortunately, Rubin's rules were not created to accommodate latent variable modeling, and they cannot be used to pool the χ^2. Therefore, as one would expect, the fit indices that are derived from the χ^2 statistic (e.g., RMSEA, CFI, TLI) cannot be pooled using Rubin's Rules either.

The issue of pooling MI-based fit indices has been explored in the statistical and methodological literature at length, but a widely applicable and easily implemented solution has yet to be proposed. Unfortunately, simply averaging the M χ^2 statistics is an untenable solution that will lead to a pooled statistic that is much too large and will reject the hypothesized model too often (i.e., the pooled statistic will have a highly inflated type I Error rate; Asparouhov & Muthén, 2010a; Lang, 2013).

One successful, albeit somewhat tedious, approach that has been implemented in several popular software packages was developed by Meng and Rubin (1992). Their approach is a multiple step procedure that centers on calculating a χ^2 statistic of the form given by Equation 17.14 (i.e., the difference in the minimized likelihoods of a full and restricted model). The first step involves aggregating the M χ^2 statistics and parameter estimates produced by the analysis phase of an ordinary implementation of MI:

$$\overline{\chi^2} = \frac{1}{M}\sum_{m=1}^{M}\chi^2_m, \tag{17.15}$$

$$\overline{Q_0} = \frac{1}{M}\sum_{m=1}^{M}\widehat{Q}_{0m}, \tag{17.16}$$

$$\overline{Q_1} = \frac{1}{M}\sum_{m=1}^{M}\widehat{Q}_{1m,} \tag{17.17}$$

where χ^2_m, $\widehat{Q}_{om}$, and $\widehat{Q}_{1m}$ are the estimated χ^2 statistic, null model (fully saturated) parameter estimates, and hypothesized model parameter estimates, respectively, derived from the m-th imputed data set, and M is the number of imputations.

The next step is to calculate an updated χ^2 statistic for each imputed data set by fixing the null and hypothesized parameter values at $\overline{Q_0}$ and $\overline{Q_1}$, respectively, and evaluating a special case of equation 17.14 within each of the imputed data sets:

$$\widetilde{\chi^2_m} = -2[\ell_{ML}(\overline{Q}_1|Y^{(m)}) - \ell_{ML}(\overline{Q}_0|Y^{(m)})], \tag{17.18}$$

where $\ell_{ML}(\overline{Q}_0|Y^{(m)})$ represents the ordinary, complete-data, loglikelihood function fit to the m-th imputed data set and the aggregated point estimates given by equation 17.16, and $\ell_{ML}(\overline{Q}_1|Y^{(m)})$ represents this same loglikelihood function fit to the same imputed data set and the aggregated point estimates given by equation 17.17.

Next, the m estimates of $\widetilde{\chi^2_m}$ are pooled by simply taking their average across the imputed data sets:

$$\overline{\widetilde{\chi^2}} = \frac{1}{M}\sum_{m=1}^{M}\widetilde{\chi^2_m}, \tag{17.19}$$

where $\widetilde{\chi^2_m}$ are the updated χ^2 statistics from equation 17.18, and M is the number of imputations. Finally, the adjusted χ^2 statistic can be calculated as follows:

$$\chi^2_{imp} = \frac{\overline{\widetilde{\chi^2}}}{1+r_3}, \tag{17.20}$$

where $\overline{\widetilde{\chi^2}}$ is the pooled χ^2 statistic from equation 17.19, and r_3 is a correction factor given by

$$r_3 = \frac{M+1}{(M-1)(p_1-p_0)}(\overline{\chi^2} - \overline{\widetilde{\chi^2}}), \tag{17.21}$$

$\overline{\chi^2}$ is the aggregate χ^2 statistic from equation 17.15, $\overline{\widetilde{\chi^2}}$ is the pooled χ^2 statistic from equation 17.19, p_1 and p_0 are the number of freely estimated parameters from the hypothesized and null models, respectively, and M is the number of imputations.

The χ^2_{imp} statistic has been shown to perform well when compared to the χ^2_{FIML} statistic given by equation 17.14 when the amount of missing data is low or the number of imputations is large (Asparouhov & Muthén, 2010a). Though the process of calculating χ^2_{imp} manually can be onerous, this approach is well implemented in the Mplus software package (Muthén & Muthén, 2012) as the default method of pooling χ^2 statistics when fitting ML-based, single-level structural equation models. It is also available in the R package semTools (Pornprasertmanit et al., 2013) as an option for pooling χ^2 statistics from structural equation models estimated with the R package lavaan (Rosseel, 2012).

The question of how to best assess model fit with missing data has been a very active area of missing data research over the course of the last 20 years, and many interesting applications have been developed whose discussion falls outside the scope of this chapter (e.g., the application of parametric bootstrapping to the assessment of model fit by Enders, 2002; Savalei & Yuan, 2009). One such family of techniques still warrants a brief introduction, though. These are the so-called two-stage estimators that are based on the EM algorithm. The two-stage estimation approach was developed by Yuan and Bentler (2000) as a way to carry out ML-based missing data analysis under difficult situations, such as under nonnormal data distributions. Before Graham's (2003) saturated correlates approach was developed and implemented, a two-stage approach was the only way to get auxiliary variables into an FIML analysis. It has remained a fruitful starting point for several recent advances in assessing model fit with missing data. For example, Cai and Lee (2009) adapt the two-stage estimation approach to produce a correctly distributed χ^2 statistic by incorporating the Meng and Rubin (1991) supplemental EM algorithm, and Savalei and Bentler (2009) derived their own correction to produce accurate standard errors and χ^2 statistics, which they show to perform comparably to FIML estimates. Savalei and Falk (2014) showed that this method can perform better than FIML when data are nonnormally distributed.

One downside of approaches like Meng and Rubin's (1992) technique and the corrected versions of the Yuan and Bentler (2000) two-stage estimator is that they tend to be difficult to implement without good software integration. To mitigate this difficulty certain authors have explored the possibility of pooling the imputed data structures prior to the analysis phase of MI. Yet, all such studies have found that the χ^2 statistics derived from these pooled data structures required a *post hoc* correction before they followed a χ^2 distribution (Lang, 2013; Lee & Cai, 2012). Lee and Cai (2012) derived such a correction by adapting Proposition 4 from Browne (1984) to produce a test statistic T_{MB} that asymptotically follows a central χ^2 distribution. They also provided a SAS Macro that can be used to implement their approach software.

Lang and Little (2014) proposed an approach that was designed to be easily implemented with any statistical analysis software without relying on specialized code. Their approach (which we dub the supermatrix technique) is essentially an expansion of the initial aggregation phase of the Lee and Cai (2012) two-stage approach. Using a Monte Carlo simulation study they provided empirical evidence to suggest that accurate hypothesis tests can be accomplished by appealing to nested-model χ^2 difference tests without the need for post hoc correction to the component χ^2 statistics (even though the component χ^2 statistics are biased measures of model fit when considered individually).

To illustrate how the supermatrix technique is implemented, consider a hypothetical missing data analysis in which you begin with an incomplete $N \times p$ data set. Application of the supermatrix technique can then be broken into four basic steps:

1. Create a set of M multiple imputations using any MI algorithm.
2. Stack the M imputed data sets into an aggregate $MN \times p$ data frame.
3. Calculate a single $p \times p$ covariance matrix from the stacked data from step 2.
4. Use the covariance matrix from step 3 and the original sample size N as the sufficient statistics and sample size, respectively, for subsequent model fitting.

Figure 17.2 gives a graphical summary of the supermatrix approach for a hypothetical example in which the original incomplete data consists of four observations of three variables. The results of a Monte Carlo simulation study conducted by Lang (2013) suggested that fit indices derived from structural equation models fit using the supermatrix as sufficient statistics will have inflated type I Error rates (i.e., they will overreject well-fitting models) and should not be used to assess overall model fit. However, simulation results from Lang and Little (2014) showed very good performance for nested-model $\Delta\chi^2$ statistics computed from parent and child models that are both fit to a supermatrix. When $\Delta\chi^2$ statistics were calculated from parent and child models fit to supermatrices, Lang and Little (2014) found that these $\Delta\chi^2$ statistics were nearly identical to analogous $\Delta\chi^2$ statistics calculated from parent and child models fit to fully observed data.

Mediation Analysis

Mediation is often of central interest to researchers in social and behavioral science research. Mediation is said to occur when the effect of an independent variable (X) on a dependent variable (Y) is transmitted by a third variable (M) (Baron & Kenny, 1986; Sobel, 1982). M is termed a mediator as it mediates the effect of X on Y. A mediating effect (also termed an indirect effect) can be quantified by and tested through the product of the two

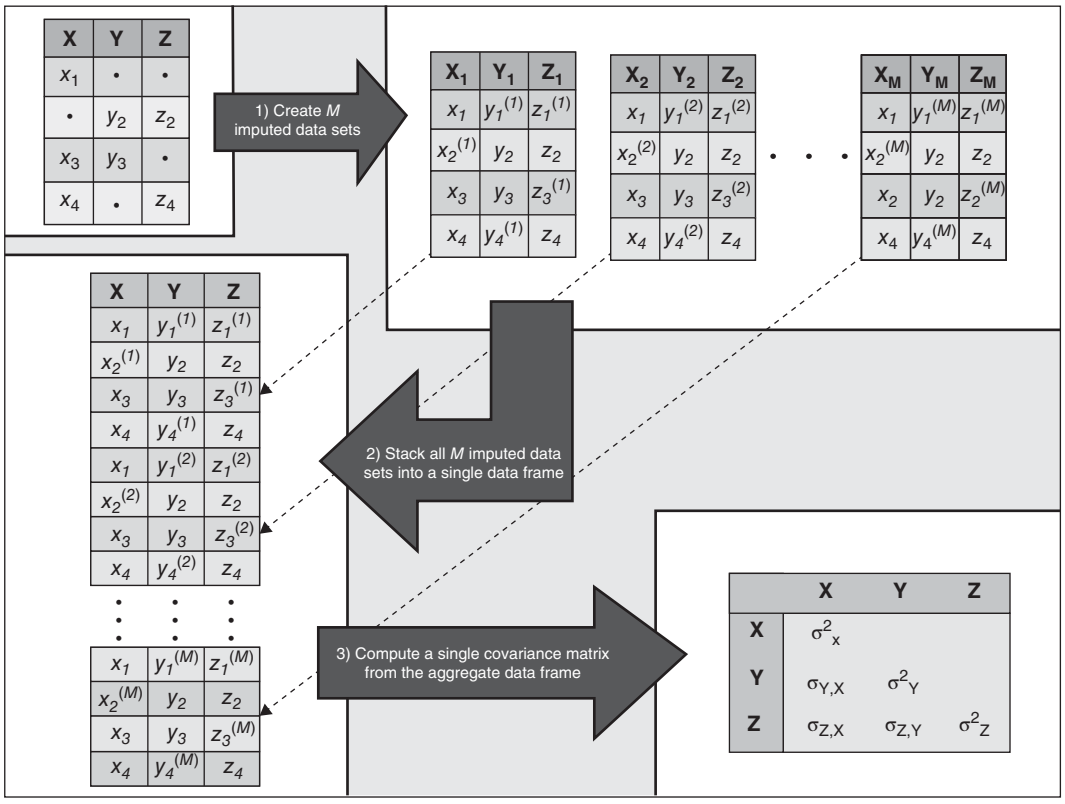

Figure 17.2 A graphical representation of the supermatrix technique as applied to a data set with four observations and three variables. *Source:* From Lang and Little (2013). Used with permission.

direct effects (denoted by *ab*): (1) the effect of *X* on *M* (*a* effect); and (2) the effect of M on Y controlling for *X* (*b* effect). A well-known strategy to test *ab* is to empirically establish the sampling distribution of *ab* through nonparametric bootstrapping and then use the confidence interval computed from the sampling distribution to test the null hypothesis that $ab = 0$ (MacKinnon, Lockwood, & Williams, 2004). A nonparametric bootstrapping procedure starts with drawing a large number of samples with replacement (e.g., 1,000) with the same sample size of the original data, assuming that the original sample is the population (Efron, 1979; Efron & Tibshirani, 1994). A mediation model is then fit to each of the bootstrap samples, resulting in a large number of point estimates of *ab,* which form the empirical sampling distribution of *ab*.

When there are missing data, nonparametric bootstrapping can be combined with FIML or MI to test mediation effect (Wu & Jia, 2013; Zhang & Wang, 2013). To combine nonparametric bootstrapping with FIML, one needs to bootstrap first and then run the target analysis using FIML for each bootstrapped sample (denoted by BOOT[FIML]). Many software packages such as Mplus and EQS have automated this procedure. To combine bootstrapping with MI, two procedures have been proposed. One is to bootstrap first and then run MI for each bootstrap sample. This procedure is computationally intensive because it requires running MI for each bootstrap sample. In other words, if there are 1,000 bootstrapped samples, the MI needs to be run 1,000 times. This large number of runs would impose a tremendous amount of computational burden. To mitigate this problem, Wu and Jia (2013) suggested running MI first to obtain a number of imputed data sets and then running the bootstrap procedure for each imputed data set (denoted by MI[BOOT]). Because MI(BOOT) requires only 1 run of MI, it is more computationally efficient than BOOT(MI). Wu and Jia (2013) showed that MI(BOOT) performed comparably to BOOT(FIML) when data are normally distributed and missing data are ignorable. However, one should be cautious about using either procedure to test mediation as MNAR, nonnormality, or both can distort the point and interval estimates of a nonzero *ab* for both procedures.

In addition to nonparametric bootstrapping, Bayesian estimation methods are well suited to mediation analysis and can be readily extended to treat missing data (Biesanz, Falk, & Savalei, 2010; Enders, Fairchild, & MacKinnon,

2013; Yuan & MacKinnon, 2009). The Bayesian method generates a posterior distribution of *ab* (i.e., a distribution of *ab* conditional on the observed data) based on which the statistical inference of *ab* can be made. However, past research on Bayesian approach is limited to normal data. More studies need to be conducted to examine the performance of the Bayesian approach when the normality assumption is violated and to compare it with the other strategies.

When to Use FIML Versus MI

FIML and MI provide comparable point and standard error estimates given that (1) the multivariate normality assumption is satisfied, (2) the missing data are ignorable (i.e., MCAR and MAR), (3) missing data model is the same, and (4) the number of imputations in MI approaches infinity (Collins, Schafer, & Kam, 2001; Graham et al., 2007; Little & Rubin, 2002; Schafer, 1997; Schafer & Graham, 2002). However, they have their own pros and cons in practice. Some of these have been mentioned in the previous sections. Here we provide a more detailed comparison of the two techniques.

There are many reasons researchers might prefer FIML. First, FIML is more efficient than MI. The standard error estimates from MI will generally be larger than those from FIML although the difference is trivial when the number of imputations is large. Second, FIML is also easier to implement because it is a one-step approach and available in most of the commercial software packages (e.g., Mplus, LISREL, EQS, AMOS, SAS PROC CALIS, and lavaan in R). In contrast, MI involves multiple steps that have not been fully automated. In addition, implementation of MI requires many decisions. As described before, researchers might need to decide on an appropriate number of imputations, the correct imputation model (with the relationships among the variables correctly specified), and an appropriate number of burn-in and between-imputation iterations. Finally, it is also easier to obtain model fit indices with FIML as described previously.

However, there are benefits of using MI. Certain imputation algorithms and imputation models might provide a better treatment of categorical variables and nonparametric relationships among the variables (Asparouhov & Muthén, 2010a; White, Royston, & Wood, 2011). In addition, MI creates complete data sets. As a result, statistical methods that are only implemented for use with complete data can be applied. Under certain circumstances, MI has to be adopted (Enders, 2010; Gottschall, West, & Enders, 2012). One circumstance occurs when there are item-level missing data. To illustrate, suppose *X, Y*, and *M* in a mediation model are scale scores that are computed by averaging multiple item scores. If some of the items have missing data, the best way to handle the missing data would be imputing them at the item level and then calculating the scale scores from the imputed item scores (Gottschall, West, & Enders, 2012). By doing this item-level imputation, the observed items' scores are used to recover the missing information. FIML is inferior in this case as it relies on the analysis model in which the item scores are not directly included, resulting in underuse of the available information. Another circumstance in which MI may work better is when the model contains categorical dependent variables. Though FIML can be used with categorical data, when there are more than two categories or the model is complicated, this becomes extremely computationally intensive. Instead, the most common estimation technique is to use a diagonally weighted least squares estimator on the matrix of polychoric correlations (this is called "WLSMV" in Mplus, where it is the default estimator for categorical variables). Because least squares estimators cannot handle missing data efficiently, MI allows the researcher to deal with the missingness first (e.g., by using MICE to impute categorical variables) and use the least-squares estimator to analyze the model on the imputed data sets (Asparouhov & Muthén, 2010a, 2010b).

REVIEW OF MISSING DATA PRACTICES IN PSYCHOLOGICAL RESEARCH

In his introduction to the special section of *Psychological Methods* on missing data analysis, West (2001) noted that a great many methodological advances had been made in the treatment of missing data analysis in the preceding 25 years. In an interview shortly thereafter, West predicts that increasing implementation of principled missing data tools will be hallmark of psychological research in the early twenty-first century (Azar, 2002). Many of the advances that West (2001) was referencing had, by the turn of the twenty-first century, yet to make their way into practice in the applied social science literature.

The *American Psychological Association* was clearly cognizant of the need for improved treatment of missing data. This concern is evident when reviewing the recommendations of the Task Force on Statistical Inference published in 1999. One of the key recommendations of this task force was that authors publishing in psychology journals should accurately report on the missingness in their studies so that its impact on the conclusions can be judged transparently (Wilkinson & Task Force on Statistical Inference, 1999). The committee also went on to advise

that researchers adopt optimal missing data treatments and eschew antiquated ad hoc approaches. They condemned the use of deletion methods, in particular, by stating, "The two popular methods for dealing with missing data that are found in basic statistics packages—listwise and pairwise deletion of missing values—are among the worst methods available for practical applications" (p. 598).

So how prophetic was West's claim? Have there been considerable improvements in missing data practices since 2000? Unfortunately, even in the shadow of an ever growing monolith of evidence that ad hoc missing data tools are universally inferior to modern principled techniques, psychological researchers have been relatively slow to adopt more sophisticated missing data tools. Reviews of the missing data practices employed in psychological studies published in 1999, 2003, and 2012 have all found that ad hoc techniques, and deletion based techniques in particular, remain the most prevalent treatment for missing data (Bodner, 2006; Little et al., 2014; Peugh & Enders, 2004). However, all hope is not lost, because there are signs that the field is on a trajectory of improvement.

Recognizing that the aforementioned recommendations of the Task Force on Statistical Inference represented a turning point for missing data analysis in the social sciences, Bodner (2006) and Peugh and Enders (2004) reviewed the missing data practices reported in samples of journal articles published in 1999. These studies' findings were convergent and bleak. Perhaps most troubling was the very high frequency with which missing data were not reported at all (i.e., the presence of missingness often had to be inferred from discrepancies in the degrees of freedom reported for test statistics). Additionally, for those cases in which the missing data treatment could be elucidated, a principled technique was never used, and deletion-based approaches were, by far, the most frequently applied treatments.

To judge the improvement in missing data analysis in the years following the recommendations of the Task Force on Statistical Inference, Peugh & Enders (2004) also reviewed the missing data practices reported in a sample of journal articles published in 2003. They found a discernible improvement in missing data practices, especially in terms of reporting practices. This second review found much more accurate reporting of missing data (i.e., a higher proportion of authors explicitly acknowledged the presence of missingness in their studies). They also note a higher frequency of authors explicitly discussing the assumptions underlying the missing data analysis (e.g., actively testing the MCAR assumption). Unfortunately, ad hoc approaches were still the norm, and deletion techniques remained the most common missing data treatment. However, they did record several instances of principled techniques being employed, whereas there had not been any use of principled approaches in their review of journal articles from 1999.[3]

Finally, Little et al. (2014) conducted a comprehensive review of the missing data practices reported in empirical studies from the 2012 volume of the *Journal of Pediatric Psychology* and found further evidence for a trajectory of improvement in missing data practices. The improvement in reporting practices vis-à-vis those found by Bodner (2006) and Peugh and Enders (2004) was considerable. The majority of the articles examined transparently acknowledged the presence of missingness in their studies and explicitly described their treatment thereof. There was also a considerable increase in the usage of principled missing data tools (especially FIML) relative to the rates reported by Bodner (2006) and Peugh and Enders (2004). A sizable minority of the articles examined employed FIML (or some variant of FIML) to treat the missingness in their studies. Unfortunately, ad hoc approaches were still the most frequently employed techniques, and several papers mixed ad hoc approaches with principled techniques (e.g., listwise deletion of attrition and imputation of the remaining arbitrary missingness).

An interesting finding of the Little et al. (2014) review was that every study that employed FIML either fit a structural equation model using Mplus (Muthén & Muthén, 2012) or it fit a multilevel model. Because FIML estimation is the default option when analyzing incomplete data in Mplus, and multilevel modeling relies on FIML (or some specialized variant of FIML) to accommodate the inherently unbalanced data for which it is designed, the

[3]Principled techniques are defined as any missing data technique that treats the nonresponse by considering the underlying distribution of the missing data and either fills in these missing values via predictive models constructed to produce predicted values that conform to that underlying distribution (in the case of MI) or partition the missingness out of the likelihood function by appealing to the Rubin (1976) partitioning of the complete data distribution, which is only possible when explicitly considering the distribution of the missing values (as in EM and FIML). These principled techniques are usually considered in contrast to ad hoc approaches that are so called because they are simple one-off convenience solutions to the missing data that basically ignore any missing data that ever existed. In the strictest sense principled and ad hoc are not mutually exclusive. You can have a principled ad hoc approach if it is built up from initial consideration of the distribution of the missing values, but it is specialized to a specific problem and not generalizable to any other analysis.

greater usage of principled techniques observed by Little et al. (2014) may not represent a meaningful improvement in practice. Although, this is a pessimistic outlook, the fact that all of the reported FIML analyses were conducted by naively employing a restrictive strategy (i.e., they did not include auxiliary variables in the FIML model) lends credibility to the suggestion.

Judging by the patterns of missing data practices observed in the reviews presented by Bodner (2006), Little, et al. (2014), and Peugh and Enders (2004) it is apparent that missing data are becoming a more active consideration for researchers as time goes on. Similar findings are reported by Wood, White, and Thompson (2004), who employed similar methodology to analyzed the missing data practices reported in a sample of studies published in the 2001 volume of several top-tier medical journals. However, the findings of Little et al. (2014) suggest that many applied researchers in psychology are still inadequately informed when it comes to optimal missing data treatments, and many decisions in a missing data analysis are guided by software defaults. While optimal missing data tools are becoming better integrated into popular software every year (Enders, 2010), the findings discussed above suggest that there is still a need for education on how to best implement these tools as they become available.

WHY CHANGE?

Too often, entreaties to employ modern approaches to address missing data or to incorporate planned missingness as a design feature are met with an unfounded fear or unwarranted hubris. As detailed in Table 17.1, the traditional methods of handling missing data are rife with error and bias. Maintaining a staunch commitment to the practices of old is an untenable position to take (Wilkinson & Task Force on Statistical Inference, 1999). The only time that *some* of these practices are warranted is when the missing data are MCAR and power is not an issue (Enders, 2010; Little & Rubin, 2002), or when the amount of missing data is very small (e.g., less than 5%; Graham, 2009). Otherwise, invalid conclusions will result. Fundamentally, failing to address the bias created by missing data represents a miscarriage of social justice. Because results are biased when traditional approaches are employed, policy recommendations based on the analyses of faulty data lead to failures in providing accurate guidance for stakeholders and decision makers. Efforts to simplify analyses by shortcutting the appropriate ways of addressing missing data are unconscionable. Baseless fears or unjustified hubris are not legitimate excuses to avoid appropriately treating the missing data.

Rather than ignoring the issue in the abject desire that the bad consequences of missing data won't be too bad, we should aggressively address the mechanisms of missing data to minimize their undermining influences (Wilkinson & Task Force on Statistical Inference, 1999). In this vein, thoroughly examining and reporting on potential predictors of missingness would benefit future research because investigators could identify potential predictors of missingness to be included into a data-collection protocol. Such information could be added to the supplemental materials for a published paper and posted on a reliable web page. Such virtual repositories would provide a wealth of information for future study planning.

PLANNED MISSING DATA DESIGNS

The preceding discussion of missing data has centered on the unplanned missingness that inevitably occurs in human science research. We now turn our attention to planned missing data designs and the recent research that is still emerging in this area (e.g., Graham, Hofer, & MacKinnon, 1996; Graham, Taylor, & Cumsille, 2001; Graham, Taylor, Olchowski, Cumsille, 2006; Jia et al., 2014; Jorgensen et al., 2014; Rhemtulla, Jia, Wu, & Little, 2014, Rhemtulla, Savalei, et al., 2014). Planned missing data designs have been around for some time but maybe not obviously recognized as such. The Solomon four-square design, for example, is a planned missing data design (see Table 17.4, Groups 1–4; see also Iacobucci, 1995). This design is often used with classical missing data handling procedures. As such, researchers have not taken full advantage of it. If classical analyses are used, it is a very underpowered design. If modern missing data handling procedures are used, on the other hand, it becomes a very powerful pre–post

TABLE 17.4 The Solomon Four-Group Design as a Planned Missing Design with the Addition of Two Additional Groups for a Complete Planned Missing Design

Group	Pretest[1]	Treatment/intervention	Posttest[1]
1	O_1	X	O_2
2	O_3		O_4
3	Planned missing	X	O_5
4	Planned missing		O_6
5	O_7	X	Planned missing
6	O_8		Planned missing

[1]O reflects the observed variables, including all demographics and outcome scores and X represents a treatment or intervention that has been implemented. The subscripts differentiate the different groups at the different testing occasions.

experimental design. The participants who do not receive the pretest scores are randomly assigned to be in Group 3 and Group 4 (Table 17.4). These missing pretest scores are imputed if a modern missing data approach is used, thereby increasing the power of the overall design. A fully planned missing data design might also add two additional groups (Groups 5 & 6 in Table 17.4) to allow for more power at less cost.

Planned missing data designs leverage the capabilities of the modern missing data handling procedures to minimize the loss in power that traditional approaches suffer. Planned missing data designs also are used because they can substantially reduce costs and, in many cases, increase validity by reducing participant burden/fatigue and minimize other threats to validity, such as test reactivity and unplanned missing data (Harel, Stratton, & Aseltine, 2011; Popham, 1993). Planned missing data designs are most useful in the context of large sample research involving latent variable SEM techniques that extend easily to longitudinal designs (Little, 2013). In the following, therefore, we will assume that multiple indicators of constructs are generally used, reasonably large sample sizes are available (e.g., > 140), and that latent variable SEM or one of its variants will be used (see Little, 2013, for a discussion of the various options). This latter assumption is not essential for using all of the planned missing designs we will discuss but it is for some of them.

Harel et al. (2011) investigated whether planned missingness can be used to mitigate test reactivity in a pre-post control group experimental design. In a suicide prevention assessment trial, students received either all or a subset of items from the Signs of Suicide 17-item questionnaire at pretest and the complete questionnaire 3 months postintervention. Three notable findings arose: first, students who were given more items to complete were less likely to complete all of them: 27% of those who were given all 17 items failed to answer all of them, compared to 14% who were given just 6 items and 18% who were given 8 items. Second, students who were given the full questionnaire at baseline were three times more likely to skip the posttest assessment entirely (21% compared with 7% for those who received a truncated questionnaire at baseline). Third, of those students who attempted the posttest questionnaire, those who received the full questionnaire at baseline were again less likely to complete all items at posttest (25% of these students skipped items compared with 15% of students who received a truncated questionnaire at baseline), despite the fact that all students received the full 17-item questionnaire at posttest. These results suggest that planned missing designs can significantly reduce rates of unplanned missing data—both item nonresponse and attrition—by substantially reducing participant burden.

In addition to reducing the rates of unplanned missingness, Harel et al. (2011) showed that the planned missing strategy alleviated the effects of test reactivity. Test reactivity occurs when persons assigned to the control group get better simply by virtue of being tested with protocols that clearly indicate the purpose of a study. With the planned missing protocol used by Harel et al., those participants who received only some of the signs of suicide items did not react to the protocol, whereas those who received the whole questionnaire showed changes at post-test that obscured the effect of the intervention.

The Harel et al. (2011) study is a unique application of a planned missing data design that highlights the utility of such designs. In the following, we will discuss more standard applications of planned missing data designs and extend them to the case of longitudinal data collections: (1) multiform designs, which focus on shortening the questionnaire protocol; (2) the two-method design, which focuses on leveraging high-quality measures to increase power; and (3) wave-missing designs, which focus on reducing the costs of longitudinal data collection.

Multiform Planned Missing Protocols

The simplest multiform example is the three-form planned missing data design, an instance of which is presented in Table 17.5. Multiform designs have been described in various literatures under various names and with various analysis models (e.g., Bunting & Adamson, 2000; Bunting, Adamson, & Mulhall, 2002; Dings, Childs, & Kingston, 2002; Gonzalez & Eltinge, 2008; Mislevy, Beaton, Kaplan, & Sheehan, 1992; Raghunathan & Grizzle, 1995; Shoemaker, 1973; Wacholder, Carroll, Pee, & Gail, 1994). As seen in the example of a three-forms design in Table 17.5, items are divided into four different item sets and then assembled to create three questionnaire protocol forms. Participants are randomly assigned to fill out one of the three forms. The items that are not included in a form are thereby missing completely at random (i.e., MCAR) because the investigator controls, through random assignment, which variables are missing for each person.

TABLE 17.5 Example of a Three-Form Planned Missing Design

Form	Common Set X	Variable Set A	Variable Set B	Variable Set C
1	Complete	Complete	Complete	Missing
2	Complete	Complete	Missing	Complete
3	Complete	Missing	Complete	Complete

Multiform questionnaire protocols are a way to create short forms that fit within a specified time frame, to reduce overall costs, and to minimize respondent burden and fatigue. Each participant receives a questionnaire protocol that can be substantially shorter than the full set of protocol questions. The benefit of the multiform design is that it leverages the capabilities of the modern missing data treatments to maintain the information (both reliability and validity) that is inherent in the full set of questions. Moreover, the planned missing protocol has the potential to increase validity by reducing burden, fatigue, unplanned missing, and test reactivity (e.g., Harel et al., 2011) as well as practice and retest effects with longitudinal data (Beglinger et al., 2005; Jorgensen et al., 2013; Salthouse & Tucker-Drob, 2008).

These many benefits notwithstanding, planned missing protocols can be less efficient than complete case protocols. Recall that efficiency, which is related to power, reflects the size of the standard error for a given parameter estimate. The power loss associated with the planned missing protocol can be offset by an increasing the sample size to produce the same efficiency as the design would have had with complete data. The extent to which parameter efficiency suffers depends on the pattern of missing data, the parameter type, and the strength of correlations between variables (Garnier-Villaréal et al., in press; Rhemtulla, Jia, et al., 2014; Rhemtulla, Savalei, et al., 2014).

One salient recommendation that has come out of our recent research on optimal planned missing data designs is that efficiency is maximized when groups of highly correlated items (e.g., items from the same scale) are split across item sets, such that every participant answers a proportion of the items on every scale. Intuitively, this makes sense—once a participant has responded to four items on a six-item conscientiousness scale, four items on a six-item neuroticism scale, and four items on a six-item extraversion scale, the incremental benefit of responding to another two items on each of those scales is small. In contrast, if a participant responds to all six items on the conscientiousness scale and the neuroticism scale, and zero items on the extraversion scale, even though in both cases the participant has answered 12/18 questions, more information is missing when a whole scale is absent. In the first case, we have a pretty good estimate of that participant's personality along all three dimensions; in the second case, we have a slightly better estimate of personality along two dimensions but no estimate at all on the third. As such, planned missing designs where scales are split across sets result in much more powerful analyses.

Similarly, having indicators of constructs in the X block minimizes the reduction in efficiency for many parameters. As with most complex modeling endeavors, we recommend careful planning and preliminary simulation runs to identify any potential weakness of a planned missing data design. Even if poorly constructed, however, a planned missing data design brings more benefits than costs when compared with the business as usual approach that permeates current literature.

As with many statistical techniques, the details of how to create a multiform design can be more cumbersome than a first glance may suggest. A multiform design is no different. A number of important issues need to be considered when using a multiform design in general. We will discuss these issues in the context of the three-form design. By way of example, we will walk through the creation of three forms of the Inventory of the Forms and Functions of Aggression (iFFA) survey (Little, Jones, Henrich, & Hawley, 2003). The iFFA measures six constructs of aggression each with six items: Pure Overt, Instrumental-Overt, Reactive-Overt, Pure Relational, Instrumental-Relational, and Reactive-Relational. The iFFA is a self-report battery that is age appropriate from elementary age to late adolescence. For this hypothetical instrument, we will also collect demographic information and an important screening item for suicide ideation—"During the past 3 months, did you ever seriously consider attempting suicide (yes or no)?"—as well as self-reports reports on truancy, detentions, and visits to the principal's office.

As shown in Table 17.5, the three-form design consists of an X block of items, which is administered to all participants. In creating a three-form protocol from these variables, all singly indicated constructs (i.e., constructs that are measured by just one item, including truancy frequency, detention frequency, and number of principal visits), demographic variables (age, gender, race/ethnicity), and any critical screening variables (suicide ideation) are assigned to the X block. For the latent constructs with multiple indicators, the items for each construct would be assigned based on the item characteristics. Indicators of constructs can be classified as (1) parallel, (2) tau-equivalent, or (3) congeneric. Parallel items are psychometrically identical in their measurement of a construct (as can be found in abilities testing, for example). In the behavioral and social sciences, constructs are more likely to be either tau-equivalent or congeneric. With tau-equivalent items, each items is about equally good at representing the construct (i.e., each item loads on the construct to about the same degree). With congeneric items, some items are stronger indicators of the construct (i.e., have high

loadings) then other items of the construct (i.e., items with lower loadings). The iFFA is a battery with tau-equivalent indicators. A loneliness scale with items such as "I feel lonely" and "I feel like no one likes me" would likely have congeneric qualities with the "I feel lonely" item being a marker variable of the construct loneliness and the "I feel like no one like me" would be a lower loading (yet important) indicator of the construct.

With this slightly tangential discussion in mind, items representing the same construct would be spread among the X, A, B, and C blocks of times. If the items are tau-equivalent the process can be essentially random. With six items for a construct, two of the four blocks of items would have two items assigned to them. The key here would be to balance the number of items in the A, B, and C blocks to ensure about equal numbers so that each of the three forms is of equal length. If one of the forms is longer than the other two, unplanned missing data might emerge at a greater frequency for the longer form. A set of dummy codes representing the assigned form could be used in the imputation model to account for this feature if it were to occur. If items are congeneric and one item can be identified as the strongest representative of the construct, it would be assigned to the X block. The remaining items would be distributed as evenly as possible among the A, B, and C blocks.

As mentioned previously, when building a multiform protocol, the efficiency of the parameters estimated from the resulting data set is increased if the between block correlations are high. Spreading items of the same construct across the item blocks helps ensure that the between block correlations are high. Putting all the items of a given construct into the same item block will increase the within block correlations but will have a tendency to reduce the between block correlations, which can lower efficiency. Sometimes, questions are blocked or created as a testlet. Here, the set of items in a block or testlet cannot be spread among the different item sets. In this case, the block of items or testlet must be assigned to one of the items sets. If only one block or testlet is involved it would be best placed in the X set. If two or more of them exist, then they could be assigned to different blocks of items.

Extending the three-form design longitudinally is also a matter for consideration. As mentioned, the three-form planned missing data design allows researchers to measure more items from more participants on more occasions using the same budget as a complete data design. It also reduces burden, fatigue, and response reactivity. After randomly assigning participants to complete one of three forms on the first occasion, for subsequent measurements, one might assign participants to complete the same form, a different form that they haven't seen yet, or use random assignment again. Retest effects are expected when making repeated measurements, and assigning different forms over time would decrease the number of variables that participants see on consecutive occasions, thus decreasing the degree to which retest effects manifest in variables not included in the X block. Using a Monte Carlo simulation approach, Jorgensen et al. (2014) compared the different assignment strategies in the context of autoregressive latent-variable panel models, a commonly used type of longitudinal model. Data were simulated based on a fixed, moderately large sample size using a range of population parameter values, and certain patterns (corresponding to each of the three methods of assigning forms) of complete data were replaced with missingness, replacing either 11% or 22% of complete data with planned missingness. The results indicated negligible differences between assignment methods only in the absence of retest effects, which is not a likely scenario in practice. When they introduced practice effects in the form of small (Cohen's $d = 0.1$) mean increases for items seen on consecutive occasions, strong invariance models (with intercepts constrained to equality across occasions) showed an increase in the latent mean, although the population mean was zero. This bias manifested less when forms were randomly assigned on each occasion, but not nearly so much as when different forms were assigned systematically, such that no one would see the same form twice until seeing all other forms first. Reduction of bias due to retest effects makes it preferable to systematically assign different forms over time.

Two-Method Planned Missing Design

In many studies, researchers are put in the difficult situation of choosing between two methods for measuring a critical construct. Often, one method, such as blood cortisol levels for measuring stress, is a highly valid but expensive tool whereas a second method, such as a self-report battery of perceived stress, is a less valid but easily (inexpensively) administered tool. In situations like this, the expensive measure is considered the gold standard for assessing a construct, but the costs of using it are prohibitive. If the expensive measure is chosen, the costs are often reduced by reducing the sample size, which typically results in an underpowered or highly simplified study. In contrast, if the inexpensive measure is chosen, the increases in sample size and design complexity are offset by the fact that the inexpensive measure contains systematic bias (e.g., due to the self-report nature of the measure).

This scenario does not have to be an either–or choice. Instead, the two-method planning missing data design provides an ingenious way to leverage the capabilities of both modern missing data treatments and latent variable structural equation modeling. When two methods for measuring the same underlying construct exist (or can be developed), the two-method design allows for larger sample sizes while maintaining the high validity of using only an expensive gold standard tool. Table 17.6 provides a list of candidate constructs for which two methods exist. From physiological indices, to classroom observations, to clinical diagnoses, many constructs have expensive gold standard ways of measuring them. Many of these constructs also have easily administered alternatives. In any of these situations, the two-method design can be implemented.

One key to the two-method planned missing data design is the use of latent variable structural equation modeling. Figure 17.3 shows a couple of examples of two-method construct representations. As shown in Figure 17.3, the two-method planned missing data design relies on the bifactor model and the common factor model to represent the construct of interest as well as a bias factor. It also relies on the ability to represent both the gold standard measure and the biased measure with multiple indicators. Using multiple indicators is essential to disentangle the reliable from the unreliable variance and then to further disentangle the biased information from the unbiased information about the focal construct of interest.

A second key to the two-method planned missing data design is that all participants are assigned to receive the biased measure. For the unbiased, gold standard measure, only a subset of participants are randomly assigned to be assessed. The ratio of expensive to cheap observations depends on the degree of correlation between the two methods of measuring the construct and on the degree of reliability of the two measures. Graham et al. (2006) provided a straightforward way to calculate the ratio that hits the sweet spot in terms of power and cost. Generally speaking, the amount of planned missing data for this design can be quite high if the biased measure is not too biased and both measures are measured reasonably reliably.

TABLE 17.6 Possible Candidate Constructs for Use with the Two-Method Planned Missing Data Design

Construct	Expensive/Gold Standard	Inexpensive/Biased Measure
Stress	Cortisol assays	Self-report perceived stress
Intelligence	Wechsler WAIS assessments	Multiple-choice test of ability
Smoking cessation	Blood draws	Self-report
Student/teacher behavior	Classroom observations	Self-, Peer-, or Teacher-report
Nutrition	Face-to-face-interview	Self-report survey
Adiposity	Densitometry, hydrostatic weighing, or dual energy x-ray absorptiometry	Body mass index

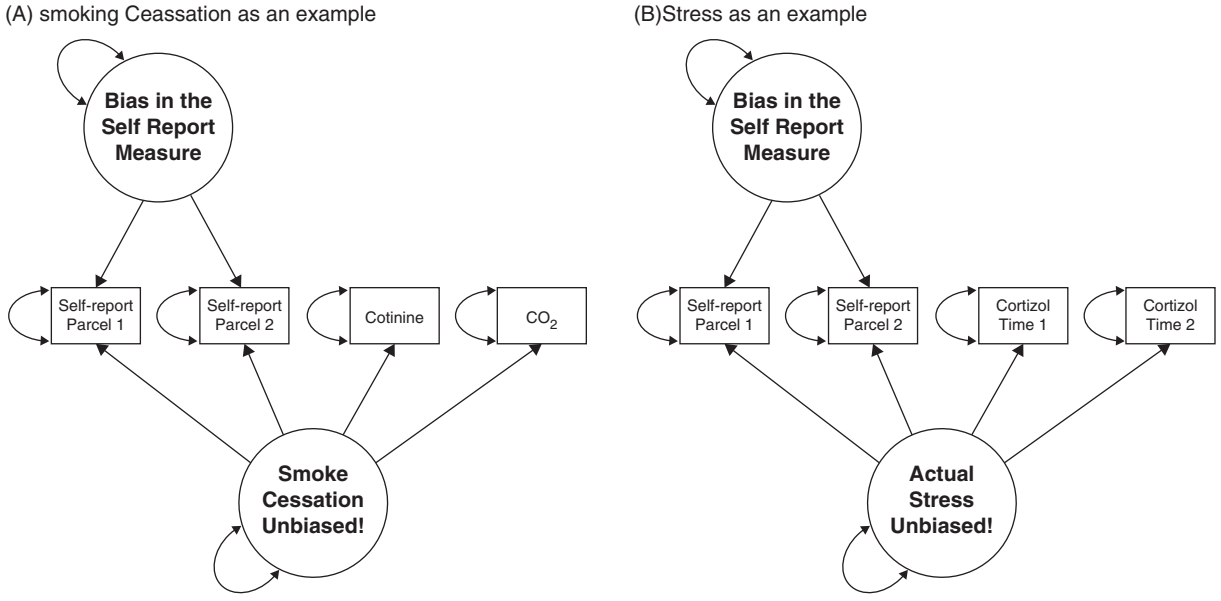

Figure 17.3 Two variations of a two-method planned missing model. (*Note*: Only a subset of individuals are randomly selected to receive the expensive measure.)

Obtaining an optimal number of indicators for each construct is not difficult if one considers the use of parceling techniques to provide the correct level of aggregation needed to create multiple indicators for each construct. Although the use of parcels is somewhat a matter of debate (and the nature of the debate is beyond the scope of this chapter), the ways parcels can be used for purposes of the two-method planned missing data design are straightforward (see, e.g., Little, Cunningham, Shahar, & Widaman, 2002; Little, Rhemtulla, Gibson, & Schoemann, 2013).

To extend the two-method planned missing data design to longitudinal data collection procedures, we need to discuss some nuances for how it should be implemented. In a simulation study of the power and efficiency of the two-method planned missing data design, Garnier-Villarréal et al. (2013) and Rhemtulla and Little (2013) provide a number of useful recommendations for extending this model to the longitudinal case.

Wave-Missing Designs

A number of wave-missing designs are available to developmental researchers. These designs and their variants have different nuances and considerations that must be considered to implement them well. Some of the wave-missing designs involve random assignment and thus make the missing information MCAR. Recall that MCAR missing (missing completely at random) is the hallmark of planned missing data designs because there is no introduction of bias with MCAR missingness, only a decrease in power. As such, these designs provide tremendous potential. Some wave-missing designs, however, are not based on random assignment to missing data pattern. One such design is the accelerated longitudinal design (Table 17.7). In this design, the missing information is not randomly assigned but, instead, is a feature of the cohort from which participants are selected. Such missing data, however, are due to a predictable MAR process and can therefore be recovered to provide unbiased parameter estimates. In the following, we discuss three wave missing designs: the developmental lag missing design introduced by McArdle and Woodcock (1997); the accelerated longitudinal design originally introduced by Bell (1953); and the growth curve wave missing design introduced by Graham and colleagues (2001).

McArdle and Woodcock (1997), for example, introduced a planned missing data design that allowed them to examine memory loss and retest effects over 8 days. Their design involved only two measurement occasions for each participant but the interval of time between the two measurements ranged across participants. Putting the responses into bins of baseline and six successive waves, they used growth curve modeling procedures to represent a slope construct of change over time and a separate retest construct. In one model, the retest effect was estimated to be a constant value regardless of the length of time between measurement occasions. In a second model, the retest effect was specified to be an exponentially declined effect. This exponentially declining retest construct fit the data better than the constant effect model, suggesting that retest effects are more pronounced with shorter intervals of measurement and less pronounced as the time span between occasions gets longer.

Bell (1953) introduced the accelerated longitudinal design as a way to estimate age trends from cross-sequential data. Figure 17.4 shows the three sequential data designs

TABLE 17.7 Converting a Cohort-Sequential Data Set into an Accelerated Longitudinal Design

	Age in years; months for each cohort at each assessment																			
Age/cohort	0 Months			4 Months			8 Months			12 Months			16 Months			20 Months				
Age 11 years	11;0			11;4			11;8			12;0			12;4			12;8				
Age 12 years	12;0			12;4			12;8			13;0			13;4			13;8				
Age 13 years	13;0			13;4			13;8			14;0			14;4			14;8				
Age 14 years	14;0			14;4			14;8			15;0			15;4			15;8				
Age 15 years	15;0			15;4			15;8			16;0			16;4			16;8				
Age 16 years	16;0			16;4			16;8			17;0			17;4			17;8				
	Full span of the ages covered																			
	11;0	11;4	11;8	12;0	12;4	12;8	13;0	13;4	13;8	14;0	14;4	14;8	15;0	15;4	15;8	16;0	16;4	16;8	17;0	17;4	17;8
Age 11 years	W1	W2	W3	W4	W5	W6															
Age 12 years				W1	W2	W3	W4	W5	W6												
Age 13 years							W1	W2	W3	W4	W5	W6									
Age 14 years										W1	W2	W3	W4	W5	W6						
Age 15 years													W1	W2	W3	W4	W5	W6			
Age 16 years																W1	W2	W3	W4	W5	W6

that are used to disentangle two of the three confounded effects in longitudinal data. Specifically, age, cohort, and time of measurement cannot be separated in a single cohort longitudinal study. By broadening the measurement frame, however, two of the three effects can be adequately disentangled (see Little, 2013; Wohwill, 1973). With the cross-sequential design (which is often mislabeled the cohort-sequential design), it is possible to realign the data set to represent the ages of the participants regardless of the cohort or wave at which the information was assessed. Figure 17.4 shows how the cross-sequential data are transformed into an accelerated longitudinal design.

The final design in this section is the growth curve planned missing design. Rhemtulla, Jia, et al. (2014) examined the performance of three types of planned missing designs in multivariate latent growth models, including a three-form design (where participants are assigned to be missing a subset of items at each occasion), a wave-missing design (where participants are assigned to be missing a subset of measurement occasions), and a design that combined both types of missingness. They found that the three-form design resulted in high convergence rates, little bias, and high efficiency relative to complete data for almost all parameter types. In contrast, the wave-missing and combined designs resulted in biased parameter estimates at sample sizes smaller than 500, and dramatically lower power for many of the structural parameters, including the variance and covariances among latent slopes. Based on these results, they recommended that wave missing designs are only well suited to latent growth curve models when the sample is very large (e.g., $N > 1000$) or effect sizes are large. In contrast, three-form missingness is an easy and effective way to achieve the advantages of a planned missing design without sacrificing accuracy or precision.

CONCLUSIONS

As should be clear, missing data should no longer be considered a bane to researchers. Modern techniques, when applied in an appropriately principled manner, will yield unbiased and suitably powered parameter estimates for any statistical model chosen. Accurate inferences are possible even under conditions of selective nonresponse (i.e., when the missing data mechanism is MAR). To optimize the ability to recover from the losses associated with unplanned missing data, we admonish researchers to identify and measure all known and likely predictors of nonresponse. To facilitate this practice, researchers should carefully scrutinize extant data sets to identify variables that are predictive of the unplanned missing data. The details of such an analysis can easily be included as an online appendix for interested researchers to access. This online appendix can also contain summary reports of the fraction of missing information in the means and variances of the variables on the data set (perhaps in the form of a histogram of the FMI values of the means and the FMI values for the variances). As well as provide a detailed log of the steps and options that were selected in treating the missing data. With the ease and capacity of web repositories, we can easily be much more transparent in sharing information about a given data set.

Another admonishment that we offer is to leverage the advantages of using planned missing data designs in

conjunction with modern treatments and latent variable analyses. The clear gains in cost savings and the potential gains in validity are both sufficient reasons to employ these designs. We acknowledge that the details of how to properly implement planned missing data designs can be more cumbersome than the traditional collect-everything-from-everyone approach. The rapidly expanding literature in this area provides the needed details for proper guidance in constructing data collection protocols with planned missing elements (as new works emerge, they will be added to our online bibliography at immap.educ.ttu.edu). We see the benefits of these designs in terms of the costs, veracity, and verisimilitude of research enterprise as far outweighing the time and thought needed to optimally include planned missing data designs in all future studies. In fact, planned missing elements can also be implemented in active longitudinal studies going forward.

CHAPTER OVERVIEW

The variable-oriented approach has been the dominant paradigm in psychological research for most of its history. Person-oriented approaches have been advocated strongly at several junctures in this history; for example, at the turn of the twentieth century by James, Dewey, and Stern, in the 1930s by Lewin and Allport, in the 1960s by Block, and in the 1980s to the present by Magnusson, Bergman, and von Eye. Yet, even though there has been a noticeable increase in the use of person-oriented approaches, the majority of published research is still variable-oriented.

By variable-oriented approaches we mean theoretical and statistical approaches that discuss or demonstrate relationships among variables. For example, when we find that childhood depression is positively related to maternal depression, we are discussing the relationship between two variables. This may say little about a specific child. Assuming a moderate positive correlation, there will be many children whose childhood depression and maternal depression scores are far from the regression line, for instance, being fairly high in childhood depression and fairly low in maternal depression, contrary to the positive linear relationship indicated by the correlation coefficient. In developmental research, variable-oriented research focuses on constancy and change among the variables. Variable-oriented research also assumes that there are universal laws involving human behavior, thus, information is not lost when specific variable relationships that are part of a larger process are examined and when data are aggregated across individuals. In contrast, person-oriented approaches focus on patterns or profiles that describe individuals or groups of individuals, the constancy and change of these patterns or profiles, and whether or how these patterns or profiles relate to other profiles or patterns within as well as events outside the individual.

Kuhn (1962/2012) argued that it is inevitable that paradigms[2] become entrenched. Scientific training focuses on inculcating the values, theory, and methods of a specific paradigm; in essence, students are schooled in anticipation of joining a specific scientific community whose members were also indoctrinated in the paradigm. Thus, the basic building blocks upon which the student and then the scientist conduct research are unlikely to be questioned. In fact, Kuhn argued "that commitment and the apparent consensus it produces are prerequisites for normal science, i.e.,

[1]Color versions of Figures 18.1, 18.4–18.7 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

[2]In the 1969 postscript to his book, Kuhn noted that paradigm had two meanings: (1) "the entire constellation of beliefs, values, techniques, and so on shared by the members of a given community," a meaning Kuhn believed was better exemplified by the term *disciplinary matrix*; and (2) exemplars, examples to which scientists refer to understand the common knowledge base of a discipline. In this chapter, the first meaning of paradigm is used.

for the genesis and continuation of a particular research tradition" (p. 11).

This commitment and consensus to the dominant paradigm are two of the major reasons that paradigm shifts occur slowly. For example, there is no doubt few, if any, undergraduate or graduate students understand that the science they are being taught uses a variable-oriented paradigm. Without specifically defining the paradigm, the presentation of material in textbooks assumes the validity and worth of research that elaborates the relationships among variables. Statistics courses, beginning at the undergraduate level, further instill the variable-oriented approach, focusing on methods that aggregate individuals (e.g., analysis of variance [ANOVA], regression) and often make questionable assumptions about linearity, data distributions, and random error.

The dominant paradigm finds a way to integrate anomalous findings until the moment when it cannot. Kuhn (1962/2012) noted that over time a crisis is reached that makes a new paradigm more acceptable. At present, psychology is dominated by the variable orientation. There does not yet appear to be a crisis in psychological research that necessitates the abandonment of the variable-oriented approach or that propels the person-oriented approach to greater ascendance. However, at the same time, there is a slow but steady accretion of person-oriented research in various fields of psychology, such as developmental and developmental psychopathology (e.g., Martinez-Torteya, Bogat, von Eye, & Levendosky, 2009), clinical (e.g., Lundh, Saboonchi, & Wangby, 2008), personality (e.g., Laible, Carlo, Panfile, Eye, & Parker, 2010), and industrial organizational (e.g., Foti, Thompson, & Allgood, 2011), and in other disciplines such as education (e.g., Boscardin, Muthén, Francis, & Baker, 2008), criminal justice (e.g., Sampson & Laub, 2005), kinesiology (e.g., Sjoquist et al., 2010), medicine (e.g., Axen et al., 2011), public health (e.g., Lennon, McAllister, Kuang, & Herman, 2005), and sociology (e.g., Kim & Fram, 2009). There is also a burgeoning focus on complementary theory and methods to the person-oriented approach, including idiographic science (e.g., Molenaar, 2004, 2007, 2010).

In Kuhnian terms, the person-oriented approach is an alternative paradigm, because "it regularly raises questions that cannot be resolved by the criteria of normal science" (Kuhn, 1962/2012, p. 109). If a paradigm shift from variable- to person-oriented approaches occurs, or if the person-oriented approach becomes a promising alternative to the variable-oriented approach, it will be because the person-oriented approach affects a change in what are considered legitimate problems to solve as well as what are acceptable solutions to address those problems.

The type versus trait debate in personality is a good example of how difficult it is to affect a paradigm shift. Research on personality has centered for years on a specific question: "Should the field conceptualize personality in terms of the individual attributes that vary across people or the overarching configuration of attributes that defines each person?" (Donnellan & Robins, 2010, p. 1072). The trait approach, consistent with a variable-oriented approach, searches for universals based on the presence of attributes that vary across people. The five-factor model (FFM; McCrae & Alik, 2002) is the most widely used trait approach. The type approach, consistent with the person-oriented approach, focuses on understanding the personality of the individual. There is strong research evidence for three personality types: ego resilients, overcontrollers, and undercontrollers (Robins, John, Caspi, Moffitt, & Stouthamer-Loeber, 1996).

Various rationales have been offered against types and for traits. One is that the three types have not been found in all samples (e.g., Costa, Herbst, McCrae, Samuels, & Ozer, 2002). Even Donnellan and Robins (2010), who found merit in types and defend the person-oriented approach, suggested that the inability to replicate the three types in every sample may be the result of, among other factors, sampling error. Building on this reasoning, Costa et al. (2002) argued that the failure to replicate the three personality types in every sample indicates the superiority of the trait (FFM) approach. Both assertions disregard research that the five factors also have not been replicated in every sample (e.g., Vassend & Skrondal, 2011). These statements reflect how deeply ingrained the variable-oriented approach is in scientific thinking, or, stated another way, to most psychologists, the variable-oriented approach *is* current scientific thinking. When scientists search for universals and cannot consistently find them, they conclude that there is a flaw in their theory or in the specific methods they used (e.g., sampling error). The paradigm—that is, the overarching perspective that guides their specific theories and research methods and underpins these inconsistent findings—is rarely considered.

Using the person-oriented approach as a paradigm, finding or not finding the three personality types in every sample does not mean that these types are wrong, inconclusive, or not useful. It simply means that certain profiles are good descriptors of only certain individuals. Individuals or groups of individuals who do not fit into one of the three types are not exemplars of theory or methods failure, but, rather, may represent individuals or groups that occur at low frequency within certain samples. That is, there is likely to be heterogeneity in samples.

The tension between a variable- and person-oriented approach is also apparent in psychopathology research

and practice. To illustrate, we focus on the issue of heterogeneity vs. homogeneity in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM; American Psychiatric Association, 2013)*. The categorical classification of the *DSM*, based on a medical diagnosis approach, is structured so that mental disorders are defined by the presence or absence of specific symptoms. Advantages to a categorical diagnostic classification system include providing a common language among mental health professionals that improves communication as well as scaffolding that allows researchers and practitioners to determine the reliability and validity of their clinical decisions (e.g., Maughan, 2005).

The *DSM* categories are based on empirical research that finds general patterns of specific behaviors/symptoms across individuals who meet a specific diagnosis. Thus, the categories consist of criteria that, in general, are associated with a particular disorder. The authors of the *DSM* acknowledge that there will be heterogeneity within diagnostic categories. However, the diagnostic categories start with the premise that heterogeneity of symptom features is not the most salient feature in understanding a specific type of disorder.

Ignoring heterogeneity or subgroups within diagnostic categories may have significant implications for both practice and research. For example, in randomized clinical trials of empirically supported treatments, diagnoses are made before clients/participants are enrolled. If the presence of subgroups is not assessed, the results of the clinical trial may be less clearly understood. We know that treatments do not have salutary effects on all participants and that there is a range of drop out in clinical trials. Certainly there are many factors affecting these two outcomes, but individual differences are no doubt one of them. In the 1960s, psychotherapy researchers (e.g., Kiesler, 1966; Strupp & Bergin, 1969) called for methods to elaborate specific therapist behaviors that would help specific clients and produce specific types of behavior change—a charge consistent with a person-oriented approach. Kiesler challenged the notion that all therapists, clients, and treatments were alike, and he labeled the desire of researchers to treat them as such *uniformity myths*.

One possible solution to the problems with heterogeneity identified by Kiesler and others would have been to conceptualize psychotherapy and psychotherapy research from a person-oriented approach. Such a perspective would have, in part, focused on understanding patterns of clients, therapists, treatments, and behaviors that led to successful outcomes. But the variable-oriented approach was and is the dominant paradigm; thus, it framed the concern with heterogeneity identified by Kiesler and others. The effect of the criticism was that many psychotherapy researchers attempted to reduce heterogeneity by creating more homogenous treatments (e.g., manualized treatments) and more homogeneous patient groups exposed to treatment (e.g., *DSM* diagnosable conditions, such as depression). The attempt to create homogeneous patient groups may have been illusory, given the inherent heterogeneity in the diagnostic categories[3]. And, importantly, the creation of homogeneous groups and the subsequent use of variable-oriented methods to analyze data did not answer the basic criticism of the field, which suggested that understanding the effects of specific treatments and therapists on specific patients should be the focus of researchers' efforts. It is easy to see how a person-oriented approach to psychotherapy outcome research would have led the field in different directions, focusing on patterns and profiles of therapist, client, and treatment factors that are related to change.

The purpose of this chapter is to elucidate the person-oriented approach. To do this, we organize the chapter into four sections. In the first section, we describe the tenets and criticisms of the variable- and person-oriented approaches. In the second section, we provide a historical context for the modern formulation of the person-oriented approach by focusing on the work of three early protagonists who advocated this approach at different times during the twentieth century (Stern, Lewin, and Block). In the third section, we discuss three methods of data analysis (structural equation modeling, log-linear modeling, and cluster analysis) to determine whether and how they can be used in the context of person-oriented research. Finally, the last section concludes with a summary and future directions for person-oriented research.

DESCRIPTION OF THE VARIABLE- AND PERSON-ORIENTED APPROACHES

Kuhn (1962/2012) used the term *paradigm* and later *disciplinary matrix* to refer to theory and methods of a normal science. In discussing the person orientation, Sterba and Bauer (2010) use the term *approach*, meaning an overall rubric that encompasses theoretical principles and the methods used to elucidate those principles. Regardless of the nomenclature, the point is that any scientific

[3]There is a movement in psychopathology research away from taxonomies and toward dimensional conceptualizations of mental health disorders. However, the dimensional approaches are variable oriented.

perspective cannot divorce theory and methods, as they are intimately tied to and inform one another. Theory and data analytic techniques from one paradigm can reach conclusions only consonant with that paradigm (Cairns, 1983; Magnusson, 1985, 1995). We will elucidate this essential quality of paradigms as we describe both the variable- and person-oriented approaches.

Variable-Oriented Approach

The dominance of the variable-oriented approach in scientific research makes it difficult to explain or define it—the variable-oriented approach is likely to be considered science itself, and not just a paradigm guiding scientific inquiry (Bergman & Andersson, 2010). We discuss two broad assumptions that characterize the variable-oriented approach.

First, that objects are best understood by focusing on their component parts in isolation is a foundation of the variable-oriented approach (Kelso, 2000). The variable-oriented approach is based on the premise that examining one *aspect* of the whole is thought to reflect the inherent properties of the whole, and that characteristics of the entire entity "have properties irreducible to the individual-level yet nevertheless affecting individual-level phenomena" (Subramanian, Jones, Kaddour, & Krieger, 2009, p. 350). A variable is considered important to the extent that individuals are the same or different on the specific dimension it measures. The focus is on individual variables, not patterns or profiles of variables. Bergman and Andersson (2010) also noted that when statistical analyses of the variables are undertaken, simplifying assumptions often are made about the structure of the variables.

Second, the variable-oriented approach focuses on finding universal laws that describe and predict human behavior. As theory and hypotheses are driven by this assumption, researchers expect to find homogeneity across the samples or populations studied. To the extent that these universals are not found within a specific sample or population, the theory or methods are considered flawed (see earlier discussion of the type vs. trait controversy). When heterogeneity is considered, it is often based on subgroups defined by the researcher that derive from a priori assumptions that those subgroups differ on relevant factors (e.g., males vs. females; schizophrenics vs. nonschizophrenics); these assumptions may or may not be valid.

The focus on universals often means that assumptions underlying widely used statistical analyses are ignored. For example, aggregation of data, which we discuss at length later in this section, is a widely used technique. Because, in the search for universal laws, the variable-oriented approach focuses on the importance of interindividual differences rather than intraindividual differences, aggregation is considered appropriate. "Theories are often formalized in terms of causal relationships between constructs which are regarded as dimensions on which a single individual may vary across time and on which different individuals vary" (Bergman & Andersson, 2010, p. 155).

Related to aggregation is the problem of outliers. Variable-oriented researchers are usually willing to eliminate or replace them. Outliers are, by definition, statistically rare. There are different types of outliers, including distance outliers (those far from the mean), leverage outliers (those that have undue influence vis-à-vis other scores on specific parameters), and inliers (scores close to other scores but which still have a proportionally extreme effect on specific parameters). Statistical methods have been proposed for dealing with outliers, including considering the outlier scores missing and imputing values to replace the deleted scores. The assumption is that outliers represent error rather than true values. This assumption of outliers as error fails to consider that (1) outliers may be members of a different population than the majority of individuals in the sample, and (2) the study of this different population (regardless of how small it is) vis-à-vis the other population may be important (von Eye et al., 2015).

In addition, there is a form of aggregation that occurs in calculating the value of a specific variable. Most variables are scored using a cumulative technique where the more answers an individual gives the more of that variable (e.g., depression) the individual is assumed to have. This is in contrast to other techniques, such as differential scale measurement, where an individual's pattern on the various questions that constitute the variable might be considered; for example, ogive rules, where extreme responses are given more weight than responses that approximate the median (Loevinger & Wessler, 1970). Although not typically used in person-oriented research, approaches such as item response theory (IRT) can be adapted (see von Eye et al., 2015).

In addition, commonly employed statistical analyses often assume that relationships among variables are linear and that "errors are random, follow a normal distribution, and are not related to the true scores" (Bergman & Andersson, 2010, p. 156). And, finally, factors that might affect an individual's score on the key variables are considered nuisance variables that confound understanding of the key variables; thus, they are typically controlled in the analyses. The problems with these assumptions are

discussed in more detail below in the section on limitations of the variable-oriented approach.

Like any scientific paradigm, the variable-oriented approach has legitimate advantages. For example, Kuhn (1962/2012) argued that the areas of inquiry toward which a paradigm directs scientists "leads to a detail of information and to a precision of the observation-theory match that could be achieved in no other way" (p. 64). That is, in the social sciences, variable-oriented theories and methods identify, distinguish, and classify the component parts of the object under investigation (e.g., the child, the family, the school classroom). The variable-oriented approach provides the researcher with objectivity as a result of "clearly defined measurements, the additional information value that comes out of good scales, the usefulness of inferential statistics based on variables, the strength of model testing, and the possibilities for causal inferences that may arise from the study of relationships with proper control for confounders . . . " (Bergman & Andersson, 2010, p. 156). The variable-oriented approach, through its focus on understanding the relationships among precisely defined variables, also can aid identification of mechanisms that occur in the overall process under investigation (Magnusson & Törestad, 1993). Some argue that the variable approach provides the foundation on which science rests—without it we could not move beyond basic descriptive information or idiographic approaches (e.g., Mandara, 2003).

As with any paradigm, there are situations or circumstances about which the variable-oriented approach provides completely accurate data and conclusions. Even Jack Block, a major proponent of the person-oriented approach, whom we shall discuss in detail later, suggested that sometimes the variable-oriented approach was appropriate. Regarding data analysis, the person-oriented approach may not be needed if (1) the variable-oriented approach provides sufficient explanation of the theory or hypothesis tested (e.g., in those cases in which the theory tested and data analysis conducted are focused only on making statements about the aggregate, and not the individual), and (2) the process studied over time is ergodic; that is, the process is stationary and inter- and intraindividual change are identical (Molenaar, 2004).[4] In a Kuhnian sense, it is only through the refinement of the variable-oriented approach that psychologists can ascertain anomalies; that is, we see the novel only when we know what to expect and when the expected does not occur.

[4]However, Molenaar argued that ergodicity can almost never exist in development.

Limitations of the Variable-Oriented Approach

Two overall disadvantages with the variable-oriented approach have been articulated. The first concerns assumptions of variable-oriented data analytic techniques. A major problem in this regard is the logical error of using variable-oriented data to make conclusions about individuals or subgroups. Leo Tolstoy's famous opening line of *Anna Karenina* captures this problem: "Happy families are all alike; every unhappy family is unhappy in its own way." The first phrase is variable-oriented—if you've seen one happy family you've seen them all; whereas the second phrase is person-oriented—unhappy families find myriad ways to make themselves miserable. Perhaps Tolstoy knew very few happy families, and his assessment was that they all had similar traits; for example, perhaps all of these families had a high level of involvement and the children and parents were typically happy. Researchers using the variable-oriented approach might draw the same conclusion as Tolstoy by assessing numerous families, measuring family involvement and happiness, and then examining the covariance between the two variables. Such research tells us something about the aggregate—how the variables involvement and happiness are generally related, but it tells us little about a specific family. Although it would be easy for researchers if all happy families were alike, there is no indication that this is the case. Involvement is likely only one of several variables that are associated with family happiness.

An *ecological fallacy* exists when "aggregated data are analyzed and the results are assumed to apply to relationships at the individual level" (Everitt, 1998, p. 110). Robinson (1950) first demonstrated the ecological fallacy by examining the data from the 1930 U.S. census. Individual correlations indicated a negative correlation ($r = -0.11$) between illiteracy and nativity (i.e., whether one was foreign-born or not), suggesting that the foreign-born were less literate than native born Americans. However, when the same correlation was calculated at the state level, the correlation was $r = .53$, suggesting just the opposite—that foreign-born individuals were more literate than the American born. Another sociologist, in a discussion of proper replication as it related to Durkheim's suicide data and his methods, coined the term *ecological fallacy*, defined as "the invalid transfer of aggregate results to the individual" (Selvin, 1958, p. 613).

In the field of epidemiology, there has been a lively debate disputing Robinson's (1950) admonition that the aggregate may not apply to the individual case. Subramanian et al. (2009) summarized some of the critiques, including searching for instances where there might be

correspondence between aggregate- and individual-level associations, reducing bias in estimates of aggregate models so they more closely approximate the individual, demonstrating that the individual-level relationships among variables can be as error-filled as the aggregate level relationships among those variables, and elucidating "solutions that approximate individual-level relationship based on the information that bounds them at the aggregate level" (p. 343). Finally, the critique extends to the term ecological fallacy itself, which some researchers feel diminishes the importance of the ecological and inappropriately privileges individualism; Susser (1994) indicated the better label might be *aggregative fallacy*.

From a Kuhnian perspective, these attempts to discredit the general assertion—that the aggregate does not always apply to the individual—speak to how strongly the variable-oriented approach is held in the field of epidemiology (and elsewhere) and exemplifies Kuhn's (1962/2012) principle that until a paradigm shift occurs, scientists will continue to fit anomalous data into the dominant paradigm. Regardless of the critiques suggesting that applying the aggregate to the individual may not be problematic, much research since Robinson (who demonstrated the fallacy using bivariate correlations) has indicated that the problem occurs frequently and the same fallacy can exist for any parameter that is estimated at the individual and aggregate level (e.g., Schmitz, 2000; von Eye & Bergman, 2003; von Eye & Bogat, 2006).

von Eye and colleagues (2003, 2015) provide a striking example of the ecological fallacy in the development of alcoholism (Perrine, 1995). The data came from a sample of male adults, collected over the course of 3 years, who provided daily information regarding how much alcohol they had consumed the day prior to the interview. In one article (von Eye & Bergman, 2003), the first four participants in the data set were examined (respondents 3000, 3004, 3005, and 3007). Autocorrelograms, a visual representation of the relationship of each participant's scores with each other as a function of time, were created for each individual as well as an aggregate for the four participants. As the authors noted, the aggregate autocorrelogram indicated that the group had a specific pattern of drinking behavior that consisted of high and positive correlations during weekdays. Unfortunately, this pattern did not represent any of the individual participants' drinking patterns. For example, one participant demonstrated a fairly erratic pattern that was not predictable day-to-day or over time. Another participant's pattern was also erratic, yet it was possible to predict his day-to-day consumption even if his consumption could not be predicted over a longer time period. In a more recent chapter, von Eye and colleagues (von Eye, Bergman, & Hsieh, 2015) demonstrated that these results were not a coincidence of subject selection. They chose the next four participants in the data set, conducted similar analyses, and found similar results; that is, the aggregate autocorrelation plot does not represent any of the individual participants' plots.

Schmitz (2000) developed four theorems, based on methods characteristics, that highlight problems of aggregating data and then applying it to the individual. The first theorem is that individual trajectories cannot be determined from aggregated trajectories. Schmitz's second theorem is that cross sectional and interindividual relationships cannot be used to describe processes within the individual. The third focuses on asynchronous relationships. In longitudinal research, cross-lagged panel analyses may not capture the relationships among the variables that are true of any given individual. Finally, the fourth theorem suggests that the sequence of aggregating and prediction should start with the individual, not the group.

The variable-oriented approach, which generalizes from the aggregate to the individual, assumes that the data are perfect (e.g., aggregate- and individual-level data have the same parameter estimates). However, we do not live in a perfect world, and, because of this, the researcher is faced with two general problems when he or she generalizes from the aggregate to the individual. First, data in each individual case do not always speak to the same effect. Individual- and aggregate-level information can only be equal if the parameter estimates are unbiased; that is, correctly specified. Second, aggregating is often confounded with unmeasured variables. *Lurking variables* are those omitted from the design or data analysis that might lead the researcher to unknowingly make false or misleading conclusions. Lurking variables might also underlie spurious relations among other variables as well as mask heterogeneity in a population or sample (von Eye et al., 2015). There is, as yet, no perfect answer to problems with aggregation, although sampling, design, and data analysis solutions have been proposed (Subramanian et al., 2009; von Eye & Bogat, 2006).

In addition to problems with aggregation, four other methodological problems often occur with the variable-oriented approach (Bergman & Andersson, 2010). First, rarely is it the case that models generated using all subjects in a sample or population describe specific individuals or subgroups. Researchers seldom decompose these models to examine possible subgroup differences. Variable-oriented solutions to the problems of subgroup differences (e.g., adding exogenous variables such as gender to a structural

equation model) are usually not true resolutions. For example, the inclusion of an exogenous variable, such as socioeconomic status, in a structural equation model does not address whether the relationships among the variables are similar or different among subgroups that differ on socioeconomic status.

The second issue is that model fit is often considered a statement about the fit of the model to the data, but this is not always the case. Bergman and Andersson (2010) noted that the accuracy of model fit depends on the veracity of the underlying assumptions. Most models create a data summary matrix based on pairwise linear relationships, which cannot account for the presence of higher order interactions or nonlinear relationships. Models are based on the goodness of the data of which they are composed. This means that, fairly often, the model fit only tells us about "the fit to a flawed summary of the data" (p. 156). Meehl's paradox (1950) demonstrated there are occasions in which no significant main effects or lower order interactions are present, and the highest order effect explains all the variability (Krauth & Lienert, 1973; von Eye, 2002). Thus, omitting higher order interactions in a specific model will sometimes completely misrepresent the data and the underlying relationships among the variables.

Third, Toomela (2009) argued that post–World War II psychological science is built on the assumption that cause–effect relationships are linear; therefore, standard data analytic techniques, which assume linear relationships among variables, are considered sufficient to answer most research questions. Unfortunately, it is unlikely that most human behavior is linear. For example, two variables may have a relationship with each other, but only under certain conditions. Interventions might have a negative effect on a participant early on, but later show a positive effect; for other participants, the positive effect may occur early and then erode and become negative over time. There are numerous examples of how development is typically not linear. For example, Sampson and Laub (2005) discussed turning points; that is, rare events in the life of an individual that lead to a cessation in the trajectory of crime. And Fogel, Garvey, Hsu, & West-Stroming (2006) noted a bridging frame that explains how mother-infant communication followed an inverted U-shaped curve as it moved from a dyadic mode (mother–infant) to a triadic guided mode (mother shows infant toy) to a triadic not-guided mode (mother shows infant toy and infant plays with it) in the first months of life.

It is also a basic assumption in most statistical analyses that errors are random and normally distributed. In addition, random effects are assumed to be independent of model covariates. These assumptions are unlikely to hold and can have serious consequences for understanding data. For example, statistical models make implicit assumptions about the variables we *do not* measure or include—that they are equal across individuals or situations (Ram & Nesselroade, 2007). For example, psychological research on depression assumes that environmental factors are not an important influence on individuals' depressive symptoms. Environmental factors may not be measured or various aspects of the environment (e.g., socioeconomic status) may be controlled, thus ignoring epidemiological research indicating that, in the United States, neighborhood characteristics are associated with depression, independent of individual characteristics (e.g., see Kim, 2008, for a review).

Before closing this section, we discuss two metatheoretical disadvantages of the variable-oriented approach: (1) whether developmentalists are, in fact, concerned with understanding individual behavior, and (2) if they are, what is the best way to accomplish this goal. First, in some fields of research, it may not be necessary or important to understand the individual. One of the points made by Subramanian et al. (2009) is that epidemiologists and sociologists are not always interested in the individual. For example, an individual's income may not be the same (it might be higher or lower) as the average income in the neighborhood or census tract where he or she lives. However, the effect of the overall neighborhood aggregation of SES may play an important role in individual behavior, or it, by itself, may be the focus of interest. However, studies in developmental psychopathology are interested in individual behavior.

The second metatheoretical issue concerns systems theory. If systems theory is, at present, the most accurate way to describe human behavior, then it is not possible to understand an individual by studying aspects of the individual in isolation; we can only understand an individual by studying multiple aspects of the person and his or her environment and how these aspects relate to each other. Magnusson and Törestad (1993) noted that to understand an individual's dynamic psychological functioning, at a minimum, we must understand his or her thoughts and actions as an intentional, active being; his or her biological systems, including genetics; and his or her interface with the social environments as well as how all of these factors affect each other in the present and over time. This relates to Lerner and Busch-Rossnagel's (1981) conception of the individual as someone who generates his or her development. Thus far, the variable-oriented approach has not been especially effective at elucidating humans as dynamic systems.

Person-Oriented Approach

The modern-day person-oriented approach derives from a zeitgeist shift from research on development and developmental psychopathology using an individualistic perspective to research that considers the importance of a holistic, dynamic system in studying the individual (e.g., Bergman & Magnusson, 1997; Cicchetti & Scheider-Rosen, 1986; Magnusson, 1988). Bergman and Magnusson (1997) argued that the current emphasis on holistic-dynamic systems theory derives from three sources: (1) the scientific movement to integrate our understanding of biological processes with behavioral, cognitive, and environmental factors; (2) recent advances in methods focused on nonlinear dynamic systems; and (3) a renewed interest in longitudinal research.

Dynamic systems[5] stand in contrast to static, linear models (e.g., Bergman & Andersson, 2010). "The problem of reconciling phenomena that at the macroscopic level appear ordered, irreversible and determined with phenomena that at the microscopic level appear variable, reversible and stochastic lies at the heart of the DSP [dynamic systems perspective] and self-organization . . . " (Witherington, 2007, p. 134). Dynamic systems theory and models focus attention on understanding change and when and how something new results from that change. Whatever process or variable is studied, at a particular moment, that process or variable resulted from an assemblage of dynamic components that formed, through nonlinear processes, into patterns. Dynamic systems are characterized by moments of equilibrium and moments of disequilibrium; at any given moment, the system can stay stable or become unstable (Kelso, 1995).

Bergman and Magnusson (Bergman & Magnusson, 1991, 1997; Magnusson, 1988) described five tenets of the person-oriented approach. These have been further expanded and elaborated by von Eye and colleagues (e.g., von Eye & Bogat, 2006; von Eye & Bergman, 2003). We start with the original five (Bergman & Magnusson, 1997, all quotes p. 293).

1. "The process is partly specific to the individual." Sterba and Bauer (2010) labeled this the *individual specificity* principle. Although it is tempting to look for universals that describe human behavior, it is unlikely that many universals, at least as related to complex behavior, exist. Even as related to brain function, where we are tempted to state unequivocally that a specific function is controlled by a specific part of the brain, we know that in some individuals, other parts of the brain can take over the same function.

There will not be a universal that fully describes every individual. Even researchers taking a variable-oriented approach recognize this problem. For example, Morey and Hopwood (2009) employed item response theory to differentiate an individual's development along an alcohol dependence continuum to aid understanding of the effectiveness of a treatment protocol. Such efforts attempt to increase predictive power by creating greater homogeneity, when there is known or suspected heterogeneity in the sample or population. But the focus on prediction can interfere with progress in understanding certain kinds of human phenomena such as development, personality, or psychopathology (Magnusson & Törestad, 1993). Prediction can be a goal, a "conceptual and methodological tool" (Magnusson & Törestad, 1993, p. 442), or both. If prediction is a goal, then it takes front and center in our scientific theory and methods. However, if we consider prediction a tool in our research arsenal, sometimes aligned with prediction as a goal, then it can help to elucidate aspects of the phenomena we wish to understand. Magnusson and Törestad (1993) expressed concern that the current focus on prediction, solely as a goal, and its attendant research methods, has led psychology to understand mechanisms, but not processes.

Importantly, individual specificity implies that there are real individual differences that are not the result of errors in measurement or sampling. These individual differences may appear in different samples or within subgroups within one sample. von Eye et al. (2015) noted that outliers (or inliers), typically excluded from variable-oriented approaches, may, in some cases, typify this individuality. A variable-oriented approach, which often uses linear models to determine the relationship among variables across a sample or population, cannot describe how those variables relate in the life of a specific individual or subgroups of individuals (e.g., Magnusson & Törestad, 1993).

2. "The process is complex and is conceptualized as involving many factors that interact at various levels which may be mutually related in a complicated manner." This tenet focuses on the complexity of human development and functioning; Sterba and Bauer (2010) labeled this principle *complex interactions*. Magnusson & Törestad (1993)

[5]There are at least two competing metatheoretical approaches to dynamic systems: contextualism and organicism–contextualism (see Witherington, 2007, for a discussion). It is beyond the scope of this chapter to discuss these. In the discussion of dynamic systems in this chapter, we are referring to the organicism–contextualist metatheory, which best complements the person-oriented approach.

labeled this multidetermination; that is, scientific understanding of the human system will be determined by multiple factors or conditions. It is unlikely that one or two variables and their interactions could describe an individual sufficiently.

The complexity of human psychological functioning has been compared to general systems theory with its emphasis on dynamic, nonlinear, complex processes (e.g., Magnusson & Törestad, 1993). The separation of specific aspects of a human process or the assumption that a linear relationship is present among several aspects cannot capture human behavior at any given time or its course and development over time. Numerous writers have noted the importance of examining the whole person as a system with the underlying assumption that the whole is more than the sum of its parts.

Human processes involve transactions among psychological, biological, and environmental factors. Recent theoretical and empirical work has begun to integrate these. For example, adaptive calibration models suggest that children react to specific environments based on biological responsivity (Del Giudice, Ellis, & Shirtcliff, 2011; Del Giudice, Hinnant, Ellis, & El-Sheikh, 2012; Ellis, Del Giudice, & Shirtcliff, 2013). Vedeler and Garvey (2009) proposed an integration of epigenesis and dynamic systems; in other words, human functioning at all levels (gene to culture) is understood as a dynamically evolving system.

3. "There is a meaningful coherence and structure (a) in individual growth and (b) in differences between individuals' process characteristics. The lawfulness of the processes, within functionally organized structures, is reflected in the development and functioning of all subsystems as well as in the functioning of the organized totality." Sterba and Bauer (2010) labeled this principle *interindividual differences in intraindividual change*. The dynamic, holistic perspective suggests that the organism consists of coherent processes (e.g., biological, psychological). This integration occurs with lower order processes, which then coordinate with higher order processes. However, there may well be individual differences in how various systems are organized and integrated (Magnusson & Törestad, 1993). From a developmental perspective, the organization and integration of these systems may differ, as some may come online earlier or later in particular individuals. These differences in development can have important implications. For example, prior to puberty, genes account for essentially 0% of the variance in disordered eating, but genetic effects become important (>50%) in mid-to-late adolescence (e.g., Klump, Burt, McGue & Iacono, 2007); the genetic effects are quite specific—they only occur midpuberty (Klump, Keel, Sisk, & Burt, 2010) and only for girls (Klump et al., 2012).

4. "Processes occur in a lawful way within structures that are organized and function as patterns of operating factors, where each factor derives its meaning from its relations to the others." This tenet focuses on *interdependence* (Magnusson & Törestad, 1993), and it may be one of the most important tenets of the person-oriented approach. Sterba and Bauer (2010) labeled this principle *pattern summary*; von Eye et al. (2015) suggest a revised label that focuses on the link between theory and methods—*principle of patterns as units of analysis*. This tenet also relates to Sterba and Bauer's (2010) additional sixth principle—*holism* (generated from other writings on the person-oriented approach; Bergman & Magnusson, 1997; von Eye & Bergman, 2003; von Eye & Bogat, 2006) wherein our understanding of any given factor is based on the relationship it has to other factors.

One criticism of the person-oriented approach is that there is nothing inherently distinctive about it. In other words, if person-oriented methods have, at their core, variables, then how is this approach different? The difference lies in the last phrase of the aforementioned principle. Variables are not of interest in and of themselves; they have meaning only insofar as they are one indivisible part of a variable pattern (Bergman & Magnusson, 1997). Because any one variable cannot describe an individual or process—in fact, specific variables can have meaning for one person but not for others—the person-oriented researcher focuses on patterns, profiles, or configurations of these variables as they relate to each other and other profiles. If the profiles or patterns are meaningful, they should provide more information than a variable-oriented approach (see, e.g., Martinez-Torteya et al., 2009, on resilience).

5. "Although there is, theoretically, an infinite variety of differences with regard to process characteristics and observed states at a detailed level, at a more global level there will often be a small number of more frequently observed patterns ('common types'). The assumption applies both intraindividually (viewed over time for the same person) and interindividually (for different individuals at the same time or over time)." This tenet clarifies the concept of *individual* and *individuality*. The person approach holds that no individual is identical to another. However, as von Eye et al. (2010) noted, some differences can be ignored, as they are not important, are not interpretable, or are not significant in all contexts or specific contexts (e.g., a GRE score of 670 vs. 671). Because

measurement error is inherent in any variable or process we measure, small differences are usually meaningless. These inherent properties of measurement mean that there will not be a limitless number of meaningful subgroups in any sample or population. Sterba and Bauer (2010) labeled this principle *pattern parsimony*. Patterns involve some level of coordination and synergy; thus, it will not be necessary to study all the components of an action (or emotion, thought, etc.). For example, Kelso (1995) proposed that dynamic systems are characterized by dissipation and disequilibrium (the analogy is to thermal dynamics). Because of this, he argued that only some factors contribute to a specific behavior. He gives the example that when a baby speaks "ba" there are 36 separate muscles involved; we do not usually need to understand the coordination of this musculature to study phonemes.

In translating this tenet to research methods, consideration of the search for the precise number of subgroups in the data is important. For example, if cluster analysis is to be the statistical method used, Bergman and collaborators (Bergman et al., 2003) recommended having a sample size large enough to generate about 6–10 clusters. von Eye and Bergman (2003) suggest that known effect sizes should be taken into account in making groups, and a statistical base model, based on theoretical considerations, should also provide guidance.

Three assumptions, relevant to this tenet and the search for subgroups, have been advanced (Bogat et al., 2005; von Eye & Bogat, 2006). We explain each of these, and give examples where appropriate. The first is that "a sample is analyzed under the assumption that it was drawn from more than one population" (von Eye & Bogat, 2006, p. 394). There are a few ways the researcher can address this assumption. One is to determine a priori groups (e.g., younger vs. older children, males vs. females). This approach may have merit if the a priori groups are homogeneous relative to the variables under consideration. Theory often guides the generation of hypotheses that predict a priori group differences; however, often the research on which those hypotheses is based is variable-oriented, and the prior researchers may not have searched for heterogeneity within the groups. If a priori groups are used in data analysis, the researcher should establish that the groups are homogeneous by, for example, determining that there are not outliers in the groups, validating groups on variables in the space of variables not used to make the groupings, and ensuring that dimensional identity (see Tenet 6) can be demonstrated. In other words, *typical* subgroups (e.g., age, gender) may not be homogeneous groups; these variables may only be one component of a pattern that defines a more consistent subgroup.

Another way to form groups is to decompose data using techniques such as cluster analysis, latent class analysis, or other methods of finite mixture decomposition. One advantage of these approaches is that they can generate groups of different sizes, including groups that may include only a few individuals; from a person-oriented perspective, this flexibility is important (von Eye, Bogat, & Rhodes, 2006). An example of this type of group formation was undertaken by Bogat et al. (2012). The relationship between stress and HPA axis dysregulation is multiply determined, affected by characteristics of the stress itself as well as the psychological consequences of the stress (see Miller et al., 2007, for a review). Research to date has typically examined one or two aspects of the stress or the psychological response to it and, predictably, findings are mixed as to whether these factors are associated with dysregulation at all or hyper- or hypo-corticolism.

Bogat et al. (2012) tested whether individuals have heterogeneous responses to stress and whether profiles of women who differed on specific variables might better elucidate the relationship between stress and HPA axis dysregulation. Data from a cross sectional study of mothers (n = 182) experiencing (or not experiencing) intimate partner violence were analyzed. Initial attempts to fit the psychological, cortisol, and intimate partner violence data using structural equation modeling were unsuccessful. Thus, latent profile analysis was conducted using scores on pregnancy intimate partner violence, postpartum intimate partner violence, depression, anxiety, PTSD symptoms, the cortisol awakening response slope (awakening to 30 minutes postawakening), and the morning to evening cortisol slope (30 minutes postawakening to 5 p.m.). Models with one to six latent profiles were estimated using Mplus6. Fit indices (AIC and BIC) suggested that the model with five latent profiles, each of a different size, was the best fitting model (Figure 18.1).

Latent Profile 1 (n = 51) included women with significant levels of depression and anxiety, moderate levels of IPV during pregnancy, and lack of the expected cortisol awakening response. Women in Latent Profile 2 (n = 85) were characterized by relatively healthy adaptation, with low levels of IPV during pregnancy and postpartum, the lowest levels of depressive, anxiety, and PTSD symptoms, and the expected pattern of diurnal cortisol secretion. Latent Profile 3 (n = 11) consisted of women with high levels of IPV during pregnancy and postpartum with moderate levels of depression, anxiety, and PTSD, as well as dampened cortisol levels in the morning with a flattened diurnal. Latent Profile 4 (n = 3) consisted of women with the most severe violence scores at both pregnancy and

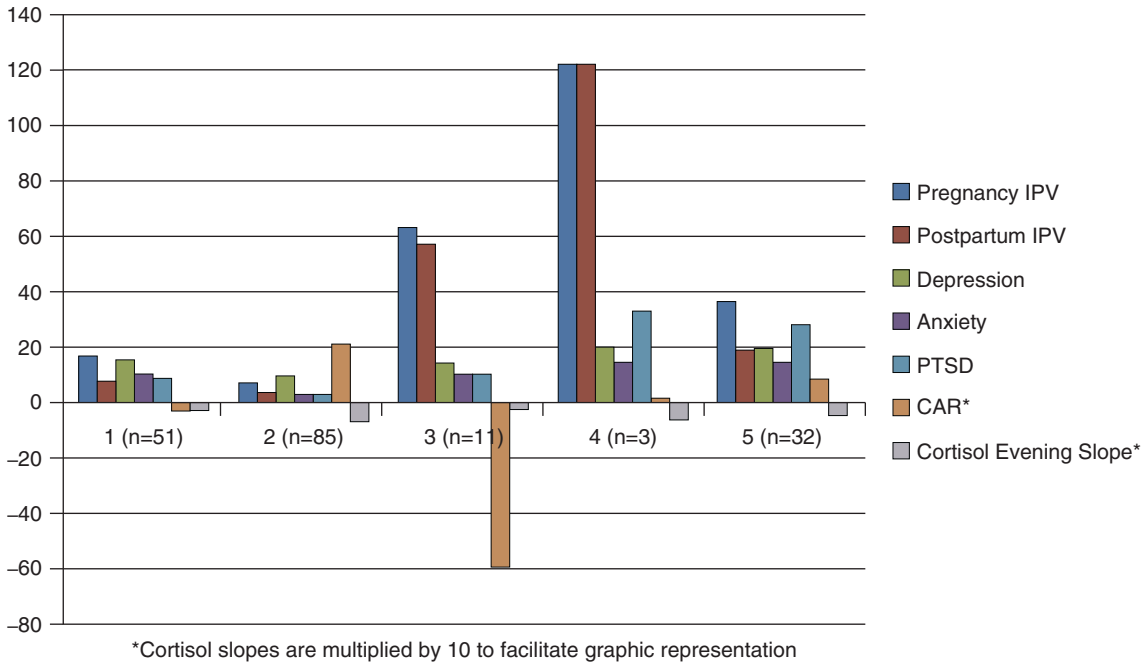

Figure 18.1 Five biopsychological profiles of women experiencing intimate partner violence. See footnote 1.

postpartum, high levels of psychopathology, no cortisol awakening response; and a normal evening slope. Latent Profile 5 (n = 32) included women with moderate levels of IPV at pregnancy and postpartum, the highest levels of psychopathology but who showed a cortisol diurnal pattern similar to that of the healthy group.

A third way to form groups is to ascertain patterns of function or development that characterize certain individuals (e.g., changers vs. nonchangers). An example of this type of grouping was research that identified trajectories of early reading difficulties among children studied from kindergarten to Grade 2 (Boscardin, Muthén, Francis, & Baker, 2008). Growth modeling with mixture components (e.g., Muthén, 2000, 2001; Muthén & Muthén, 2000), using 12 data points, was used to create the groups. This method was chosen, in part, because it allowed for the possibility of heterogeneous subgroups within the model. The number of classes for phonological awareness in kindergarten and word recognition development in Grades 1 and 2 were modeled separately. When these models were combined, the authors allowed for the possibility that the children might stay in the same class or change class membership over time. The final model was composed of 10 classes of students with different trajectories related to reading prerequisite skills and later deficits in reading development.

Finally, groups can be formed by asking "whether groups of cases exist that deviate systematically from predictions that can be made based on parameters that had been estimated under the assumption that only one population exists" (von Eye & Bogat, 2006, p. 394). An example of forming groups in this manner was research conducted by Bogat, Levendosky, DeJonghe, Davidson, and von Eye (2004). The participants (n = 163) were part of a larger, prospective longitudinal study examining risk and resilience among women and children experiencing intimate partner violence. This particular research examined the temporal effects of intimate partner violence on women's mental health using women's data from three time points: the last trimester of pregnancy (Time 1), the child's first birthday (Time 2), and the child's second birthday (Time 3). The authors asked whether there were groups of women that could be formed based on temporal experiences of intimate partner violence that would differ from the sample as a whole.

The women were grouped into eight patterns of intimate partner violence based on their reports at each of the three time periods (e.g., 000 = no violence at any time; 110 = violence at time 1 and time 2). An 8 (patterns) × 3 (observation points) mixed effect repeated measures ANOVA was performed for each of the dependent measures (self-esteem, anxiety, depression, and posttraumatic stress symptoms), decomposing them into linear and quadratic orthogonal polynomials; this allowed for the examination of different mental health trajectories. Here,

we focus on whether there were group differences in the time × pattern interactions. There were for self-esteem and depression but not for anxiety and posttraumatic stress disorder symptoms. For example, regarding self-esteem, across all participants, self-esteem increased during Time 1 and Time 2 and then tapered off at Time 3. There were, however, group differences regarding the quadratic polynomials. The no violence group (i.e., 000) showed a steady, linear increase; the chronic violence group (i.e., 111) showed an increase followed by a decline; and the group with only Time 2 violence (i.e., 010) showed high levels of self-esteem, which then tapered off. For depression, across all participants, symptoms declined over time. However, there was a significant group × quadratic effect for three groups (chronic violence, 111; Time 2 violence only, 010; Time 3 violence only, 001), indicating an increase in depressive symptoms at Time 3. Thus, examining mental health trajectories over the course of more than two years indicated that the chronicity and timing of intimate partner violence mattered; that is, in this sample, there were subgroup differences based on intimate partner violence experiences.

The second assumption relevant to this tenet is that "attempts are made to establish external validity of the groupings." If methods such as those suggested above are used (e.g., cluster analysis, latent class or profile analysis), a relatively small number of groups are generated with group-specific profiles. External validity can be established by comparing these groups on variables not used to constitute the group profiles. Different techniques for group comparisons are available. For example, in latent profile analysis, covariates can be included within the model to determine uncertainty within profiles (Roeder, Lynch, & Nagin, 1999). Another approach, to validate latent classes, involves rerunning the final latent class model by adding additional variables, on which groups are expected to differ. One can then conduct difference tests to compare models in which those additional variables are allowed to vary across the classes with models that assume the additional variables do not vary (e.g., see Ansara & Hindin, 2010).

Finally, the third assumption is that "the groups are interpreted based on theory." It is not difficult to find groupings of individuals in a data set, but whether these groups are distinct in important ways only can be ascertained relative to theory. Bergman, Magnusson, and El-Khouri (2003) indicated the importance of either a priori meaning of the groups or the ability to interpret the groups based on extant theory.

A recent paper, examining profiles of behavioral and adrenocortical functioning among 7-month-olds, illustrates these three assumptions concerning groups and the person orientation (Towe-Goodman et al., 2012). The authors employed latent profile analysis to generate profiles of infants, covariates were used to test the validity of the profiles, and theory was used to interpret the results. We briefly describe the rationale for the hypotheses, the findings regarding the profiles, and the interpretation of one aspect of the findings.

Understanding relationships among the biological and behavioral indicators of coping with stress is important as problems in these domains in early childhood are associated with vulnerability or resilience to stress across the life span (Davies, Sturge-Apple, Cicchetti, & Cummings, 2007; Gunnar & Quevedo, 2007). However, little is known about the coordination of these systems in infancy, and research has failed to find consistent relationships between these systems (e.g., Keenan, Grace, & Gunthorpe, 2003; Ramsay & Lewis, 2003). The lack of reliable findings suggested to Towe-Goodman et al. that there might be patterns or configurations of adrenocorticol and behavioral stress responses among infants exposed to interparental conflict. This was the case; a four-class solution provided the best fit to the data. Compared with the reference group ("low reactors"), children who were in the "high cortisol reactivity, moderate negative behavior" group were more likely to have higher negative affect and to live in households where conflict occurred as well as less likely to demonstrate successful self-regulatory behaviors under stress. The findings were interpreted, in part, based on the emotional security hypothesis (Davies & Forman, 2002). Children might maintain emotional security in households with high levels of parent conflict by minimizing overt displays of distress, even when they are experiencing high physiological arousal. This behavioral suppression may result from learning that it is dangerous to draw attention to themselves, as this might lead the parents to aggress toward them.

These are the basic tenets of the person orientation. Other important additions to these tenets have been suggested; we discuss two of them.

6. *Dimensional identity*. There have been developing statements about the meaning of dimensional identity. The expression originated with Schmidt (1977), who postulated that scales used for comparison be commensurable. Von Eye and Bergman (2003) suggested that scales used for inter- or intraindividual comparisons should also have the same dimensional structure and be invariant over time. If dimensional identity is not given, scales cannot be used for comparison. The result that dimensional identity does not exist is of interest in itself. It points to the possibility

that multiple populations exist. In addition, this result indicates where these populations possibly differ from each other.

7. *The ecological context of human behavior*. Three additions to the original person-oriented tenets, relating to the ecological context, were developed by Bogat (2009), using the basic structure and language of the original tenets put forward by Bergman and Magnusson (1997). *1. The structure and dynamics of individual behavior are, at least in part, specific to the environment in which the individual lives and works. 2. There is lawfulness and structure to (a) intrasystemic constancy and change and (b) intersystemic differences in constancy and change. These processes can be described by patterns of the involved factors. 3. Validity is specific to individuals and environments*.

In discussing the individual as a holistic, dynamic being, Bergman and Magnusson (1997) emphasized that an individual's behavior can be influenced by factors from the neuronal to the cultural. The setting in which an individual works, lives, or loves is as much a factor in his or her development as cognitive, biological, and psychological processes. The effects of context can be dramatic. For example, marriage dampens criminal behavior, an effect that seems to be contextual rather than based on an individual personality characteristic (Horney, Osgood, & Marshall, 1995; Sampson, Laub, & Wimer, 2006).

Bronfenbrenner and Morris (1983) defined context as "any event or condition outside the organism that is presumed to influence, or be influenced by, the person's development" (p. 359). Within this broad definition, Bronfenbrenner (1977) elaborated four nested levels of the environment: (1) the *microsystem* (social settings in which the individual is embedded, such as the family); (2) the *mesosystem* (the connections between the various microsystems, such as the family's relationship with the church); (3) the *exosystem* (larger structures that subsume the micro and mesosystems, such as neighborhoods); and (4) the overarching *macrosystem* (i.e., culture and its various components, such as political systems). Later formulations included a fifth level—the *chronosystem*—which described how interactions within or among the four other levels, were influenced by time (Bronfenbrenner, 1986a, 1986b).

This five-level, broad contextual rubric helps focus the researcher's attention on the wide array of contexts that can affect an individual; however, *which* specific contexts should be measured or included in a specific research study are less obvious. Bronfenbrenner's contextual levels focus on the social environment; however, others have argued that the physical environment might also play an important role in child development (e.g., Widaman, 2007).

Unfortunately, of all the components of the person-oriented approach, the contextual component is probably the least developed and understood. In the limitations section, we explain why this might be the case.

Limitations of the Person-Oriented Approach

Here we discuss three limitations to the person-oriented approach: (1) generating testable hypotheses; (2) conducting pattern analyses; and (3) measuring and analyzing the contexts in which human behavior occurs.

The first limitation is that the person-oriented approach does not lead easily to testable hypotheses. Bergman and colleagues (Bergman & Anderson, 2010; Bergman & Trost, 2006) argued that, in part, hypothesis generation is difficult because the person-oriented approach "is quite general and its translation into specific theory for a scientific problem can be difficult" (p. 158). On this point, we take a slightly different perspective. If the person-oriented and variable-oriented approaches are considered general paradigms for scientific inquiry, then, in and of themselves, they do not lead to specific testable hypotheses. Rather, they provide the structure under which theories and hypotheses are generated.

However, even so, hypotheses from a person-oriented approach may be difficult to generate because there has not been enough attention to the match between theory and methods. Sterba and Bauer (2010) rightly object to the casual use of the term person-oriented any time individuals are grouped. They emphasize the importance of understanding what person-oriented methods can be used to test what principles of the person orientation. For example, they propose a matrix in which the person-oriented principles are crossed with four person-oriented methods (i.e., less restrictive variable-oriented approaches, classification, hybrid classification, and single subject). They conclude that the correspondence between principle and method may sometimes be a match (e.g., pattern summary × single subject), sometimes a mismatch (e.g., pattern summary cannot be tested with less restrictive variable-oriented methods), or sometimes a limited or conditional match (e.g., individual specificity is only conditionally testable with hybrid classification models). Of course, as statistical techniques evolve, these correspondences may change [e.g., in the same special issue in which Sterba & Bauer's article appeared, Molenaar (2010) argued that all person-oriented principles can be tested with dynamic factor analysis].

Generating testable hypotheses using a person-oriented approach may also be difficult because most extant research

is variable-oriented. As Bergman and Andersson (2010) note, it is often difficult to use variable-oriented findings to develop person-oriented theory and methods. However, sometimes when an accrual of variable-oriented research on a specific topic generates contradictory findings in different samples or when different variables are included in the analyses, a reconceptualization of the research using person-oriented theory and methods may be beneficial and advance the science (e.g., the infant and adult cortisol research, cited earlier).

The second limitation involves how to conduct data analysis of patterns (Bergman & Andersson, 2010). Person-oriented theory focuses on the importance of understanding patterns; however, the statistical techniques for analyzing patterns are underdeveloped. For example, Bergman and Andersson (2010) noted that many current data analytic techniques to determine patterns depend on dissimilarity matrices (e.g., cluster analysis), yet there is not widespread agreement on what the appropriate measure of dissimilarity should be. Configural frequency analysis is a particularly promising technique because it creates all possible patterns within the variable space; the researcher can then identify which patterns occur more or less frequently than expected under a specific hypothesis.

In addition to understanding patterns, in and of themselves, there is the additional problem of modeling dynamic processes in those patterns that occur over time. Kelso (1995) noted that the principles of dynamic pattern formulation confront us with two problems. The first is *the problem of complexity of substance*—how a pattern is constructed from a large number of components. The second is the *problem of pattern complexity*—how patterns accommodate complexity in whatever function they ultimately serve (e.g., by changing, by selection, by bifurcation). In the field of developmental psychopathology (as in most fields), we are far from understanding how patterns form and how they operate. However, we can assume that the relationship of the components of patterns as well as the relationship of patterns with other patterns is most often nonlinear. Thus, new data analytic techniques will be necessary to capture these processes.

Dynamic systems modeling approaches, focused on recursive differential and difference equations, show some promise, and there has been, of late, much interest in this strategy (e.g., Kunnen, 2012; Valsiner, Molenaar, Lyra, & Chaudhary, 2009). Other approaches, for example, state-space nonstationary time series modeling (e.g., Molenaar, Sinclair, Rovine, Ram, & Corneal, 2009), which puts no constraints on the parameter estimates, has been used in idiographic approaches.

Analyzing patterns involves decisions about which variables are essential to constitute the patterns, since we cannot measure everything in every research study. In discussing patterning of contextual influence, Widaman (2007) suggested three contextual patterns to consider. Big Bang events, which are likely to be one-time, unrepeatable, stressful life events (e.g., death of a parent), are known to have a strong influence on development, but only in the context of other factors (e.g., age of child, socioeconomic status). Repetitious, smaller events, as the name implies, occur frequently, over the course of time. Big Bang events correspond to major life stressors; repetitious smaller events correspond to daily hassles. Finally, there are intermittent but salient events (e.g., inconsistent parenting behavior).

The third limitation concerns context. What is context and how should it be measured? What contexts are most relevant to assess in the field of developmental psychopathology? These are not simple questions, and it is beyond the purview of this chapter to answer them fully. However, here we address several problems with the conceptualization and measurement of context.

One problem faced by the researcher is how to define context in terms of how it differs from as well as might be dependent on individual-level data. For example, Oakes (2009), cited the work of Coleman (1990), who put forward a simple model of how social change occurs: society is composed of individuals and individuals constitute society. That is, "Institutions and other social phenomena play a key role in analyses, but these phenomena must be grounded to the activity of individuals.... Group-level phenomena are never simple aggregations but rather complex dynamic and multilevel phenomena" (Oakes, 2009, p. 364).

There are conceptual as well as statistical problems associated with determining and measuring context. Sometimes context is "defined purely on the aggregate" as in whether or not there is a Head Start program in a specific community; sometimes context is a summary statistic of an aggregate of individuals (e.g., prevalence or incidence data, neighborhood socioeconomic status; Greenland, 2001).

Greenland (2001) offered an example from the field of epidemiology regarding how aggregate measures can introduce problems of cross-level confounding when measuring the effect of context. Table 18.1 (from Greenland, 2001) presents data for two areas, *A* and *B* (which differ on a contextual variable, such as a law or social program), and their influence on the rate of a health outcome (e.g., smoking). The rates in Panel 1 indicate no contextual effect; in essence

TABLE 18.1 An Example Demonstrating the Complete Confounding of Contextual and Individual Effects in Ecologic Data

	Area A			Area B		
	$X = 1$	$X = 0$	Total	$X = 1$	$X = 0$	Total
1. Ecologic (marginal) data						
Y = 1	?	?	560	?	?	560
N	60	40	100	40	60	100
Rate	?	?	5.6	?	?	5.6
2. Possibility 1 ($RRx = 2$, $RR_A = 7/8$)						
Y = 1	420	140	560	320	240	560
N	60	40	100	40	60	100
Rate	7.0	3.5	5.6	8.0	4.0	5.6
3. Possibility 2 ($RR_X = 1/2$, $RR_A = 8/7$)						
Y=1	240	320	560	140	420	560
N	60	40	100	40	60	100
Rate	4.0	8.0	5.6	3.5	7.0	5.6

Note: The ecologic data cannot identify the effect of group (A versus B) on the rate of the outcome $Y = 1$ when only a marginal summary of the individual-level covariate X is available. N = denominator (in thousands of person-years); RR_A and RR_X are the rate ratios for the true effects of A versus B and of $X = 1$ versus $X = 0$, respectively.
Source: Greenland, S. (2001). Ecologic versus individual-level sources of bias in ecologic estimates of contextual health effects. *International Journal of Epidemiology, 30*, 1343–1350. Reprinted with permission from Oxford University Press.

$RR_A = 1$ (the true effects of A vs. B). Because the presence of a risk factor (X) is unknown, it cannot affect RR_A. Panels 2 and 3 show circumstances under which the same result as Panel 1 can be obtained, even though risk and context are different. For example, in Panel 2, area A has a positive contextual difference ($RR_A = 7/8$; that is <1), but that is obscured by a higher prevalence of a harmful risk factor ($RR_X = 2$; that is >1). Panel 3 demonstrates how this confounding can take place when the situation is reversed; that is, when the contextual difference is negative ($RR_A = 8/7$) and there is a higher prevalence of a beneficial factor ($RR_X = 1/2$).

Greenland argued that in some cases, the differences in risk factors between areas A and B might be negligible. However, he noted that in other cases, the differences might be substantial, for example, in the case of alcohol consumption. At moderate levels alcohol consumption may be protective, whereas at high levels it may be detrimental. Thus, without knowing more about the distribution of moderate and heavy drinkers within an area, the direction or the strength of confounding of RR_X on RR_A would be difficult to determine.

Another problem is that the meaning of context may vary over time. We noted earlier that marriage itself is associated with decreased criminal behavior. However, Gottfredson (2005) suggested that marriage is an age-dependent variable, and the meaning of marriage will differ accordingly. "At very young ages, marriage may index low self-control . . . , during the early to late thirties higher levels [of self-control] . . . And repeated marriage may signify low rather than high self-control" (p. 51). This presents a very specific problem of dimensional identity, which may have strong effects on the data, and, thus, the conclusions that are drawn from them.

Although developmental psychology and developmental psychopathology researchers study contextual factors (e.g., parenting, SES, prenatal programming), the focus is usually on a specific variable; rarely is the focus on the associations among multiple factors and levels in which individuals exist. For example, of the articles published in psychology from 2000–2005, at least one-third that had a significant focus on race, did not have a significant focus on socioeconomic status (Carlson, 2006, as cited in Cauce, 2008). Culture, race, and ethnicity are important contextual factors, yet, at present, we understand little about how they transact with individuals.

The field of developmental psychopathology often focuses on identifying early risk factors that predict later problem behaviors. Sampson and Laub (2005) argued that sometimes the search for childhood risk factors may be misguided, especially when the focus is on "early childhood attributes that are presumed to be stable over the life course" (p. 40). Their research, examining criminal behavior among males from age 7 to 70 (Laub & Sampson, 2003), found that risk factors generally did not predict future behavior. When the sample was divided into

high- and low-risk groups (based on early detrimental family and individual factors), both groups had identical trajectories of criminal behavior—criminal behavior peaked at age 15 and then desisted over time to negligible levels. Decomposing the sample another way, a five-group solution was found; each group had a slightly different trajectory of peak and drop off of criminal activity. However, similar to the two-group solution, criminal activity declined for all groups over time. In addition, the authors found no evidence that two childhood risk factors (parental deviance and mental health) differentiated the five groups in meaningful ways.

One solution to the focus on risk perspective is for person-oriented research to examine positive development. For example, Richard Lerner's (e.g., Lerner, Taylor, & von Eye, 2002; Lerner, von Eye, Lerner, & Lewin-Bizan, 2009) positive youth development model focuses on strengths, including those of the adolescent (school engagement, self-regulation, and hope about the future) and the environment (social networks, individuals, institutions, and resources). Healthy development (as exemplified by competence, confidence, character, caring, and connection) occurs as a result of positive synergy between youth and environmental assets.

This section has elucidated the principles of both the variable- and person-oriented approaches as well as outlined limitations of each. In the following section, we discuss the genesis of many of the tenets of the person-oriented approach by focusing on the theories and research of three seminal psychologists.

THREE EARLY PROTAGONISTS OF THE PERSON-ORIENTED APPROACH

In this section, we discuss the work of William Stern, Kurt Lewin, and Jack Block, three key personality theorists and researchers, whose ideas presaged the modern-day person-oriented approach. In examining their work, it is evident that the field of personality has debated the merits of some variant of the person-oriented vs. the variable-oriented approach, since its inception (e.g., holistic vs. individualistic; idiographic vs. nomothetic; traits vs. types). We recognize that there are other important figures (e.g., Allport, Binet, Brunswik, Cairns); however, the scope of this chapter does not allow us to cover the entire history of the field.

The three protagonists worked during the ascendance of the variable-oriented approach. Various historical explanations have been offered as to why the variable-oriented approach came to dominate psychological science. One idea is that a consensus was reached in psychology regarding which statistical methods were scientific. For example, Stam (2010) focused on the Galtonian view in psychology, where "numbers . . . *represent* some empirical reality" (p. 147, italics in the original). He argued that this focus moved psychologists away from people and toward characteristics of tests, as aggregation occurred hand-in-hand with this representation. Lamiell (2009) discussed attempts to integrate experimental and correlational methods, which resulted in neo-Galtonian notions that "the statistical concepts and methods common to both forms of inquiry—involving the analysis of means, variances, and covariances (i.e., correlations)—made the merger of these two research programs both possible and eminently sensible" (p. 36). Another idea, advanced by Toomela (2009), suggests that causality, understanding, and explanation, after World War II, focused almost exclusively on linear models. In doing so, psychology adopted simple, mechanistic models and rejected more complicated models for understanding human behavior (see also Stam, 2010). Magnusson (2000) focused on the move to a stimulus-response paradigm in the 1950s and 1960s, which focused on molar behaviors rather than a holistic, integrated formulation of human behavior.

As we mentioned earlier, Kuhn (1962/2012) argued that paradigms stay dominant, in part, because researchers are able to integrate anomalous findings into these paradigms. This certainly occurred with the person- and variable-oriented approaches. Lamiell (2003) provided an example in his discussion of Allport and McClelland's perspectives on the findings of Hartshorne, May, and Shuttleworth (the Character Education Inquiry; Hartshorne & May, 1928, 1929; Hartshorne, May, & Shuttleworth, 1930). In this classic research, numerous components of specific child traits (e.g., helpfulness, dishonesty) were measured across settings; however, the correlations among these components were negligible, leading Hartshorne and May (1928) to conclude that these were not traits, but simply habits. Allport (1937), attempting to integrate nomothetic and idiographic approaches, suggested that the findings proved "only that children are not consistent *in the same way*, not that they are inconsistent with *themselves*" (p. 250). In other words, there might be unmeasured traits influencing the results (an early example of the lurking variable argument), and/or that individual children might have unique motives for the same behavior (e.g., one child might steal because of a *bravado* trait, another because of a *social inferiority* trait). Alternatively, as Lamiell (2003) pointed out, McClelland (1951), defending the nomothetic tradition, argued that the research had methodological

flaws; the children were too young to demonstrate traits (which were learned from past experiences), a significant methodological problem.[6]

The three historical figures we discuss here were immersed in the debates about the prominence the individual should have in psychological science. They all came down on the side of the individual.

William Stern

William Stern (1871–1938) is well known in the field of psychology for specific contributions (e.g., developing the intelligence quotient), yet he is almost unknown as relates to his philosophical writings on critical personalism. In fact, Lamiell (e.g., 2009) suggested that Allport might have been one of the few psychologists who valued Stern's theoretical contributions.[7] His lack of renown is unfortunate, given that Stern's ideas foreshadow important principles of the person-oriented approach.

Stern began his career by developing the field of differential psychology; that is, the study of individual differences. to study individual differences, differential psychologists developed tests and compared individuals and/or groups on these tests. For example, as is well known, in the late nineteenth and early twentieth century, Binet and Cattell were developing intelligence tests and administering them to different individuals and populations. Stern's book on differential psychology first appeared in 1900, with a revision in 1911. He was interested in specifying differences between individuals and groups, ascertaining what caused these differences, and how the variations were demonstrated; however, although the book dealt with both inter- and intraindividual differences, Stern's emphasis was interindividual differences (Lamiell, 2010a). Stern became concerned with the testing movement (especially America's obsession with intelligence testing and its reliance on norms determined through aggregation), and ultimately repudiated his own contributions to the field (Lamiell, 2010a). In the process, Stern embraced his interests in metaphysics and philosophy, articulating his theory of critical personalism—"a genuine differential psychology" (Stam, 2010, p. 149).

For Stern (1917/2009), the individual was a unitas multiplex; that is, multiple components that are organized in a coherent, and purely teleological, manner. The idea of the individual as unitas multiplex augurs Bergman and Magnusson's (1997) second and third tenets concerning the complexity of process and the meaningful coherence in development and functioning. Stern was concerned that psychology had focused primarily on elucidating the multiple components of human experience at the expense of understanding the "unified individual." Stern noted that simply aggregating all the components of the individual did not, in and of itself, explain higher-order processes.

The unity of the individual was to be understood on four levels: "phenomena (mental experiences), acts (doings), dispositions (strivings, capabilities), and subjects (I)" (Stern, 1917/2009, p. 115, n.b. all quotes below from this source). Although heuristically, one could look at each in isolation, none could be understood fully without an appreciation of how their interrelationships created a totality. By *phenomena*, Stern meant individual self-perceptions, such as ideas or feelings. *Acts* involved the interconnections and unifications of self-perceptions that occurred within a short time frame or within the moment. However, such a temporal framework, if taken in isolation, provides a misleading picture of the individual. Stern extended the time frame by considering *dispositions*, enduring qualities or attributes of the individual that predispose him/her to various perceptions. The relationship between these three components is as follows: Acts mediate the relationship between dispositions and perceptions. For example, Stern noted that intelligence "is not the power to set into course thoughts or thought sequences of a particular kind, but instead the disposition to adjust oneself through acts of thought to new situations and demands" (p. 122).

The fourth component was the I—the unification of the dispositions. Stern defined the I as existence itself. "The I experiences phenomena, executes acts, [and] owns dispositions" (p. 124). The I included both the psychological and physical aspects of the person.

From these four components, Stern defined personality as "an entity that we encounter as a living whole which, that in and of itself strives for and is capable of realizing the enduring purposes of that whole" (p. 131). This definition puts front and center Stern's focus on the teleology of the personality system. The personality was both self- and other-oriented (*autotelie* and *heterotelie*, respectively), and worked to integrate these two purposes, even though they were sometimes in opposition. Stern referred to this as *introception*. In addition, personality was not fixed by the four components, they simply potentiated the individual's transactions with the environment. Here Stern's writings

[6]The reader may be interested in a more recent exemplification of fitting anomalous data into the dominant paradigm of personality research (Borkenau & Ostendorf, 1998).

[7]Over the last 30 years, James Lamiell has, nearly single-handedly, brought Stern's ideas to an American audience.

relate to the ecological context tenet of the person-oriented approach. The transaction of the person and the environment, he termed *convergence*. In Stern's view, an individual's goal focus was insufficient; it had to be augmented by the environment. The environment would influence the individual, but the individual's specific dispositions would influence his/her experience with the environment.

It is apparent that Stern's theories relate closely to the tenets of the person-oriented approach. In addition, his delineation of research methods (separating, for instance, research on the individual and research on groups of individuals), also echoes person-oriented approaches. As Lamiell (2010b) noted, Stern believed in large-scale research and the use of modern statistical methods; at the same time, he understood that there was a distinction between knowledge about an individual and knowledge collected across a group regarding specific attributes that individuals might have. This concern presaged the dilemma of the ecological fallacy, discussed earlier, and specifically relates to Jack Block's writings decades later that the search for universal traits is problematic because they say little about the individual.

Kurt Lewin

Lewin (1890–1947) and Stern knew of each other's work (Stam, 2010). Although their theories diverged in important ways, they shared a concern regarding psychology's misguided focus on aggregation and the search for universals and lawfulness.

Lewin (1931) believed that psychology was tethered, in problematic ways, to Aristotelian logic. He was concerned that psychology focused on regularity, specifically in the sense of frequency. Thus, psychologists were primarily concerned with lawfulness (regularities across individuals) and unconcerned with the individual case. In fact, "the individual event seems to him [the psychologist] fortuitous, unimportant, scientifically indifferent" even though it may have "critically determined the destiny of the person involved" (p. 151). Lewin argued that the focus on lawfulness prevented psychology from investigating large swaths of human experience (e.g., will and affect), because these types of experiences were likely to occur less frequently than other experiences. As is obvious, Lewin, like Stern, was concerned that psychologists discounted the importance of the individual, the first tenet of the person-oriented approach.

According to Lewin, in their quest to discover universal laws of human behavior, psychologists established groupings of convenience, leading to incomplete, mechanistic understandings. For example, he wrote:

> Whatever is common to children of a given age is set up as the fundamental character of that age. The fact that three-year-old children are quite often negative is considered evidence that negativism is inherent in the nature of three-year-olds, and the concept of a negativistic age or stage is then regarded as an explanation (though perhaps not a complete one) for the appearance of negativism in a given particular case. (p. 153)

Again, these sentiments reflect tenets of the person-oriented approach, including avoiding the ecological fallacy, the importance of creating meaningful groups, and a focus on understanding process rather than simply mechanisms.

Lewin also felt that psychology's concentration on classes and frequency of behavior led to the use of statistics that obscured individual differences. Although psychology was preoccupied with developing fundamental principles, in practice, Lewin believed, research described averages across individuals. "It is forgotten that there is just no such thing as an 'average situation' any more than an average child" (p. 172). Lewin's critique of the use of averages in statistical methods focused on the lack of precision that was inherent in this approach. He wrote: "The demands of psychology upon the *stringency* of its propositions go no farther than to require a validity 'in general,' or 'on the average,' or 'as a rule.' . . . *psychology does not regard exceptions as counter-arguments so long as their frequency is not too great*" (p. 156, italics in the original). Here again, Lewin's ideas foreshadow the importance of avoiding the ecological fallacy and the need to focus on individual behavior.

Lewin (1931) anticipated that psychology would move from an Aristotelian to a Galilean concept formation; he based this idea on Ernst Cassirer's analysis of t he fields of mathematics and physics. In part, a Galilean formulation would lead psychologists to develop theories that provided complete, not partial, explanations for the phenomena under study. Central to these theories was the notion that the causes of human behavior were multiply determined, and did not rest exclusively within the individual. He noted that numerous factors might affect an individual, including his or her personality, the groups within which an individual was embedded, culture, and economic forces. Lewin (1939) was greatly influenced by the Gestalt psychologists; however, he felt that the whole and its individual parts were of equal importance. "The whole is not 'more' than the sum of its parts, but it has different properties. The statement should be: 'The whole is different from the sum of its parts'" (p. 885).

Lewin's theory of multicausality ultimately evolved into his "field theory," which proposed that human behavior resulted from the interactions among many different

systems; that is, a dynamic field. Lewin's (1936) famous formula, expressed in mathematical terms, stated that behavior is a function of the person and the environment: $B = F\ (P,\ E)$. Lewin argued that the focus for psychological research was on the life space, which consisted of the needs of the individual as well as the environment in which he or she existed [$B = F\ (P,\ E) = F(L\ Sp)$] (Lewin, 1939). The focus on multicausality and the inclusion of the environment, as well as the person, in theory and method, are preludes to the second and third tenets of the person-oriented approach—that processes involve many interacting factors, and that within these interactions there is coherence and lawfulness. Lewin's work also reflects the fourth tenet with its focus on the importance of understanding each factor only in relation to other factors.

Lewin (1931) was also an experimentalist, who believed in creating ideal or paradigmatic situations rather than simply recreating conditions that occurred frequently.

> The general validity, for example, of the law of movement on an inclined plane is not established by taking the average of as many cases as possible of real stones actually rolling down hills, and then considering this average as the most probable case. It is based rather upon the 'frictionless' rolling of an "ideal" sphere down an 'absolutely straight' and hard plane, that is, upon a process that even the laboratory can only approximate, and which is most extremely improbable in daily life. (p. 161)

For example, Lewin, Lippitt, and White (1939) studied aggressive behavior by organizing clubs of 10-year old boys that were guided by three types of leaders (i.e., laissez-faire, authoritarian, and democratic). Process data were collected, including a written verbatim account of all conversations, visual recordings, and moment-by-moment structural, quantitative, and interpretative accounts of group process. The authors found that most of the acts of aggression occurred during emotion-laden moments (e.g., criticism of the group from an outsider). These acts of aggression seemed to be spontaneous acts resulting from a build-up of tensions based on leadership style and the restriction in "space of free movement" that resulted from that style. Other factors considered important were the "rigidity of the group structure," which provides a restraining force but also increases tension within the individual, and whether the child came from a culture where aggression was an accepted way of acting.

This is necessarily a very brief review of Lewin's theory. We do not discuss the aspects of his theory that are, at present, most well known, including action research, group process, and leadership styles. What is most interesting to us is that the criticisms of psychology that Lewin raised, which are similar to those raised by advocates of the person-oriented approach, are largely forgotten. We now turn our attention to Jack Block.

Jack Block

Block (1924–2010) is often rightly cited as one of the fathers of the modern person-oriented approach. He is perhaps most widely known today as a contrarian (a label he gave himself) who offered strong critiques of the Five-Factor Model (FFM) of personality (e.g., Block, 1995, 2001, 2010), as it came to dominate the theory and research of personality. Although researchers have acknowledged the validity of some of his critiques of the FFM (e.g., McAdams & Walden, 2010), the overarching concern in which the specific critiques are subsumed—that variables, rather than people, had become the focus of personality research—is often overlooked or downplayed.

Block began his career at a time when the debate about how personality was to be defined (whether there were universal truths about personality as well as which statistical techniques provided the best way to understand personality) was quite active. In 1946, Cattell defined the *R-technique* as an approach to studying personality that focused on correlating variables; hence, a variable-oriented approach to analyzing data. Alternatively, the *Q-technique* correlated persons. Some researchers (e.g., Eysenck, 1954) felt that the two approaches were the same; that is, they always led to similar results. Along with others (e.g., Cronbach, 1953; Stephenson, 1953), Block (1955) disputed this assertion, arguing that depending on the heterogeneity or homogeneity of the sample, the results would be different. In other words, in a heterogeneous sample, composed of more than one subgroup, it was possible that the covariance structures for specific variables would differ by subgroup. In homogeneous samples, the covariance structures would be the same.

Writings throughout his career reflected Block's concern that personality psychologists focused too much attention on variables and not enough on individuals. His strongest defense and advocacy of the person orientation can be found in *Lives Through Time*, Block's (1971) seminal investigation of personality development. Many of the principles of the person orientation that he elaborated can be seen in the following quote from this book, when he wrote that psychologists should aspire to understand personality in the way that laypeople do, which is "[a] configuration and systematic connection of personality variables as these dynamically operate within a particular

person" (Block, 1971, p. 13),[8] a point made by some current personality researchers, as well (e.g., Donnellan & Robins, 2010).

There are a number of important components to this statement. First, laypeople naturally discuss people, not variables; whereas the opposite tends to be true of many psychologists. Block acknowledged that this problem was not unique to the study of personality. For example, he cited an article wherein the authors ask "where is the perceiver in perceptual theory?" The second important aspect of this statement is that personality consists of a configuration of characteristics. One characteristic cannot describe someone's personality adequately. A person who is quiet in large social situations may be perceived as shy; however, when that same person is seen talking freely and intimately among his close friends, the observer may need to adjust his or her perception.

Finally, the third component of Block's statement speaks to the importance of configurations of personality variables operating in a dynamic fashion. He argued that personality theory put too much emphasis on examining stability (i.e., uniformity of development across people and time) at the expense of overlooking instances of change and what drives such change. For example, when personality psychologists find differences in individuals across time, they are likely to ascribe these to measurement error in the assessment instrument (in particular when the instrument was constructed based on classical test theory), random error, or the choice of an unimportant (i.e., nonuniversal) variable. Block disputed this bias by demonstrating in his longitudinal research that there were groups of individuals whom he labeled changers and nonchangers; importantly, these subgroups were better able to explain personality development compared to a priori groupings based on such variables as gender.

Block recognized that there was strong pressure among personality researchers to adhere to the uniformity myth.[9] Many researchers had argued that if uniformity across people did not exist, the result would be a lack of lawfulness; that is, the discovery of too many different types of personality would undermine the search for universal principles or types. Block argued against this perspective by decoupling lawfulness and universality. He wrote, when the two are conflated it means that "the seeking of one may preclude finding the second . . . [in fact, in not doing so] a greater lawfulness may be discerned as what is general and undifferentiated is partitioned into smaller but more homogeneous classes for study" (1971, p. 11). In fact, Block believed smaller groups were likely of great interest to the researcher, and, furthermore felt that random samples might not include certain types of infrequently occurring individuals. He felt so strongly about this that his recommendation for future longitudinal researchers was to *not* recruit a random sample, but rather to focus theory and research questions on a relevant, non-random, sample.

As mentioned earlier, Block felt that theory and research were synergistic. In other words, it was inevitable that researchers holding variable-oriented theories would find support for these theories, as they employed variable-oriented assessments and data analytic techniques that could not find support for person-oriented theories. This was a point he made continually throughout his life. For example, in his critique of the FFM, he eschewed the notion that five personality factors derived for adults could be readily transposed onto childhood personality (Block, 2010). In other words, he implied that researchers who believed in stability rather than change and who focused on variables, rather than people, might conclude (falsely) that adult and child personality traits were interchangeable. Thus, early in his career, to examine the person in personality, Block turned to a new assessment tool just gaining popularity.

Q-Technique

Although often attributed to Block, the *Q-technique* (also called *Q-set* or *Q-sort*) was not invented by him. Stephenson (1935) introduced this technique in an article aptly titled "Correlating Persons Instead of Tests." Stephenson was concerned with a specific problem within psychology—that large numbers of participants were needed to collect the data that would allow psychologists to correlate tests or estimates and then conduct factor analyses, especially as related to Spearman's *g*, *c*, and *w* factors.

He went on to argue that laboratory experiments become almost "burdensome" because of the need to collect data from so many individuals. He proposed the *Q-technique* as an antidote to this problem: "Can we make factor studies on a *few* individuals, and bring the

[8]Block was not arguing that laypeople should provide scientific definitions of personality for the researcher. In fact, one of his ongoing critiques of the FFM was that the list of adjectives used to define the traits had been derived from undergraduate students asked to list traits that best described themselves and their acquaintances.

[9]The term uniformity myth, as discussed earlier, was also used by psychotherapy outcome researchers to suggest the folly in assuming that clients, therapists, and behavior were similar and that individual differences did not matter (e.g., Kiesler, 1966).

methods of correlations and factor analysis into the laboratory?" (p. 18, italics in original; see also Nesselroade & Molenaar, 2010).

His solution was to invert the typical process. Instead of obtaining a few tests on a large number of people, he proposed that psychologists obtain many tests on a few people. Stephenson's demonstration of his new technique was a study on taste (i.e., aesthetics), what he considered an important, but understudied, facet of an individual's personality. He took 60 color samples (no blacks, pure grays, light creams or whites were included) and gave them to 12 women and eight men with the instruction to grade each quickly and spontaneously from best to least liked. His small experiment found two factors; that is, two groups of individuals whose preferences correlated positively with each other. Factor 1 was composed of 12 individuals who preferred the subtle colors (which Stephenson labeled as the most tasteful); Factor 2 was composed of eight individuals who preferred the pure bright colors (which Stephenson labeled as vivid but crude).

Interestingly, although Stephenson's procedure had the participants sort the cards (self-report), Block's initial Q-set was developed so that professionals could make appraisals of others (other-report). Also, although Stephenson developed this technique as a special type of factor analysis, the method became used as an assessment tool unrelated to factor analysis (e.g., Rogers, 1961).

Block's Q-Set

Block's (1961) original purpose in developing his *California Q-set* was to define more precisely the characteristics of personality widely used by professionals (e.g., authoritarian personality) as an aid to future research, including better communication and precision among scientists. Thus, as stated already, the Q-set was given to professionals to evaluate patients or research participants. Although it had earlier permutations, the Q-set Block presented in his 1961 monograph consisted of 100 statements, each of which described a specific personality trait (e.g., "is an interesting, arresting person; seeks reassurance from others; emphasizes being with others; gregarious"). Although the statements do not represent conceptualizations from any specific theoretical orientation, Block felt they reflected current informed opinion among professionals in personality psychology, clinical psychology, and psychiatry.

Block conceived of the standard statements as a language and the sorting algorithm of the traits as a grammar. Each observer is given the 100 statements on separate cards; the task is to sort the statements into nine categories where one represents the category least representative of the person and nine represents the category that is most representative. The number of statements that the observer places in each category differ and range from 5 to 18.

Block saw the Q-set as offering both *ipsative* and *normative* data. That is, the information provided a distinct profile of characteristics specifically about the individual being assessed; however, across all the participant data, Block was able to find representative types. The normative data were particularly interesting over time; for example, certain of the 100 characteristics in the Q-set were rarely if ever used to rate individuals at specific stages of development.

As noted earlier, Block was essentially concerned with issues of change and stability over time, as he felt that such knowledge would lead us to understand the developmental paths that lead to the same outcome (equifinality) or similar developmental paths that lead to different outcomes (multifinality). To study trends, Block developed profiles of personality variables based on their correspondence, salience level, and salience heterogeneity over time. This resulted in seven categories. For example, the category "sameness" described personality variables where the correspondence across time was high, and changes in the salience level and salience heterogeneity were minimal. The category "decreasing salience values, order maintained" described personality variables that correlated well over time but whose salience, as a group, declined over time. Using these categories of personality variables, Block examined continuity and change in specific groups (e.g., men, adolescents). The findings using this approach were deemed uninteresting by Block, " . . . the plethora of slight to moderate across-time relationships supports only the by-now banal recognition that human beings do indeed remain somewhat true to themselves over considerable lengths of time" (p. 88). Block understood that there was an inherent flaw in summarizing information about variables across diverse people; he recognized that such an approach would mask subgroups.

For example, in taking a different approach (i.e., factor analyzing the individual profiles), Block found that there were some subjects who did not fit the majority types he found. He labeled these individuals *residuals* and noted that they had one of two characteristics. The first were individuals who did not fit any of the types; the second were individuals who fit well within multiple types. It should be noted that in 1971, Block was not entirely convinced that factor analysis was the best data analytic strategy to find types or residuals. In fact, he wished to find natural groupings, but did not have the computational power to use techniques that could find them. In later years, some of his most pointed criticisms of the FFM were based on

researcher's reliance on factor analysis (e.g., Block, 1995, 2001, 2010), including the assumption that mathematically forced orthogonality accurately represented psychological understanding (i.e., the five factors did not operate independently in an individual).

It is obvious that Block's theory of personality and research touched on each of the person-oriented tenets described earlier. One of the important components of the modern person-oriented approach is that context matters. Unfortunately, the Q-set was deficient in measuring context; a problem of which Block was aware. The Q-set questions tried to take into account individual behavior in diverse settings, but the questions did not specifically focus on this dimension of human behavior. When an individual's behavior varied, Block often attributed this to context. In his longitudinal research, Block did not have the assessment tools or methods to explore the context of an individual's behavior, so he simply averaged the various discrepancies.

In summary, Block was considered a contrarian, and he focused many of his critical essays in his later years, and, even the year that he died, on arguing against the FFM, which had come to dominate personality research. He offered many specific criticisms; however, these were all embedded in his most fundamental belief, the person-orientation. He promoted a focus on the person, rather than variables, with specific emphasis on examining profiles; he encouraged psychologists to develop intraindividual theories rather than theories of interindividual differences; and he promoted the notion of the individual as a dynamic system. Block (1995) wrote:

> Once the parameters that define the personality system of a generic individual have been conceptually posited and empirically identified, these parameters become the essential, nonarbitrary, overarching variables or concepts for a personality of interindividual differences. The differences between individuals would then be understandable as due to the different specific values these parameters take in different individual personality systems. It would be a sweet intellectual accomplishment if the theoretical constructs required for dynamically understanding within-individual functioning could also be used for understanding the differences between individuals. Personality psychologists might aspire to this goal. In that effort, our science—in its theoretical reach and empirical grasp—may better realize its deep aspirations: to provide a bio-social theory of intraindividual development, the moment-to-moment psychodynamic functioning within the individual, the life themes coherently reflected in the adaptive changes of individuals over time and context, *and the* personality differences among individuals. (p. 210)

STATISTICAL APPROACHES

Methods of Person-Oriented Data Analysis

In this section, we discuss and exemplify application of methods of person-oriented data analysis. With these aims in mind, we adopt the role of the data analyst. This poor soul is often handed a data set along with two requests. First, test the hypotheses that had been specified when the grant proposal was written. Second, let the data speak a little as well, and perform exploratory analyses, just to make sure anything interesting was not overlooked. In the current context, there may be a third request, which is that analyses be performed from a person-oriented perspective. For the third request to be realistic, data have to be collected so that person-oriented analyses can be performed. von Eye and Bogat (2007; von Eye, 2010) specified a set of conditions for person-oriented data collection and analysis. Two conditions are most important. First, the sample should be large enough for person-oriented analysis to become possible. When data are collected with the goal of performing person-oriented data analysis, the number of cases must correspond to the anticipated number of groups or populations the data are assumed to be collected from. Each of the subpopulations must be large enough for the analysis to be possible in each of the subpopulations, and for comparative analyses to be possible as well. This desiderate applies both when subpopulations are known prior to data collection and when the researchers just assume that more than one population might exist. In the first case, power analysis can be used to determine the required size of samples from each population. In the second case, the number of populations may be unknown, rendering the a priori determination of sample sizes complicated. The second condition for person-oriented data analysis is that dimensional identity prevails (see the earlier section on the tenets of person-oriented research). Only if variables, test instruments, or dimensions have the same meaning and characteristics in each of the subpopulations, comparative statements with these variables, instruments, or dimensions are possible.

Person-oriented research implies that a specific set of methods of data analysis is employed; however, it also implies that theory, data collection, and data analysis complement each other. This is reflected in a statement by Sterba and Bauer (2010), according to which

> person-oriented approach = person-oriented theory + person-oriented methods

The remainder of this section is structured as follows. We discuss three popular methods of analysis and ask whether and how they can be used in the context of person-oriented research. The methods are structural equation modeling, log-linear modeling, and cluster analysis. Configural frequency analysis (Lienert, & Krauth, 1975; von Eye, 2002; von Eye, & Gutierrez-Pena, 2004), among the chief methods used in person-oriented research, is presented in a separate chapter in this volume (von Eye & Mun, 2015). For each method, we highlight the elements of person-oriented research that are represented, and we give an empirical data example. We posit that each of these methods requires unique assumptions and allows researchers to analyze data in respects of importance for person-oriented research.

Structural Equation Modeling

Structural equation modeling (SEM; Bollen, 1989; Jöreskog & Sörbom, 2001; Kline, 2011; McArdle, 2012; Muthén & Muthén, 1998–2012) allows one to combine methods of factor analysis with methods of regression analysis. In SEM, factor analysis is enriched by providing the option of classifying variables into dependent and independent, and regression analysis is enriched by allowing latent variables to be regressed onto each other. It is also possible to perform exploratory or confirmatory factor analysis without distinguishing between dependent and independent variables, and to estimate regression or path models at the level of manifest variables. In Jöreskog and Sörbom's (2001) LISREL notation, a structural model can be described as

$$\eta = -\mathrm{B}\eta + \Gamma\xi + \zeta$$

where

- η is a [m, 1] random vector of latent variables (factors) on the dependent variable side (the y-side of the model);
- $-\mathrm{B}$ is an [m, m] matrix of regression coefficients that describe the structural relations among the η factors; the diagonal elements of β are zero; β can be symmetric or asymmetric;
- ξ is a [n, 1] random vector of latent variables (factors) on the independent variable side (the x-side of the model);
- Γ is an [m, n] matrix of regression coefficients that describe the structural relations among factors on the x- and the y-sides of the model (factors from the y-side are regressed onto factors on the x-side of the model); and
- ζ is a [m, 1] vector of residuals; this vector represents imperfections of the model in the sense that not all of the variance of the η factors can be explained by the model; these are random disturbances, also called equation errors.

The measurement models for the manifest variables on the x- and the y-sides of the model describe the factorial structure of the dependent and the independent variables. The models are

$$y = \Lambda y\eta + \varepsilon,$$

and

$$x = \Lambda x\xi + \delta,$$

where

- x is a [p, 1] vector of observed (manifest) variables on the x-side of the model, with p indicating the number of manifest x-variables;
- y is a [q, 1] vector of observed variables on the y-side of the model, with q indicating the number of y-variables;
- $\Lambda\, x$ is a [q, n] matrix of the loadings of the x-variables on their latent variables, ξ;
- $\Lambda\, y$ is a [p, m] matrix of the loadings of the y-variables on their latent variables, η; and
- ξ and δ are the residuals of the manifest y- and x-variables, respectively; ε and δ are convolutions of measurement errors and model imperfections.

Later, in this section, we present an example of a structural model in which we only use manifest variables. One characteristic of the structural model that is important for the present discussion of methods of data analysis from a person-oriented perspective is that the input matrix for the estimation of the model is a variance-covariance matrix, that is, a matrix with the variances of the observed variables in its diagonal and all covariances in the off-diagonal cells. Here, it is not important that this matrix can be substituted, under certain conditions, by a matrix of, for example, correlations or tetrachoric coefficients. Important is that, by definition, information about individuals disappears when variances and covariances are calculated. The individual is no longer visible. There are, however, two interesting exceptions. The first involves estimating models at the level of individuals (see, e.g., Nesselroade & Molenaar, 1998; Molenaar & Newell, 2010). The second involves identifying groups by using, for example, mixture distribution models (Muthén & Muthén, 1998–2012) or defining groups, and then estimating multigroup models. In this chapter, we focus on *multigroup models*.

Either of these approaches to modeling development is of great importance for person-oriented research. They

allow characteristics of individuals or groups of individuals to be modeled. This way, justice is done to unique characteristics of individuals or groups of individuals instead of averaging differences out and estimating models that describe the average individual, which, according to Walls and Schafer (2006), may not exist (see also the earlier section on Kurt Lewin).

Multigroup models allow researchers to specify hypotheses concerning the parameters in which they do versus do not allow the comparison groups to differ. Specifically, let G groups be given, then, the model for group g involves the eight parameter matrices $\Lambda_y^g, \Lambda_x^g, B^g, \Phi^g, \Psi^g, \Theta_\varepsilon^g, \Theta_\delta^g$, where the superscript indexes the groups. Now, to give an example of the hypotheses that can be specified, suppose that, in a two-group comparison, the structural parameters in the B and the Γ matrices are supposed to be equal. This can be expressed as $B^1 = B^2$ and $\Gamma^1 = \Gamma^2$. Under these hypotheses, the parameters in all other matrices can be different. In LISREL, the following options for parameter constraints and estimation are available. Matrices in the comparison groups can be constrained

- to have the same patterns of fixed and freed elements,
- to have the same patterns and starting values in the iteration process, and
- to have invariant elements, that is, estimates are constrained to be numerically exactly the same for the comparison groups.

It is interesting to note that the number of variables does not have to be equal in the comparison groups. In addition, residual variances and covariances can be estimated for individual groups only. Hierarchies of constraints have been proposed, but here, we will not use any of the hierarchical procedures.

Data Example

The following example uses data that were collected for a study on the development of aggression in adolescence. Finkelstein, von Eye, and Preece (1994) administered a questionnaire to 75 11-year-old girls and 39 same-age boys who indicated the degree to which they perceived in themselves aggressive impulses (AI), were verbally aggressive against adults (VAAA), and physically aggressive against peers (PAAP). The questionnaire was administered again when the adolescents were 13 and 15 years of age. We hypothesize that, at age 13, aggressive impulses are explanatory of physical aggression against peers and that this process is mediated by verbal aggression against adults. To test this hypothesis, we first estimate a path model without the direct path from AI85 to PAAP85, that is, the direct effects model

$$PAAP85 = \alpha_1 + \beta_{21} VAAA85 + \zeta_1$$

and

$$VAAA85 = \alpha_2 + \gamma_{11} AI85 + \zeta_2$$

If needed, we also estimate the model that does include the direct path

$$PAAP85 = \alpha_3 + \gamma_{21} AI85 + \zeta_3$$

The first model is, in a first run, estimated for the entire group of respondents. The model – data fit for this model is excellent. We obtain $\chi^2 = 0.68$ ($df = 1; p = 0.41$), RMSEA = 0.00, CFI = 1.00, and GFI = 1.00 and decide to retain the model. Because of this excellent fit, the model with the direct path does not need to be estimated.

In a first person-oriented step of analyzing the relations among aggressive impulses, verbal aggression against adults, and physical aggression against peers, we ask whether any of the questionnaire variables can be predicted from gender. In other words, we ask whether responses are gender-specific. To answer this question, we include gender in the model. For the following model, we place gender on the x-side of the model, and AI85, VAAA85, and PAAP85 on the y-side. We predict PAAP85 from VAAA85, which, in turn is predicted from AI85. Each of these variables is predicted from gender. The model – data fit for this model is excellent as well. We obtain $\chi^2 = 0.56$ ($df = 2; p = 0.75$), RMSEA = 0.00, CFI = 1.00, and GFI = 1.00 and decide to retain the model. Figure 18.2 displays this model (standardized scores given).

In the model in Figure 18.2, the path hypotheses are confirmed. AI85 predicts VAAA85, which predicts PAAP85. In contrast, only the PAAP responses are gender-specific ($t = 4.89; p < 0.01$). The paths from Gender to AI85 and to VAAA85 remain nonsignificant ($t = 0.07$, n.s.; $t = 1.64$, n.s.). From this result, we conclude that the two gender groups may differ in their responses to the aggression questionnaire, and we specify a two-group model. We adopt a descending strategy where the strictest model is estimated first. In this model, we set all parameters equal for the two groups. Specifically, we set $\theta_\delta^1 = \theta_\delta^2, B^1 = B^2, \Gamma^1 = \Gamma^2$, and $\Theta_\varepsilon^1 = \Theta_\varepsilon^2$. Not unexpectedly, this model fails to describe the data well. Based on the overall goodness-of-fit $\chi^2 = 22.58$ ($df = 7; p = 0.002$), RMSEA = 0.20, CFI = 0.63, and GFI = 0.89, none of

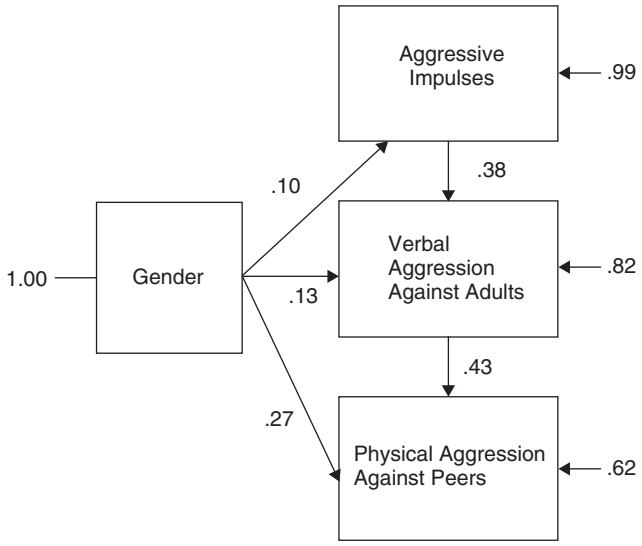

Figure 18.2 Path model of aggressive impulses, verbal aggression against adults and physical aggression against peers. All predicted from gender. *Source*: Data from 1985.

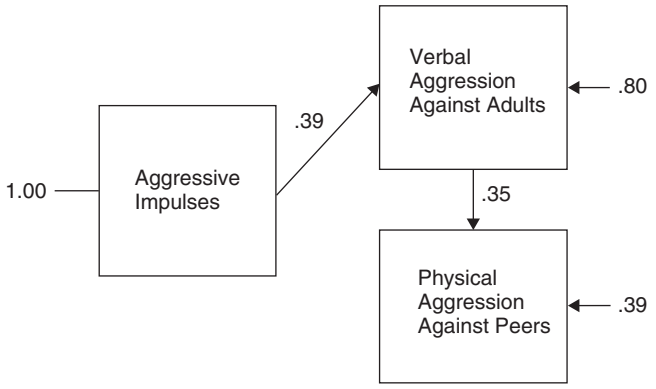

Figure 18.3 Two-group model of aggressive impulses, verbal aggression against adults, and physical aggression against peers; standardized solution for female respondents given. *Source*: Data from 1985.

which is in support of the model, we reject it. We conclude already at this point that male and female respondents differ in their answers to Finkelstein et al.'s (1994) aggression questionnaire.

We now relax the restrictions placed in the first model. Instead of navigating through one of the hierarchies of imposing or relaxing restrictions, we consider that Gender differences seem to exist in the responses concerning physical aggression against peers (PAAP85; Figure 18.2). In the present model, the parameters related to PAAP85 are located in matrix B (parameter β_{21}) and in matrix Ψ (parameter ψ_{33}). We relax the parameter constraints, and now specify that the parameters in the matrices B and Ψ exhibit the same pattern for the two comparison groups, but they are allowed to differ from each other in magnitude. The resulting model describes the data very well. Specifically, we obtain the overall goodness-of-fit $\chi^2 = 1.22$ ($df = 4; p = 0.87$), RMSEA = 0.0, CFI = 1.00, and GFI = 1.00. Each of these statistics is in support of the model, and we decide to retain it. This model is given in Figure 18.3 (standardized solution given for female respondents).

Several elements of this model reflect group differences. First, we note that the model describes the male responses slightly better than the female responses. The female submodel contributes 79.02% to the overall χ^2, and the male submodel contributes only 20.98%. These differences are tiny, but they are interpreted as pointing in this direction. More important are possible differences between the parameters that were relaxed for this solution. In Figure 18.3, we see that, for the female respondents, the parameter for the path from AI85 to VAAA85 is estimated to be 0.39. For male respondents, this parameter was fixed to be equal. In contrast, the parameter from VAAA85 to PAAP85 is 0.35 in the female group and 0.64 in the male group. The difference between these two estimates is significant when only the β parameters are compared and the ψ parameters are assumed to be invariant across the comparison groups ($\Delta\chi^2 = 18.85; \Delta df = 2; p < 0.01$). We conclude that female and male adolescent respondents differ in the path from VAAA85 to PAAP85 in the sense that this path, although significant in both comparison groups, is stronger in males than in females.

Discussion

Not surprisingly, structural modeling of manifest variable path models allows one to identify the parameters in which comparison groups differ. In this respect, structural modeling is well capable to test hypotheses that are compatible with a person-oriented research perspective. SEM offers many options, including, for example, hierarchical modeling, modeling data of individuals, growth curve modeling in multigroup designs, or means modeling. Still, it is hard to label SEM a standard method for person-oriented research. We, therefore, have to identify the elements that make SEM suitable for such research. We discuss three options.

First, as is well known, the input matrix for standard SEM is a covariance matrix. Therefore, the individual does not play a role or, even worse, the individual is not visible. However, most SEM programs are able to make individuals visible, in some form. For example, to the best of our knowledge, every SEM program is capable of creating and saving factor scores. These scores will, in person-oriented

research, not necessarily be used to estimate factor score regression models (for options, see Hoshino & Bentler, 2011). However, the individual's relative position in a factor space can be ascertained. This way, outliers can be made out and factor scores from different factors can be related to each other, with the options of identifying outliers, or specifying individual profiles. In other words, every SEM program allows one to identify those individuals for which a factor solution is less than perfect in the sense that the individual becomes an outlier. From a person-oriented perspective, these are the individuals for which a model may not apply. (Note: When factor scores are used, the covariance matrix that is used as input information must contain all relevant information. That is, one must assume that higher order interactions do not exist or explain only negligible portions of the targeted variability, that is, the variability that allows one to distinguish between individuals.)

The second option, and this was illustrated in the data example on aggression development, is that SEM is a very powerful methodology that can be used to distinguish among subpopulations that are known a priori. Differences in most any parameter can be ascertained.

The third option involves SEM mixture modeling (Arminger & Stein, 1997; Dolan & van der Maas, 1997). Two approaches to SEM mixture modeling have been proposed (Vermunt & Magidson, 2004). The first involves specifying an SEM model and then modeling within-class covariance matrices under the assumption that there are multivariate normal mixtures. This approach is also known as latent class clustering or model-based clustering (Banfield & Raftery, 1993; Mun, von Eye, Bates, & Vaschillo, 2008). In the context of SEM mixture modeling, the class-specific mean and covariances are restricted to the specified SEM structure. This structure reflects, for instance, factors or growth curves. The second approach involves incorporating latent classes into a structural model, thus capturing unobserved heterogeneity. Here, the unobserved variable is class membership. SEM mixture models can be estimated by some SEM software packages (e.g., Mplus; Muthén & Muthén, 1998/2012) and is of importance in particular when researchers assume that data were collected from more than one population, but number and size of populations are unknown.

These three options show that SEM is suitable for person-oriented research—when certain assumptions apply (Sterba & Bauer, 2010; von Eye, 2010). Most important, in the present context, is the assumption of *dimensional identity* that was previously discussed, in the context of the tenets of person-oriented research (von Eye & Bergman, 2003). Dimensional identity implies that the variables that are used to describe individuals are the same in all parameters in the comparison groups. That is, they have the same meaning, the same factor and covariance structures, and they are commensurable, both cross sectionally and longitudinally. If this assumption holds, individuals and groups of individuals can be compared using these variables. If, however, this assumption must be rejected and there is, for example, *differential item functioning*, that is, item characteristics fail to be invariant across comparison groups, scores on the scales that include such items are no longer comparable. Not all is lost in such a case. The information that there is differential item functioning or that factorial structures vary across comparison groups may be of interest itself. However, group means cannot be compared, and neither can scale scores. Before testing multigroup structural models or estimating SEM mixture models, researchers, therefore, are well advised to make sure that dimensional identity prevails.

There exists, however, an interesting exception. There are variables that have natural meaning. Examples of such variables are physiological measures, voxel counts for brain activity, response time, number of items recalled, and many other measures that are not based on instruments constructed using psychometric tools. When this kind of variable is employed, differences in means or covariance structures are most important for the person-oriented researcher because they are no longer indicative of flaws in instruments but of possibly meaningful differences between groups or individuals.

Log-Linear Modeling

Types of Log-Linear Models

Log-linear models are special cases of generalized linear models in which categorical variables are analyzed (Agresti, 2012; von Eye & Mun, 2013). The generalized linear model (GLM) relates a vector, η, to one or more explanatory variables by way of a linear model, $\eta = X\beta$, where X contains the predictors or the effects posited by a model, and β is a parameter vector. In a linear regression model, β contains the regression weights. Now, let η be related to the expected value of the linear model by $\eta = g(\mu)$, where μ is the expected value, and g(.) is a monotone function. This function is called the *link function*. For cases of the general linear model (e.g., analysis of variance or regression), the link function is the identity function. That is, $\eta = \mu$. In log-linear modeling, one obtains

$$\log \mu = X\beta$$

and for the general linear model, one obtains

$$\mu = X\beta$$

These equations illustrate that the general linear model and the log-linear model have the same form (see Agresti, 2012; McCullagh & Nelder, 1989; von Eye & Mun, 2013). Differences are evident in the link function and in the nature of the expected values. In regression and in analysis of variance, expected values are estimated for an observed variable, the outcome or dependent variable, typically in the units of this variable. In log-linear modeling, expected values typically are estimated for counts. By implication, main effects in regression or analysis of variance involve two variables, the independent and the dependent variables, and in log-linear modeling, main effects concern the distribution of the categories of just one variable. This applies accordingly to interactions.

Three ways of specifying log-linear models have been discussed. The first involves *hierarchical log-linear models*, the second involves *nonhierarchical models*, and the third involves *nonstandard models* (Mair & von Eye, 2007; von Eye & Mun, 2013). Log-linear models are hierarchical if

- all lower order relatives of terms included in a model are also part of the model;
- the model contains only terms that can be expressed within the hierarchy of effects; and
- no constraints are specified for parameters (except zero-sum constraints; see von Eye & Mun, 2013).

Log-linear models are nonhierarchical if

- they contain only a selection of the possible lower order relatives of the terms in the model; and
- if the second and the third condition for hierarchical models are also fulfilled.

Log-linear models are nonstandard if

- they contain terms that cannot be specified in the hierarchy of models; or
- if they include covariates, parameter constraints, or special effects that cannot be specified in the hierarchy of models.

In the following sections, we first present examples of log-linear models, and we review parameter interpretation. This is followed by a data example and a discussion of log-linear modeling in the context of person-oriented research. For the examples, consider the four categorical variables, A, B, C, and D. A first model that can be considered for these variables (and is not the null model of no effects) is that of variable independence. This model includes all main effects but proposes that there are no interactions. The model is

$$\log m = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D$$

where m is the vector of model frequencies, and the superscripts indicate the variables involved in the main effects. A second model could propose that A is associated with B and C is associated with D. This model is

$$\log m = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D + \lambda^{AB} + \lambda^{CD}$$

where the double superscripts indicate the associations (interactions) included in the model.

When, for instance, the main effect of any variable is removed from this model, for example, when, after removal of the main effect of A

$$\log m = \lambda + \lambda^B + \lambda^C + \lambda^D + \lambda^{AB} + \lambda^{CD}$$

researchers consider a nonhierarchical model. This model is nonhierarchical because the main effect of variable A that was removed is a lower order relative of the interaction between A and B.

An example of a nonstandard model is

$$\log m = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D + \lambda^{AB} + \lambda^{CD} + \lambda^{Covariate}$$

where the covariate is a term that cannot be expressed in terms of elements of a hierarchical model. Examples of covariates are continuous variables whose cell-specific averages are used as special effects.

Parameter Interpretation

The interpretation of log-linear model parameters is based on three arguments (von Eye & Mun, 2013). The first is statistical significance. To test the null hypothesis that an individual parameter is zero, researchers routinely employ t-tests. Second, the magnitude of parameters is of interest. Parameters can be transformed into odds ratios that have a natural interpretation. Third, and most important, is the meaning of a parameter. The meaning is expressed in terms of contrasts in the columns of the design matrix, X. For clear-cut parameter interpretation, that is, interpretation

that is independent of other parameters in the model, the λ parameters can be interpreted, based on X, as

$$\lambda = (X'X)^{-1}X' \log m$$

where X is the design matrix that contains, in its column vectors, the effects included in a model.

It is most important that the interpretation corresponds to the contrasts specified in the design matrix. To give an illustration of this type of parameter interpretation, we use the example given by von Eye and Mun (2013, p. 135). Consider a 2×2 table that results from crossing the variables A and B. For this matrix, we specify the saturated model, that is, the model with all possible parameters. The model is, in explicit form,

$$\begin{bmatrix} \log m_{11} \\ \log m_{12} \\ \log m_{21} \\ \log m_{22} \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix} \begin{bmatrix} \lambda \\ \lambda^A \\ \lambda^B \\ \lambda^{AB} \end{bmatrix} + \begin{bmatrix} \epsilon_{21} \\ \epsilon_{12} \\ \epsilon_{21} \\ \epsilon_{22} \end{bmatrix}$$

The first column vector of this model contains the logarithms of the observed cell frequencies. The first column vector in the design matrix represents the constant. The second, representing the main effect of Variable A, contrasts the first category of A with the second category. The third vector, representing the main effect of Variable B, contrasts the two categories of Variable B. The last column vector represents the A × B interaction. It results from element-wise multiplication of the main effect vectors of the interacting variables. After the design matrix follow the parameter and the residual vectors. One parameter is estimated for each effect, that is, each column in the design matrix.

The inner products (and the correlations) of any two of the vectors of the design matrix in the previous equation are zero. Therefore, parameter interpretation is easy. Inserting into

$\lambda = (X'X)^{-1}X' \log m$ yields, for the four parameters of this model,

$$\lambda = 1/4(\log m_{11} + \log m_{12} + \log m_{21} + \log m_{22}),$$
$$\lambda^A = 1/4(\log m_{11} + \log m_{12} - \log m_{21} - \log m_{22}),$$
$$\lambda^B = 1/4(\log m_{11} - \log m_{21} + \log m_{21} - \log m_{22}),$$
$$\lambda_{AB} = 1/4(\log m_{11} - \log m_{12} - \log m_{21} + \log m_{22}).$$

Each of these equations corresponds to the effects specified in the design matrix. This can be seen by the equal weights of the logarithms of the cell frequencies and the signs of each term. These are the same as in the design matrix. For more examples, and for examples of design matrices that do not possess this characteristic, see von Eye and Mun (2013).

Multiple approaches have been developed for log-linear analysis of longitudinal data. Models that come with a straightforward interpretation include those for which repeatedly observed variables are crossed (see, for example, von Eye & Mun, 2013). In the following data example, we present such a model.

Data Example

For the following example, we again use the data from the Finkelstein et al. (1994) study on the development of aggression. We ask whether the development of aggressive impulses over a span of 4 years (AI83 and AI87) is related to the development of physical aggression against peers (PAAP83 and PAAP85). For the following analyses, we dichotomize these variables at the grand median of aggressive impulses and the grand median of physical aggression against peers. This approach allows us to identify individuals who, overall, stay constant or display change relative to the average.

We estimate two models. The first is the model of variable independence,

$$\log m = \lambda + \lambda^{\text{AI83}} + \lambda^{\text{AI87}} + \lambda^{\text{PAAP83}} + \lambda^{\text{PAAP87}}$$

This model is estimated to have a reference for more complex models and to find out whether effects exist at all in the AI83 × AI85 × PAAP83 × PAAP87 cross-classification. For the model of variable independence, we obtain an overall goodness-of-fit maximum likelihood χ^2 of 56.50, which, for $df = 11$ suggests that this model fails to describe the data well ($p < 0.01$). We need a more complex model. Skipping the model development steps in which we successively added terms to the reference model, we describe the final model. This model includes the associations between the repeated observations of AI and PAAP as well as the cross sectional associations between AI83 and PAAP83 and AI87 and PAAP87. In other words, this is the model

$$\log m = \lambda + \lambda^{\text{AI83}} + \lambda^{\text{AI87}} + \lambda^{\text{PAAP83}} + \lambda^{\text{PAAP87}} + \lambda^{\text{AI83,AI87}} + \Lambda^{\text{PAAP83,PAAP87}} + \lambda^{\text{AI83,PAAP83}} + \lambda^{\text{AI87,PAAP87}}$$

The new terms are presented in the second row of the equation. The overall goodness-of-fit maximum likelihood

TABLE 18.2 Observed and Expected Frequencies for Log-Linear Model of the Development of Aggressive Impulses and Physical Aggression Against Peers in Adolescents

AI83 AI87 PAAP83 PAAP87	Observed frequencies	Expected frequencies
1111	24	24.49
1112	2	2.50
1121	12	12.82
1122	8	6.19
1211	4	4.79
1212	4	2.22
1221	4	2.51
1222	3	5.48
2111	8	7.22
2112	1	0.74
2121	10	9.47
2122	3	4.57
2211	6	5.50
2212	1	2.54
2221	6	7.21
2222	18	15.76

χ^2 of 6.64 suggests that, for $df = 11$, this model does describe the data well ($p = 0.47$). Table 18.2 displays the observed and the expected cell frequencies for this model. Table 18.2 shows that the observed and the expected cell frequencies are close to each other throughout. The largest standardized deviate is 1.20 (for cell 1212). This value is nonsignificant ($p = 0.12$), thus supporting the model. Table 18.3 displays the significance tests for the model parameters.

The significance tests in Table 18.3 suggest that, of the parameters of interest (these are the interactions), only one is nonsignificant (AI83 × PAAP83). We conclude that the auto-associations AI83 × AI85 and PAAP 83 × PAAP87 and the cross sectional association AI87 × PAAP87 are sufficient to explain the data in Table 18.2. There is no need to include the cross-lagged associations AI83 × PAAP87 and PAAP83 × AI87. Before finally retaining this model, we ask whether the parameters of interest come with a clear-cut interpretation. This is the case. The column vectors of the design matrix (not shown here) correlate to zero, and each of the parameters can be interpreted as specified in the design matrix.

We present one example, the parameter for the interaction between AI83 and AI87. This parameter has the interpretation

$$\begin{aligned}\lambda^{AB} = 1/16 \log m_{1111} + \log m_{1112} + \log m_{1121} + \log m_{1122} \\ - \log m_{1211} - \log m_{1212} - \log m_{1221} - \log m_{1222} \\ - \log m_{2111} - \log m_{2112} - \log m_{2121} - \log m_{2122} \\ + \log m_{2211} + \log m_{2212} + \log m_{2221} + \log m_{2222}\end{aligned}$$

We, therefore, retain the model. The substantive interpretation of this model is that self-perceived aggressive impulses and physical aggression against peers are stable over a span of four adolescent years and that, at age 15 (but not at age 11), aggressive impulses are significantly related to physical aggression against peers.

Discussion

The example given in the last section illustrates standard log-linear modeling. Many other and more complex models have been proposed (see, e.g., Agresti, 2012; von Eye & Mun, 2013). Examples of such models include logistic regression models (which can always equivalently be expressed in terms of log-linear models; see von Eye, Mair, & Bogat, 2005), latent class models, mixture distribution models, or path models. Even some IRT models can be expressed in terms of log-linear models (Meiser, 1996). Clearly, one of the greatest benefits of using log-linear models lies in their generality. We now ask whether log-linear models can be used for person-oriented research. This is possible in a number of designs.

First, log-linear models allow researchers to naturally include classification or stratification variables. This is possible when sampling is multinomial, that is when every

TABLE 18.3 Parameters of the Model of the Development of Aggressive Impulses and Physical Aggression Against Peers in Adolescents

Term tested	The model without the term				Removal of term from model		
	LOG(MLE)	Chi-square	df	*p*-value	Chi-square	df	*p*-value

AI83*AI87	−37.025	18.210	8	0.020	11.568	1	0.001
PAAP83*PAAP87	−37.662	19.484	8	0.012	12.842	1	0.000
AI83*PAAP83	−33.954	12.068	8	0.148	5.425	1	0.020
AI87*PAAP87	−37.940	20.040	8	0.010	13.398	1	0.000

new case can, in principle, be assigned to any cell of a cross-classification, but also when sampling is product-multinomial, that is, when the number of cases in a stratum or group of respondents is determined a priori. Parameter estimation is the same for both cases, but there are constraints concerning the models that can be estimated. In product-multinomial sampling designs, the estimated model must always reproduce the marginal probabilities of the variables for which these probabilities are fixed. In either case, log-linear models allow one to compare groups of individuals. The comparison can result in interactions that indicate the variable relations that are group-specific.

Alternatively, one can estimate Mantel-Haenszel-type statistics that allow one to answer the question whether interactions differ across groups (for an overview, see Fidalgo, 2005). The important characteristic of the log-linear methods that allow one to compare groups of individuals, under certain conditions and over time, is that this comparison already represents an approach to person-oriented research. These comparisons presuppose that researchers hypothesize that the comparison groups differ from each other, for example in a conditional pattern of interactions among variables. The only condition that must be met for this comparison is that of dimensional identity. Variables must have the same meaning for all comparison groups.

Interestingly, if interaction patterns are defined to be constituting elements of dimensional identity, there should be no differential interaction patterns. If, however, a researcher asks whether such patterns vary across comparison groups under the condition that, otherwise, dimensional identity prevails, results of such a comparison would indicate where dimensional identity is violated (if groups differ). This result in itself amounts to a statement of interest to person-oriented researchers. If, in contrast, interaction patterns are not part of the definition of dimensional identity, a study on differential interaction patterns can be of interest to person-oriented, idiographic, and differential developmentalists alike.

In brief, when dimensional identity can be made plausible, the comparison of a priori existing groups is of interest from a person-oriented research perspective. In this respect, log-linear models are comparable to analysis of variance (von Eye & Bogat, 2007) and structural modeling. In many instances, however, researchers just assume that multiple populations exist. Number and size of these populations are unknown. In these cases, groups need to be identified and group differences need to be established. Groups can be identified by using such methods as cluster analysis, latent class analysis, or mixture distribution decomposition.

It is important to realize that group differences can manifest in any parameter-(s). When metric variables are on the outcome side, mean differences can be examined (ANOVA). When variables are categorical, marginal distributions can be compared. In either case, groups can differ in variances, covariances, factor structures, parameters of structural models, trajectories, validity and reliability of variables, or any combination of these. Person-oriented researchers are interested in all of these.

It is also important to realize that groups may not come in prespecified sizes. Groups can be as large as standard populations and as small as just one individual. Person-oriented as well as idiographic developmental research recommend estimating parameters first at the level of the individual. Aggregation is done at the level of parameter estimates, if it is done at all. The development of methods of analysis of individual data and small group-data needs to make progress for this to be possible. Fortunately, methods for the analysis of single-subject data, in particular longitudinal data, are being developed at a rapid pace and integrated into the canon of methods for the analysis of longitudinal developmental data (e.g., Dolan, Molenaar, & Boomsma, 1989; Molenaar, 1997; Molenaar, Huizenga, & Nesselroade, 2003; Molenaar & Newell, 2010; Rovine, Molenaar, & Corneal, 1999). This development includes metric as well as categorical outcome variables (van Rijn, 2008; van Rijn & Molenaar, 2005).

Cluster Analysis

Taxometric methods, in particular cluster analysis, are the most frequently used methods for the identification of groupings that are unknown before analysis. Using these methods, one can extract groupings from a data set that contain members that

- are maximally similar to each other, while being
- maximally dissimilar to members of other groupings

The number of taxometric methods is very large. The decision about which method to select is important, because results can differ dramatically depending on the method selected. von Eye, Mun, and Indurkhya (2004) present an example of an artificial data set that can lead to classifications that are completely unrelated to each other when different taxometric methods are used. Specifically, the cross-classification of the clusters created for this data set comes with a $\chi^2 = 0.0$.

The most fundamental issue with taxometric methods concerns the measurement of the degree of similarity or

dissimilarity between individuals. The choice of which variables to include in the profile to be analyzed and the type of similarity or dissimilarity measure to be used must be carefully considered and theoretically motivated. The scaling of the variables must be commensurable and, in most cases, continuous variables must be standardized before analysis (see Bergman, Magnusson, & El-Khouri, 2003, for exceptions).

In the following section of this chapter, we first present a specification of the taxometry problem. We then review, discuss, and extend eight decisions to be made when selecting a taxometric procedure for person-oriented researchers by von Eye et al. (2004). This is followed by a data example.

Taxometry: Specification of the Problem

To illustrate the problem, we use a data example. We use Finkelstein et al.'s data on the development of aggression again. In this study, the variable self-perceived Aggressive Impulses (AI) was observed three times, in 1983, 1985, and 1987, in a sample of 114 adolescents (67 females). The trajectories AI are depicted in Figure 18.4, by Gender.

Figure 18.4 shows that all possible patterns of ups and downs were observed, and that not a single adolescent gave the same responses at all three occasions. Now, proceeding as von Eye et al. (2004) with the artificial data set, we illustrate that two cluster solutions of the same data can result in quite different classifications. We apply two methods of clustering to the aggressive impulse data, thus creating clusters of trajectories of aggressive impulses during adolescence, and then examine the cross-classification of these two cluster solutions. We create a first cluster solution by using the popular Ward method, based on Euclidean distances between the trajectories. We create the second solution with Ward's method again, but, this time, based on the correlations between the trajectories. For the distance-based classification, we select the four cluster solution, and for the correlation-based classification, we select the three cluster solution. The cross-classification appears in Table 18.4.

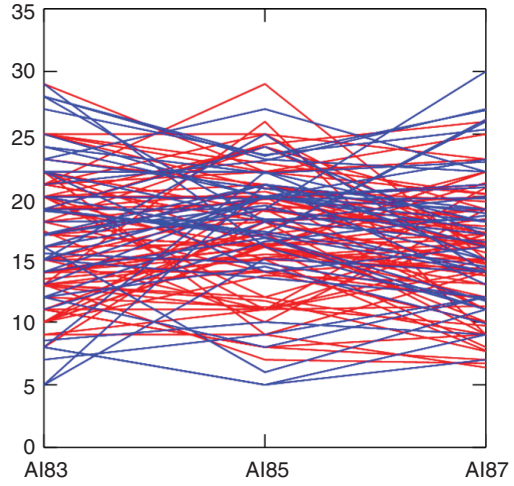

Figure 18.4 Developmental trajectories of self-perceived aggressive impulses in 114 adolescents. See footnote 1.

TABLE 18.4 Cross-Classification of Two Cluster Solutions

	1	2	3	Total
1	21	9	0	30
2	20	9	0	29
3	24	15	1	40
4	3	12	0	15
Total	**68**	**45**	**1**	**114**

Table 18.4 shows that the clusters of the distance-based solution differ in size (row totals), but each contains at least 14 of the 114 cases of the sample, that is, more than 13% of the total. In contrast, the three clusters of the correlation-based solution differ dramatically in size. The smallest cluster contains a singleton, that is, just one individual. The largest contains 68 respondents, that is, almost 60% of the total. The cross-classification of the two cluster solutions created for the aggression data comes with a $\chi^2 = 14.25$. For $df = 6$, this value suggests that knowledge of one of the two cluster solutions also contains information about the second solution ($p = 0.03$). One might be tempted to interpret this result as indicating that the two solutions are *similar*. Fact is, however, that not one of the clusters from the distance-based solution remains intact when the two solutions are crossed. Each of the two larger clusters of the correlation-based solutions feeds from the four clusters of the distance-based solution. The singleton of the correlation-based solution is a peaceful member of the third cluster of the distance-based solution. We now proceed to the specification of the taxometry problem.

In this section, we give a general definition of the clustering or classification problem (Bock, 1974, p. 22; Hartigan, 1975). Consider N objects (i.e., cases), $O_1, \ldots, O_N$. For these objects, a data matrix, x_{ki}, a similarity matrix,[10] d_{jk}, or a relation, $\prec$, can be calculated, the elements x_{ki}, d_{jk}, or $\prec$ of which represent the similarity structure of the set of objects, $S = \{O_1, \ldots, O_N\}$. Searched for is a *classification*,

[10] In later sections of this section we also discuss distance matrices. For the present purposes, we specify that the term *similarity matrix* subsumes distance matrices and other matrices that can be created to describe relations between objects.

$A = (A_1, A_2, \dots)$ of S. The subsets of this classification, that is, $A_1, A_2, \dots$ are classes (groups or clusters) that reflect the similarity structure of the objects, and imply data reduction. These two requirements can be fulfilled if both the objects within a group are maximally similar to each other and cross-class dissimilarity is maximized. The first characteristic is called *homogeneity*; the second is called *separation*. In the following sections, we review and extend the decisions that von Eye et al. (2004) discussed for the selection of a method of clustering.

Decisions for Clustering

von Eye et al. (2004) considered the following eight cluster characteristics: clusters are (1) disjoint versus overlapping; (2) hierarchical versus nonhierarchical; (3) agglomerative versus divisive; (4) exhaustive versus selective; (5) stochastic versus deterministic; (6) based on correlation versus distance measure; (7) convex versus nonconvex; and (8) represent manifest versus latent variables. The authors also discussed methods of classification that are based on such a priori set criteria as cutoffs or ranges of admissible scores and natural classifications that result from cross-classifying categorical variables. Here, we focus on taxometric clustering and on natural classifications. Cross-classifications of categorical variables are discussed in the earlier section on log-linear modeling.

Before discussing the eight criteria, it should be emphasized that there is no such thing as a true cluster solution. Instead, researchers use classification algorithms to structure data. The resulting clusters or groups reflect characteristics of the methods that were applied as well as data characteristics. Different methods are sensitive to different data characteristics. Therefore, different cluster solutions describe different data characteristics to the extent that different clustering methods are capable of depicting them.

Criterion 1: Disjunct Versus Overlapping Clusters

Disjunct classifications have the characteristic that each object O_j belongs to only one class, A_i, or cluster. In contrast, overlapping classifications allow each object O_j to belong to more than one class. Rarely, clusters naturally will be completely disjunct. Groups of cases will exist that are not easily assigned to a group. How can one deal with situations of this kind? We discuss two solutions. First, one can create nonoverlapping clusters by changing cluster parameters. This can be achieved by, for instance, reducing the diameters of clusters as long as necessary for them to no longer overlap. The number of cases located outside clusters will increase as the diameters shrink. This way, the overlap can be reduced to zero. The cases not located inside the (imaginary) cluster hull can be (1) treated as a separate group, (2) considered members of no cluster, (3) assigned to clusters at random, (4) assigned to the cluster to which they most likely belong, or (4) allowed to form separate small groupings, even singletons.

Second, one can consider whether overlapping cluster solutions may be natural or appropriate. There may be cases for which it is reasonable to assume that they belong to more than one group. For instance, an athlete may be both a soccer and a basketball player, or a student may be both a stellar performer and a political activist.

Separation of clusters indicates the degree to which clusters are disjunct. Separation can be measured only if groupings are created that are allowed to overlap. If groupings are not naturally disjunct—groupings based on manifest categorical variables are naturally disjunct—the idea that clusters are nonoverlapping clusters is perceived, by some, as artificial. Therefore, application of methods that create nonoverlapping clusters by default may require justification.

Based on this, it is surprising that a look at the literature suggests that, in empirical applications of clustering methods, researchers overwhelmingly use methods that result in nonoverlapping clusters. Similarly, most statistical software packages do not even include methods that allow researchers to create disjunct clusters. Two programs that provide this option include ADCLUS by Arabie and Caroll (1980) and Pyramid by Aude, Diaz Lazcoz, Codani, and Risler (1999; Everitt, Landau, & Leese, 2001).

Criterion 2: Hierarchical Versus Nonhierarchical Clusters

Classification algorithms can create solutions that are either hierarchical or nonhierarchical. A strength of a hierarchical cluster analysis is the simple relationship between solutions with different numbers of clusters. (For instance, a six-clusters solution is identical to a seven-clusters solution except that two clusters of the second solution are fused to constitute one cluster in the first solution.) This information is helpful for understanding the classification structure and in choosing the number of clusters. It also makes it feasible to present findings based on both a fine-grained classification with many clusters and a simpler classification with fewer clusters (since the relationship between the two classifications is straightforward and easily explained).

Hierarchical clustering algorithms create series of cluster solutions. The series are either *agglomerative* or *divisive*. Agglomerative series result from grouping objects together

into larger and larger groups. One of the chief characteristics of agglomerative hierarchical procedures is that smaller numbers of clusters result from merging clusters. Cases who were members of the same cluster will stay members of the same cluster. Divisive procedures are hierarchical if they create greater numbers of clusters by splitting larger clusters (the choice between agglomerative and divisive algorithms is discussed later under Criterion 3). A clustering method is hierarchical if cases that are members of the same cluster when clusters contain fewer cases are members of the same cluster when the cluster contains more cases. The results of hierarchical clustering are routinely displayed in the form of dendrograms (cluster trees). Figure 18.5 displays the dendrogram that results when Ward's method, based on Euclidean distances, is used to cluster the aggressive impulses trajectories shown in Figure 18.4.

Clustering algorithms are nonhierarchical when they create just one solution instead of a series of solutions. Examples of such procedures include methods that identify space density maxima and assign objects to the cluster that is defined by the nearest density center. Examples of such algorithms include the methods discussed by von Eye and Wirsing (1978, 1980) and the well-known k-means method. The number of clusters in nonhierarchical clustering is either user-determined as in k-means, or is determined by the number of space density maxima that were found based on a priori specified criteria. Hierarchical methods always create $N - 1$ solutions. A decision as to which solution to interpret is a key part of hierarchical cluster analysis.

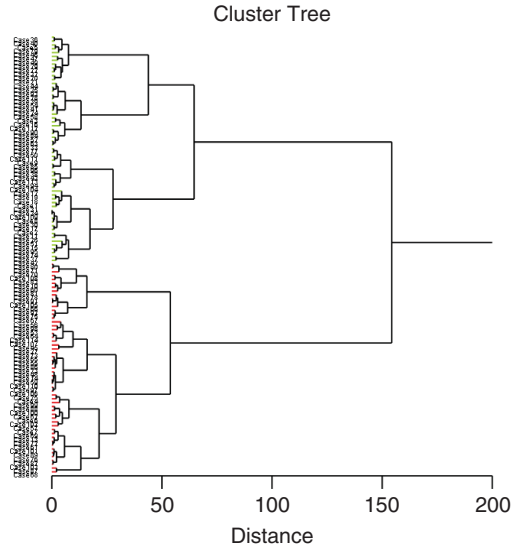

Figure 18.5 Dendrogram of Ward's clustering of aggressive impulses in adolescents. See footnote 1.

Several methods have been proposed to select from the hierarchy of cluster solutions. One involves examining a distance scale as the one used for the x-axis in Figure 18.5. Based on distance scales, the solution is selected that fulfills two conditions:

1. The number of clusters is near the desired number (see Bergman's, 2000, postulate of targeting a number of 4–10 clusters)
2. A large increase in the distance scale value has occurred

When these two conditions are fulfilled, one selects the solution right before the large increase on the distance scale. This large distance suggests that two heterogeneous clusters (clusters that are far apart from each other) had been fused into one. In the example in Figure 18.5, many researchers will select either the four- or the two-cluster solution. Because of weaknesses of selecting solutions based on distances, many other cluster evaluation methods have been discussed. Among these are methods that use various forms of the Rand Index (1971). This index measures the similarity between two cluster solutions, for example a random solution and the solution preferred by the researchers. Recent investigations have shown that the Hubert-Arabie-adjusted Rand index performs well in cluster solution evaluation (Steinley, 2004; Volkovich, Avros, & Golani, 2011). Interestingly, it has been shown that the Hubert-Arabie-adjusted Rand index is a twin of the well-known Cohen's kappa (Cohen, 1960; Warrens, 2008).

The choice between hierarchical or nonhierarchical methods can be based on two criteria. The first is whether the hierarchy of cluster solutions can be interpreted. When this is the case, hierarchical methods are selected. When, however, the series of cluster solutions is not interpreted or not interpretable, and when researchers have expectations concerning the number of clusters, nonhierarchical solutions may be selected. Only a very small number of solutions—maybe only one—needs to be calculated, and interpretation is typically straightforward. The second criterion is thus the extent to which researchers use prior knowledge when performing a cluster analysis.

Criterion 3: Agglomerative Versus Divisive Clustering

In this section, we discuss the choice between *agglomerative* and *divisive* clustering. Agglomerative clustering starts under the assumption that each object, O_j, constitutes a separate cluster. With the goals of reducing redundancy and creating a parsimonious solution, agglomerative methods join the clusters (at the beginning of the procedure, these are all individuals) that are the most similar to each

other, or, in more general terms, clusters are joined when some loss, measured, for instance, in units of decrease in information, increase on a distance scale, or difference in R^2, is minimal. This is repeated until either a stopping criterion has been reached or until the final two groupings are joined.

Divisive clustering considers, before the first step is taken, all case members of one large cluster. Beginning with the second step, divisive clustering splits the existing cluster(s). This is done such that a benefit, measured in units similar to the ones used for agglomeration, is maximized. This step is repeated until either a stopping criterion, for instance, some R^2 threshold, has been reached or until each individual constitutes its own cluster. Evidently, what is the starting point for the agglomerative procedure is the end point for the divisive procedure.

The results of both agglomeration and division clustering can be depicted in the form of *dendrograms* (tree structures). Consider, again, Figure 18.5. If the dendrogram in this figure is the result of agglomeration, we read Figure 18.3 from left to right. At the left of the dendrogram, each individual is represented. In the first steps, the most similar objects are joined to form one cluster. In each of these steps a new cluster is created. Relatively soon, clusters are joined. In the last step, the clusters that resulted from the first $n - 2$ agglomeration steps are joined, and every case belongs to the one and only cluster. Researchers interpret the solution that best meets optimality criteria as the ones discussed previously, plausibility criteria, and criteria derived from theory.

To illustrate the divisive procedure, we use Figure 18.5 again. This time, however, we read it from right to left. Before the first step (at Step 0), the procedure considers all objects members of one big cluster. Beginning with Step 1, this big cluster is subdivided into ever smaller clusters, until each object constitutes its own cluster. As for all hierarchical procedures, criteria of optimality, theory, and plausibility can be used to select a solution.

When deciding which of the two procedures to select, agglomerative or the divisive clustering, researchers keep in mind that results from both methods are often the same. Therefore, method selection is largely guided by preferences and program availability. Most software packages offer exclusively agglomerative procedures. Examples of agglomerative procedures that are available in many software packages include Single Linkage (aka Nearest Neighbor), Complete Linkage (aka Furthest Neighbor), Average Linkage, Centroid Clustering, Median Clustering, Weighted-Average Linkage, Beta-Flexible, Density Linkage, and Ward's method.

Criterion 4: Exhaustive Versus Nonexhaustive Clustering

Classifications are *exhaustive* if every case, O_j, belongs to a cluster. Nonexhaustive classifications involve only some of the N objects. The cases assigned to clusters are sometimes called the *most important* objects. Cases not assigned to a cluster are often either ignored or discarded and thrown into a *poubelle*, that is, a garbage can. From a person-oriented perspective, the distinction between exhaustive and nonexhaustive classifications is not always conclusive. If a researcher assumes that populations can be as small as just one individual, nonclassified cases constitute classes also. In addition, Bergman (1988) suggested that it may be wise not to assign all cases to a grouping under all conditions. He called these unclassified cases a residue and argued that it can be important to remove them before cluster analysis for both theoretical reasons (true unique cases) and practical reasons (an outlier could be caused by errors of measurement that can distort the findings of a cluster analysis). Further, he did not regard them as a *poubelle* but as important cases to be analyzed separately and claimed that the proportion of residue cases in the sample can provide important information about the classificability of the data set. Still, in most applications, singletons (one-case clusters) are considered cases that are not classified. Even clusters with only two cases are often ignored in follow-up analyses or assigned to the poubelle.

One way to illustrate nonexhaustive classifications involves configural frequency analysis (CFA; Lienert & Krauth, 1975; von Eye, 2002; more detail on CFA can be found in the chapter on CFA in this volume). CFA examines cross-classifications of categorical variables under the question whether the observed number of cases in a cell differs from the expected number. If the null hypothesis of no difference is rejected for a cell, CFA states that this cell constitutes a type if more cases than expected were found, and an antitype, if fewer cases than expected were found. It is a routine result of CFA that only a selection of cells constitutes types and antitypes. The frequencies in other cells do not deviate from expectancy. The designation as 'belongs to a CFA type' or 'belongs to a CFA antitype' is, therefore, nonexhaustive.

Many methods of classification can create exhaustive as well as nonexhaustive solutions. In hierarchical classifications, a nonexhaustive solution would include one or more singletons or clusters that contain only two or three objects. In nonhierarchical classification, one can create solutions with relatively large numbers of clusters. Some of these may then contain very small numbers of cases. It is important to note that classification methods differ in their tendencies

to yield small clusters. Methods that build clusters by letting objects gravitate toward a center of gravity (centroid) tend to allow larger clusters to swallow smaller clusters. Examples of such methods are the centroid method, complete linkage, average linkage, and Ward's method.

Pros and cons for exhaustive versus nonexhaustive classification are evident. On the pro side of exhaustive classification is that every object is assigned to a group. By implication, the sample under study is not reduced in size. At the expense of this strategy is, however, that, for some cases (e.g., outliers), it may be unnatural to belong to a group. Also on the con side of exhaustive clustering is the possibility that single-case clusters result. In follow-up analyses, researchers often experience problems with single-case clusters because individual cases can be hard to statistically compare with other clusters. For instance, multivariate analysis of variance (MANOVA) can be problematic for subsequent comparisons when one or more cells contain only one case.

Criterion 5: Stochastic Versus Deterministic Clustering

Stochastic models consider data points realizations of random variables. This seems appropriate under the following assumptions: (1) there is natural variation within each grouping; (2) the manifest variables that are used for classification are measured with error; and (3) the cases used for classification are a random sample. When these assumptions are met, stochastic models allow researchers to test hypotheses concerning possible group structures. In contrast, *deterministic models* consider data points fixed sets of objects. Variability is not considered random.

Pros and cons of these two approaches are evident. Among the pros of stochastic models is that statistical decisions about hypotheses that are compatible with the existence of groupings (substructures) become possible. One downside is that a null hypothesis for the existence of a particular grouping structure is not always easily specified. Among the pros of deterministic models is that parametric assumptions do not need to be made. Another downside is that existing error structures are ignored.

The question as to which of the two approaches, stochastic and deterministic clustering, is preferred by users, comes with a clear answer. Most applications use deterministic models. There certainly are multiple reasons for this preference. One reason may be that deterministic models seem easy to interpret. Another reason is that programs for stochastic clustering are part of only a few of the general purpose statistical software packages; S-plus, R, and SAS are among these.

An example of stochastic classification can be seen in a method introduced by von Eye and Gardiner (2004; von Eye & Bogat, 2005). The authors propose splitting the multivariate space of the variables to be used for classification into sectors. For each sector, the probability is estimated from the data under a hypothesis of *data generation*. Examples of data generation processes are those that generate multinormally distributed data, or uniformly distributed data. Based on the estimated probability, an expected frequency can be calculated, which then is compared with the frequency that was observed for this sector. Algorithmically, the following six steps are performed.

1. Splitting each of the d variables into c_j segments, with $c_j > 1$ and $j = 1, \ldots, d$, where j indexes the variables;
2. Crossing the segmented variables; this results in a cross-classification with $\Pi_j\, c_j$ sectors;
3. Estimating the probability of each sector. Typically, these probability do not exist a priori. Therefore, they are estimated from the data. Each of the $\Pi_j\, c_j$ sectors has the boundaries c_i^1 and c_{i+1}^1 on the first variable, c_j^2 and c_{j+1}^2 on the second variable, …, and c_l^d and c_{l+1}^d on the d-th variable, where the subscripts indicate the segments and the superscripts indicate the variables. The probability of being located in the sector with these boundaries is

$$p\left(z_i^1 - z_{i+1}^1, z_j^2 - z_{j+1}^2, \ldots, z_l^d - z_{l+1}^d\right) = \int_{z_i^1}^{z_{i+1}^2} \int_{z_j^2}^{z_{j+1}^2} \cdots \int_{z_l^d}^{z_{l+1}^d} \Psi\left(z^1, z^2, \ldots, z^d\right) \mathrm{dz}^1\, \mathrm{dz}^2 \ldots \mathrm{dz}^{\mathrm{d}}$$

   A numerical solution for this expression was proposed by Genz (1992).
4. Estimating expected sector frequencies as $e_{i,j,\ldots,l} = Np_{i,j,\ldots,l}$, where $p_{i,j,\ldots,l}$ is short for the expression given in the last equation.
5. Performing sector-specific tests. The null hypothesis for each of the tests is $E[o_{i,j,\ldots,l}] = e_{i,j,\ldots,l}$, where $o_{i,j,\ldots,l}$ is the observed frequency for the sector with subscripts $i, j, \ldots, l$. The tests can be performed using most of the residual tests from log-linear modeling. These include, for example, the Pearson X^2–component test, $X_{i,j,\ldots,l} = (o_{i,j,\ldots,l} - e_{i,j,\ldots,l})^2/e_{i,j,\ldots,l}$, where $o_{i,j,\ldots,l}$ is the observed frequency for the sector with subscripts $i, j, \ldots, l$, and $e_{i,j,\ldots,l}$ is the corresponding expected frequency. α-protection is advisable.

Based on the sector-specific test, an omnibus test can be devised by summing up the X^2–components. The resulting summary statistic can be used to test whether, overall, the cross-classification of segments follows a multinormal distribution. The test is approximately distributed as χ^2 with $df = (\Pi^d{}_{j=1} c_j) - 2d - d_{cov} - 1$, where c_j is the number of segments of the jth variable. The term d_{cov} indicates the number of covariances taken into account, typically $d_{cov} = (d)$. That is, typically all covariances are taken into account.

6. Changing the number of segments and restarting at Step 1. This sequence of steps is repeated until the clusters (sectors) are detected that contain significantly more (or fewer) cases than expected. A data example follows after all of the eight criteria have been reviewed.

Criterion 6: The Selection of Base Measures

Many clustering methods start from an $N \times N$ similarity matrix, e.g., a covariance matrix, a correlation matrix, a distance matrix, or a matrix that contains coefficients that count [in percent] the number of incidences in which two objects' characteristics match. The coefficients in such similarity matrices are termed *base measures*. The results of simulation studies suggest that "... resulting clusters depend more on the underlying similarity criterion than on the physical process of cluster formation" (Wishart, 1970, p.1).

The most popular base measures used in applications are Pearson's correlation, r, and the Euclidean distance. Correlation measures classify objects as identical if their profiles are parallel. r is not sensitive to differences in standard deviation, mean, or both. Distance measures quantify spatial distance, regardless of whether profiles are parallel or not. Correlation and distance scores coincide only if the distance, $d = 0$. For an illustration of these relations, see von Eye, Mun, and Indurkhya (2004).

When it comes to selecting from the many available base measures, it is important to keep in mind that, as we said earlier in this section, there is no true cluster solution. Clustering algorithms, in particular base measures, are sensitive to specific data characteristics, but not to others. Therefore, before selecting a base measure, researchers can do worse than answering the question concerning the data characteristics they wish to base their cluster solution on. For example, when spatial proximity is considered, the focus is on level or magnitude of behavior over time, or, if there exists a distinction that separates top from bottom clusters of developmental trajectories, a distance measure makes sense. It should be noted that variables must be commensurable when Euclidean distances are selected. If variables are not commensurable, variables with larger scores and variances can dominate the cluster solution. When, however, the similarity of profiles is of importance, that is, the degree to which profiles are parallel, trend characteristics are more interesting than levels, when researchers are interested in shape, fluctuation, or curvature similarity, and that regardless of possible differences in location and spread, a correlation measure may be more appropriate.

In some instances, a selection of a particular base measure may be hard to justify. In these instances, two strategies can be considered. First, one can create classifications using a selection of base measures. The inspection of the resulting classifications may reveal that some are more meaningful than others. A second strategy can involve using base measures that possess the characteristics of distance as well as correlational base measures. An example of such a coefficient is Cattell's (1949) coefficient, r_P. This coefficient is sensitive to profile shape, mean differences, and differences in standard deviations. To the best of our knowledge, however, this coefficient is not included in any of the general-purpose statistical software packages.

Criterion 7: Convex Versus Nonconvex Clusters

The shape of clusters can be of importance, for at least two reasons. First, when clusters take a shape that can be depicted, for example, in the form of an ellipsoid or a rectangle, verbal description of clusters will be straightforward as well. Second, when new objects are classified based on an existing cluster structure, one can ask whether these objects are located within the (imaginary) hull that represents a cluster. Many classification methods do create clusters that are *convex* in shape. Subsets (clusters) A_i are convex if any two points (cases), O_i and O_j, for $i \neq j$, can be connected by a straight line that is entirely located within A_i. Examples of convex clusters include ellipses, squares, circles, rectangles, and other types of quadrics (von Eye & Wirsing, 1978, 1980).

A number of classification methods, however, create *nonconvex* clusters. Examples include algorithms that create clusters that can take the shape of bananas. These clusters are not convex because connecting straight lines between data points can be located outside the cluster hull. Among the classification methods that yield nonconvex clusters is the *single linkage* algorithm. This algorithm agglomerates clusters based on the shortest distance of any cluster member with another element that did not belong to the cluster before. Thus, it tends to create chains rather than convex agglomerates. Hartigan (1975) noted

that "single linkage clusters are famously strung out in long sausage shapes, in which objects far apart are linked together by a chain of close objects" (p. 200) (for graphical illustrations see Hartigan, 1975, pp. 201, 202).

Usually, researchers opt for convex clusters because they can be described by using measures of central tendency or parameters that represent their hull. In particular instances, however, chain structures may be interpretable. This can be the case, for example, when events such as the next best step are grouped or social network structures.

Criterion 8: Manifest Variable Versus Latent Variable Grouping

The clustering algorithms discussed thus far in this chapter operate at the level of *manifest*, that is, observed variables. Cases are classified based on their relative distances or similarities. The resulting clusters are described also at the level of manifest variables. In contrast, there are methods that create *latent*, that is, unobserved variables, based on relations among manifest variables. As in structural equation modeling or factor analysis, these latent variables are specified to explain the covariation among the observed variables. Most popular among these methods are *latent class analysis* (LCA; Lazarsfeld & Henry, 1968; Rost & Langeheine, 1997), and latent class mixture models (LCMM; Muthén, 2001; Nagin, 1999). In this section, we briefly review these methods of latent variable grouping.

LCMM is a variant of latent growth curve modeling that is used to depict heterogeneous latent classes of trajectories. In a first approach, Muthén (2001) used baseline data to cluster cases. Then, a latent variable structure is specified to model classes' trajectories. The method is Bayesian and classes' trajectories are conditional on class membership. For evaluation, this method uses posterior predictors of class membership. In a second approach, the semiparametric, group-based approach introduced by Nagin (1999) enables researchers to model data with reference to the zero-inflated Poisson, censored normal, and binary logit distributions. A unified approach that combines these methods with IRT and multilevel modeling was recently proposed by Hsieh and collaborators (Hsieh, von Eye, & Maier, 2010; Hiseh, von Eye, Maier, & Chen, 2013).

Unobserved latent classes are defined to explain individual differences from the aggregated developmental trajectory in a population. Fixed-effect growth, that is, a fixed trajectory, is hypothesized for each class. That is, all members of one latent class are hypothesized to exhibit the same within-class developmental trajectory. The trajectories are class-specific, that is, trajectories vary across classes.

LCA of categorical variables is based on the concept of *local independence*. For each latent class, the joint probability of the observed frequencies is expressed as the product of the marginal probabilities. In other words, within each latent class, the observed variables are independent. Note, however, that local independence is a common characteristic only of the original latent class models. Mixed Markov models, in particular those for longitudinal data, do not create latent classes based on the restriction of local independence (Langeheine & van de Pol, 1993).

When it comes to describing individuals, LCA models share the characteristic that all members of a latent class have the same response probabilities for the categories of the variables included in an analysis. In other words, individuals within the same latent class are treated as identical both in their developmental trajectories and their response probabilities. In addition, members of a latent class are different than individuals in other latent classes who are also considered identical to each other. This concept is more restrictive than the concepts used in cluster analysis where members of a cluster can differ from each other but are, on average, more similar to each other than to members of other clusters.

Many researchers consider LCA the categorical variable analogue to factor analysis (Molenaar & von Eye, 1994). In the context of classification, the analogy to cluster analysis may be more interesting: LCA can also be considered a method of cluster analysis for categorical variables.

Data Example

For the following example, we reanalyze data used by von Eye and Bogat (2005). The data were collected for the first wave of a longitudinal study examining male violence toward their female partners and their children. When the women were pregnant, they were given a structured interview (the Working Model of the Child Interview; Zeanah, Benoit, Hirshberg, Barton, & Regan, 1994) to assess their perceptions and subjective experiences of their unborn children. The interviews were audio taped, transcribed, and coded on 5-point Likert scales. The three variables analyzed here—fear, joy, and anxiety—represent affective features of maternal representations (for more detail see Huth-Bocks, Levendosky, Theran, & Bogat, 2004). Each scale was coded so that low scores represent low levels of the mood represented by the scale.

We now analyze these variables using three taxometric methods, complete linkage, Ward's method, and the space-segmenting method proposed by von Eye and Gardiner (2004; von Eye & Bogat, 2005). The selection of these three methods can be explained as follows. The first

two methods are both hierarchical. We use the Euclidean distance as base measure to make results comparable and because the space-segmenting method is sensitive to agglomerations in data space as well. Of the two hierarchical algorithms, Ward's method is known for small groupings to be swallowed by larger groupings. Therefore, we expect larger clusters to result from this method than from complete linkage. The space-segmenting method can be based on the assumption of multinormality. It is, thus, a stochastic method. The other two are deterministic. All three of the methods used here are exhaustive although, theoretically, singletons could result from either hierarchical method and the space segmenting method could result in empty sectors and sectors with very small numbers of cases.

Based on the distance scales in the dendrograms (not shown here), we select for both hierarchical methods the three-cluster solution. The density plots of the three clustering variables for the three clusters from Ward's method are given in Figure 18.6. The corresponding plots for the three clusters from complete linkage are given in Figure 18.7.

Cluster 1 from Ward's method contains 48 cases. It is the smallest of the three clusters. Women in this group report average levels of fear, above average levels of joy, and slightly above average levels of anxiety. Cluster 2 is the largest cluster. It contains 103 women. These women report below average levels of fear, average levels of joy, and below average levels of anxiety. The 50 women in the third cluster report slightly above average levels of fear, clearly below average levels of joy, and elevated levels of anxiety.

Cluster 1 from complete linkage is the same as Cluster 1 from Ward's method. Cluster 2 contains 67 women who report below average levels of fear, a rather wide range with an average close to the scale midpoint of joy, and below average levels of anxiety. Cluster 3 contains 86 women who report slightly below average levels of fear, below average levels of joy, and elevated levels of anxiety.

We do not see any problems interpreting any of these profiles. More important, however, for the present discussion is that the two hierarchical solutions overlap only in part. This is shown in the cross-tabulation of the two cluster solutions in Table 18.5.

Table 18.5 shows that the first clusters from both methods contain the same respondents. The big second cluster from Ward's method is split such that 67 of the 103 women are in the second cluster from complete linkage, and the remaining 36 women are now in the third cluster from complete linkage. The third cluster from Ward's method goes entirely into the third cluster from complete linkage.

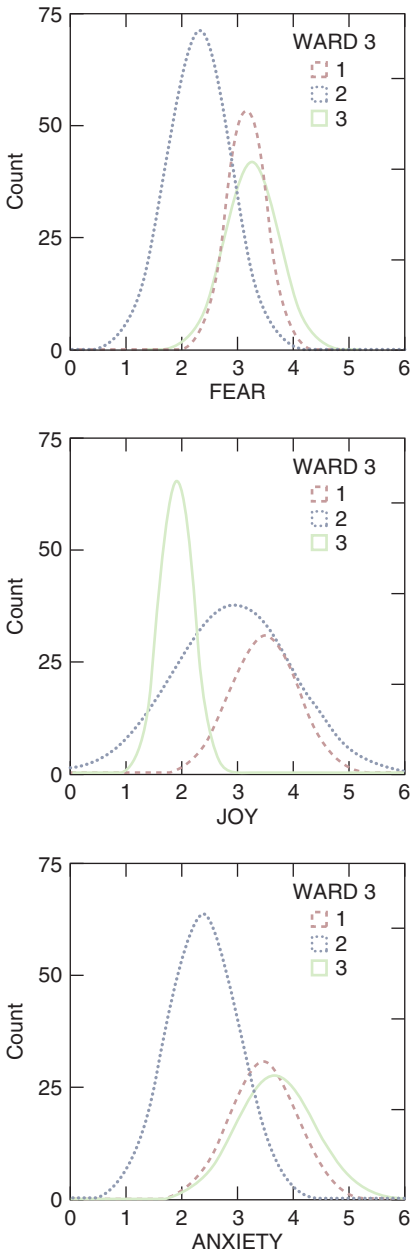

Figure 18.6 Density plots of fear, joy, and anxiety in three clusters (Ward's method). See footnote 1.

From this pattern of results, we conclude that the women in Cluster 1 are different enough from the other respondents in their location in the Fear × Joy × Anxiety space that the different characteristics of the two clustering algorithms do not affect the composition of this group. Cluster 2 from Ward's method is the largest cluster. It is possible that it resulted from swallowing small numbers of groups that, in complete linkage, stay together until they join Cluster 3. In support of this argument are (1) the agglomeration sequences that can be seen in the dendrograms (not shown

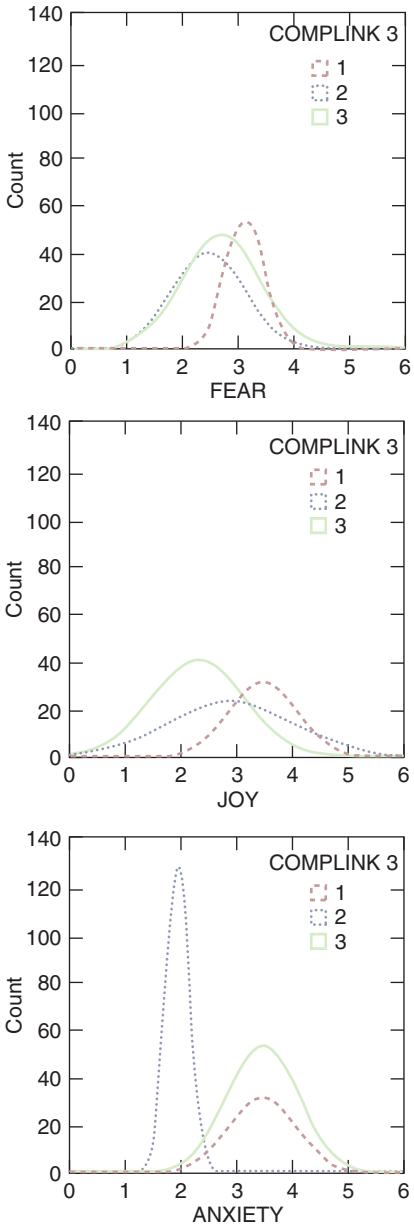

Figure 18.7 Density plots of fear, joy, and anxiety in three clusters (complete linkages). See footnote 1.

here) and (2) the fact that, in all three variables, Cluster 2 in Ward's solution has the largest variances (Figure 18.6).

The third classification of the fear–joy–anxiety data was created with the space segmenting methodology. To keep the number of sectors in the data space manageable, we dichotomized the variables at their scale-specific mean. To compare the cross-classification of the three dichotomized variables with the solutions from the hierarchical methods, we crossed the 2 × 2 × 2 table of JoyD, FearD, and AnxietyD (where the D indicates that the variables

TABLE 18.5 Cross-Tabulation of the Three-Cluster Solutions from Ward's Method (Rows) and Complete Linkage (Columns)

	1	2	3	Total
1	48	0	0	48
2	0	67	36	103
3	0	0	50	50
Total	**48**	**67**	**86**	**201**

are dichotomized) with the classifications from Ward's method and complete linkage. Table 18.6 displays the cross-classification with the solution from Ward's method.

Table 18.6 shows an interesting pattern. The first of Ward's clusters appears unchanged in the cross-classification of the three dichotomized variables. These are the individuals with the variable profile 2 2 2. The third of Ward's clusters remains intact also. These are the respondents with variable profile 2 2 1. In contrast, the second cluster from Ward's method is distributed over six of the eight possible variable profiles. This supports, from a new perspective, the interpretation of this cluster as possibly heterogeneous.

When the parallel cross-classification is created with the solution from complete linkage (table not shown here), a slightly different picture emerges. The first cluster—it is identical with the one from Ward's method—remains intact again. The second cluster is spread over the first four of the eight possible variable profiles, and the third cluster is spread over three of the eight variable profiles. This difference is not surprising, considering that the two hierarchical solutions differed in the second and the third clusters.

We estimated the cell frequencies of the 2 × 2 × 2 three-way cross-classification based on the assumption of symmetric distributions, we examined each of the eight cells by using the exact binomial test, and we protected the significance threshold α by invoking Bonferroni's procedure. Table 18.7 displays the results.

Table 18.7 shows, in its left column, the eight patterns from low levels of fear, joy, and anxiety (Pattern 1 1 1) through high levels in all three variables (Pattern 2 2 2). In its second column, the table shows the observed frequencies, m, for each pattern. This is followed by the expected frequencies, $\hat{m}$, and the binomial tail probabilities, p. The final column contains asterisks for those three patterns that were observed at different rates than expected under the assumption of independent symmetric distributions. The asterisks thus indicate clusters that deviate from the expected density in the sector that is described by the pattern in the first column. The frequencies in the remaining five patterns do not differ from expectancy.

TABLE 18.7 Space-Segment Clusters of the Cross-Classification of the Dichotomized Variables Fear, Joy, and Anxiety

Pattern	m	$\hat{m}$	p
111	13.	25.942	.00241467 *
112	13.	16.435	.22963101
121	20.	32.740	.00701107
122	23.	17.065	.08851520
211	12.	16.267	.16502180
212	50.	31.565	.00051574 *
221	22.	17.254	.14311317
222	48.	27.492	.00007017 *

The first cluster with a discrepant density is constituted by Pattern 1 1 1. Almost 26 respondents were expected to report below average levels of fear, joy, and anxiety, but only 13 did display this pattern. The second cluster with a discrepant density is constituted by Pattern 2 1 2. These are women who report above average levels of fear and anxiety and below average levels of joy. Fifty women exhibit this pattern, but only about 31 had been expected. The third cluster with a discrepant number of cases is constituted by Pattern 2 2 2. These are women who indicate above-average levels in all three emotions. About 27 had been expected to show this pattern, but 48 did.

Comparison of Cluster Solutions

The two hierarchical cluster solutions, created with Ward's method and complete linkage, can only differ because of differences in the agglomeration algorithms. As is well known, in Ward's method smaller clusters tend to gravitate toward larger clusters, thus overriding, in part, distance characteristics of cases. This can be illustrated by the large variances of the big, second cluster of the emotion data in Figure 18.6. This cluster exhibits large variances in all three variables that were used for clustering. Ward's method is, therefore, the method of choice when researchers assume that one large group of individuals exists as well as smaller groups that are remote in the data space from the large group. Ward's method also tends to create convex and, by default, nonoverlapping clusters. So does complete linkage. However, with complete linkage, there is less of a tendency for larger clusters to absorb smaller ones.

The space-segmenting method creates natural groupings by segmenting the data space in blocks. The solution of this method can be optimized by varying the number of segments (more segments result in smaller numbers of cases per segment) and by varying assumptions concerning the data-generating mechanism. For example, researchers can test the hypothesis that agglomerations near the centroid of the data space are excessive assuming the data are multinormally or, alternatively, uniformly distributed. Different numbers of segments and different distributional assumptions can result in different segments that contain more cases or segments that contain fewer cases than expected under these assumptions.

Discussion: Cluster Analysis and Person-Oriented Research

With respect to the tenets of person-oriented research, cluster analytic methods, mixture distribution decomposition, latent class analysis or, in general, taxometric methods are most interesting. These methods allow one to create groups of individuals that are similar because of their profiles and not by definition. By implication, clusters are more homogeneous than populations. Developmental trajectories are, therefore, cluster-specific and do not describe everybody. They only describe those who belong to a particular cluster. If singletons are considered clusters, cluster analysis will allow researchers to also identify those cases that cannot meaningfully be assigned to a cluster. Reasons for these individuals to be different include unique profiles and, of course, measurement error.

Another most important characteristic of cluster solution is that it is far more likely that dimensional identity holds for a cluster than for an entire population. The meaning and the test statistical characteristics of measurement instruments can be expected to be the same for everybody within a cluster (*can be expected* means should be ascertained). This is less important when variables are nominal level. It is important, however, when the variables used in a study are test scores. As was discussed by von Eye and Bergman (2003), test statistical characteristics of measurement scales can differ across populations (this is also discussed as *differential validity* or *differential item functioning*; von Eye, Bergman, & Hsieh, 2015). Whenever items or tests differ in their characteristics across groups, scores from these instruments cannot easily be compared when they describe individuals from different groups, even if they were given the same score on a scale. Individuals from the same group, however, can be compared.

Because of these interesting characteristics, many studies in which researchers used taxometric methods have been published under the auspices of person-oriented research. There are downsides, however. The first of these is that, although taxometric methods are designed to capture unmeasured heterogeneity, it can be very hard to make sure the groups that appear as clusters do exist. To establish a cluster solution, researchers typically undertake two steps. In the first, the best solution is identified. This is done, when latent class analysis is performed, by comparing information criteria from solutions that differ in the number of latent classes. The most likely grouping can thus be identified. When hierarchical clustering algorithms are applied, researchers select from solutions that differ in their distance measure, R^2, or the Rand index (Steinley, 2004). The performance of these indexes is, however, still subject to discussion and research. This is why the second step is equally important. In this step, cluster members are compared on measures that have not been used for clustering. This way, external validity of clusters can be established.

There is another reason why these steps are very important. Many taxometric methods deliver solutions under virtually all conditions. Not all of these solutions, however, describe groups that naturally or meaningfully exist. Matters are complicated by the fact previously illustrated that multiple solutions can be created, and many of these may be interpretable and meaningful. The selection from multiple solutions that have these characteristics is no easy task. Still, taxometric methods are extremely useful options when researchers suspect that unmeasured heterogeneity exists that may be interesting and should be captured because it has the potential of fogging results that are created when this heterogeneity is ignored.

CONCLUSION AND FUTURE DIRECTIONS

There is a striking continuity that connects the ideas of Stern, Lewin, and Block with those of present-day advocates of the person-oriented approach (e.g., Magnusson, Bergman, von Eye). We briefly summarize those continuities as well as suggest where, going forward, person-oriented approaches might lead research and application in developmental psychopathology.

The basic principles for psychological inquiry from a person-oriented approach have existed for more than 100 years. Understanding the individual is widely held to be central to the enterprise of psychological science. Concerns regarding a focus on lawfulness at the expense of understanding important aspects of individual human experience have been raised consistently from Stern to the present. Importantly, all theorists focus on the complexity of the process of development, indicating that there will be multiple determinants of the phenomena or process under investigation. The analogy of the individual as a dynamic system, whose component parts are integrated in a meaningful and coherent way also underpins much of the writing. Within this framework, concerns with change as well as stability are considered important aspects of human behavior. Researchers also emphasize the false dichotomy of the psychological and physiological aspects of an individual and the importance of understanding the individual and how he or she transacts with the environment.

Although research methods have evolved dramatically in the past 100 years, basic concerns with the inadequacies

of extant statistical techniques as a means to elucidate individual behavior as well as attempts to develop alternative methods has been ongoing. Concerns with aggregation of data to explain individuals is a theme that continually emerges in person-oriented research. For example, as we noted previously, Block was interested in subgroups (i.e., heterogeneity within the aggregate) and concerned about the use of factor analysis in personality research, including his own. Lewin's sentiments about the uniqueness of the individual child, quoted earlier, speak to the *ecological fallacy* decades before it received its moniker. Modern researchers, as we have noted, critique methods that aggregate individuals as well as those that make questionable and simplifying assumptions about variable relationships, data distributions, and random error. These researchers have also developed new, and revised existing, methods that circumvent some of these problems. Finally, following from the dynamic systems view, with integrated components together reflecting the system, person-oriented researchers have long realized the need to make, as far as possible, the whole person the object of study. In the early days of psychology, this goal was strived for by applying subjective methods, for example, when psychiatrists used observations and interviews to divide a sample of patients into different types. During the last decades, objective statistical methods of pattern analysis and classification have been increasingly applied; methods that are based on the pattern of variable values as the analytic unit. Hence, the old objections against a typological approach as being subjective and unscientific are no longer valid.

What measures are used to assess individuals is another thread of continuity between the past and present. Early assessments of intelligence were highly individualized (e.g., Binet). Stern's consternation with the overuse of intelligence tests and the intelligence quotient led him to develop methods that reflected person–world convergence; that is, test instruments should not compare the individual to others (as in classical test theory) but rather to himself or herself vis-à-vis the environment in which he or she interacts (Lamiell, 2010a). Loevinger's focus on differential scaling predates von Eye et al.'s (2015) reformulation of IRT as a person-oriented tool. Block's Q-set, described earlier, attempted to better reflect the complexity of the individual. von Eye (e.g., von Eye & Bergman, 2003; von Eye et al., 2015) has consistently raised concerns regarding dimensional identity of assessment instruments—items, measures, and constructs may have different meaning for different individuals at different times in their development. Going forward, issues of scaling and measurement are in need of more attention; researchers still, too often, rely on the principles of classical test theory that do not align with the person-oriented approach.

How should the field of developmental psychopathology integrate the person-oriented approach as a legitimate paradigm and not just the poor stepchild of the variable-oriented approach? One idea is that developmental psychopathology researchers explicitly identify whether they employ a variable- or person-oriented approach. At present, as far as we are aware, only research that employs a person-oriented approach identifies it as such. von Eye et al. (2015) remind us that the search for universals, which is best done via variable-oriented approaches, can be important in the early stages of a new field of inquiry. However, research conducted from a variable-oriented approach cannot normally make statements about the individual. Thus, variable-oriented research should refrain from making such statements in the hypotheses and in the interpretation of results.

The language that researchers employ in this regard is important. Hypotheses and results must be formulated such that the person- versus variable-orientation of researchers becomes visible and, more important, defensible. For example, it is not valid to state that a person with long experience as a victim will be depressed, if the basis for such a conclusion is simply a correlation between duration of exposure and depression (that would amount to committing the sin of ecological fallacy). Person-oriented statements require person-oriented research and vice versa (but the first of these is more important).

Discussion sections often include statements that the findings cannot be generalized to a population other than the one studied, but limitations inherent in the variable-oriented approach are not presented (e.g., cross sectional data do not elucidate process, universals can only be deemed such if validated by person-oriented research, assessment instruments may not have dimensional identity, aggregation of data limits the interpretation of results). Framing the argument and hypotheses as either variable- or person-oriented and acknowledging the limitations of each approach in the discussion section would be more than a mere exercise; it would provide scaffolding for clearer thinking in theory and methods. The need for transparency about the underlying paradigm driving research is analogous in some ways to Stern's (1911) delineation of four specific types of research in differential psychology (Lamiell, 2010a). More recently, in discussing the tension between person- and variable-oriented approaches, Cervone (2005) noted the need to acknowledge explicitly that these two approaches lead to two different types of information.

Focusing specifically on person-oriented research, what does the future hold as it applies to the field of developmental psychopathology? The NIMH Research Doman Criteria (RDoC, 2011), in an attempt to generate innovative and integrative research on brain and behavior, provides a starting point. The research domain criteria matrix suggested has units of analysis (from genes to paradigms) as the columns and domains/constructs (e.g., negative valence systems, cognitive systems) as the rows. The initiative emphasizes linking behavior with brain functioning and genetics. Unfortunately, developmental and environmental aspects of psychopathology are not in the matrix, although NIMH indicates that these are critical elements for researchers to consider. Research from a person-oriented approach would include environment and development in the matrix itself. Because the individual is a dynamic system, the person-oriented approach cannot explain the transaction of brain and behavior factors without taking environment and development into consideration. In addition, the patterning of these different factors within individuals or groups of individuals would be necessary for the research to be person oriented.

Already we see the first signs of person-oriented research moving in this direction. The cortisol/behavior (Towe-Goodman et al., 2011) and cortisol/mental health/environment research (Bogat et al., 2012) cited earlier, research on ADHD that bases classifications on differential patterns of brain functioning (e.g., Fair, Bathula, Nikolas, & Nigg, 2012), and formulations of temperament calling for person-oriented methods that incorporate aspects of child behavior as well as central and peripheral nervous system factors (Nigg, 2006) all begin to integrate facets of the RDoC matrix.

The NIMH RDoC is, of course, part of a wider movement within psychology and medicine toward translational research; that is, taking findings from basic research and applying them to clinical research with the goal of enhancing health or preventing problems from developing in the first place. Person-oriented research has a strong role to play in translational research. In medicine, cutting-edge cancer research eschews a one-size-fits-all treatment approach. Person-oriented approaches, whereby physicians and researchers analyze genetic and molecular abnormalities in an individual's cancer, allow for more precise treatments to cure the cancer and cause the fewest side effects possible. Person-oriented approaches offer the same promise for psychological interventions. For example, batterer intervention programs (BIPs), often mandated by courts in cases where men perpetrate intimate partner violence, are generally ineffective. A meta-analysis by Feder and Wilson (2005) found that the programs had no effect on victim's reports of revictimization and only minimal effects on police reports of violence. An NIJ meeting convened to address this problem provided guidelines for practitioners and researchers going forward (National Institute of Justice, 2011); however, only one research recommendation was somewhat person oriented ("Study experiences in BIPs of men by ethnic group"). This is unfortunate. In the case of BIPs or other interventions, translational research, using person-oriented approaches to understand individual behavior (genetic, psychological, and environmental causes), holds the promise of individualized treatments to help the broadest number of individuals.

In conclusion, a core goal of developmental psychopathology is to understand individual development. The direct and natural path to follow is then to study *individual* development of persons in real life, taking into consideration that we function as integrated organisms in interaction with our environment. This standpoint naturally leads to a person-oriented approach. Those who claim they can understand individual development by applying variable-oriented methods must carry the burden of proof that such an indirect approach is defensible.

INTRODUCTION

Developmental psychopathology constitutes the confluence of two important research traditions that both are undergoing major methodological changes—developmental science and psychopathology. Developmental science is increasingly based on the metamodel of developmental systems theory (Ford & Lerner, 1992). Developmental systems theory conceives of development as the result of multiple coacting influences that (1) are context sensitive and contingent (e.g., Gottlieb, 2001), (2) affect constructive processes in which nonlinear epigenetic influences play central roles (e.g., Lickliter & Honeycutt, 2009), and (3) evolve at multiple time scales and at multiple levels (e.g., Smith & Thelen, 2003). Accordingly, the emphasis in developmental systems theory is on the inherently stochastic and person-specific nature of developmental processes. Applications of developmental systems theory therefore require methodological approaches in which the focus is on person-specific methods (Molenaar, Lerner, & Newell, 2014; Molenaar & Newell, 2010).

The medical sciences also are undergoing major methodological changes under the banner of personalized medicine (Hamburg & Collins, 2010). While the initial approaches to personalized medicine were heavily based on genotypic characterization of patients, this now has been generalized to include intensive longitudinal assessments of phenotypic features such as physiology, behavior, etc. (Schwarz & Collins, 2007). The availability of such intensive longitudinal assessments opens up the possibility to optimize therapeutic treatment by means of new methods derived from computational engineering. In these so-called dynamic treatment methods the sequence of therapeutic manipulations is increasingly optimized in real time by means of machine learning techniques conditional on the newly available longitudinal assessments (e.g., Chakraborty & Moodie, 2013).

The trend toward personalized and person-specific methodology also is corroborated by a recent development in the foundations of psychometrics. Using general theorems of mathematical ergodic theory (Birkhoff, 1931), Molenaar (2004) proved that pooling across individuals,

[1]Color versions of Figure 19.3 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

which is the hallmark of standard statistical methods in the analysis of psychological data, only is warranted if strong so-called ergodicty criteria are met. The criteria that define *ergodicity* imply that (1) all individuals making up a population (i.e., domain of generalization) should obey exactly the same dynamic model and (2) the dynamic model should be stationary. The latter stationarity criterion implies that the process under consideration should lack any developmental features (e.g., constant mean, constant variance, constant sequential dependencies). In case one or both of these criteria are violated, the statistical analysis should be based on person-specific approaches involving intensive measurements of individual subjects. Developmental process almost by definition violates the stationarity criterion and therefore should be investigated using person-specific methods.

In an important publication Sterba & Bauer (2010) scrutinized the match between person-oriented methods and person-oriented theory. They showed that person-specific methods like dynamic factor analysis (i.e., factor analysis of intensive longitudinal assessments obtained in single-subject or replicated time-series designs) provide the best match with person-oriented principles (see also Molenaar, 2010a). Accordingly, person-oriented principles should preferably be applied using person-specific methods.

Because person-specific methodology is relatively new (in contrast to other fields of research where time-series analysis often is the standard approach to data analysis, such as for instance physics, engineering, and econometrics), we highlight in what follows differences between standard developmental methods based on analysis of interindividual variation with person-specific methods based on intraindividual variation. In particular, we will argue that the individual differences created within standard statistical developmental methods such as latent growth curve modeling violate in important respects the tenets of person-specific methodology. This implies that these standard statistical methods based on interindividual variation cannot be used to accommodate violations of ergodicity and also may have limited applicability in personalized and person-oriented approaches (Molenaar & Campbell, 2009; Voelkle, et al., 2014).

Here, we suggest applying these approaches to the field of developmental psychopathology, In summarizing the field as part of the recognition of the fiftieth anniversary of the *Journal of Child Psychology and Psychiatry*, Cicchetti and Toth (2009) indicated the importance of an approach to research in developmental psychopathology that considered all methods that allowed the description of process that typically unfolds over time. They emphasized the importance of multiple levels of analysis to achieve this goal. An important level of analysis that has received less attention in the developmental psychopathology literature is the person-specific approach based on single subject models. Given their notion that there are "multiple pathways to similar manifest outcomes and that there are different outcomes [resulting from] the same pathway," (page 4) typical prediction models based on group characteristics may be lacking when the requirement would be a prediction that can have two different outcomes given identical conditions. Given that treatment may be suggested by the prediction, the person-specific single subject approach which would concentrate more on individual characteristics may be the better bet.

Add to this that there has been an increasing tendency in the field toward the notion of person-centered care (Adams & Grieder, 2005). The idea behind this is simple. Treatments developed based on sample characteristics and applied to the individual may not appropriately address that individual's needs. A treatment regimen tailored on the individual's unique requirements may produce better results. This is akin to developing a person-specific model. Molenaar (1987; Molenaar, 2010b) has shown how this modeling approach can be successful in the therapeutic situation.

There has also been a greater emphasis on shared decision making in the therapeutic setting (Adams & Drake, 2006; Deegan et al., 2008; Ptasznik, 2011). These tendencies suggest that the person-specific, single-subject modeling approach may be an important new tool for moving the field of developmental psychopathology forward.

As Cicchetti and Toth (2009) described the type of developmental analysis we suggest, it "presupposes change and novelty, highlights the critical role of timing in the organization of behavior, underscores multiple determinants, and cautions against expecting invariant relations between causes and outcomes" (p. 1). We extend this idea of expected invariance to include individual models that can be used to achieve optimal therapeutic outcomes.

In this chapter we would like to first demonstrate the way certain common analytic approaches such as longitudinal regression modeling, linear mixed modeling (e.g., growth curve and repeated measures one-way analysis of variance [ANOVA]), multilevel autoregressive modeling, factor modeling, and cluster analysis create individual difference measures based on a common underlying model. In this sense, they are modeling interindividual variation. After showing that these approaches depend on sufficient (summary) statistics and creating individual parameter predictions based on an underlying assumed probability model, we will then compare these methods

to more person-specific approaches. We will focus on analogous single subject time-series approaches (e.g., vector autoregressive approaches for cross-lagged regression, P-technique and dynamic factor models for cross sectional or longitudinal factor models based on relatively few occasions) and show how these person-specific methods create parameters based on models that can vary from individual to individual. We will demonstrate a true intraindividual approach using personality data collected by Borkenau and Ostendorf (1996) and emotional mood data from Corneal and Nesselroade (1994; see also Molenaar et al., 2009; Rovine, Molenaar, & Corneal, 1998). We first define the difference between the concepts of intra- and interindividual differences.

Definition of Intraindividual Variation

In its most basic form intraindividual variation is variation in time of repeated measurements obtained with a single subject. We use the term *subject* for the single entity (case) that is measured repeatedly, but we understand that this entity also can be a single group of subjects like a particular mother–infant dyad, a single family, or a school. The important point to note is that here, subject is fixed; that is, it is not considered to be a randomly drawn from some population of subjects. Even though the designation for each subject as a system or dynamic system would be technically more appropriate, as psychologists we select subject.

Intraindividual variation is understood to be random variation associated with a *stochastic process* which is thought to describe the evolution of some system over time. Here, the system is a single subject and the process is measured by a set of repeated measurements indexed by time. The general idea of a stochastic process was introduced by Kolmogorov (1931) and can be illustrated as follows: suppose the cognitive performance of a single subject on the same test is measured at T consecutive occasions. According to Kolmogorov's definition of a stochastic process, the actual score observed on each occasion t, say $t = 1$, constitutes a random draw from a probability distribution of possible scores that could have been obtained at $t = 1$ under the same circumstances. This allows the consideration of the mean of each time series. Moreover, each pair of scores, say at $t = 1$ and $t = 2$, is considered to be a random draw from a bivariate probability distribution. This allows the consideration of the correlation or covariance between each pair of occasions. Together the means, variances, correlations, and higher order moments of this each series can be modeled using methods typically called time-series analysis.

Time can be continuous or discrete. In this chapter we consider only discrete time processes. To simplify the presentation we suggest that the time interval between consecutive occasions is constant, although this assumption can be dropped when discussing data obtained in, for example, ecological momentary assessment (EMA) designs. By emphasizing stochastic processes we are ruling out deterministic process; for example, those that follow a predetermined shape or trajectory caused such as growth processes. Such processes can be described by deterministic differential or difference equations and would typically be modeled using a different set of methods (Banks, 1983).

Contrasting Intraindividual Variation with Interindividual Variation

The converse of intraindividual variation is interindividual variation. These two contrasting types of variation can be distinguished in the following way. In analysis of intraindividual variation, we model each subject separately treating the subject as fixed while the estimation proceeds by pooling across the replicated measurements obtained with this subject. Because its measurements are time-dependent, the hallmark of analysis of intraindividual variation is representing by pooling across repeated occasions. The finite set of observations for each subject can be conceived of as a sample from all possible times. As a consequence, the results of a standard analysis of intraindividual variation can be generalized to all times previous to the observation interval (retrodiction), to times within the observation interval for which no observations are available (interpolation), and to future times (prediction). Hence, the domain of generalization of a pure analysis of intraindividual variation is the time domain, while no statements regarding the generalization across subjects can initially be made.

In contrast, in analysis of interindividual variation the sample of subjects is conceived of as randomly drawn from a population of subjects. Estimation proceeds by pooling data across the sample of subjects. The hallmark of analysis of interindividual variation is pooling across subjects. As a consequence, the results obtained in an analysis of interindividual variation are generalized to the population of subjects. This is the typical analytical situation in longitudinal designs. Again, analysis of interindividual variation of these repeated measures proceeds by pooling across subjects. For instance, as we will show, the standard latent growth curve model is fitted by pooling across subjects. The result of this is that any longitudinal analysis is not analysis of intraindividual variation but instead is analysis of interindividual variation.

The difference in the definitions of inter- and intraindividual variation suggests how the results of a particular analysis can be generalized (generalization across populations of subjects versus generalization across time). We note

that one of the dangers of forgetting this distinction is that inappropriate generalizations are often made based on the results of analyses based on interindividual variation. We will emphasize these below.

MODELING INTERINDIVIDUAL VARIATION THROUGH GROUP-BASED INDIVIDUAL DIFFERENCE MODELS

Many popular analytical methods create values for what are described as individual difference parameters that are based on group models. For example, the linear multilevel (or latent) growth curve model (Bryk & Raudenbush, 1992; Goldstein, 1995; Grimm, Davoudzadeh, & Ram, 2014; McArdle & Epstein, 1987) can be used to generate individual intercepts and slopes in addition to the group intercept and slope that are typically the focus of the model. While the individual measures can be used to describe differences among participants in a study, they are created based on the group parameter estimates (e.g., regression weights, common covariance structure of the residuals). The individual variable values are then predicted using these group parameter values based on certain assumptions regarding the distribution of these variables (e.g., the individual values will be normally distributed with a zero mean). This approach represents the assumption that the same model holds for all study participants. With a relatively few number of occasions of measurement, this assumption cannot be tested.[2] With more intensive time-series data, however, this assumption can be tested, and individual models can be determined. It may be the case that different individuals require different models. There may be unknown subgroups whose data may be described by a common model, but this is not known a priori. With more intensive time-series data, a separate model can be determined for each study participant. Individuals with common models can then be clustered to form subgroups (Gonzales & Ferrer, 2014; Nesselroade & Molenaar, 1999).

One common model where this can become evident is the longitudinal lagged regression model based on a panel design. Here, we will compare how the group-based model relates to the person-specific vector autoregressive model.

A second family of analytic procedures that we will consider encompasses methods based on the linear mixed model, which include multilevel growth curve modeling, repeated measures ANOVA, and multilevel autoregressive models. As an example, for the linear multilevel growth curve model, individual slopes and intercepts are generated as part of the solution. These are often interpreted as individual difference measures. They are based on post hoc predictions of the model and are common to all participants in the sense that they represent variations in the parameters of a single underlying model under the assumption of a particular probability distribution for the residuals (Robinson, 1991). The common underlying model makes these individual difference measures much different than those that would result from a separate time-series model for each individual.

Another model we consider is the longitudinal factor model. With a few occasions of measurement investigators can test whether a factor structure is invariant across occasions and the degree of invariance that can be assumed. But this factor model is the result of a *subjects* × *variables* data set where the variables for the different occasions are the variables of the model. As an alternative we will consider a factor analysis based on collecting multiple *variables* on multiple *occasions* on a single *subject*. Here, *occasions* essentially takes the place of *subjects*. A correlation (or covariance) matrix can be constructed which can be used to estimate individual factor models. The factor loadings and factor correlations of these different individual models can be compared both to each other and to results of the group-based *subjects* × *variables* as we show for the data presented by Borkenau and Ostendorf (1998) and Corneal and Nesselroade (1991; Molenaar et al., 2009; Rovine, Molenaar, & Corneal, 1998).

Other modeling approaches attempt to account for heterogeneity of intraindividual variation in creating individual difference parameters. Latent class trajectory analysis (Nagin, 1999) and growth mixture modeling (Muthén & Sheden, 1999) create subgroups by implicitly clustering individuals with similar predicted parameter values. Although these methods allow heterogeneity in terms of differences in the predicted parameter values, there will still be strong distribution assumptions within subgroups (Sterba & Bauer, 2010). For example, a particular subgroup within a growth mixture model will have a specified mean and covariance structure that assumes homogeneity within that subgroup. These types of models still require a common group model of which the individual parameters represent instances of that model though with wider variation across subgroups. By requiring the common model, these approaches still describe interindividual variability.

Multilevel autoregressive (AR) models use an autoregressive model as the Level 1 (time-related level) model. The Level 2 or individual-level model allows covariates that are invariant across occasions to account for variability in the Level 1 parameters. However, this results in a set

[2] Unless mixture modeling is used, but then the same assumptions reapply in each of the finite number of subpopulations.

of fixed effect parameters that are added to the overall or group level equation again resulting in a common model for all individuals. As in the multilevel growth curve model, individual AR parameters are predicted post hoc under the strict assumptions that the same AR process (e.g., AR(1), AR(2)) holds for all individuals, and the individual parameter values deviate from the group parameter values by residual values that conform to a multivariate normal distribution. If the order of the process is not identical for individuals, or if the order of the process is the same, but the true distribution of the parameter does not follow a strict normal distribution, this approach represents a misspecification of the model.

The person-oriented literature (Bergman, 2012; Bergman & Andersson, 2010) often refers to a cluster analytic approach to time-series data. Given the strong similarity between many clustering methods and standard factor analysis, such person-oriented approaches are often really describing interindividual differences.

The Multilevel Growth Curve Model

The linear growth curve model (Bryk & Raudenbush, 1992; Goldstein, 1995; McArdle & Epstein, 1987) is member of the linear mixed model family (Laird & Ware, 1982).

A simple linear growth curve model with a time-invariant covariate x can be written as

$$y_{it} = \beta_0 + \beta_1 TIME + \beta_2 x_i + \beta_3 (x * TIME) + \upsilon_{i0} + \upsilon_{i1} TIME + r_{it} \quad (19.1)$$

where $\beta_0, \beta_1, \beta_2$, and β_3 are fixed effects regression coefficients, and $\upsilon_{i0}, \upsilon_{i1}$, and r_{it} are the random effects which are the deviation of the individual intercept around the group intercept, the deviation of the individual slope around the group slope, and the deviations of the individual observed variable values around their own regression line. As in all linear mixed models we estimate the expected values of the fixed effects and the covariance matrix of the random effects. These estimates are based on data pooled across individuals. The covariance matrix of the random effects is given by

$$\sigma^2 V = \sigma^2 (ZDZ^T + I) \quad (19.2)$$

where σ^2 is the pooled variance of the individual residuals around the individual's regression (assumed equal across occasions for the typical multilevel linear growth curve model), Z is the set of design column vectors for the random intercept and slope parameters, and D is covariance matrix of the random intercepts and slopes. It is a convention to refer to the total covariance matrix of the random effects as $\sigma^2 V$, which defines V by factoring the residual variance out of the total covariance.

This covariance matrix along with the fixed effects can be used to predict values of the individual random effects under the assumptions of this single common model under a multivariate normal distribution (Henderson, 1975). The equation for best linear unbiased predictions (BLUPs) was given by Robinson (1991) as

$$\hat{\gamma}_i = DZ^T \hat{V}^{-1} (y_i - X\hat{\beta}) \quad (19.3)$$

where $\hat{\gamma}_i$ is the vector of predicted random effects (intercept and slope) for subject i, X is the design matrix for the fixed effect parameters (group intercept and slope), and β is the set of estimated fixed effect parameters.

These random effects are often described as individual difference measures, and in the sense that they vary across individuals, they are. This interpretation is the result, in part, of the multilevel formulation of the linear mixed model as presented by Goldstein (1995), and included in the formatting of software such as HLM (Bryk & Raudenbush, 1992). For example, the multilevel model version of the linear growth curve shown above can be rewritten as

Level 1:

$$y_{it} = \pi_{i0} + \pi_{i1} TIME + r_{it}$$

Level 2:

$$\pi_{i0} = \beta_{00} + \beta_{10} x_i + \upsilon_{i0}$$
$$\pi_{i1} = \beta_{01} + \beta_{11} x_i + \upsilon_{i1} \quad (19.4)$$

where in Level 1, π_{i0} is the individual's intercept, and π_{i1} is the individual's linear slope. These random effects comprise the individual equation. In Level 2 we included a covariate, x, that varies from individual to individual but is otherwise time invariant. Here the individual intercept that has been passed on from Level 1 deviates around the group intercept, β_{00}, by an amount, υ_{i0}, and the individual slope deviates from the group slope, β_{01}, by an amount, υ_{i1}. In both Level 2 equations, we included a covariate, which is purported to account for variability in the individual slopes and intercepts. Here, the random effects are r_{it}, υ_{i0}, and υ_{i1}. The fixed effects are the group intercept, β_{00}, the group slope, β_{01}, and the regression coefficient related to the covariate, β_{11}. For the linear mixed model, we estimate the expected values of the fixed effects, and the covariance matrix of the random effects.

Given the format of this multilevel model, it appears that a separate equation is estimated for each individual. This appearance is part of the reason why the model is mistaken for a true model of intraindividual differences. However, substituting Level 2 into Level 1, we get

$$\begin{aligned} y_{it} &= (\beta_{00} + \beta_{10}x_i + \upsilon_{i0}) + (\beta_{01} + \beta_{11}x_i + \upsilon_{i1})TIME + r_{it} \\ y_{it} &= \beta_{00} + \beta_{01}TIME + \beta_{10}x_i + \beta_{11}(x * TIME) \\ &\quad + (\upsilon_{i0} + \upsilon_{i1}TIME) + r_{it} \end{aligned} \tag{19.5}$$

which is identical to the linear mixed model equation presented above in which the individual difference equation has disappeared and is replaced by a single equation with fixed and random effects. It is this equation which is estimated in programs like SAS PROC MIXED, SAS MIXED, and R LME.

The random effects here and as estimated by programs such as HLM are the same regression residuals predicted under the same set of assumptions under a specific group-based regression model. The empirical Bayes estimates of HLM are identical to the solution of the Henderson linear model equations implemented by programs such as SAS PROC MIXED (Littell et al., 2006).

This model assumes that the same trajectory shape describes each individual, and individuals only differ in, for example, the steepness of the slope, or the height of the intercept. When a common model does not hold, the growth curve approach may misrepresent how individuals differ resulting in an inference that gives a less than optimal description about the course of change (Liu et al., 2012). Given the short longitudinal data that are most typically available in growth curve analysis, the possibility of testing to see whether the model adequately describes the sample is often not available. The person-specific analog to the growth curve model would require fitting a separate polynomial equation to each individual. The proper order (i.e., the parameters that can describe the shape of the curve) would be empirically determined for each individual. With most studies, these data are not available. When sufficient data to estimate the individual curve would be available, the estimate of a relatively low order polynomial would only make sense for certain simple true growth processes. Since the growth curve model is often used for modeling some arbitrary change process that does not follow a known growth function, the fitting of a growth curve to time-series data may not even make much sense. For a relatively few number of repeated occasions of measurement, the growth curve approach often represents a necessary practical compromise.

The Linear Latent Growth Curve Model

Latent curve models (Bollen & Curran, 2006; Meredith & Tisak, 1990) represent a very common approach to fitting curves through the means of repeatedly measured data. Hearkening back to the work of Tucker (1958) and Rao (1958), these approaches are primarily based on factor analytic methods. A very popular set of models based on a parameterization is presented by McArdle and Epstein (1987) and McArdle and Aber (1990). The latent growth curve model with either fixed or estimated basis vector coefficients (actually fixed or estimated factor loadings), is strongly related to the multilevel growth curve model.

For example, the linear growth curve model uses a highly constrained factor model to estimate the same set of fixed effects parameters as the linear mixed model. Here the model is again used to define straight lines with different intercepts and different slopes. To vary things slightly we have included two groups in the model and no covariate. While we concentrate on the straight-line model, curves other than straight lines can be modeled either by using polynomial terms (powers, centered powers, or orthogonal polynomials) or by estimating factor loadings (McArdle & Hamagami, 1991).

This model can be estimated as a structural equation measurement model. Using LISREL notation, the general matrix equation for the measurement model is

$$\vec{y} = \Lambda\vec{\eta} + \vec{\varepsilon} \tag{19.6}$$

where $\vec{y}$ is the vector of observed variables, Λ is a partitioned matrix of fixed factor loadings corresponding to the fixed and random effects, $\vec{\eta}$ is a partitioned vector representing the fixed and random regression parameters, and $\vec{\varepsilon}$ is a vector of regression residuals.

For two groups with four repeated measures, the matrix form of the linear growth curve model is

$$\begin{bmatrix} y_{i1} \\ y_{i2} \\ y_{i3} \\ y_{i4} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 2 & 0 & 0 & 1 & 2 \\ 1 & 3 & 0 & 0 & 1 & 3 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \\ \gamma_{i1} \\ \gamma_{i2} \end{bmatrix} + \begin{bmatrix} \varepsilon_{i1} \\ \varepsilon_{i2} \\ \varepsilon_{i3} \\ \varepsilon_{i4} \end{bmatrix} \text{ Group 1}$$

$$\begin{bmatrix} y_{i1} \\ y_{i2} \\ y_{i3} \\ y_{i4} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 2 & 1 & 2 & 1 & 2 \\ 1 & 3 & 1 & 3 & 1 & 3 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \\ \gamma_{i1} \\ \gamma_{i2} \end{bmatrix} + \begin{bmatrix} \varepsilon_{i1} \\ \varepsilon_{i2} \\ \varepsilon_{i3} \\ \varepsilon_{i4} \end{bmatrix} \text{ Group 2} \tag{19.7}$$

where β_1 and β_2 are the respective intercept and slope for the first group, and β_3 and β_4 are the respective differences in intercept and slope between the two groups. Because columns 3 and 4 are 0s for Group 1, β_3 and β_4 are not added to the Group 1 equation. β_3 and β_4 are added to the model for Group 2. The βs are fixed for the sample. γ_1 and γ_2 are the random effects (in this case random slopes and intercepts). These correspond to columns 5 and 6. In theory the random effects for each individual provide the difference between the group intercept and the individual intercept (γ_1) and the group slope and the individual slope (γ_2). In this model, factor scores take the place of the random effects in the linear mixed model. In estimating the model, the covariance matrix of the random effects, along with the covariance matrix of the ε_t are estimated. Factor scores are then predicted post hoc to yield the individual random effects under the same assumptions as in the linear mixed model. This highly constrained factor model is identical to a two-group linear mixed model/multilevel growth model. As such, it is a model of interindividual differences.

The Multilevel Autoregressive Model

Given that it is now more common to collect more intensive longitudinal data, some researchers have begun to turn to time-series methods in an attempt to model these data. Some of these approaches look at estimating a separate model for each individual, but others have attempted to use a multilevel-type approach. One method that is gaining more popularity is the multilevel autoregressive (AR) model in which the Level 1 model is an autoregressive model of a particular order. These models are thought to be particularly appropriate for data that Nesselroade (1991) described as belonging to a stable process, one without a discernible trend. Having a Level 1 autoregressive model has resulted in what some authors refer to as dynamic multilevel modeling (Suls, Green, & Hillis, 1998). Using a first-order autoregressive model, they referred to the AR parameter as a measure of inertia in that in the presence of a perturbation (a movement away from equilibrium), the autoregressive parameter tended to return the series toward the equilibrium point at the mean of the series (Hamaker, 2012; Kuppens, Allen, & Sheeber, 2010).

Consider an AR(1) process that is considered appropriate to describe all members of a sample, the multilevel AR model can be written as

Level 1:

$$y_{i,t+1} = \pi_{i0} + \pi_{i1} y_{i,t} + r_{i,t+1}$$

Level 2:

$$\begin{aligned} \pi_{i0} &= \beta_{00} + \beta_{10} x_i + \upsilon_{i0} \\ \pi_{i1} &= \beta_{01} + \beta_{11} x_i + \upsilon_{i1} \end{aligned} \tag{19.8}$$

where an intercept, π_{i0}, and the AR coefficient, π_{i1}, are both conditioned on some covariate, x. As required by the stationarity condition, $-1 > \pi_{i1} > 1$.

As before, we could substitute Level 2 into Level 1 to come up with a single linear mixed model equation to estimate the fixed effects of the model along with the covariance matrix of the random effects (Rovine & Walls, 2006). But instead we just wish to point out that the same assumptions of the multilevel model hold here; namely, that the AR(1) process holds equally well for all individuals, and that the individual AR(1) coefficients, the random effects, can be predicted post hoc under a common model assuming that the coefficients conform to a multivariate normal distribution. Different processes for different individuals cannot be accommodated by this model. It is therefore a model concerned with interindividual variation.

One innovation in this approach has been the addition of a random innovation variance (Wang, Hamaker, & Bergeman, 2012), which determines each individual's innovation variance in addition to their AR parameter value. Again, these individual error variances are predicted post hoc based on a common model and a specific assumed error distribution. That makes this model markedly distinct from a true model of intraindividual differences.

Lagged Regression Models

As an example of a lagged regression we consider the cross-lagged regression model with two variables, x and y, each measured on four occasions with the assumption that x at each occasion predicts y at the next occasion, and in turn, y at each occasion predicts x at the next occasion (Kenny, 2005). The model for such data is shown in Figure 19.1. Given any path model, the set of regression equations that result is given by the set of tracing rules (Wright, 1934). Simply stated, each variable in the model is a dependent variable in its own regression equation. Predictor variables for that equation are connected via one-headed arrows. Two-headed arrows represent correlations[3] or covariances (depending on the scaling) between

[3]From this point when we use the term *correlation* it will be implicit that the association coefficient could be a correlation, covariance, or sum of the cross-products depending on the requirements of scaling for the model.

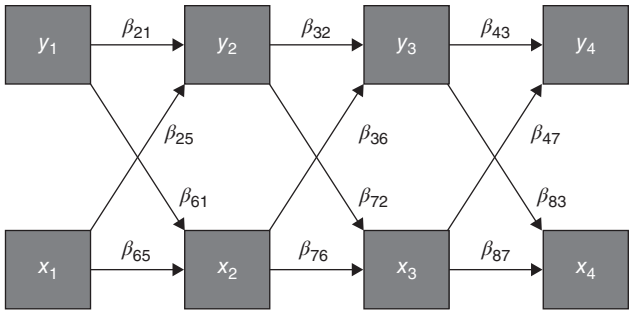

Figure 19.1 A cross-lagged regression model (regression coefficients only).

variables. Errors are linked to a particular dependent variable through one-headed arrows. To simplify the figures, we do not include errors in the models as shown.[4] We also do not include any concurrent regression relationships.

The set of regression equations resulting from the model in Figure 19.1 is

$$\begin{aligned} y_1 &= \zeta_1 \\ y_2 &= \beta_{21}y_1 + \beta_{25}x_1 + \zeta_2 \\ y_3 &= \beta_{32}y_2 + \beta_{36}x_2 + \zeta_3 \\ y_4 &= \beta_{43}y_3 + \beta_{47}x_3 + \zeta_4 \\ x_1 &= \zeta_5 \\ x_2 &= \beta_{61}y_1 + \beta_{65}x_1 + \zeta_6 \\ x_3 &= \beta_{72}y_2 + \beta_{76}x_2 + \zeta_7 \\ x_4 &= \beta_{83}y_3 + \beta_{87}x_3 + \zeta_8 \end{aligned} \tag{19.9}$$

where β represents a regression coefficient, and ζ represents an equation residual. As y_1 and x_1 are not predicted by other variables, they are considered *exogenous*, and all other variables (which are predicted) are considered *endogenous*. Exogenous variables are marked by the fact that their correlation equals the correlation between their equation residuals.

To estimate the regression coefficients and residual variances of the model, we use a covariance structure modeling approach that expresses the associations between variables (correlations, covariances, or sums of squares and cross-products) as functions of the parameters to be estimated. Here we use the LISREL model (Jöreskog & Sorböm, 1996) for these relationships. To conform to the LISREL model, we rename the variables as follows: $\eta_1 = y_1$; $\eta_2 = y_2$; $\eta_3 = y_3$; $\eta_4 = y_4$; $\eta_5 = x_1$; $\eta_6 = x_2$; $\eta_7 = x_3$; $\eta_8 = x_4$. Placing the ηs in equation (19.9) yields

$$\begin{aligned} \eta_1 &= \zeta_1 \\ \eta_2 &= \beta_{21}\eta_1 + \beta_{25}\eta_5 + \zeta_2 \\ \eta_3 &= \beta_{32}\eta_2 + \beta_{36}\eta_6 + \zeta_3 \\ \eta_4 &= \beta_{43}\eta_3 + \beta_{47}\eta_7 + \zeta_4 \\ \eta_5 &= \zeta_5 \\ \eta_6 &= \beta_{61}\eta_1 + \beta_{65}\eta_5 + \zeta_6 \\ \eta_7 &= \beta_{72}\eta_2 + \beta_{76}\eta_6 + \zeta_7 \\ \eta_8 &= \beta_{83}\eta_3 + \beta_{87}\eta_7 + \zeta_8 \end{aligned} \tag{19.10}$$

This can be summarized by the matrix equation

$$\vec{\eta} = B\vec{\eta} + \vec{\zeta} \tag{19.11}$$

where $\vec{\eta}$ is an 8×1 vector of variables, $\vec{\zeta}$ is an 8×1 vector of equation residuals, and β is an 8×8 matrix of regression weights indexed according to the previous regression weights. This is a regression equation with all variables acting as possible dependent variables in their own regression equation. Which variables predict each of the dependent variables is determined by the path model. Equation 19.11 can be used to develop an equation for the expected associations among all of the variables. The difference between the observed variable covariance matrix, S, and the expected $\hat{\Sigma}$ based on the model can be used to determine the fit of the model.

In terms of estimating this model, the required input for generating the regression estimates is the covariance matrix. Individual data points are not required for the estimation of the parameters. As in ordinary regression, the equation residuals, ζ, can be predicted post hoc using the parameter estimates. These residuals are model based in that the group model parameters must be known before the residuals can be calculated.

The Vector Autoregression Model

We now present the person-specific analog of the cross-lagged regression model. Here we consider two time series, x and y, measure on a single subject. We hypothesize that x_t predicts y_{t+1} and y_t predicts x_{t+1}. This model appears in Figure 19.2.

This is an example of a first-order vector autoregression model (Lutkepohl, 2006). Here, the order of the process represents which of the previous occasions are used to predict the next occasion. With just the previous occasion as a predictor, it is a first-order process. If we used the previous

[4] We also indicate the observed variables as squares. In many SEM programs, regression relationships among latent variables (often shown as circles) are modeled. For observed variable regression, latent variables are set as equivalent to observed variables.

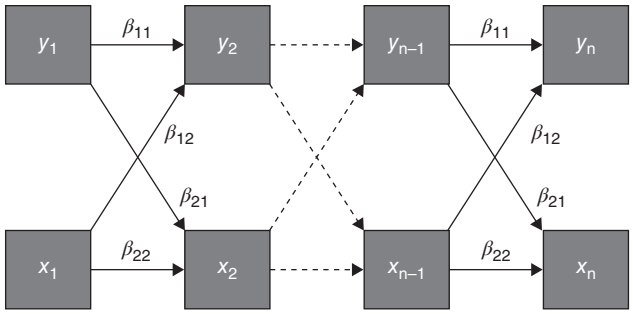

Figure 19.2 A first-order cross-legged vector autoregression model (regression coefficients only).

two occasions to predict, it would be a second-order process. The first-order model presented is equivalent to the set of equations

$$y_{t+1} = \beta_{11} y_t + \beta_{12} x_t + \varepsilon_{1t+1}$$
$$x_{t+1} = \beta_{21} y_t + \beta_{22} x_t + \varepsilon_{2t+1} \quad (19.12)$$

The matrix representation of these equations is

$$\begin{bmatrix} y_{t+1} \\ x_{t+1} \end{bmatrix} = \begin{bmatrix} \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \end{bmatrix} \begin{bmatrix} y_t \\ x_t \end{bmatrix} + \begin{bmatrix} \varepsilon_{1t+1} \\ \varepsilon_{2t+1} \end{bmatrix} \quad (19.13)$$

While this looks much like the cross-lagged regression model described above, here we estimate a separate model for each individual. As a result the $\begin{bmatrix} \beta_{11} & \beta_{12} \\ \beta_{21} & \beta_{22} \end{bmatrix}$ matrix is person specific and not dependent on other individuals' results.

By changing the regression weight matrix, we can create the analog for many different lagged regression models. For example, $\begin{bmatrix} \beta_{11} & 0 \\ 0 & \beta_{22} \end{bmatrix}$ represents the analog to the stability only model (i.e., x_t predicts x_{t+1}, y_t predicts y_{t+1}). The matrix, $\begin{bmatrix} \beta_{11} & \beta_{12} \\ 0 & \beta_{22} \end{bmatrix}$, represents prediction from x_t to y_{t+1}. This latter situation represents the test of Granger causality (Granger, 1969). Here, x is a Granger cause of y. Granger causality has been used in neural network analysis (Seth, 2008), connectivity mapping of fMRI brain scan data (Roebroeck et al., 2005), and econometric modeling (Hatemi, 2012).

Here we assume that the same order of autoregression and the same order of lagged prediction (i.e., x predicting y) would hold for each individual. However, in a true individual approach we would estimate distinct models, which would include determining the order of autoregression for each time series and the order of the lagged prediction. With the proper models, we could determine which individuals have the same models—for example, whether the order of their models is the same, whether the regression coefficients are the same, or whether the variance of the errors is the same. Group models could be constructed for those individuals who have identical models. Nesselroade and Molenaar (1999) suggested methods for pooling the results of individual time series. This approach of creating samples based on the equivalence of individual models guarantees that *ergodicity*, as defined already, is satisfied and that a subgroup with an identical pooled model adequately describes each individual in the subgroup. Using such a strategy, it is most likely that different subgroups based on different (sometimes qualitatively different) models can emerge. When there are different models, the underlying process generating the series would be expected to be different for the subgroups, and this becomes an important and interesting research result. These models can, of course easily be extended to any number of variables.

THE DATA BOX AND FACTOR ANALYSIS

The conceptual framework that allows one to consider the difference between intra- and interindividual approaches in multivariate studies is often linked to Cattell's data box. In his *Handbook for Multivariate Experimental Psychology*, Cattell (1952, 1966a) presented a classification scheme for determining the appropriate analysis for data collected in a multivariate study. The data box as shown in Figure 19.3 has three dimensions: *variables*, *individuals*, and *occasions*. Each two-dimensional slice or *facet* of the box represents a way of constructing an association matrix with each slice having a dimension of interest and a dimension across which the data will be pooled. Cattell gave each two-dimension facet a letter name. The most commonly used are the *R* and *P* facets. When interested in pooling across *individuals* to create a *variable* × *variable* correlation matrix, we are using the *R* facet resulting in *R-technique*. This results in the most common form of factor analysis of interindividual variation. Both common cross sectional and longitudinal factor analysis are examples of *R-technique*. In longitudinal factor analysis the variables collected on multiple occasions are treated along the variables dimension. The data are still pooled across individuals to form a correlation matrix among the variables. Since multilevel growth curve models, repeated measures ANOVA, and latent growth curve models are pooled across individuals, each can be thought of as belonging to the *R-technique* class of analyses.

For person-specific models, the *P* facet takes data for a single subject and pools across occasions to create

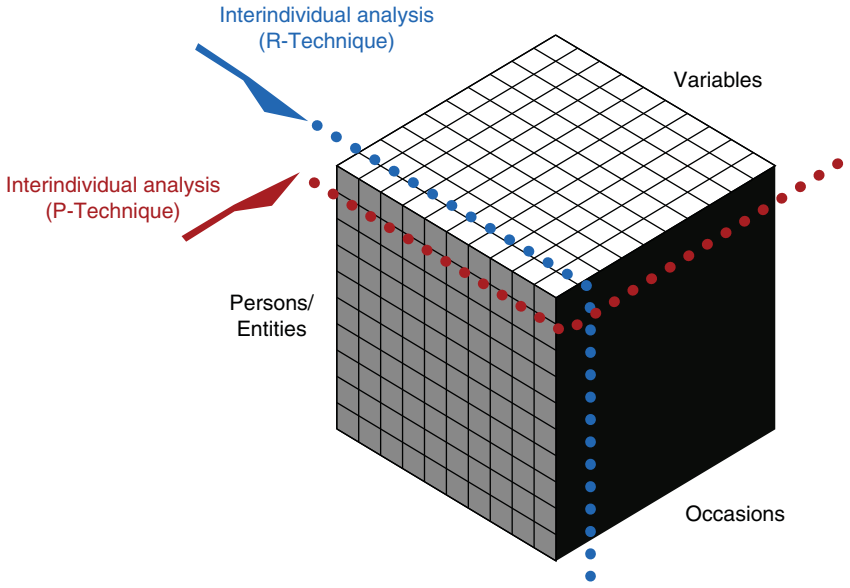

Figure 19.3 The Data Box. See footnote 1.

a *variable* × *variable* correlation matrix of intraindividual variation. Factor analysis of this type of data set is referred to as *P-technique*. The difference between *R*- and *P-technique* is thus the dimension across which one pools based on the way data are collected, where *R-technique* pools across persons and *P-technique* pools across occasions. Facets for both *R*- and *P-technique* appear in Figure 19.3.

Factor Models for Longitudinal Data

Factor models for longitudinal data represent an extension of the common factor model (Gorsuch, 1983; Harman, 1976). The common factor model can be expressed as

$$\vec{y} = \Lambda\vec{\eta} + \vec{\varepsilon} \tag{19.14}$$

where $\vec{y}$ represents the vector of observed variables, Λ represents the matrix of regression weights linking the latent variables to the observed variable, $\vec{\eta}$ represents the vector of latent variable factor scores, and $\vec{\varepsilon}$ represents the vector of measurement errors. Given any factor model the expected covariance matrix of the observed variable based on the model is

$$\hat{\Sigma} = \Lambda\Phi\Lambda^T + \Theta_\varepsilon \tag{19.15}$$

where $\hat{\Sigma}$ is the expected covariance matrix of the observed variables based on the model, Λ is the matrix of factor loadings (i.e., regression weights), Φ is the covariance matrix of the latent variables, and Θ_ε is the covariance matrix of the measurement errors or uniquenesses. In the exploratory common factor model with set number of factors, each observed variable loads on each factor. This means that with, for an example with three factors, each factor predicts each of the observed variables. With means added to the model

$$\mu_y = \tau + \Lambda\kappa$$

where μ_y is the vector of means, τ is the vector of intercepts, and κ is the vector of factor score means[5].

To consider a longitudinal version of factor analysis for the situation in which there are relatively few occasions of measurement, we move to the confirmatory version of the factor model based on *R-technique*. The exploratory longitudinal factor model (for instance, a longitudinal factor model in which at each occasion the factors are uncorrelated, there only are autoregressions between the factor scores, and in which the factor loadings at each occasion only have minimal identifiability constraints) still becomes a confirmatory factor model when fitted to the longitudinal covariance matrix. The confirmatory factor model allows the researcher to specify certain hypotheses based on the parameters of the model. For example, the researcher could expect certain variables to load only on certain factors.

[5]Additional constraints are required; otherwise, the means model would be overparameterized.

Consider the situation in which the researcher has collected the same three variables on three separate occasions assuming that the three variables are indicators of the same latent construct. A sample pattern based on a confirmatory model would have each factor represent the same latent variable at a particular occasion resulting in loadings of 0 for those variables on the other occasions. This would result in the following in the following Λ matrix:

$$\begin{array}{c} \\ y_{1T1} \\ y_{2T1} \\ y_{3T1} \\ y_{1T2} \\ y_{2T2} \\ y_{3T2} \\ y_{1T3} \\ y_{2T3} \\ y_{3T3} \end{array} \begin{array}{c} \begin{array}{ccc} \eta_{T1} & \eta_{T2} & \eta_{T3} \end{array} \\ \begin{bmatrix} \lambda_{11} & 0 & 0 \\ \lambda_{21} & 0 & 0 \\ \lambda_{31} & 0 & 0 \\ 0 & \lambda_{42} & 0 \\ 0 & \lambda_{52} & 0 \\ 0 & \lambda_{62} & 0 \\ 0 & 0 & \lambda_{73} \\ 0 & 0 & \lambda_{83} \\ 0 & 0 & \lambda_{93} \end{bmatrix} \end{array} \tag{19.16}$$

and each row represents a regression equation where the observed along margin represents the dependent variable that is predicted by the latent variables along the top with regression coefficients indicated by the factor loadings.

The covariance matrix among the factors is

$$\Phi = \begin{bmatrix} \phi_{11} & & \\ \phi_{21} & \phi_{22} & \\ \phi_{31} & \phi_{32} & \phi_{33} \end{bmatrix} \tag{19.17}$$

In exploratory factor models, the variance of the measurement errors, the uniquenesses, are estimated. In CFA under certain circumstances measurement errors can be correlated. In this model, we expect that the same variable measured on different occasions may result in correlated measurement errors. This would result in the following covariance matrix of measurement errors:

$$\Theta_\varepsilon = \begin{bmatrix} \theta_{11} & & & & & & & & \\ 0 & \theta_{22} & & & & & & & \\ 0 & 0 & \theta_{33} & & & & & & \\ \theta_{41} & 0 & 0 & \theta_{44} & & & & & \\ 0 & \theta_{52} & 0 & 0 & \theta_{55} & & & & \\ 0 & 0 & \theta_{63} & 0 & 0 & \theta_{66} & & & \\ \theta_{71} & 0 & 0 & \theta_{74} & 0 & 0 & \theta_{77} & & \\ 0 & \theta_{82} & 0 & 0 & \theta_{85} & 0 & 0 & \theta_{88} & \\ 0 & 0 & \theta_{93} & 0 & 0 & \theta_{96} & 0 & 0 & \theta_{99} \end{bmatrix} \tag{19.18}$$

In this model each factor is indicated by three observed variables. In addition to the regression relationships between the latent and observed variables (the factor loadings), characteristics of the latent variables could be of interest. For example, a research question may involve whether the means of the latent variables change across time, or whether there is a distinct pattern of correlation among the latent variables across occasions of measurement.

The set of variables could be, for example, indicators of problematic behavior (e.g., subscales of the Child Behavior Checklist, Achenbach & Edelbrock (1981)), measures of temperament, attachment, or any number of other constructs that are repeatedly measured. A natural extension would have more than one latent variable at each occasion, each one repeatedly measured.

To be able to discuss group differences or characteristics of change in a repeatedly measured latent variable, a certain level of measurement invariance must exist (Meredith, 1993; Millsap & Meredith, 2004; Reise et al., 1993; Vandenberg & Lance, 2000; Widaman & Reise, 1997). The underlying notion of factorial invariance is if that assumption is violated, the same latent construct may not be measured across all groups or across all occasions. This result would strongly limit the ability to interpret any change in the construct. Suggestions for how to deal with differing degrees of factorial invariance have not always been consistent.

Improved model fitting capabilities allow one to more easily test whether invariance has been violated without necessarily suggesting what to do in response to a particular violation (Bontempo et al., 2012; Millsap & Meredith, 2004). Millsap & Kwok (2004) gave a good set of recommendations for how to assess the effect of a particular violation. Millsap (2011) emphasized the multigroup case.

For the previously shown factor pattern, the parameters to be estimated are Λ, the factor loadings; Φ, the factor covariances; and Θ_ε, the covariance matrix of the measurement errors. The model above is based on a correlation or covariance matrix. We could include information about the means as input, which would allow us to also estimate parameters related to the mean structure[6].

[6]Means in longitudinal factor models should be modeled according to a method described by Jöreskog (1978) and Sörbom (1974) to ensure that the means model is appropriate for interval-scaled variables. This requires that at the first occasion the means are freely estimated in τ_y (a saturated means model at the first occasion). Next τ_y is constrained to be invariant across later occasions and only at these later occasions the changes in means are modeled by the factor means in α. If one models all means in terms of α (including at the first occasion and leaving out τ_y) then it is required that the variables have ratio scale.

A typical sequence for testing factorial invariance may include the following levels:

1. Configural invariance—the same patterns of nonzero loadings hold across groups or occasions.
2. Metric or pattern invariance—the values of the loadings are fully invariant across groups or occasions.
3. Strong factorial invariance—the pattern matrices and the latent intercepts are fully invariant across groups or occasions.
4. Strict factorial invariance—the pattern matrices, intercepts, and unique variances are fully invariant across groups or occasions.

The first two invariance criteria were introduced by Thurstone (1947) and the third and fourth by Meredith (1993). To test models of the latent variable means, strong factorial invariance is required.

Like the cross sectional common factor model, the longitudinal factor model requires as input the correlation (or covariance) matrix of the input variables. Individual values of the variables are not needed to estimate the model. The factor loadings are group-based, not person-specific. Factor scores are generated as post hoc predictions using a similar procedure to that of the latent growth curve's random effects. In fact, the multilevel growth curve model can estimated as a structural equations model (Rovine & Molenaar, 2000). In this form, the random effects are the factor scores of the model estimated using the fixed effects and the covariance matrix of the random effects under certain specified distributional assumptions. Since estimated models are based on input matrices pooled across individuals, they are models of interindividual differences. Despite the importance and utility of this model, it is not person specific.

Person-Oriented Approaches

Certain methods described as person-oriented approaches (Bergman & Magnusson, 1997) are typically described as a counterpoint to variable-oriented analysis (Bergman & Trost, 2006). These often involve cluster analyzing repeatedly measured data to identify subgroups of individuals who have similar sets of variable values across occasions of measurement. As can be shown, under certain circumstances, a cluster analysis can be transformed into a factor analysis. As such, this analytic approach may pool across individuals. Under these circumstances, cluster analysis generalizes across individuals, not occasions. This approach is thus an interindividual differences approach rather than a person-specific approach.

P-Technique Factor Models

As previously stated, the *ergodicity* hypothesis implies that a group-based result can apply to an individual only when that model holds for each individual. Without true time-series data that assumption cannot be tested. As Molenaar (2004) argued, the result of this is that cross sectionally or longitudinally derived factor models based on a covariance matrix pooled across individuals (R-technique) can be quite different from those derived separately for each individual. The individual approach, based on P-technique factor analysis, is a true intraindividual method.

P-technique factor analysis has been used to study stepchildren's emotional experiences (Corneal & Nesselroade, 1994), changes in mood (Bath, Daly, & Nesselroade, 1976), and changes in attachment security (Mitteness & Nesselroade, 1987) using essentially the standard (R-technique) factor analytic approach with occasions taking the place of individuals.

For the basic P-technique model, the data for each subject are pooled across occasions resulting in a variable × variable association matrix. For the analogous three variable factor model shown above as a longitudinal factor model, the set of equations represented by this model is represented by the matrix equation

$$\begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix}_t = \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \end{bmatrix} [\eta]_t + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \end{bmatrix}_t \tag{19.19}$$

where a single factor replaces the occasion factors of the longitudinal factor analysis and a single set of loadings represents the requirement of invariance across the time series. This model would be estimated separately for each subject.

The Dynamic Factor Model

The P-technique makes certain assumptions regarding the nature of relationships across occasions of measurement. Most importantly, the model assumes that there are no lagged relationships among the occasion variables. The association matrix that is analyzed pairs variables at each occasion to construct the correlation. While this model has been shown to be more widely applicable than one might expect (Molenaar & Nesselroade, 2009), models that address the question of lagged relationships and determine the order of lags represent an important approach. Molenaar (1985) presented an extension of the P-technique model, the dynamic factor model that properly addresses the question of whether or not the relationship among

variables is lagged, and if so, what is the order. The dynamic factor model is

$$y_t = \sum_{u=0}^{s} \Lambda_u \eta_{t-u} + \varepsilon_t \qquad (19.20)$$

where $\Lambda_u$contains the factor loading for lag, u. With this model the researcher can determine the degree to which latent variables and residuals are correlated over time. When $s = 0$, the model reduces to the state space model in which the evolution of factors is explained by a vector autoregressive process (VAR).[7] These models and their variants have appeared under somewhat different names (Nesselroade et al., 2002). Wood and Brown (1994) showed a relatively straightforward method for implementing this model as a structural equations model.

DATA EXAMPLES

Data Example 1: The Borkenau and Ostendorf Data Set

Here, we demonstrate an instance of that situation of a violation of ergodicity assumption for personality factors based on the big five using a data set provided by Borkenau and Ostendorf (1998). This data set included 22 individuals followed on a daily basis over 90 days with 30 personality items being repeatedly measured. The participants were psychology students from the University of Halle, Germany; course credit was given for participation. The sample consisted of 19 women and three men who were mostly 19-year-olds or in their early 20s, except for three females who were in their 30s or 40s. In the current example, an exploratory factor analysis is carried out at both the cross sectional group level (R-technique) and for several individuals at the person-specific time-series level (P-technique; Nesselroade & Jones, 1991). Here, we will demonstrate that the number of cross sectional factors gives a poor indication of the factor structure for each of the three individuals considered.

In the exploratory approach to factor analysis, we initially want to determine the number of factors or latent variables that underlie the set of observed variables considered. For the Borkenau and Ostendorf data set we first determined the number of factors cross sectionally (R-technique). The scree plot for these data appears in Figure 19.4. The scree plot (Cattell, 1966b) is a commonly used visual guide for determining the number of factors in a solution. In the plot the points represent the results of an eigenvalue decomposition of the input correlation matrix. The eigenvalues are ordered from largest to smallest and can be thought of as incrementally explaining the set of correlations among the variables. Each eigenvalue corresponds to one possible factor, and some subset of these factors will be able to adequately reproduce the input correlation matrix. The question is to find this optimal number of factors. The scree plot does so by indicating the point at which the remaining factors are most likely trivial. This point is usually depicted by an *elbow* in the scree. For the cross sectional data, the elbow seems to appear at the fourth eigenvalue. For Subject A, the elbow appears at either eigenvalue 2 or eigenvalue 4; for Subject B at the third eigenvalue; and for Subject C at the second, third, or fourth eigenvalue. Because this perusal approach can be somewhat subjective, several numerical criteria have been developed. Here we employ the acceleration factor (AF; Raiche et al., 2006). The AF has been established as a good selection procedure for both R- and P-technique. The approach looks at the derivative (the slope) of the scree plot and determines where the slope changes most rapidly (accelerates). This typically represents the elbow of the curve. Using this approach, we determined that the elbow did indeed occur at the fourth eigenvalue for the cross sectional data indicating a three-factor solution. For three individuals, Subject A had a one-factor solution (elbow at the second eigenvalue), and Subjects B and C both had a two-factor solution. The solution from the cross sectional data described none of the three subjects adequately.

This example demonstrates how the number of factors determined in a group-level R-technique factor analysis may be inconsistent with subsequent individual factor models obtained via individually applied P-technique analyses.

Data Example 2: PANAS Data

Using data taken from a study of stepchildren, Corneal and Nesselroade (1994; see also Corneal & Nesselroade, 1991; Molenaar et al., 2009; Rovine, Molenaar, & Corneal, 1998; Molenaar et al., 2009) showed a similar result based on time-series assessments of emotions.

The data were measures designed to analyze the emotional experiences of stepsons as they interacted with their stepfathers over a 2-month period. After a specified type of interaction with their stepfather (including mealtimes, leisure activities, conversations, arguments, and disciplines), the stepson would complete the Positive and Negative Affect Scale (PANAS; Watson, Clark, & Tellegen, 1988) to assess the emotional content of the interaction.

[7]This VAR is implicit in the general model (20) because it is simplest to treat the evolution of factor scores as a white-noise process. Molenaar and Nesselroade (2001) showed that other choices are possible, including VARs. Only these choices have to be fixed.

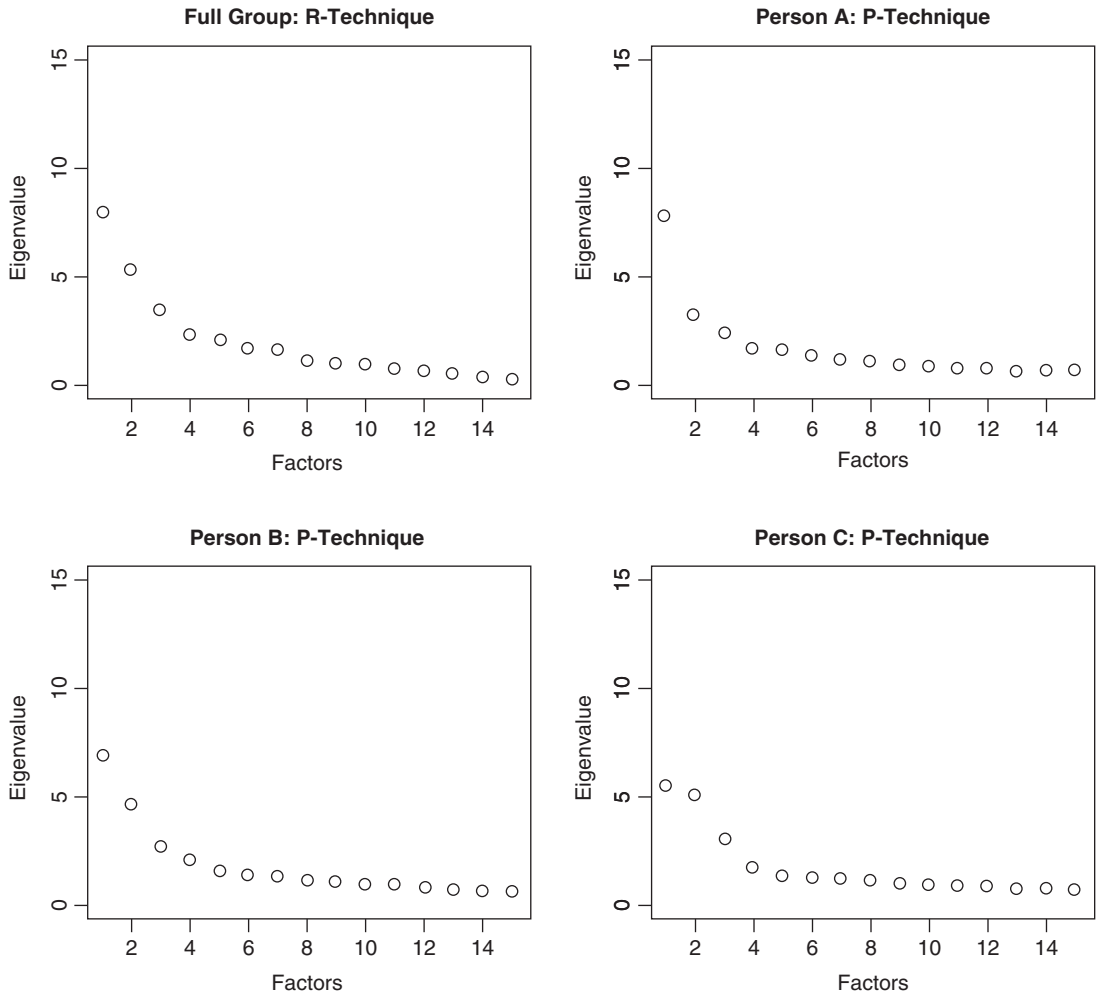

Figure 19.4 A comparison of scree plots of the Borkenau data.

To the 20 items of the PANAS, eight involvement items were added. Since the 20 items were developed for high internal consistency, the 28 items were expected to have a two-factor structure. The items representing this factor structure along the with-fit indices for Stepson 1 are shown in Table 19.1. While the two-factor solution typically shows up in the analysis of cross sectional data, the two-factor confirmatory solution showed a very poor fit. In fact the two-factor solution was a poor model for all stepsons included in this study. For each subject we first tested the two-factor model. After the model was rejected, we moved to an exploratory factor analysis to determine the proper number of factors. Using the salient loadings for each stepson, we then fit a confirmatory factor model. We include the results for three of the stepsons in Table 19.2.

The results indicate the very intuitive result that different children respond to a situation by experiencing different combinations of emotions. For Stepson 1, a five-factor solution seemed the best fit. Looking at the items that load, the factors can be described as Interest, Anger, Anxiety, Affection, and Closeness. A number of variables loaded on more than one factor. Certain variables can be expected to help define more than one factor. For example, *enthusiasm* is an indicator of both Interest and Anger with a positive loading on Interest and a negative loading on Anger. The combination of variables that load on a particular define that factor for a specific stepson. While Anger may exist as a factor for each of the stepsons, its definition in terms of the variables that comprise the factor can vary. When Stepson 1 felt *anger* during interactions with his stepfather, he felt less *accepted*. For Stepsons 5 and 6, *anger* was accompanied by a feeling of *anxiety*. Stepson 5 also felt less loved when he felt *anger*.

Stepson 5 differed from Stepson 1 in some important ways. For Stepson 4, a four-factor solution seemed most appropriate. Two factors that we labeled Strength and Shame appeared for Stepson 5 that had not occurred in Stepson 1. Stepson 6 had a three-factor solution as the best fitting model. Here, Anger and Anxiety items appeared on a single factor. Interest and Affection items also tended to appear on the same factor. A Strength factor similar to Stepson 5 also appeared.

The results shown here indicate the importance of at least considering the person-specific approach in looking at factor structures. By pooling across subjects, the investigator is assuming that differences in individuals should be treated as essentially error. If the differences are systematic and represent important descriptive information, that information is lost when pooling to estimate models. The result of using the assumed cross sectional two-factor solution to describe each subject in this study would be that a wealth of information describing how these stepsons differ in their interactions with the stepfathers would be lost.

DISCUSSION

Clearly pooling across heterogeneous cases whether they be replications, subjects, or systems can be ill advised. Applying analysis of interindividual variation to heterogeneous data that involves pooling across subjects that obey subject-specific models can lead to results that poorly describe individuals and poorly describe the group. We argue, instead, that such data should be subjected to the analysis of intraindividual variation that is specifically designed to detect the kind of heterogeneity that analysis of interindividual variables essentially ignores.

However, carrying out separate single-subject analysis of the intraindividual variation of a sample of subjects may yield a bewildering collection of different subject-specific dynamic models. For this situation there is obviously an urgent need for methods to bring order to these separate models. This represents the need to arrive at nomothetic models for intraindividual variation.

One promising approach to accomplish this is the so-called Idiographic Filter proposed by Nesselroade et al. (2007). The basic idea underlying the Idiographic Filter is the recognition that the way latent factors manifest themselves in observed variables can be subject-specific. For instance, in our second data example, for Stepson 5, anger is accompanied by being nervous and scared, which for Stepson 1, that is not the case. The Idiographic Filter thus allows for subject-specific factor loadings while locating homogeneity at the latent level.

Molenaar (et al., 2012) has applied a generalized version of the Idiographic Filter (iFACE) to the analysis of multivariate time series obtained with a pair of genetically related subjects allowing for subject-specific heritabilities and environmental effects. A first application of the iFACE to multilead EEG obtained in an oddball task shows clear evidence for considerable subject-specificity of heritable and environmental effects.

While the Idiographic Filter can accommodate heterogeneity due to subject-specific factor loadings, Molenaar recently developed an alternative approach called the Group Iterative Multiple Model Estimation (GIMME; Gates & Molenaar, 2012) which can accommodate arbitrary subject-specificity of both factor loadings and any other parameters in state space models using a variant of the structural equations model referred to as the unified SEM (Gates *et al*., 2010).

GIMME has been used in a number of studies including the analysis of a large and multifaceted simulated data set considered in Smith et al. (2011), who tested 38 methods to estimate connectivity networks based on multivariate fMRI time series. The methods included Bayesian net approaches and vector autoregressive modeling. None of these methods did well in terms of recovering the presence of directed links among component series. This surprising result, obtained with realistic simulation of BOLD activities of brain regions of interest under a wide variety of conditions (varying signal-to-noise, varying dimensionality of the observed time series, varying number and strength of links, etc.), created quite a stir in the brain imaging community. When GIMME was applied

to these data, all directed links and the numerical values of their weights were recovered with close to or exactly 100% fidelity (see Gates & Molenaar, 2012, for a complete report of these results). GIMME has been most often applied to brain imaging data, but more recently it has been extended to the description of behavioral processes (Belz, et al., 2013). GIMME can be freely accessed at www.nitrc.org/projects/gimme/. We note that GIMME is unique in providing a valid way to determine common dynamic models for heterogeneous replicated time series, thus yielding generalizable (nomothetic) results about idiographic processes.

We feel that the importance of the subject-specific approach to the modeling of intraindividual variation in the statistical analysis of developmental processes in particular is clear. All nonergodic processes such as developmental processes should initially be analyzed at the level of intraindividual variation, i.e., single-subject time-series analysis. From this starting point several courses of action can be followed in attempts to obtain nomothetic knowledge about intraindividual variation. One could apply the methodologies used in cognitive neuroscience and/or neuropsychology to generalize to nomothetic knowledge from single case analyses. Or one could use the Idiographic Filter or GIMME approaches for the same purpose. We hope and expect that in addition to these well-established approaches other new alternative methodologies will be found to obtain nomothetic knowledge about intraindividual variation, because this is an essential endeavor to move our science forward.

FUTURE DIRECTIONS

Cicchetti and Toth (2009) emphasized the importance of "translat[ing] basic research knowledge into real world contexts." We believe that an important way to allow this clinical translation to occur is to ensure that appropriate models are used to describe a successful therapeutic intervention. The approaches to targeting interventions based on single subject, person specific modeling seem very appropriate to this task. In particular, the notion of optimal control, of moving the individual toward a specific goal or set of goals using a model that can assess whether the person in on target and suggest a change of direction when not on target seems to be an important tool to add to the field. This approach has been successful in many other areas and disciplines. To move the field of developmental psychopathology forward we believe that this approach should be added to the toolbox of researchers. Using these methods requires the collection of more intensive data, but given the increasing popularity of data collection methods such as those based on Ecological Momentary Assessment (EMA), the single subject, person-specific modeling approach is becoming more feasible. It may take some ingenuity on the part of the researchers to design approaches that make use of these methods, but that alone represents an important challenge for clinicians and other investigators. In some areas of research, sufficient data already exist to make use of single subject methods. For example, work in the area of experience dependent brain development makes use of brain-scan data. The development of models requires individual models of developing connectivities. Methods such as the GIMME method described above are designed specifically for such a problem. As mentioned above, all nonergodic processes such as developmental processes should be analyzed as a single-subject time-series analysis. Methods such as GIMME and the idiographic filter can and should be applied to a wide range of problems in the behavioral sciences. We believe that researchers in the area of developmental psychopathology should look for opportunities to apply these methods, which will hopefully help to better describe the pathways to and out of abnormal development while describing conditions of resilience and improving the outcomes for those experiencing these problems.

INTRODUCTION

Developmental processes, either typical or atypical, are inherently about changes that occur over time in response to internal and external stimulation at the individual level. Recent development of statistical methods of analysis has resulted in a situation that is quite interesting and encouraging for researchers of developmental processes because both type and number of questions that can be answered has increased dramatically. This increased capacity allows researchers to answer scholarly questions that seemed intractable just a few years ago. Just think of dynamic modeling, modeling of trajectories and mixtures, the new models and methods for intensive longitudinal data, and for categorical or nonnormal data, or the new approaches to the analysis of causal hypotheses (for overviews, see Everitt & Howell, 2005; Laursen, Little, & Card, 2012; von Eye & Mun, 2013; von Eye & Wiedermann, 2013). The doors for sophisticated data analysis and, more important, for analysis that exactly tests the hypotheses that researchers ask are wide open.

[1]Color versions of Figures 20.1, 20.5–20.7 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

By the same token, however, this situation causes worry. A disconnect between theories of development and methodological application has also emerged. Theorists of person-oriented research (see Bergman & Magnusson, 1997; von Eye & Bergman, 2003; von Eye, Bergman, & Hsieh, 2015; see also Ch. 18) as well as idiographic psychology (Molenaar, 2004; Molenaar & Campbell, 2009) have suggested and shown that the results of typical statistical analysis are not applicable at the level of individuals. This is because most statistical methods perform analysis on aggregated data (e.g., means and covariances). A prominent example is the analysis of covariance matrices in structural equation modeling. These matrices contain variances in their diagonal cells and covariances in their off-diagonal cells. By definition, these aggregate measures indicate variability that is averaged over the individual cases included in a study. The cases themselves are considered random and, thus, replaceable (by other random cases).

Because of these characteristics, it is rare that any results from aggregated data do indeed apply to the individual. In longitudinal research, in particular dynamic modeling, very strict ergodicity conditions must be fulfilled for the results of aggregate-level, statistical inference to be applicable to the individual (see Loken, 2010; Molenaar, 2004; von Eye, Bergman, & Hsieh, 2015). Examples of such rigid conditions

include stationarity, that is, the data follow a stochastic process whose joint probability distribution is not sensitive to shifts in time and space. The parameters of such stochastic processes, for example, the mean and variance, will also be insensitive to shifts in time and space. Clearly, most developmental processes violate the stationarity condition. Note that we argue not that any data analytic techniques based on aggregate level data are not useful but that these characteristics necessitate that one needs to be aware of these assumptions and be cautious in interpreting results.

To be less confined and be truer to theories, what is needed, therefore, are methods of statistical data analysis that have the following two characteristics. First, they allow one to make statements about individuals or groups of individuals. Second, they do not require that improbable conditions for the process under study be met. *Configural frequency analysis* (CFA; Lienert & Krauth, 1975; von Eye, 2002; von Eye & Gutiérrez-Peña, 2004; von Eye, Mair, & Mun, 2010) is such a method. In this chapter, we introduce readers to CFA and give examples of questions that can be answered using this method. These questions differ from those that can be answered using standard methods of analysis. Instead of targeting relationships among variables, they target individual or groups of configurations, that is, individual profiles.

Before we discuss the technical aspects of CFA, its application and computation, we ask, however, where the disconnect between developmental theories and analytic practices has occurred in the field of developmental research. The answer to this question can be used to locate or develop statistical methods that do not suffer from the problems mentioned previously. To answer this question, we use the example of Eysenck's (1958) approach to the development of a personality theory (von Eye & Bogat, 2006). As is illustrated in Figure 20.1, Eysenck's approach involves proceeding through a hierarchy of steps.

At the lowest level of the hierarchy, indicated by the boxes at the bottom of the figure, researchers focus on what Eysenck terms *specific reactions*. These are behaviors that are observed for an individual, at a particular moment. For example, a child may act in defiance of his/her mother's instruction to clean up after playing with toys. Specific reactions are just observed and recorded. No evaluation or comparison is involved or intended. The next higher level in the hierarchy is that of *habitual reactions*. For example, the child tends to exhibit hostile behaviors toward the mother whenever instructed to clean up after playing. At the level of habitual reactions, ipsative comparisons (e.g., the same individual's behavior compared with that from a day or week before) but also comparisons with other individuals (e.g., different individuals at a given moment) can be made. In more general terms, at this level, statements are already made that go beyond specific observations. The third level is that of *personality characteristics such as perseverance, rigidity, or irritability*. At this level, statements are made that carry the researcher beyond a particular behavior observation, even beyond the individual that was observed. For example, one can talk about communication style preferences, regardless of the individuals who may or may not exhibit these preferences. At the highest level, *personality types* are defined. These types are based on grouping personality characteristics. In Eysenck's theory, we find the type of extraverted versus introverted personality characteristics, the type of stable versus labile personality characteristics, and the type of psychoticism.

Figure 20.1 shows where the disconnect occurs: between the levels of habitual reactions and personality characteristics (separated by the dotted line). Below the dotted line, descriptive or comparative statements are made about individuals. Above the dotted line, statements describe personality characteristics. These statements are abstract, and references to the individual are not necessarily implied. Standard statistical analysis relates personality characteristics to one another (cluster analysis of cases being among the few exceptions). In contrast, CFA analyzes individuals with particular profiles. Specifically, CFA creates all possible profiles for a set of categorical variables, and answers the question whether individual profiles were observed at different rates than expected from prior knowledge or theory. Analyses that focus on the information provided above the dotted line (variables) have been termed *variable oriented*. Analyses that focus on the information

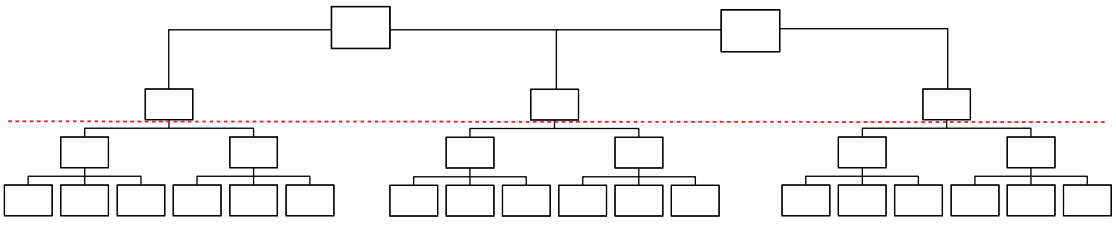

Figure 20.1 Constructing models of personality. See footnote 1. Source: Eysenck (1958).

provided below the dotted line (individuals) have been termed *person oriented* (see Bergman & Magnusson, 1997; von Eye, Bergman, & Hsieh, 2015; Ch. 18). CFA is regarded as among the prime methods of analysis for person-oriented research (Bergman, Magnusson, & El-Khouri, 2003). Although person-oriented research requires many other considerations, such as study design and assessment, this chapter focuses on CFA, a particular analytical approach that is useful in person-oriented research.

CFA proceeds from the person-oriented assumption that development is best described by patterns of characteristics (instead of variable relations). This is most relevant for research in developmental psychopathology, where we find that the development of pathological processes can be very specific to particular groups of individuals, causes, timing, and circumstances. This applies accordingly to translational and intervention research. These topics are taken up again later in this chapter.

This chapter is structured as follows. First, we introduce readers to CFA. We cover conceptual and technical aspects of CFA. This introduction will be selective. More detail can be found in von Eye (2002) and von Eye, Mair, and Mun (2010). After this introduction, we present models of CFA that are of importance for research in developmental psychopathology. Throughout, examples will be given with real data.

Introduction to Configural Frequency Analysis

CFA was proposed by Lienert in 1968 as a method that is particularly suited for clinical research and has since been developed further. CFA allows researchers to answer the question whether, given explicit expectations, individuals with certain profiles were observed at higher or lower rates than expected. The answers to this question can be used to provide support for a hypothesis or a theory. In addition, CFA can test whether the definition or the operationalization of a concept is valid. To give an example, consider a certain mood that is associated with depression. Individuals diagnosed as depressed often feel sad, anxious, hopeless, worthless, guilty, or irritable. In contrast, individuals diagnosed as depressed rarely feel happy or proud. Therefore, the null hypothesis stipulating that sad and happy moods can coexist in time within a person will, in an empirical study, be rejected. The two variables sadness and happiness are related such that the individual mood profile [sad, happy] is expected with below chance probability. Interestingly, it can also be discussed whether the profiles [not sad, happy], [not sad, unhappy], and [sad, unhappy] will be observed with above or below chance probability. In CFA, individual profiles are examined.

CFA is used to analyze cross-classifications of categorical variables. In this respect, CFA is comparable with log-linear modeling (Bishof, Fienberg, & Holland, 1975; von Eye & Mun, 2013), logistic regression (see Agresti, 1998), or latent class analysis (see Goodman, 1974). CFA differs, however, from these methods in that it does not attempt to explain the relations among variables. It allows one to examine individual cells of cross-classifications (also called *configurations*, *cells*, *patterns*, or *profiles*) with the question whether their occurrence frequencies differ from expectancy. Groups of cells can also be examined.

More generally, cross-classifications of categorical variables can be analyzed with specific aims in mind. Goodman (1984) listed the aims of examining

1. the joint distribution of the variables that span a cross-classification;
2. the association structure of these variables; and
3. the dependency structure of these variables. CFA adds a fourth aim. It asks whether individual cells or groups of cells deviate from the expectancy that is specified using a probability model. Later in this chapter, we describe in more detail how a CFA probability model is specified. Von Eye and Gutiérrez-Peña (2004) note that CFA is used to identify those *cells of a cross-classification where the action is*. In these cells, *local associations* (Havránek & Lienert, 1984) become apparent. That is, in particular cells, there is an association among the variables that span a cross-classification, as is manifested by above-chance or below-chance frequencies of observations. In other cells, observations are as frequent as expected with reference to the probability model (also called *base model*). Cells that contain more cases than expected are labeled as constituting a *CFA type*. Cells that contain fewer cases than expected are labeled as constituting a *CFA antitype*.

To illustrate these concepts, we present a first data example. The data in this example were collected in the context of the Mother–Infant Study (MIS; Bogat, Levendosky, DeJonghe, Davidson, & von Eye, 2004; Huth-Bocks, Levendosky, & Bogat, 2002). The study first assessed women in their last trimester of pregnancy and again at 2 months postpartum and followed up the women and their children every year until the children were 14 years old. The women in the study reported a range of experiences of intimate partner violence, from none to severe. Intimate partner violence was defined as

male violence toward a female partner. Research questions concerned factors that predict risk and resilience in women exposed to intimate partner violence and their children as well as aspects of the home environment (e.g., maternal mental health, parenting style); and individual child characteristics (e.g., temperament) that predict maladaptive socioemotional outcomes (e.g., aggression; for results, see, e.g., Bogat et al., 2004; Huth-Bocks, Levendosky, Bogat, & von Eye, 2004; www.msu.edu/∼mis/).

For the first data example, we use the variables posttraumatic stress disorder (PTSD) symptoms (P), Income (I), and Depression (D) observed at the first occasion, that is, in the last trimester of pregnancy. The variables were binned close to their median. For each of the variables, 1 indicates below the cutoff and 2 above the cutoff. Table 20.1 displays the CFA results for the $2 \times 2 \times 2$, P × I × D cross-classification. Without going into the technical details, which will be introduced later, we report that this table was analyzed under the base model of variable independence, standard normal z scores were used to evaluate the individual cells, and α was protected using the Holland–Copenhaver procedure.

The overall goodness-of-fit likelihood ratio X^2 for the base model of variable independence for the data in Table 20.1 is 45.60. For $df = 4$, this value suggests that the model is rejected ($p < 0.01$). This is the typical situation for a CFA that results in types and antitypes. In Table 20.1, we see two types and one antitype. The first type is constituted by configuration 1 2 1. These are women whose PTSD and Depression symptom scores were below the cutoff, and income was above the cutoff. Significantly more women showed this profile than expected with reference to the base model of variable independence. The second type, constituted by configuration 2 1 2, shows just the opposite profile. These are women with elevated PTSD and Depression symptom scores and Income below the cutoff. Again, significantly more women than expected showed this profile.

TABLE 20.1 First-Order CFA of the Cross-Classification of PTSD (P), Income (I), and Depression (D)

	Configuration				
PID	m	$\hat{m}$	Statistic	p	
111	28.00	37.317	−1.5251	.063612	
112	12.00	15.847	−.9663	.166938	
121	53.00	30.770	4.0076	.000031	Type
122	4.00	13.067	−2.5082	.006067	Antitype
211	37.00	42.703	−.8727	.191425	
212	37.00	18.134	4.4303	.000005	Type
221	28.00	35.211	−1.2152	.112144	
222	9.00	14.953	−1.5394	.061855	

The sole antitype in Table 20.1 is constituted by configuration 1 2 2. The women with this profile exhibit below-the-cutoff scores in PTSD, and above-the-cutoff scores in Income and Depression. This profile was observed four times, which is significantly below the expected frequency of about 13.

The results shown in Table 20.1 are typical of CFA results in a number of aspects. First, in Table 20.1, the largest cell does constitute a type and the smallest cell does constitute an antitype. This is not always the case. The main reason for this characteristic of CFA results is that CFA focuses on *discrepancies from expectation* instead of sheer size of cells (the base model of zero-order CFA is the only exception; Lienert & von Eye, 1989; von Eye, 2002). Therefore, even relatively small cells can contain more cases than expected, and relatively large cells can contain fewer cases than expected. Later in this chapter, Table 20.12 shows an example in which one of the smallest cells constitutes a type.

Second, CFA tables of types and antitypes are interpreted after the base model is rejected. However, we note that the rejection of a base model does not guarantee that types and antitypes exist. If a base model describes the data well, there will be no noteworthy discrepancies between observed and expected cell frequencies, and the search for types and antitypes that indicate the location of significant discrepancies is largely pointless. And finally, only a selection of cells (configurations) emerges as type or antitype constituting. The remaining cells do not statistically deviate from the base model.

In the following sections, we describe technical elements of CFA (for more detail, see von Eye, 2002; von Eye & Gutiérrez-Peña, 2004; von Eye, Mair, & Mun, 2010).

CFA: Technical Elements

We begin the description of technical elements of CFA with a discussion of CFA base models. These models are of crucial importance because the interpretation of CFA types and antitypes depends on the effects that are (not) included in the base model. In general, the base model includes all effects that are not of interest to the researcher. If the base model is rejected, at least some of the effects the researcher is interested in are bound to exist. Naturally, *different base models can lead to different expected cell frequencies* (Mellenbergh, 1996) and, thus, different patterns of types and antitypes. Therefore, the selection of base models is not arbitrary.

Definition of CFA Base Models. Most CFA base models are log-linear models (for base models that are not

log-linear, see von Eye, 2002). Therefore, expected cell frequencies for most CFA models can be estimated using the log-frequency model

$$\log \hat{m} = X\lambda$$

where $\hat{m}$ is the array of model frequencies, that is, frequencies that conform to the model specifications. X is the *design matrix* (also called *indicator* matrix). Its vectors reflect the CFA base model or, in other contexts, the log-linear model under study. λ is the vector of model parameters. These parameters are not of primary interest in frequentist CFA. Instead, CFA focuses on the discrepancies between the expected and the observed cell frequencies. In contrast to log-linear modeling, CFA is not applied with the goal to identify a model that describes the data sufficiently and parsimoniously. Rather, CFA is applied with the goal of identifying the configurations that contradict the base model. These configurations reflect the effects of interest.

CFA base models have three main characteristics (von Eye, 2004a):

1. They contain all effects that are *not* of interest to the researcher;
2. They reflect theoretical assumptions concerning the nature of the variables as either of equal status or grouped into predictors and criteria; and
3. Consider the sampling scheme under which the data were collected. In the following paragraphs, we discuss two of these three characteristics. We begin with the third.

In practically all CFA applications, the sampling scheme is either *multinomial* or *product-multinomial*. When the scheme is multinomial, cases can be placed in any cell of a cross-classification, with no constraints. Marginal probabilities of the data collected under this sampling scheme are neither a priori given nor determined. In contrast, when the sampling scheme is product-multinomial, marginal probabilities of the data collected using this sampling scheme are given a priori. So, when a study focuses on the effects of smoking, researchers may wish to implement a balanced design such that equal numbers of smokers and nonsmokers go into the table. In this case, no additional smokers can enter the study when this subsample is filled. From a data analytic perspective, the sampling scheme has no implications for parameter estimation. However, the number and type of base models that can be estimated are restricted under the product-multinomial sampling scheme (for more detail, see von Eye et al., 2010).

The first of these characteristics is most important for the interpretation of types and antitypes. A CFA base model contains all effects that are *not* of interest to the researcher. Consider two examples. The base model used for the analysis reported in Table 20.1 was the model of variable independence. That is, the base model included only the main effects of the three variables PTSD, Income, and Depression. This model prevails only if the three variables are indeed independent of one another. If, however, one or more of the three possible two-way interactions, or the three-way interaction among all three variables exist, the model is rejected. In other words, from the fact that the base model of variable independence is rejected, we conclude that interactions exist. From the emergence of types and antitypes and the existence of configurations that do not contradict the base model, we conclude that local associations exist (Havránek, & Lienert, 1984). Types and antitypes that result from the bae model of variable independence thus indicate that interactions exist and where the interactions exist.

For the second example, consider the base model of Prediction CFA (PCFA; Heilmann & Lienert, 1982; Heilmann, Lienert, & Maly, 1979; Lienert & Krauth, 1973a; von Eye, Mair, & Bogat, 2005; von Eye & Rovine, 1994). This base model includes two sets of effects. The first is defined by all possible effects on the predictor side. The model is thus saturated within the predictors. Types and antitypes cannot emerge just because predictors are related to one another. Second and in parallel, the base PCFA model is also saturated in the criterion variables. Therefore, types and antitypes cannot emerge just because criterion variables are related to one another. Third, the PCFA base model proposes independence between the two sets of variables: predictors and criterion variables. If this model is rejected, types and antitypes, by necessity, reflect relationships that link predictor variables with criterion variables. This characteristic is exemplified when we specify log-linear CFA base models, in the following paragraphs.

For the purposes of this chapter and in correspondence with the literature on log-linear modeling and CFA, we use two ways to specify a CFA base model. The first is the *log-linear notation*. Its main characteristic is that every main effect, interaction, special effect, and covariate are represented in the equation. Consider the base model for the example in Table 20.1. This model contains only the main effects of P, I, and D. The general log-linear model $\log \hat{m} = X\lambda$ is then, in this particular case,

$$\log \hat{m} = \lambda + \lambda^P + \lambda^I + \lambda^D$$

where $\hat{m}$ is the vector of expected cell frequencies (model frequencies), λ is the intercept, and the superscripted λs represent the main effects of the variables *P, I*, and *D*, respectively. In this particular case, each λ corresponds to one parameter. When effects require more than one parameter, which is the case when variables have more than two categories, subscripts are used to differentiate these categories.

To illustrate the PCFA base model, consider the two predictors, *P*1 and *P*2, and the two criterion variables, *C*1 and *C*2. The log-linear base model for these four variables is

$$\log \hat{m} = \lambda + \lambda^{P1} + \lambda^{P2} + \lambda^{C1} + \lambda^{C2} + \lambda^{P1,P2} + \lambda^{C1,C2}$$

The first line of this equation contains the main effects of all variables in the model. The second line contains the interaction between the two predictor variables and the interaction between the two criterion variables. All log-linear base models can be expressed using this notation.

In addition to the log-linear notation, we use the *bracket notation*. This notation includes each effect in a pair of brackets. For main effects, a bracket pair will include just one variable. For two-way interactions, the bracket pair includes two variables, and so forth. The base model of variable independence used for Table 20.1 contains three main effects. In bracket notation, this model is [*P*], [*I*], [*D*]. The PCFA base model is, for the last example, [*P*1], [*P*2], [*C*1], [*C*2], [*P*1, *P*2], [*C*1, *C*2].

Many CFA base models are hierarchical log-linear models. In these hierarchical models, the lower order relatives of higher order terms are implied. Therefore, these lower order terms can be omitted in the model specification. They are included in the model, but, in the specification, they are redundant. The base model of variable independence cannot be simplified further, because the main effects are the lowest order effects in a log-linear model. In contrast, the PCFA base model can be simplified to [*P*1, *P*2], [*C*1, *C*2]. In this chapter, to be consistent with the CFA literature, and because some CFA base models are not hierarchical, we specify base models so that every effect under consideration is made explicit.

We now ask which effects can be the causes for types and antitypes in the base model of variable independence. As we said before, these are effects that represent interactions. In the first data example, these are the effects [*P, I*], [*P, D*], [*I, D*], and [*P, I, D*], that is three two-way and one three-way interactions. If any of these effects exists, types and antitypes can emerge from the base model [*P*], [*I*], [*D*].

For the PCFA base model of the second example, the following effects may exist and cause types and antitypes to emerge:

- Two-way interactions: [*P*1, *C*1], [*P*1, *C*2], [*P*2, *C*1], and [*P*2, *C*2];
- Three-way interactions: [*P*1, *P*2, *C*1], [*P*1, *P*2, *C*2], [*P*1, *C*1, *C*2], and [*P*2, *C*1, *C*2];
- Four-way interaction: [*P*1, *P*2, *C*1, *C*2].

Each of these interaction terms contains at least one predictor and at least one criterion variable. Types from PCFA indicate which predictor configurations allow one to predict the occurrence of which criterion configuration. PCFA antitypes allow one to predict which criterion configuration cannot be expected to occur after which predictor configuration. Given the right context, causal inference may be possible. Types could then be interpreted as predictor configurations that cause criterion configurations to occur. Antitypes could then be interpreted as predictor configurations that prevent criterion configurations from occurring.

Classes of CFA Base Models

Two classes of log-linear CFA base models have been discussed: *global* models and *regional models* (von Eye, 1988, 2002). Global models share the characteristic that all variables have the same status. There are no predictors, no criterion variables, no mediators or moderators. This situation is comparable to standard exploratory factor analysis in which all variables have the same status as well.

There is a hierarchy of global CFA base models. Beginning at the bottom of the hierarchy, the first model is that of zero-order CFA (Lienert & von Eye, 1984, 1989), which is also called *Configural Cluster Analysis* (CCA). The base model of CCA is a null model. It assumes that no effects exist in the cross-classification of the variables under study. Types, which, here, are also called *configural clusters*, reflect agglomerations of cases in the data space. This characteristic makes zero-order CFA comparable to the cluster analytic methods that use spatial distance to cluster individual cases. Antitypes, which are also called *configural anticlusters i*n the context of CCA, reflect sectors of the data space that contain surprisingly small numbers of cases or none. These sectors of the data space are typically ignored in cluster analysis. The log-linear base model for CCA is $\log \hat{m} = \lambda$. In other words, the base model for CCA proposes a uniform distribution of cases.

On the next higher level of the hierarchy of global CFA base models, we find *first-order CFA*. This is the original model used by Lienert (1968). First-order CFA includes all

main effects but nothing else. It thus takes differences in marginal probabilities into account. Types and antitypes reflect local associations of first or higher order. To illustrate, consider the four variables *A, B, C*, and *D*. For these four variables, the first-order CFA base model is

$$\log \hat{m} = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D$$

The following interactions are not part of the first-order base model and can, therefore, cause types and antitypes to exist (in bracket notation):

- Two-way interactions [*A, B*], [*A, C*], [*A, D*], [*B, C*], [*B, D*], and [*C, D*];
- Three-way interactions [*A, B, C*], [*A, B, D*], [*A, C, D*], and [*B, C, D*]
- Four-way interaction [*A, B, C, D*].

The first data example in this chapter (Table 20.1) used first-order CFA as the base model. Most applications of CFA utilize first-order CFA as the base model, which takes only main effects into account. In many instances, first-order CFA base models are used to determine whether there are any effects. In most of the examples presented in this chapter, the first-order CFA base model is also used for this purpose.

On the next-higher level of the hierarchy of CFA base models, we find second-order CFA. This model assumes that two-way interactions exist. Types and antitypes can, therefore, emerge only if third- or higher order interactions exist. To illustrate second-order CFA, consider, again, the four variables *A, B, C*, and *D*. The second-order CFA base model for these variables is

$$\begin{aligned}\log \hat{m} = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D \\ +\lambda^{AB} + \lambda^{AC} + \lambda^{AD} + \lambda^{BC} + \lambda^{BD} + \lambda^{CD}\end{aligned}$$

The second line of this equation contains the two-way interactions that, in first-order CFA, may cause types and antitypes. The possible interactions that are not part of the second-order CFA base model can, therefore, cause types and antitypes to exist (in bracket notation) are

- Three-way interactions [*A, B, C*], [*A, B, D*], [*A, C, D*], and [*B, C, D*]; and the
- Four-way interaction [*A, B, C, D*].

Although rarely applied, second-order CFA can be of interest for a number of reasons. The most important of these is that it uses first-order relations as a basis for analysis as do factor analysis, multidimensional scaling, correspondence analysis, and some structural equation models. However, in contrast to these models, second-order CFA asks whether there exists systematic variability above and beyond what is explained by first-order interactions (i.e., all pairwise interactions). Factor analysis as well as the other methods on the list attempt to model the structure evident only in first-order relations. For an application of second-order CFA in psychopathological research, see von Eye and Lienert (1984).

Base models higher than second-order have not been discussed in detail in the CFA literature. However, higher order base models can easily be specified in the context of hierarchical log-linear models. Using the four variables *A, B, C*, and *D*, the third-order CFA base model is

$$\begin{aligned}\log \hat{m} = \lambda + \lambda^A + \lambda^B + \lambda^C + \lambda^D \\ +\lambda^{AB} + \lambda^{AC} + \lambda^{AD} + \lambda^{BC} + \lambda^{BD} + \lambda^{CD} \\ +\lambda^{ABC} + \lambda^{ABD} + \lambda^{ACD} + \lambda^{BCD}\end{aligned}$$

Using this model, only the four-way interaction [*A, B, C, D*] can be the cause of types and antitypes. In some of the paradoxes discussed in the statistics literature, for example, the Meehl's paradox (Meehl, 1950; von Eye, 2002), the highest order interaction carries the entire association in a cross-classification. To explore whether this is the case for a concrete data set, a CFA with a '*d*-1'st-order base model can be performed, where *d* denotes the number of variables. If types and antitypes still emerge from this base model, one can proceed and test hypotheses that are compatible with Meehl's paradox. This applies accordingly to Simpson's paradox (but not necessarily to other paradoxes; Krauth, 2005), and some of the recently discussed configural moderator models (von Eye & Mun, 2013).

In all global CFA base models, types and antitypes contradict the assumptions about associations that are made when estimating the expected cell frequencies. The resulting configurations stand out in the sense that they are observed at different rates from those that conform to the base model. An example of such a configuration is a pattern of symptoms that describes a nosological unit. These symptoms are not necessarily predictors of each other, and, conceptually, they cannot necessarily be grouped as dependent or independent variables, nor as mediators or moderators. For this reason, increasing numbers of CFA applications can be found in developmental psychopathology (e.g., Bogat, Levendosky, & von Eye, 2005; Martinez-Torteya, Bogat, von Eye, & Levendosky, 2009; von Eye & Bogat, 2006).

In contrast, *regional CFA base models* do distinguish groups of variables. Predictors are distinguished from

criterion variables, dependent variables from independent variables, covariates are treated differently than the variables that span the cross-classification, and mediator as well as moderator models can be tested. It is most important to note that most longitudinal CFA base models are regional models. A selection of these base models is explained later in this chapter. Therefore, we review only two examples in the present context.

The first example is that of Prediction CFA (PCFA). As discussed in previous sections of this chapter, the PCFA base model includes two sets of effects or variables. The first set includes all possible effects on the predictor side, rendering the model saturated in the predictors. This characteristic has the effect that types and antitypes cannot emerge because there are associations within the predictors. The PCFA base model is also saturated in the criterion variables. Therefore, types and antitypes cannot emerge because the criterion variables are related to each other. The third characteristic of the PCFA base model is that it proposes independence between predictor and criterion variables. If this base model is rejected, types and antitypes, by necessity, reflect relationships that link predictor variables to criterion variables.

The second example is that of Multigroup CFA. This CFA model also contains two groups of variables. The first group contains the variables that are used to compare the groups, that is, the *discriminator variables*. The Multigroup CFA base model is saturated in these variables. Therefore, types and antitypes (also called *discrimination types*) cannot emerge because the discriminator variables are related to each other. The second group of variables describes the groups. In most CFA applications, so far, this group contains only one variable, the grouping variable. For this variable, only the main effect is considered. This is done to take differences in group size into account. Interactions among the discriminator variables and the grouping variables are not part of the base model. Therefore, discrimination types and antitypes reflect such interactions, by necessity.

Consider, for example, the four variables *G, A, B*, and *C. G* is the grouping variable and *A, B*, and *C* are used to discriminate the groups. The multigroup CFA base model for these variables is

$$\log \hat{m} = \lambda + \lambda^G + \lambda^A + \lambda^B + \lambda^C + \lambda^{AB} + \lambda^{AC} + \lambda^{BC} + \lambda^{ABC}$$

Considering that this model is hierarchical, it could also have been expressed as [*G*], [*A, B, C*]. More examples of regional CFA models follow when we discuss models in more detail that are of particular interest in developmental research. Before we embark on the discussion and illustration of these models, we present, in the next section, a selection of significance tests that can be used to make type/antitype decisions.

Significance Testing in CFA

A large number of significance tests for CFA has been proposed. These tests differ in power, characteristics of the design under which they can be applied, their performance in samples of varying size, and whether they are exact or approximative. In this section, we present a selection of more popular tests. In addition, we present a test that can be applied when hypotheses are tested that involve groups of cells instead of individual cells.

The CFA Null Hypothesis. Each of the tests to be discussed and applied in this chapter can be used to test the CFA null hypothesis

$$H_0 : E[m_r] = m_r^*$$

where $E[m_r]$ is the expectancy for cell r, where r goes over all cells of a cross-classification, and m_r^* is the expected frequency for cell r under a base model. For the test of this null hypothesis, there are three possible outcomes: type, neither type nor antitype, and antitype. First, the cell constitutes a CFA type. In this case, the null hypothesis is rejected because

$$B_{N,\pi_r}(m_r - 1) \geq 1 - \alpha$$

where N is the sample size, π_r is the probability of cell r, and m_r is the observed frequency of cell r. In other words, in the first case, the null hypothesis is rejected because cell r contains more cases than expected. In the second case, the null hypothesis prevails because cell r contains as many cases as expected. In the third case, the null hypothesis is rejected because

$$B_{N,\pi_r}(m_r) \leq \alpha$$

In other words, in the third case, the null hypothesis is rejected because cell r contains fewer cases than expected under a base model. It constitutes an antitype.

CFA Tests for Individual Configurations. The first test to be presented here is the nonparametric binomial test. It can be employed under any sampling scheme (multinomial, product-multinomial sampling). Given m_r, the exact tail probability of m_r and more extreme frequencies is

$$B_r(m_r) = \sum_{j=a}^{l} \binom{N}{J} p^j q^{N-j},$$

where $q = 1 - p$, $a = 0$ if $m_r < m_r^*$ and $a = m_r$ if $m_r \geq m_r^*$, $l = m_r$ if $a = 0$, and $l = N$ if $a = m_r$. Usually, the value p is estimated from the sample. It is *a priori* known only in rare cases. As can be seen from the equation, the probability of each frequency is calculated and added to the total. There is no need to assume that a theoretical distribution is reasonably approximated. The binomial test is exact. This test is recommended when a sample is so small that the approximation properties of approximative tests are doubtful.

More powerful than the binomial test is the z test,

$$z = \frac{m_r - Np}{\sqrt{Npq}}$$

The z test can also be applied under any sampling scheme.

Among the most powerful tests is Lehmacher's (1981) normal approximation of the hypergeometric test,

$$z_{L,r} = \frac{m_r - m_r^*}{\sigma_r}$$

where σ_r is the square root of the exact variance, which can be calculated as

$$\sigma_r^2 = Np_r(1 - p_r - (N-1)(p_r - \widetilde{p}_r)),$$

and when $d = 3$ variables are studied, the values of p_r and $\widetilde{p}_r$ are estimated as

$$p_r = \frac{m_{i..}m_{.j.}m_{..k}}{N^2}$$

and

$$\widetilde{p}_r = \frac{(m_{i..} - 1)(m_{.j.} - 1)(m_{..k} - 1)}{(N-1)^d}$$

where d is the number of variables that span the cross-classification. For the present description of the values of p_r and $\widetilde{p}_r$, we used the case of $d = 3$. Lehmacher's test is powerful and tends to suggest types or antitypes even when they may not truly exist. To prevent this test from suggesting nonconservative type–antitype decisions, Küchenhoff (1986) recommended using a continuity correction for Lehmachers test, which involves reducing the difference in the numerator by 0.5. Lehmacher's test can be used only under a product-multinomial sampling scheme. That is, the marginal probabilities must be fixed for the test to be valid. Another constraint is that Lehmacher's test can be applied only under the base model of variable independence.

A test that is similarly powerful was recently proposed by von Eye and Mair (2008a): the *standardized Pearson residual*, z'_r. The test statistic is

$$z'_r = \frac{m_r - m_r^*}{\sqrt{m*_r(1 - h_r)}}$$

where h_r is the r-th diagonal element of the well-known *hat matrix, H*. This matrix is

$$H = W^{0.5}X(X'WX)^{-1}X'W^{0.5}$$

In this equation, W is a diagonal weight matrix that contains the expected frequencies, $m*_r$, in its diagonal. As the binomial test and the z test, the standardized Pearson residual can be used under any sampling scheme or base model.

Testing Groups of Configurations

The sum of the previous z statistics has an expectancy of $E(\Sigma z_r) = 0$ and a variance of t, where t is the number of terms (cells) in the summation. Now, if a group of t configurations is subjected to a CFA null hypothesis that includes the whole group, Stouffer's Z (Stouffer, Suchman, DeVinney, Star, & Williams, 1949) can be used, which is

$$Z = \left(\sum_{i=1}^{t} z_i\right) \Big/ \sqrt{t}.$$

Data Example for Stouffer's Z. The following data example illustrates the use of Stouffer's Z in CFA. For the example, we reanalyze the data in Table 94 in von Eye (2002). In a study on experimental psychoses, Lienert (1964) administered LSD50 to 65 students. When the effects of the drug set in, three symptoms were observed: Narrowed Consciousness (C), Thought Disturbance (T), and Affective Disturbance (A). Each symptom was scaled as either present (1) or absent (2). Table 20.2 displays the $2 \times 2 \times 2$ C × T × A cross-tabulation, along with the expected frequencies that were estimated under the base model of variable independence. We used the z test along with the Bonferroni-protected $\alpha = 0.00625$ (methods of α protection are discussed in the following section).

The overall goodness-of-fit likelihood ratio X^2 for the base model of variable independence for the data in Table 20.2 is 45.07. For $df = 4$, this value suggests that the model be rejected ($p < 0.01$). Still, none of the eight configurations constitutes a type or an antitype. When looking at the patterns in Table 20.2, we notice that the

TABLE 20.2 First-Order CFA of the Cross-Classification of Narrowed Consciousness (C), Thought Disturbance (T), and Affective Disturbance (A)

	Configuration			
CTA	m	$\hat{m}$	z	p
111	20.00	12.506	2.1193	.017034
112	1.00	6.848	−2.2348	.012715
121	4.00	11.402	−2.1921	.014185
122	12.00	6.244	2.3035	.010626
211	3.00	9.464	−2.1011	.017815
212	10.00	5.182	2.1162	.017164
221	15.00	8.629	2.1690	.015041
222	.00	4.725	−2.1738	.014862

bi-symptomatic configurations are all observed at low rates. These are the configurations 1 1 2, 1 2 1, and 2 1 1. We, therefore, ask, whether these three configuration constitute a *composite antitype* (also called *joint antitype*). To test the corresponding null hypothesis that they do not constitute a composite antitype, we take the z scores from Table 20.2, insert them into the formula for Stouffer's Z, and obtain

$$Z = \frac{-2.24 - 2.19 - 2.10}{\sqrt{3}} = -3.7689$$

This value suggests that the null hypothesis can be rejected. We conclude that the three bisymptomatic configurations, 1 1 2, 1 2 1, and 2 1 1, constitute a joint antitype. It is particularly unlikely that just two of the symptoms are observed.

Data Example for Comparison of CFA Tests. For the following example, we reanalyze data that were published by Magnusson in 1996. The data describe a sample of 70 male adolescents. To study the role played by physiological and psychological factors in criminal behavior, the three variables Committed a Crime (C), Hyperactivity (H), and Adrenaline level (A) were observed. Crime was coded: 1 = no crime committed, 2 = crime committed before the age of 18, and 3 = persistent crime. Hyperactivity and Adrenaline levels were both coded as 1 = low and 2 = high. Cutoffs were the means. Table 20.3 displays the 3 × 2 × 2 C × H × A cross-classification, along with the expected cell frequencies and the tail probabilities from the binomial test, the z-test, and the standardized Pearson residual. α was protected using the Holland–Copenhaver procedure (which is explained in the next section). The expected cell frequencies were estimated under the base model of variable independence.

The overall goodness-of-fit likelihood ratio X^2 for the base model of variable independence for the data in Table 20.3 is 47.14. For $df = 7$, this value suggests that the model is rejected ($p < 0.01$), and we expect types and antitypes to emerge. We now interpret the results in Table 20.3 from two perspectives. First, we discuss the substantive meaning of the type and antitype in this table. Then, we compare the three CFA significance tests.

As far as the analysis of crimes committed in adolescence is concerned, we note that of those 11 male adolescents who were grouped as persistent in their criminal behavior ($C = 3$), nine showed the pattern of high hyperactivity and low adrenaline. Pattern 3 2 1 constitutes a type. The antitype shows the same pattern (. 2 1), suggesting that with high levels of hyperactivity and low levels of adrenaline, it is particularly unlikely to be in the group of nonoffenders. In fact, not a single nonoffender showed this pattern, 1 2 1.

We also ask whether including all pairwise interactions would allow us to fully explain the frequency distribution in Table 20.3. The corresponding model is hierarchical. It is [*C, H*], [*C, A*], [*H, A*]. The results suggest that this model

TABLE 20.3 First-Order CFA of the Cross-Classification of Crime (C), Hyperactivity (H), and Adrenaline Level (A)

	Configuration

311	1.00	4.8153	.04204248	−1.7387	.041046	−2.4868	0.006	
312	1.00	3.8276	.09856945	−1.4453	.074191	−1.9171	0.028	
321	9.00	1.3133	.00000666	6.7076	.000000	7.5137	0.000	Type
322	.00	1.0439	.34932965	−1.0217	.153461	−1.1204	0.131	

Note. B = Binomial test; z = z-test; z' = standardized Pearson residual test.

must be rejected also ($LR - X^2 = 11.05$; $df = 2$; $p = 0.004$). Although this model is significantly better than the original base model of variable independence ($\Delta X^2 = 36.09$; $\Delta df = 5$; $p < 0.01$), it cannot stand by itself.

As far as the comparison of the three CFA tests is concerned, we first see that, in this example, the z test is generally more powerful than the binomial test. As we said previously, we trust the binomial test more than the z test when a sample is small. Therefore, we interpreted the results from the binomial test. The standardized Pearson residual is much more powerful than the other two tests in this example. All configurations had smaller p values than under the other two tests.

Protection of α

CFA involves multiple testing. There are mainly two reasons why multiple tests in CFA (and in other methods of analysis, for example, ANOVA) can become problematic. The first is known as *capitalizing on chance*, the second lies in the *dependency of tests*. Only the first of a series of tests on the same data keeps the a priori specified α level. When more than one test is performed, the risk of making an α error increases, even if the tests are independent. For example, if, in the context of testing for CFA types and antitypes, each of the 27 cells of a $3 \times 3 \times 3$ table is examined under $\alpha = 0.05$, the probability of incorrectly rejecting two null hypotheses is 0.24. Performing multiple tests on one sample therefore includes a high risk of capitalizing on chance if no precautions are taken to protect α.

This situation gets even worse when tests are dependent. von Weber, Lautsch, and von Eye (2003) showed that, when the expected cell frequencies in a 2×2 table are estimated under a log-linear main effect model, that is, the model of variable independence, the first CFA test indeed keeps the a priori specified α level. However, the outcomes of the second, third, and fourth CFA tests in the 2×2 table are completely dependent upon the outcome of the first test. Similarly, Krauth (2003) showed that the number of possible patterns of types and antitypes increases as the size of a table increases, but that the tests in a CFA never become completely independent.

A number of procedures exists for the protection of α. The most conservative of these, the *Bonferroni adjustment*, is the most popular procedure. This procedure specifies (1) that the sum of all adjusted significance levels not exceed the nominal α, or $\Sigma_r \alpha_r \leq \alpha$, where r indexes the cells subjected to CFA tests; and (2) that the significance threshold be the same for each test, or $\alpha_r = \alpha^*$, for all r, where α^* is the adjusted threshold. The value of α^* that meets both of these conditions is $\alpha^* = \alpha/R$.

More efficient procedures have been proposed. Based on Holm's (1979) procedure, Holland and Copenhaver (1987) proposed a procedure that does not require that $\Sigma_r \alpha_r \leq \alpha$. In this procedure, the tail probabilities of the cell-wise test statistics are rank ordered. The smallest probability is given Rank 1. The protected value of α^* is then, for the i-th test,

$$\alpha_i^* = 1 - (1 - \alpha)^{\frac{1}{r-i+1}}$$

This procedure is clearly less restrictive than the Bonferroni protection. It is also (slightly) less restrictive than Holm's (1979) procedure (for comparisons of procedures for the protection of α, see Olejnik, Li, Supattathum, & Huberty, 1979; von Eye, 2002; for procedures for special cases, see von Eye, 2002).

The Five Steps of CFA

When performing a CFA, researchers proceed in five steps (von Eye, 2002).

1. *Selection of a base model and estimation of expected frequencies*. In general, a *CFA base model* is a chance model that takes those effects into account that are NOT of interest to the researcher. The base model is used to estimate the expected cell frequencies in the table under study that are then compared with the observed cell frequencies, cell-by-cell. If a deviation between an expected and an observed cell frequency is significant, it reflects, by necessity, effects that are of interest to the researcher.
2. *Selection of a concept of deviation from independence*. Some of the measures of deviation from a base model take into account marginal frequencies, others do not. The corresponding measures are called *marginal-dependent* and *marginal-free* (Goodman, 1991). Examples of marginal-dependent measure include the Φ-coefficient, which is a relative of Pearson's X^2. Φ quantifies the strength of the association between two dichotomous variables. The strength corresponds to the degree of deviation of the observed distribution from the base model of independence between these two variables. Examples of marginal-free measures include the odds ratio, θ. Marginal-dependent and marginal-free measures can give different appraisals of deviation from a base model. Marginal-free measures have been proposed for use in two-group CFA (von Eye, Spiel, & Rovine, 1995).
3. *Selection of a significance test*. Significance tests of the null hypothesis that types or antitypes do not exist differ in that some are exact, whereas others are

approximative. They also differ in statistical power and in the sampling schemes under which they can be employed. Simulation studies have shown that the tests that perform well under many conditions include Pearson's X^2, the z-test, and the exact binomial test. When sampling is product-multinomial, the best performing tests include Lehmacher's (1981) exact and approximative hypergeometric tests.

4. *Performing significance tests under protection of* α. In both exploratory and confirmatory application of CFA, typically, a large number of tests is conducted. This number of tests is generally smaller in confirmatory CFA than in exploratory CFA. In either case, when more than one significance test is performed, the significance level, α, needs to be protected. The routine method for α protection, the Bonferroni procedure, can suggest rather conservative decisions about the existence of types and antitypes. Therefore, Holm's (1979) procedure and even less restrictive methods that have been derived from it have gained in popularity.
5. *Interpretation of types and antitypes*. The interpretation of types and antitypes utilizes the following five sources of information.
   1. The *substantive meaning of a configuration*. This meaning is determined by the definition of the categories that constitute a configuration.
   2. The *base model*. For example, when the base model distinguishes between predictor and criterion variables, the interpretation of types and antitypes differs from the one without this distinction (Mellenbergh, 1996).
   3. The *concept of deviation from expectation* as marginal-dependent versus marginal free.
   4. The *sampling scheme* (e.g., multinomial, product-multinomial).
   5. *External information* that is used to discriminate among individuals in different cells in the cross-classification under study (from each other and from the configurations that constitute types or antitypes). The discrimination is not part of CFA itself. Instead, discrimination is performed in follow-up tests that are undertaken, for example, to establish external validity of CFA types and antitypes (see von Eye, Mair, & Mun, 2010). For discrimination, variables are used that were not part of CFA.

In the remainder of this chapter, we discuss and illustrate CFA models that are of particular interest in developmental research. The models are selected based on the developmental questions they allow the researcher to answer.

CFA MODELS FOR DEVELOPMENTAL RESEARCH

The questions asked in developmental research can concern any individual parameter of the population under study, and any combination of parameters. In the first two data examples of this chapter, we asked questions concerning local associations in cross sectional data. In the following sections, we focus on questions for longitudinal data. In general, CFA allows one to answer questions concerning typical trajectories (longitudinal types) and atypical trajectories (longitudinal antitypes). The trajectories can be defined with respect to means, characteristics of shapes of curves, variability of scores, trends, intervention effects, end points of development, the predictability of trajectories, lags, effects of covariates, mediation, moderation, causal hypotheses, and many other aspects of longitudinal data.

To answer some of the questions, ordinal data are needed, for other questions, data must be at the interval level. For many questions, nominal level data are sufficient. Viewed from a data characteristics perspective, given nominal, ordinal, or interval level data, some questions can be asked, but other questions cannot be asked. For example, for nominal level data, local associations and prediction patterns can be examined. However, questions concerning constancy and change in means cannot be asked using nominal-level data. In the following sections, we point to the properties that data must possess for certain questions to be tractable.

This part of the present chapter is structured as follows. We begin with *CFA of differences* and related methods. For the simplest CFA models in this section, ordinal-level data are sufficient. For more advanced models, interval or ratio scale-level data are required. In the following section, we model *shapes of trajectories*. The first two sections are closely related to each other. The third section covers pre–post designs. We show how this type of design can be analyzed with CFA. The role of control groups is discussed. The following section covers single subject designs. In the contexts of person-oriented (Bergman & Magnusson, 1997; von Eye & Bergman, 2003; von Eye, Bergman, & Hsieh, 2015; Ch. 18) and idiographic research (Molenear, 2004; Molenaar & Campbell, 2009), long series of data are collected for individuals. CFA models for such data are presented. Prediction and autoassociation models for shorter series of data follow in the next sections.

CFA of Differences I

In this section, we ask how CFA can be used to analyze trajectories of repeatedly observed variables. Specifically, we ask whether group differences in such trajectories can be ascertained.

Longitudinal, that is, intraindividual differences can be ascertained at all scale levels. At the nominal level, differences are described by switching from one category to another. At the ordinal level, longitudinal differences imply changing rank or moving up or down on an ordinal scale such as grade in school, or on a well-being scale. At the interval level, longitudinal differences imply that change can be measured in comparable, commensurate units. For example, an increase in intelligence can be by 5 IQ points. These points indicate the same amount of change, regardless where, on the IQ scale, the change is observed. At the ratio scale level, longitudinal differences can also be assessed in units of proportion. An improvement in processing speed from 4 to 2 seconds can be interpreted as an increase by 100%. In the following discussion of CFA methods for analyzing differences, we focus on differences on variables that are measured at least at the ordinal level.

The simplest way of measuring differences involves subtracting the subsequent observation, y_{i+1}, from the previous, y_i, that is, $\Delta y = y_{i+1} - y_i$. When the number of ranks or interval-level scores is small, the number of resulting differences will also be small, and the differences can be crossed with other differences or variables right away. When the number is large, researchers often resort to binning, even dichotomizing. The resulting number of cells in a cross-classification will then be much smaller with binning than without binning.

In the literature, there has been a discussion concerning the reliability of difference scores. Quite often, one finds the argument that the reliability of difference scores is deplorable. Unfortunately, this argument is not always well grounded. We present two counter arguments why. First, when scales are ratio scale level, differences can be highly reliable. Consider a car that travels at a speed of 50 mph. After braking to come to a standstill, the speed difference is 50 mph. This difference is perfectly reliable. This applies accordingly to other ratio scale measures used in developmental research, for example, blood pressure, alpha waves, reaction time, or number of words recalled, and to some interval-level measures and rankings. Second, Zimmerman (2009) showed that, even when test scores are used, the reliability of differences is not as low and anomalous when correlations among the true scores are used instead of correlations among the observed scores. Therefore, while we are fully aware of the potential information loss that can come with binning variables (see MacCallum, Zhang, Preacher, & Rucker, 2002; von Eye & Mair, 2011), we believe that difference scores and binned difference scores can be useful.

Most popular are *first differences*, that is, differences between time-adjacent measures, e.g., the difference of the second observation, y_2, from the first, y_1, $\Delta y = y_2 - y_1$. First differences are used for a number of reasons. The two most important ones are to (1) simply find out about change, and (2) to de-trend series of measures. The second reason is of importance when methods of time series analysis are employed that require the stationarity assumption. The first reason is of importance when individual change scores or change patterns are interpreted.

To calculate *second differences*, one subtracts adjacent first differences,

$$\Delta^2 y = \Delta y_{i+1} - \Delta y_i$$

for $i = 1, \ldots, m - 1$, with m being the number of first differences in the series. The superscript in this equation indicates the order of differences. Second differences are of interest (1) when changes in change, that is, acceleration or deceleration, are of interest, or (2) when the quadratic trend is to be taken out of a series of measures. Higher order differences such as third or fourth differences can be defined in an analogous way. Table 20.4 displays a scheme that shows how differences can be calculated.

In Table 20.4, the Y scores are the (repeated) measures to be modeled. The X scores are the points on the time axis used in repeated measures studies. Difference scores are most easily comparatively interpreted when the points on X are equidistant or, at the least, the distances are the same for every case in a study.

TABLE 20.4 Calculation of First Through Fourth Differences

Raw scores		Differences			
X	Y	ΔY first differences	$\Delta^2 Y$ second differences	$\Delta^3 Y$ third differences	$\Delta^4 Y$ fourth differences
x_0	y_0				
		Δy_0			
x_1	y_1		$\Delta^2 y_0$		
		Δy_1		$\Delta^3 y_0$	
x_2	y_2		$\Delta^2 y_1$		$\Delta^4 y_0$
		Δy_2		$\Delta^3 y_1$	
x_3	y_3		$\Delta^2 y_2$		
		Δy_3			
x_4	y_4				

Differences possess important characteristics that make them interesting for longitudinal research.

1. Differences can be used to estimate the degree of a polynomial that describes a series of measures. Specifically,
   a. the *n*-th differences of a polynomial of the *n*th degree are constant; this implies that, as soon as a series of differences is constant, the polynomial of corresponding degree will describe the series perfectly; and
   b. the differences of an order higher than *n* disappear; in other words, calculating differences of a degree higher than *n* is pointless.
2. Difference variables can be used to span cross-classifications. As we said before, when the number of differences is small, they can be directly crossed with other differences, with time-varying, and with time-constant (measured only once) variables.
   a. The method of differences can be used to identify scores that are suspected to be faulty. Scores that are faulty result in the existence of higher order differences when most lower order differences have long converged to very small values, or even disappeared. In addition, the magnitude of the error can be concluded from the magnitude of the differences.

To illustrate the method of differences, we first present an example with artificial data (von Eye, 2002), and then a real data example. For the artificial data example, we use the five consecutive *x*-values of 1 through 5 and select the five *y*-values {1, 3, 4, 3, 1}. For these scores, we calculate the first, second, and third differences. The three resulting curves of the differences are depicted in Figure 20.2, along with the curve of the raw scores.

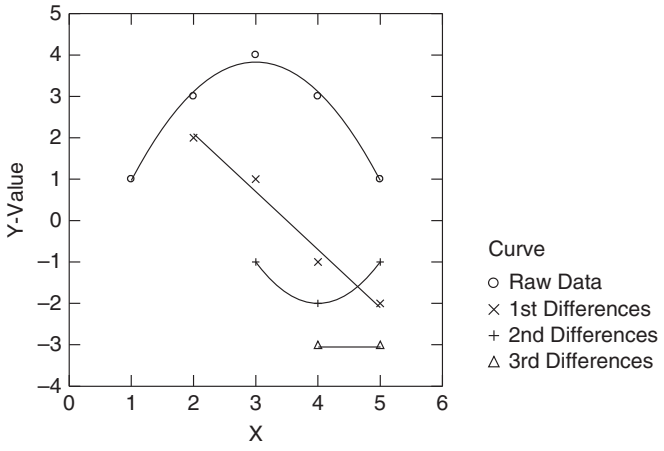

Figure 20.2 Method of differences.

Figure 20.2 shows that the raw data can be described as an inversely U-shaped function. Its slope changes from positive to negative (first differences). The change in slope is negative throughout and more pronounced around the middle of the curve (second differences). The third differences are constant, suggesting that the raw data can be perfectly described by using a third-order polynomial.

Data Example

For the real-data example, we use data that Finkelstein, von Eye, and Preece (1994) collected on the development of aggressive behavior. The authors administered a questionnaire concerning aggressive behavior to 67 adolescent girls and 47 boys at three points in time. The time intervals were 2 years apart. The questionnaire addressed the four dimensions of aggression: Aggressive Impulse, Aggression-Inhibitory Response, Verbal Aggression against Adults, and Physical Aggression against Peers. In addition, physical pubertal development was assessed using Tanner scores. In the following analyses, we use the data on physical aggression against peers (PAAP). Three scores existed per person, PAAP83, PAAP85, and PAAP87, where the numbers indicate the years in which the data were collected. When the data were collected, the respondents were, on average, 11, 13, and 15 years of age, respectively. In the following example, we ask whether the developmental change in self-rated physical aggression against peers is different for boys and girls. We perform the following three steps.

1. Calculate the differences PADIF1 = PAAP85 – PAAP83 and PADIF2 = PAAP87 – PAAP83;
2. Dichotomize the differences; here, we dichotomize the differences at their grand mean; the resulting split will not lead to groups that are exactly the same in size (the distributions of the difference scores have slightly elevated skewness); however, information about the mean is conserved;
3. Perform 2-group CFA with Gender as the grouping variable.

Descriptive statistics for the difference scores PADIF1 and PADIF2 appear in Table 20.5.

After dichotomization, both variables were coded as 1 = below the mean and 2 = above the mean. Gender was coded as 1 = female and 2 = male. Crossed, the three variables span the 2 × 2 × 2 Gender (G) × PADIF1 (P1) × PADIF2 (P2) cross-classification. We analyze this table using two CFA base models. The first is the two-group base model, the second is the standard base model of first-order CFA.

TABLE 20.5 Descriptive Statistics for the Variables PADIF1 = PAAP85 − PAAP83 and PADIF2 = PAAP87 − PAAP85

	PAAPDIF1	PAAPDIF2
N of Cases	114	114
Minimum	1.000	1.000
Maximum	2.000	2.000
Arithmetic mean	1.561	1.482
Standard deviation	0.498	0.502

Similar to the PCFA base model, the two-group model proposes that (1) the model is saturated in the variables used to discriminate between the two groups, and (2) the grouping variable is independent of the discriminator variables. In the present example, the two-group base model is

$$\log \hat{m} = \lambda + \lambda^{G} + \lambda^{P1} + \lambda^{P2} + \lambda^{P1,P2}$$

This model can be rejected only if the grouping variable, Gender, is associated with the discriminator variables, *P*1 and *P*2. Specifically, this model can be rejected if one or more of the following interactions exist: [*G, P*1], [*G, P*2], and [*G, P*1, *P*2].

This base model has an interesting characteristic. It makes the association between the variables *P*1 and *P*2 part of the model. Considering that these two variables describe temporal elements of the development of physical aggression against peers, this association reflects the serial dependency of *P*1 and *P*2. Types and antitypes cannot, therefore, emerge just because *P*1 and *P*2 show an autoassociation (comparable to autocorrelation).

The second base model is that of first-order CFA,

$$\log \hat{m} = \lambda + \lambda^{G} + \lambda^{P1} + \lambda^{P2}$$

This model contains only the main effects of the variables that span the cross-classification of *G*, *P*1, and *P*2. Therefore, the autoassociation of *P*1 and *P*2 can be among the reasons why this model is rejected (if it is rejected). For the type–antitype decisions under both base models, we use the normal approximation of the binomial test and the Holland–Copenhaver procedure of α protection.

Table 20.6 displays the 2 × 2 × 2 Gender (G) × PADIF1 (P1) × PADIF2 (P2) Cross-Classification along with the results of two-group CFA. The overall goodness-of-fit likelihood ratio X^2 for the base model of two-group CFA for the data in the table is 12.58. For $df = 3$, this value suggests that the model is rejected ($p = 0.006$), and we expect that discrimination types and antitypes may exist.

The results in Table 20.6 suggest that the two gender groups differ in two profiles. Significantly more male than female respondents display the trajectory of individuals who consistently change to self-perceived ever lower levels of physical aggression against peers. The second discrimination type suggests that significantly more female than male respondents change to self-perceived, ever higher levels of physical aggression against peers. The remaining two comparisons—both concern up-and-down patterns of change—were observed about as often as expected under the base model.

TABLE 20.6 Two-Group CFA of the Gender (G) × PADIF1 (P1) × PADIF2 (P2) Cross-Classification, with Gender as the Grouping Variable

	Configuration			
P1 P2 G	*m*	*z*	*p*	Type?
111	8.00			
112	16.00	−2.849	.002190	Discrimination type
121	17.00			
122	9.00	.780	.217801	
211	19.00			
212	16.00	−.648	.258591	
221	23.00			
222	6.00	2.602	.004632	Discrimination type

The two types also come with significant odds ratios. Specifically, males are 1.337 times more likely than females to show trajectory pattern 1 1 ($z = -2.474$; $p = 0.007$), and females are 1.273 times more likely than females to show trajectory pattern 2 2 ($z = 2.520$; $p = 0.006$).

From a data analytic perspective, it is important to point to the fact that two-group CFA involves only half the number of tests as the corresponding standard CFA. Therefore, the protected α-level is less restrictive in two-group CFA than in standard one-group CFA. Consider the example in Table 20.6. In this table, four tests were performed instead of eight tests that are needed in standard, first-order CFA. One implication of a less restrictive, protected α is that types and antitypes are more likely to be detected. Table 20.7 displays the results from first-order CFA that was performed using the same significance test and α protection as for the two-group CFA in Table 20.6.

The overall goodness-of-fit likelihood ratio X^2 for the base model of first-order CFA for the data in Table 20.7 is 13.09. For $df = 4$, this value suggests that the model is rejected ($p = 0.011$). This result leads to the expectation that types and antitypes may exist. However, as is evident from Table 20.7, none of the configurations deviates significantly from expectation, when the stricter protected α is used.

In an add-on step of the analysis of the data in Tables 20.6 and 20.7, we ask which log-linear model could

TABLE 20.7 First-Order CFA of the Gender (G) × PADIF1 (P1) × PADIF2 (P2) Cross-Classification

	Configuration			
P1 P2 G	m	$\hat{m}$	z	$p(z)$
111	8.00	15.209	−1.9856	.023538
112	16.00	10.669	1.7144	.043226
121	17.00	14.11	.8011	.211539
122	9.00	9.945	−.3138	.376848
211	19.00	19.467	−.1162	.453743
212	16.00	13.656	.6761	.249482
221	23.00	18.147	1.2424	.107053
222	6.00	12.730	−2.0013	.022679

be used to adequately describe the frequency distribution. We find that the model $\log \hat{m} = \lambda + \lambda^G + \lambda^{P1} + \lambda^{P2} + \lambda^{G,P2}$ explains the data very well ($\mathrm{LR} - X^2 = 4.398$; $df = 3$; $p = 0.222$). This model suggests that there is an association between Gender and change in Physical Aggression Against Peers between the ages of 13 and 15. This result is plausible and easy to interpret. However, the specifics of the results, in particular, the findings that (1) male adolescents are more likely than female adolescents to exhibit a repeated reduction in self-perceived physical aggression and that (2) repeated increases in aggression are comparatively more likely in female adolescents can most easily be obtained using CFA.

In sum, two-group CFA of trajectories shows, in the present example, a typical pattern of CFA results. A selection of configurations allows one to discriminate between the comparison groups. Other configurations are observed as often as expected, in both comparison groups. In addition, two-group CFA of differences has the interesting characteristic that the analyzed cross-classification is much smaller than the cross-classification of the original variables. Consider a study in which an ordinal variable with five ranks is observed three times. Crossing these observations results in a table with $5^3 = 125$ cells. Creating first differences reduces the number of variables from 3 to 2. Binning the differences into three categories such as change toward higher ranks, lower ranks, and no change, and crossing the two resulting change variables results in a table with $3 \times 3 = 9$ cells, a savings of 92.8%. Naturally, this savings goes hand in hand with loss of information. However, it provides the researcher with the opportunity to capture interesting parts of the original information and to make them the focus of data analysis, or to include additional information such as covariates. In the next section, we discuss a priori probabilities in the analysis of differences (von Eye, 2002; von Eye, Mair, & Mun, 2010; von Eye & Mun, 2007, 2012).

CFA of Differences II: Structural Zeros

So far in this chapter and, in most applications of CFA, researchers proceed from the assumption that the variables under study can be completely crossed. That is, each category of every variable can be observed under each category of every other variable. When difference variables as the ones discussed in the last section are crossed with covariates or difference variables that are based on other variables, this assumption is practically always met. However, there is one interesting exception. This exception concerns crossing difference variables of different order of the same original variable with each other.

Consider, for example, a variable that is observed three times. For the resulting three measures, two measures of first differences can be calculated (Δ_1^1 = Time 2 – Time 1, and Δ_2^1 = Time 3 – Time 2) and one measure of second differences ($\Delta_2^2 = \Delta_2^1 - \Delta_1^1$). Now, let the difference measures be dichotomized at zero (this is also called *sign-transformed*). The resulting scores indicate whether the differences indicate an upswing or a downswing of differences. Let the original variable also be dichotomized. Crossed, these three indicators span a $2 \times 2 \times 2$ contingency table, with cell indices 0 0 0, 0 0 1, 0 1 0, 0 1 1, 1 0 0, 1 0 1, 1 1 0, and 1 1 1.

Of these eight cells, two are logically impossible and therefore, cannot contain any case at all. These are the cells with patterns 0 1 0 and 1 0 1, where the order of indices is original variable—first differences—second differences. The first of these patterns suggests a decrease that is followed by an increase and, overall, a negative quadratic trend. This pattern would reflect a ∪-shaped curve that is, simultaneously, ∩-shaped. The second pattern indicates an initial increase that is followed by a decrease in tandem with an overall positive quadratic trend. This pattern would reflect a ∩-shaped curve that is, simultaneously, ∪-shaped. Neither is logically possible. Because these shapes are contradictory, configurations 0 1 0 and 1 0 1 must be declared *structural zeros*.

Structural zeros are different from observed zeros. When, in a sample, a pattern was not observed but, theoretically, maybe in a larger sample, there could be cases that exhibit this pattern, the zero is called a *sampling zero*. If, however, it is impossible to observe a particular pattern, mostly for logical and design reasons, the zero is structural. These two types of zeros are treated differently when it comes to estimating expected cell frequencies. Sampling zeros are treated just as the other frequencies. An expected value is estimated and the zero is compared with the estimate (exceptions exist when there are so many

zeros that parameter estimation is impeded). In contrast, cells that contain structural zeros must be blanked out. For these cells, no expected frequency is estimated, and there is no comparison of observed with expected frequencies.

Von Eye and Mun (2007) presented the following definition of impossible patterns in the analysis of categorized differences: *Combinations of sign patterns are impossible* if lower order and higher order signs suggest different orientations of a series of measures. This applies to patterns of difference signs of any order.

The authors proposed a procedure with which all candidate patterns for contradictory descriptions of orientation can be identified. Candidates for a search are all patterns that indicate a change in orientation from *up* to *down* and vice versa. Patterns that show no change do not need to be considered. Now, let Δ_j^1 and Δ_{j+1}^1 be the first differences between the adjacent measure pairs x_{j+1} and x_j, and x_{j+2} and x_{j+1}, respectively, for $j = 1, \ldots, I-1$, and Δ_k^2 the corresponding second difference, that is, $\Delta_{k+1}^2 - \Delta_k^2$. Let sgn Δ_j^1, sgn Δ_{j+1}^1, and sgn Δ_k^2 be the signs of these differences. The following two steps are performed to identify the structural zeros.

Step 1: Compare each pair of sgn Δ_j^1 and sgn Δ_{j+1}^1 with the corresponding sgn Δ_k^2. If both sgn $\Delta_j^1 \neq$ sgn Δ_{j+1}^1 and sgn $\Delta_{j+1}^1 \neq$ sgn Δ_k^2, then the pattern is impossible. For example, if the sign pattern + − at a given difference level is combined with sign + at the next higher level, the sign pattern is impossible. The first differences would indicate a negative orientation, whereas the second difference would indicate a positive orientation. Accordingly, the sign pattern − + at a given level cannot be combined with the sign − at the next higher level. If a sign pair is classified as impossible, proceed to the next sign pattern. If a sign pattern is impossible, all other patterns that could be combined with the impossible pattern are impossible also.

Step 2: Proceed to the next pair of signs, and start over, at Step 1. Continue until all patterns of signs are examined.

This procedure can be applied to sign patterns of all levels. If a researcher decides to skip levels, the procedure can be adjusted. For example, pattern + − at level k cannot go with the sign – at level $k + 2$.

To give an example of a possible pattern, let k indicate first differences and let $k + 2$ indicate third differences. In this situation, consider the sign pattern + − + for first differences and + for third differences. The first signs indicate an initial increase that is followed by a decrease, and then an increase. The third difference indicates an increase in acceleration. To give an example of an impossible pattern, consider the series 9, 15, 10, 6. For this sequence, the first differences sign pattern is + − −, the second differences sign pattern is − +, and the corresponding third difference has the sign +, thus indicating a ∩-shaped trend. For this series, a negative sign for the third difference is impossible. A complete example with an artificial data set is given by von Eye and Mun (2007). A real-data example follows.

Data Example

In the data example in the following paragraphs, we use the data on adolescent development of aggression again that we used previously for the example in Table 20.6. For the earlier example, we had analyzed the first differences of Physical Aggression Against Peers. Here, we analyze first and second differences. Specifically, we create a 2 × 2 × 2 table by crossing PADIF1 = PAAP85 − PAAP83 (abbreviated by P1), PADIF2 = PAAP87 − PAAP85 (abbreviated by P2), and P2DIF = PADIF2 − PADIF1 (abbreviated by ΔP). The resulting cross-classification contains two structural zeros. The first is in cell 1 2 2. It only makes sense that nobody shows this pattern. The pattern would describe a ∪-shaped curve that is, simultaneously, ∩-shaped. The second structural zero is found in cell 2 1 2. This pattern describes a ∩-shaped curve that is, simultaneously, ∪-shaped. Neither is logically possible.

The 2 × 2 × 2 P1 × P2 × ΔP cross-classification is analyzed using two CFA base models. The first is the log-linear main effect model of variable independence,

$$\log \hat{m} = \lambda + \lambda^{P1} + \lambda^{P2} + \lambda^{\Delta P}$$

In this model, no provision is taken for the structural zeros. Therefore, the expected frequencies for Cells 1 2 2 and 2 1 2 will be greater than zero. The second base model declares these two cells structural zeros. The model is

$$\log \hat{m} = \lambda + \lambda^{P1} + \lambda^{P2} + \lambda^{\Delta P} + \lambda^{s1} + \lambda^{s2},$$

where the $s1$ and the $s2$ in the superscript represent the first and the second vectors that indicate structural zeros. Under this base model, the expected frequencies for Cells 1 2 2 and 2 1 2 will be zero. Table 20.8 displays the results of the first-order CFA under the first base model. Table 20.9 displays the results of first-order CFA under the second base model. For both CFA runs, we use the z test and protect α using the Holland–Copenhaver procedure.

The overall goodness-of-fit likelihood ratio X^2 for the base model of first-order CFA for the data in Table 20.8 is 85.72. For $df = 4$, this value suggests that the model is rejected ($p < 0.01$), and we anticipate that types and antitypes emerge. The table shows two types and two

221	17.00	20.354	−.7434	.228617	
222	12.00	19.821	−1.7567	.039488	

antitypes. The first type is constituted by cell 1 2 2. This pattern describes a curve that shows an initial decrease that is followed by an increase, with positive acceleration (positive quadratic trend). 11 cases were expected to exhibit this pattern, but 26 did exhibit it, a significant discrepancy. The second type is constituted by cell 2 1 1. It shows just the opposite pattern. Instead of the expected 18, 35 adolescents showed an initial increase in physical aggression that was followed by a decrease, with negative acceleration.

For the present purposes, the two antitypes are most interesting. The first, constituted by cell 1 2 1, indicates that not a single adolescent showed a decrease that is followed by an increase which, at the same time, indicates a negative quadratic trend. The second, constituted by cell 2 1 2 indicates that no one showed an initial increase, followed by a decrease together with an overall positive quadratic trend. It only makes sense that nobody showed these patterns. The first antitype would be a ∪-shaped curve that is, simultaneously, ∩-shaped. The second antitype would be a ∩-shaped curve that is, simultaneously, ∪-shaped. Neither is logically possible. Because of this pattern of contradictory shapes, the Cells 1 2 1 and 2 1 2 must be declared structural zeros. The second CFA base model considered here takes the characteristic of Cells 1 2 1 and 2 1 2 as structural zeros into account. Results appear in Table 20.9.

The overall goodness-of-fit likelihood ratio X^2 for the base model of first-order CFA for the data in Table 20.9 is 20.40. For $df = 2$, this value suggests that the model is rejected ($p < 0.01$). This model is significantly better than the one that does not take the structural zeros into account ($\Delta X^2 = 65.32$; $\Delta df = 2$; $p < 0.01$), but it cannot stand by itself. Therefore, we anticipate that types and antitypes emerge. The table shows that only one of the two types from Table 20.8 reemerges. It is constituted by cell 1 2 2.

We conclude that, in the present example, taking into account the structural zeros does not lead to a fitting model that is more parsimonious than the saturated model. Each of the structural zeros reduces the degrees of freedom by one. In the present example, there is one degree of freedom left to invest before we reach the saturated model (which is not more parsimonious than the data themselves). Including the interaction between the two first difference-variables results in a well-fitting model (likelihood ratio $X^2 = 1.517$; $df = 1$; $p = 0.218$), and the interaction parameter is significant. However, as before, the details of the interaction can be identified and interpreted in particular with CFA methods.

Extensions

Two extensions of the method of differences are particularly of note. The first concerns possible a priori probabilities. As shown by von Eye (2002), differences of any order come with a priori probabilities. Consider a series of three ordinal-level scores that describe the development of depression, with 1 indicating no depression, 2 indicating elevated depression, and 3 indicating clinical depression. For three observation points, the six sequences 1 2 3, 1 3 2, 2 1 3, 2 3 1, 3 1 2, and 3 2 1 are possible. These sequences are equally likely. Calculating, however, the first differences for the six sequences, one obtains the sign patterns + +, + −, − +, + −, − +, and − −. These patterns are not equally likely. Specifically, the probabilities are $p(++) = 0.167$, $p(+-) = 0.333$, $p(-+) = 0.333$, and $p(--) = 0.167$. Similarly, if differences are scored so that *no change* can be part of the resulting pattern, the possible patterns come with a priori probabilities that are not uniform. Uniformly distributed difference patterns can result only for continuous variables. This applies accordingly to higher order differences. Estimating expected frequencies without taking a priori probabilities into account can cause severely biased estimates for type and antitype patterns or, in log-linear modeling, severely biased parameter estimates.

A second extension of CFA or log-linear models for difference scores concerns the inclusion of additional

TABLE 20.10 First-Order CFA of the Gender × P1 × P2 × ΔP Cross-Classification; Structural Zeros Taken into Account

Configuration

variables or covariates. For example, given the results in Tables 20.6 and 20.9, one can ask whether the type/antitype pattern found in Table 20.9 is gender specific. Table 20.10 displays the results for this question, with structural zeros taken into account. To make these results comparable with the ones in Table 20.9, the z test was used again, along with the Holland–Copenhaver procedure for α protection.

The overall goodness-of-fit likelihood ratio X^2 for the base model of first-order CFA for the data in Table 20.10 is 33.55. For $df = 7$, this value suggests that the model is rejected ($p < 0.01$). Only one type results. It is constituted by Pattern 1 1 2 2, suggesting that females are significantly more likely than expected to initially show a decrease in aggression, that is followed by an increase, with an overall positively accelerated trend. For male adolescents, the same pattern was observed at a rate that did not differ from expectancy.

Candidates for covariates include time-invariant variables such as gender, once-observed variables such as living conditions, and repeatedly observed variables such as diagnoses, or physiological measures of development.

CFA of Trajectories: Typical and Atypical Development

In person-oriented (Bergman & Magnusson, 1997; von Eye & Bergman, 2003; von Eye, Bergman, & Hsieh, 2015; Ch. 18) and idiographic research (Molenaar, 2004; Molenaar & Campbell, 2009), it has been shown that, to be able to replace individual series of repeated observations with cross sectional data from many individuals and to draw inference conclusions as if data came from repeated observations, the data must be stationary. This condition is rarely reasonable and fulfilled in developmental processes such as learning or in temporal etiological processes. Therefore, it has been recommended that data not be aggregated across individuals. Instead, parameters are to be estimated first for longitudinal data, at the level of the individual. Aggregation can then be performed based on parameter profiles.

In this section, we present a CFA method that does exactly this, in three steps, for interval-level or ratio scale-level variables. In a first step, polynomials are estimated for each individual. These polynomials describe the trajectory of development. At least two consecutive interval- or ratio scale-level measures are needed. The method is more fruitful, however, when a series consists of three or more measures. In its second step, the polynomial parameters are binned, that is, reduced to a smaller number of binned parameters that are then crossed for CFA or log-linear analysis. In the third step, the parameter ranges are crossed with each other or with other variables and then subjected to CFA (von Eye, 2002; von Eye & Nesselroade, 1992).

There are many forms of polynomials (Abramowitz & Stegun, 1972). Using an approach that is easily related to regression analysis, a series of scores y_j can be approximated by the polynomial

$$\hat{y} = f(x) = P_I(x) = b_0x^0 + b_1x^1 + b_2x^2 + \ldots + b_Ix^I = \sum_{i=0}^{I} b_ix^i$$

where the x are either the scores of a predictor variable that is observed at the same observation points as y, or scores that describe the observation points (1, 2, ...). The number I is called the *degree of the polynomial* or the *order of the polynomial*.

In statistical data analysis, polynomials are well known and often used. For example, a standard regression analysis which fits a straight line to the data uses P1(x), that is, a first-order polynomial. Quadratic regression slopes are also often considered. In repeated measures analysis of variance with polynomial contrasts, polynomials up to order I can be estimated for I + 1 repeated measures. Polynomials are attractive tools for the description of series of measures, for a number of reasons.

1. Any series of scores can be perfectly described using a polynomial. Note, however, that estimating a polynomial that goes exactly through the observed data points is not advisable, because practically all observed

data points come with measurement error and the polynomial parameter estimates must not be affected by this error. However, this characteristic of polynomials gives researchers the option of adjusting the degree of the estimated polynomial as needed. Typically, the degree of the estimated polynomial is much below the number of observation points.

2. The coefficients of orthogonal polynomials do not need to be calculated (in particular when the points on x are equidistant). They are either part of software already, or they can be found on the Internet (e.g., www.watpon.com/table/polynomial.pdf; for detail on the estimation of polynomial coefficients, see Abramowitz & Stegun, 1972).
3. When orthogonal polynomials are used, the polynomial parameters are independent of each other. Therefore, polynomial elements of any degree can be removed from an equation without affecting other parameters. The remaining parameters do not need to be reestimated.
4. Polynomial approximation of series of scores is attractive in particular when the series are relatively short, as is the case in most social and behavioral science applications. Among the main reasons for this are that (1) a polynomial can be devised so that it approximates the observed series as closely as desired, and that (2) polynomial parameters have the same interpretation as standard regression parameters. For example, the intercepts have the same interpretation and the parameter for the first-order polynomial is equivalent to the standard regression slope.

On the downside, we find that

1. Although any series of scores can perfectly be approximated with polynomials, certain patterns are hard to approximate in the sense that polynomials of high orders may be needed for a satisfactory description. Among those patterns are cyclical series of scores (orthogonal trigonometric polynomials can be useful here) and series that approach an asymptote.
2. In many instances, the estimated polynomials cannot be used for purposes of extrapolation. Any polynomial approximates infinity, on both ends. Therefore, polynomials are valid only for the series used for estimation.

In most applications, researchers use families of orthogonal polynomials instead of standard polynomials. In these families, the element of order I is a polynomial of order I itself. Specifically,

$$f(x) = a_0\phi_0(x) + a_1\phi_1(x) + a_2\phi_2(x) + \ \ldots\ + a_I\phi_I(x) = \sum_{i=0}^{I} a_i\phi_i(x)$$

where $\phi_i(x)$ is an i-th order polynomial. The coefficients a_i are the estimated weights. They are comparable to the weights estimated in regression analysis (and can be estimated using least squares methods). This system of polynomials is orthogonal over the interval a $\leq x \leq b$, with respect to the weight function $w(x)$ if

$$\int_a^b w(x)P_n(x)P_m(x)dx = 0$$

where $P_n(x)$ and $P_m(x)$ are polynomials of degree n and m, respectively, and $n \neq m$. At the level of individual polynomials, the two polynomials $\phi_i(x)$ and $\phi_j(x)$ are orthogonal to each other if

$$\sum_{k=1}^{n} \phi_i(x_k)\phi_j(\mathrm{x}_k) = 0$$

where n is the number of points on x, and $i \neq j$.

Data Example

In the following example, we reanalyze data published by von Eye and Nesselroade (1992; von Eye, 2002). 42 college students were presented a state anxiety questionnaire four times (Nesselroade, Pruchno, & Jacobs, 1986). Each time, all respondents completed both parallel forms, A and B, of the questionnaire. This way, two series of four repeated measures resulted for each student. Von Eye and Nesselroade approximated each of these series using the second order orthogonal polynomial

$$y = \overline{y} + b_1 t + b_2 t^2$$

where $\overline{y}$ is the arithmetic mean of the scores in the series, and t counts the equidistant observation points (t = 1, 2, 3, 4). For each student, one set of parameters was estimated for each of the two series. For example, the first student's parameter estimates were $\overline{y} = 37.8$, $b_1 = 1.0$, and $b_2 = -0.8$ for parallel form A, and $\overline{y} = 38.3$, $b_1 = 0.95$, and $b_2 = -0.6$ for parallel form B. These estimates suggest that this student's scores increase with time (*linear trend*, *slope*, b_1). However, the negative quadratic trend b_2 (also called

curvature) suggests that toward the end this student's scores increase less rapidly or even become lower, countering the linear trend. This applies to both parallel forms of the instrument.

For the present re-analyses, we use the mean and the slope. The means were dichotomized at their medians, with 1 indicating above the median and 2 indicating below the median. The estimates for the slopes, b_1, were dichotomized at zero. Thus, 1 indicates a positive trend and 2 indicates a negative trend. Positive trends indicate increasing state anxiety, negative trends suggest decreasing state anxiety. Thus, zero is a natural cutoff point. The four variables A_0, A_1, B_0, and B_1 resulted from dichotomizing the parameter estimates. A_0 and B_0 represent the means of the two parallel test forms, and A_1 and B_1 represent the two linear slopes. Crossed, these four variables form the $2 \times 2 \times 2 \times 2$ $A_0 \times A_1 \times B_0 \times B_1$ contingency table.

We use first-order CFA for the analysis of this cross-classification (Table 20.11). Because of the relatively small sample size, we use the binomial test and protect α using the Holland–Copenhaver method. Table 20.11 displays the results. For the base model, we obtain an overall goodness-of-fit likelihood-ratio $X^2 = 57.56$. For $df = 11$, this value suggests that the base model must be rejected ($p < 0.01$), and we have reason to expect types and antitypes to emerge.

First-order CFA suggests the existence of two types (note that von Eye, 2002, used Anscombe's z test instead of the binomial test, and found an antitype in addition; it was constituted by cell 2 2 1 1). The types suggest that the parallel forms of the test perform as expected. The first type, constituted by configuration 1 1 1 1, describes those students who scored above the median in both parallel test forms, and showed a linear increase in state anxiety over the four measurement occasions, also in both parallel test forms. Instead of the expected about 3 respondents, 10 displayed this pattern. The second type, constituted by configuration 2 2 2 2, contains individuals who scored below the median in both parallel test forms and exhibited a trend toward lower scores over the four occasions, in both parallel test forms. Only about 2 individuals had been expected to show this pattern, but 10 did show it. The two configurations 1 1 1 1 and 2 2 2 2, thus, describe *typical* (or *prevailing*) developmental patterns. In this example, there are no *atypical developmental patterns*, which would be indicated by antitypes. However, readers are encouraged to test whether patterns that indicate that the two parallel forms result in diverging statements constitute a composite antitype.

As always, after performing a CFA, we ask whether there is a log-linear model that explains the frequency distribution in the cross-classification in Table 20.11. The model $[A_0]$, $[A_1]$, $[B_0]$, $[B_1]$, $[A_0, B_0]$, $[A_1, B_1]$ describes the data well ($\mathrm{LR} - X^2 = 12.79$; $df = 11$; $p = 0.172$). The two interactions suggest that the means as well as the linear slopes are associated with the other. This model supports the interpretation that the two forms of the state anxiety instrument are parallel. CFA suggests that this result is carried in particular by patterns 1 1 1 1 and 2 2 2 2.

Extensions of the method of polynomial configural analysis are straightforward. For example, one can ask whether groups of individuals differ in characteristics of their trajectories; one can ask whether covariates allow one to come to more differentiated conclusions; one can ask whether once-observed variables play a role; or one can ask whether characteristics of trajectories can be predicted, at the level of configurations, from other variables such as age or gender. Later in this chapter, we discuss CFA methods to predict trajectories.

Analyzing Series That Differ in Length

Thus far, the series of scores that we subjected to CFA shared the characteristic that they were all equal in length. However, there are many situations in which series differ in length. Apart from missing data which are dealt with using different tools, series can differ in length, for example, because clients need different numbers of therapy sessions, learners need different numbers of trials before they reach a criterion, workers are employed for different numbers of years before they retire, chess players need different

numbers of moves before a problem is solved, or students take different numbers of semesters before they complete their degree.

In all these and other cases, estimating and imputing missing data makes no sense, and neither does using such methods as full information maximum likelihood (FIML) estimation. These and other methods of missing data handling require the assumption that missing data could have been available to the analyst. In the sample cases, however, data do not and cannot exist because the process has come to an end (see the distinction between zeros, missing data, and nonexisting data; von Eye, 1989). Different methods are, therefore, needed to deal with the situation in which series of scores differ in length.

Lienert and von Eye (1986) proposed methods to characterize the characteristics of series of different length so that they can be analyzed with CFA. The principle behind these methods is that every feature of a series can be scaled, including length itself. For example, consider a sample of series of measures, the shortest of which includes k scores. For this series, polynomials can be estimated up to an order of $I = k - 1$. Now, because all other series include k scores or more, polynomials of order $I = k - 1$ can also be estimated for these series. The series can, therefore, be compared based on these polynomials. Technically, this procedure is the same as the one described in the last section, and will not be repeated here.

Similarly, when longer series are modeled using trigonometric functions, as is done in spectral analysis, spectral coefficients can be used for comparisons for the wave lengths that are applicable to the shortest of the comparison series. CFA methods for the analysis of coefficients from spectral analysis have not been discussed, so far. This possibility should be pursued in more detail in future work.

Here, we review and exemplify the methods proposed by Lienert and von Eye (1986). The authors proposed describing series of ordinal or higher level scores, regardless of length, with respect to the following three characteristics:

1. *Trend*. Series can be coded based on whether trends exist. The original method proposed by Lienert and von Eye (1986) focused on linear trends. However, depending on scale level and length of the shortest series, not only change in the linear trend (quadratic, second order polynomial), but also change in curvature (cubic, third order polynomial) and higher order components can be considered as well. Naturally, the intercept or mean can also be made part of the CFA analysis. A special case is what is called the *monotonic trend* of a series of length k. For ordinal variables, trends in changes in ordinal scores or ranks can be considered. A series is said to exhibit a monotonic trend if the inequality $y_{i+1} \geq y_i$ holds for every $i = 1, \ldots, k - 1$. This characteristic is known as *weak monotonicity*. This applies accordingly for $y_{i+1} \leq y_i$. If this inequality is violated just once, the series is said to not display a monotonic trend. Monotonicity is interesting because the trend it describes is not necessarily linear. Suppose the differences between time-adjacent measures fulfill the inequality but decrease over time, the curve approximates an asymptote but still is monotonic. Similarly, if the differences increase systematically with x, the curve is monotonic but can look similar to a quadratic curve. Finally, if the differences vary unsystematically, the curve zigzags its way to higher scores. The minimum number of scores needed for this criterion to be applicable is $k = 2$.
2. *Early completion*. In many studies, a series terminates when a particular criterion is reached. Examples of such criteria include recall rates in learning experiments and behavior thresholds in psychotherapy. Here, at least two options can be considered. First, one can specify a threshold and code a series asking whether the threshold was reached or not. Second, one can create an ordinal variable that provides a binning of the lengths of the series. The minimum number of scores needed for the early completion criterion to be applicable is 1 (e.g., a participant in a learning experiment reaches a 100% recall rate after the first trial).
3. *Qualitative characteristics*. In addition to the two criteria just discussed, any other characteristic of a curve can be considered. Examples of such characteristics include the number of errors in a problem solving task, the type of therapy used to cure a patient, the lengths of the intervals between therapy sessions, or the number of comorbid conditions that improved over the course of a treatment.

For use in CFA, the scores that describe these and other characteristics are binned, if needed, and the resulting categorical variables are crossed. The cross-classification from this procedure can then be analyzed using, for example, log-linear modeling, latent class analysis, or CFA.

Data Example

For the following example, we use data from the MIS (Bogat et al., 2004; Huth-Bocks et al., 2002; see first data example). The study assessed a sample of 206 women in their last trimester of pregnancy and at 2 months postpartum, and the women and their children every year until

the children were 14 years old. The women in the study reported a range of intimate partner violence experiences, from none to severe.

For the following data example, we use the variables Depression (*D*), Anxiety (*A*), and PTSD (*P*). We use data from the first three observation points, that is, the first three years of observation, and ask whether trends as measured in terms of weak monotonicity of the three variables are related to each other. In other words, we ask whether the three variables develop in unison. Most important from the perspective of analyzing series that differ in length is that, after three years, a portion of the original participants had left the study already. Reasons for dropping out include death of child (three instances), loss of custody, and moving away. Still, we include data from the entire sample of 206. For each of the participants, weak monotonicity could be evaluated, based on the procedure outlined before.

The three variables were coded as 1 if the criterion of weak monotonicity for a decline in scores was fulfilled and as 2 if the criterion was not fulfilled. In other words, the respondents were given a 1 if, for both comparisons of time-adjacent scores, the later score was below the earlier score. For respondents who dropped out after the second wave of data collection, only one comparison was used to determine the coding. This was done for all three variables. Using the coded complete data, we estimate two CFA base models. For both models, we use the normal approximation of the binomial test and the Holland–Copenhaver procedure for α protection. The first base model is that of standard first-order CFA of variable independence. The second is that of two-group CFA. The first model is

$$\log \hat{m} = \lambda + \lambda^D + \lambda^A + \lambda^P$$

and the second model is

$$\log \hat{m} = \lambda + \lambda^D + \lambda^A + \lambda^P + \lambda^{D,A}$$

The second model was estimated to determine whether respondents with a monotonic decrease in PTSD symptoms differ from those with a nonmonotonic development of PTSD symptoms in the development of Depression and Anxiety. To prevent estimation problems that the zero frequency in cell 2 1 1 could cause for the second of these models, we invoke the delta option for both models with $\Delta = 0.01$.

For the first model, we calculate an overall goodness-of-fit likelihood-ratio of $X^2 = 14.99$. For $df = 4$, this value leads to the rejection of the base model ($p < 0.01$) and we anticipate that types and antitypes may emerge. Table 20.12 displays results from first-order CFA.

TABLE 20.12 First-order CFA of the Cross-Classification of Monotonic Trend Information of Three Data Waves of Depression (*D*), Anxiety (*A*), and PTSD (*P*)

Configuration					
D A P	*m*	$\hat{m}$	*z*	*p*(*z*)	Type/antitype?

112	5.01	3.951	.5382	.295236	
121	4.01	4.617	−.2858	.387507	
122	33.01	36.938	−.7131	.237895	
211	.01	1.728	−1.3126	.094664	
212	11.01	13.827	−.7843	.216445	
221	15.01	16.160	−.2981	.382828	
222	135.01	129.284	.8219	.205570	

First-order CFA shows an interesting result. Only one type resulted. This type describes the women who show a decline in the scores of all three variables. Only four, but still significantly more women than expected showed this pattern. None of the other patterns deviates significantly from expectancy.

The two-group CFA base model was estimated under the assumption that women who show monotonic decrease in PTSD may differ in levels of Depression and Anxiety from those women who do not show a monotonic decrease in PTSD. The base model for this two-group CFA can be rejected only if one or more of the following interactions exist: [*D, P*], [*A, P*], and [*D, A, P*]. Each of these interactions includes variable *P*, that is, PTSD. For this base model, we obtain the overall goodness-of-fit likelihood-ratio of $X^2 = 9.178$. For $df = 3$, this value leads to the rejection of the base model ($p = 0.027$), and we anticipate that discrimination types may emerge. Table 20.13 displays results from two-group CFA.

TABLE 20.13 Two-Group CFA of the Cross-Classification of Monotonic Trend Information of Three Data Waves of Depression (*D*), Anxiety (*A*), and PTSD (*P*), with PTSD as the Grouping Variable

Configuration				
D A P	*m*	statistic	*p*	Type?
111	4.01			
112	5.01	3.255	.000567	Discrimination Type
121	4.01			
122	33.01	−.063	.474961	
211	.01			
212	11.01	−1.197	.115600	
221	15.01			
222	135.01	−.832	.202799	

Two-group CFA presents one discrimination type. This type results from the comparison of cell 1 1 1 with cell 1 1 2. It suggests that significantly more women whose PTSD symptom scores systematically decrease show Pattern 1 1 than women whose PTSD scores do not decrease. In other words, women whose PTSD symptom scores show a monotonic decrease are significantly more likely to also show monotonic decreases in their depression and anxiety symptom scores than women whose PTSD symptom scores do not show a monotonic decrease.

On a methodological note, this result may sound implausible, when one considers that Pattern 1 1 2 is exhibited by five women but Pattern 1 1 1 only by four. However, Tables 20.12 and 20.13 also show that, in general, far more women fail to fulfill the weak monotonicity criterion than fulfilling it. From this perspective, the number five is far fewer than one would expect based on the ratios found for the other three comparison patterns.

A similar result is found when the odds ratio is calculated for cells 1 1 1 and 1 1 2 compared with all other cells combined. This odds ratio is 7.54 (log odds ratio = 2.019). This value indicates that the rate of women with Pattern 1 1 1 is more than twice as often found than women with Pattern 1 1 2 when the aggregate of all other patterns is used for a reference ($p < 0.01$).

Extensions

The approach to analyzing series that differ in length can be extended in several ways. First, one can include once-measured variables and time-invariant measures in the base model. Examples of such measures are grouping variables or information that remains unchanged such as the year of birth of respondents. Second, other characteristics of the series under study can be taken into account. For example, one can ask whether the score of a variable at the first occasion is predictive of trends, completion, or qualitative characteristics of a series. Later in this chapter, the predictive value of a score at the beginning of a series will be made part of a CFA prediction model.

CFA of Pre–Post Designs—An Application of Confirmatory CFA

In evaluation studies and in the study of effects of experiments or interventions, researchers typically follow a priori planned experimental designs. Hypotheses compatible with these designs are subjected to statistical testing, and detailed hypotheses are pursued, for example, by way of planned contrasts or between-group post hoc mean comparisons. In many cases, the dependent variables in such research are metrical, that is, measured at the interval or ratio scale level. In other cases, however, the dependent variables are frequency variables such as the number of correctly reproduced syllables or the number of times a person diagnosed with obsessive-compulsive disorder washes his or her hands. Both the number of syllables a person is able to reproduce and the number of hand washes may depend on intervention procedures. In these and similar cases, CFA is the method of choice for data analysis.

In the examples of CFA application used thus far, the method was employed in an *exploratory* context. When effects of experiments or intervention are examined, precise hypotheses often exist. In this situation, *confirmatory* application of CFA is in order. In confirmatory CFA, a priori specified hypotheses are tested. In other words, in confirmatory CFA, researchers determine before data collection which configurations are subjected to CFA tests. The number of these configurations is smaller than the number examined in exploratory CFA. Therefore, the procedures implemented to protect α need to take into account only this number instead of the total number of cells in the cross-classification. This difference in the number of tests has an important implication for the testing procedure in CFA: the significance threshold α^* will be less extreme.

Let t' be the number targeted in confirmatory CFA and t the total number of cells, with $t' < t$. Then, we obtain, in confirmatory CFA, for the Bonferroni-protected $\alpha'^* = \alpha/t'$ and, in exploratory CFA, the Bonferroni-protected $\alpha^* = \alpha/t$, with $\alpha'^* > \alpha^*$. This indicates that investing information in the specification and selection of hypotheses results in a less extreme significance threshold. This effect is known from the differences in significance thresholds between one-sided and two-sided testing, where investing information in the derivation of one-sided tests also results in less extreme significance thresholds.

Consider, for example, a cross-classification with 27 cells. The Bonferroni-protected α^* for this table is, in exploratory application of CFA, $\alpha^* = 0.05/27 = 0.0019$. If, in confirmatory research, only five cells are examined, the protected α'^* is $\alpha'^* = 0.05/5 = 0.01$. In this example, the difference between the protected α in exploratory and in confirmatory research is a factor of 5.4. That is, the protected α is, in exploratory research, 5.4 times more extreme than in confirmatory research. Types and antitypes are, therefore, more likely to emerge in confirmatory research than in exploratory research.

The rest of the testing procedure is unchanged from standard, exploratory CFA testing. The cells that were selected for testing are either tested using a constant significance threshold (as is the case in the Bonferroni procedure)

or the test statistics of these cells are ranked in descending order and tested until either the first discrepancy between the observed and the expected cell frequency fails to be significant or the number of a priori-specified cells is exhausted (Holm or Holland–Copenhaver procedures).

Treatment Effects in Designs with No Control Group

In the following sections, we present two data examples (Lienert & Straube, 1980; von Eye, 2002). The first example involves the examination of effects of neuroleptic drugs on inpatients diagnosed with schizophrenia, with no control group. The drugs were administered in a sample of 75 patients over a period of 2 weeks. At the beginning and end of this 2-week period, the patients were also administered the Brief Psychiatric Rating Scale (Overall & Gorham, 1962). Three of the 17 symptoms captured by this instrument are used in the following analyses: W = emotional withdrawal; T = thought disturbances; and H = hallucinations. Each of the symptoms was scaled as either present (+) or absent (−). Table 20.14 displays the data, along with the CFA results. We analyze these data in three different ways. The first is first-order, confirmatory CFA. For this CFA, we use the z test and the Holland–Copenhaver procedure for α protection.

The data in Table 20.14 are arranged in a somewhat unusual fashion. Instead of presenting all possible combinations of before–after treatment symptoms, we created an ordinal variable with the categories 3 symptoms observed (indicated by + + +), two symptoms observed (indicated by + + −, + − +, and − + +), one symptom observed (indicated by + − −, − + −, and − − +), and no symptom observed (− − −). This variable shows that, in this data example, we are interested in the number of symptoms instead of the individual symptoms.

TABLE 20.14 Evaluation of Treatment of Schizophrenics with Neuroleptic Drugs in a Pre–Post Study

Number of symptoms before treatment	Configurations	Number of symptoms after treatment (expected number in *italics*)				Totals
	WTH	3 + + +	2 + + − + − + − + +	1 + − − − + − − − +	0 − − −	
3	+ + +	1 *1.60*	10 *5.20*	4 *6.00*	0 *2.20*	15
2	+ + − + − + − + +	6 *4.05*	11 *13.17*	17 *15.20*	4 *5.57*	38
1	+ − − − + − − − +	1 *1.71*	4 *5.55*	7 *6.40*	4 *2.35*	16
0	− − −	0 *0.64*	1 *2.08*	2 *2.40*	3 *0.88*	6
Totals		8	26	30	11	75

The overall goodness-of-fit likelihood-ratio for the base model of variable independence is $X^2 = 17.79$. For $df = 9$, this value leads to the rejection of the base model ($p = 0.038$), and we anticipate that CFA discrimination types may emerge. However, the tail probability, for none of the 16 tests, exceeds the threshold dictated by this exploratory analysis. Under standard conditions of exploratory application of CFA we would, therefore, conclude that the first and the second observations are independent of each other and that the neuoleptic drugs have no systematic effect.

Having a hard time believing this, Lienert and Straube (1980) proposed using two additional methods of analysis for data as the ones presented in Table 20.14. The first involves using the *diagonal-half sign test*. This test can be used to compare the aggregate of the frequencies above the diagonal with the aggregate of the frequencies below the diagonal. For this test, the frequencies in the cells above the main diagonal (from upper left to lower right) in Table 20.14 are summed, and so are the frequencies below the main diagonal. Let the first sum be called b, and the second sum w. The patients in the upper triangle are those who moved, under the drug, from more to fewer symptoms. The patients in the lower triangle are those who moved from fewer to more symptoms. The diagonal-half sign test for the comparison of b with w is

$$z = \frac{b - w}{\sqrt{b + w}}$$

The test statistic z is approximately normally distributed. As an alternative, for small samples, the binomial test can be considered, which is

$$B(h) = \sum_{j=0}^{h} (N) p^j q^{N-j}$$

where, in the present case, $p = q = 0.5$, $N = b + w$, and h is the lesser of b and w. To illustrate the z test, we use the data in Table 20.14. For the upper triangle, we obtain $b = 10 + 4 + \ldots + 4 = 39$. For the lower triangle, we obtain $6 + \ldots + 2 = 14$. Inserting into the formula for z results in

$$z = \frac{39 - 14}{\sqrt{39 + 14}} = 3.434$$

The corresponding tail probability is 0.0003. From this result, we conclude that the neuroleptic drugs reduce the number of symptoms in schizophrenic inpatients.

The second method of analysis proposed by Lienert and Straube (1980) allows one to test more detailed hypotheses than the one concerning general change in the number of symptoms. One can create a preintervention × postintervention cross-tabulation for each symptom and analyze the resulting $I \times I$ table using the Bowker test (1948; von Eye & Spiel, 1996), where I represents the number of categories, or the McNemar test (McNemar, 1947), when $I = 2$. The test statistic for the Bowker test is

$$X^2 = \frac{\sum_i \sum_j (m_{ij} - m_{ji})^2}{m_{ij} + m_{ji}}$$

for $i > j$ and $i, j = 1, \ldots, I$. This test statistic is approximately distributed as χ^2 with $df = (I)$. When $I = 2$, one can use the McNemar test which has the same form but simplifies to

$$X^2 = \frac{(m_{12} - m_{21})^2}{m_{12} + m_{21}}$$

This statistic is approximately distributed as χ^2 with $df = 1$. When cell frequencies are small, the continuity-corrected equation

$$X^2 = \frac{(\mid m_{12} - m_{21} \mid -0.5)^2}{m_{12} + m_{21}}$$

is recommended. Von Eye (2002) presents the following application example for this equation. In the example, the question is asked whether the neuroleptic drug reduces the number of hallucinations in Lienert and Straube's (1980) neuroleptic drug treatment study in particular. The cell frequencies for hallucinations are $++ = 8$, $+- = 21$, $-+ = 9$, and $-- = 32$, where $+$ indicates presence and $-$ indicates absence of a symptom. For these values one obtains

$$X^2 = \frac{(21 - 9)^2}{21 + 9} = 4.80$$

For $df = 1$, the probability of this value is $p = 0.0285$. We, therefore, reject the null hypothesis that the neuroleptic drug treatment leads to no better than random changes in the number of hallucinations.

An interesting alternative to the tests presented in this section can be found in the literature on rater (dis)agreement. In the present context, we ask whether a shift can be ascertained that manifests in a larger number of cases than expected in the upper or lower triangle of the cross-classification of the repeated observations. This pattern corresponds with the pattern of disagreement in which one rater systematically uses higher ratings than the other. Von Eye and von Eye (2005) proposed coefficients for this case. These coefficients are derivatives of Cohen's (1960) κ (kappa) and can therefore be interpreted as proportionate reduction in error (PRE) coefficients. Focusing on the upper triangle of an agreement matrix, one can ask whether disagreement differs from expectation. To answer this question, we need to define a base model. A first option is that we define this model in a fashion similar to the base model for first-order CFA, that is, as a model of rater independence. The same model is used for Cohen's κ. A second option is to define the base model as the null model, as for Brennan and Prediger's (1981) κ_n. Using these base models, one can define coefficients of disagreement or, as in the present context, temporal shifts in symptoms, for the upper triangle of an agreement table.

A coefficient of disagreement in the upper triangle of an agreement table can be defined in a fashion analogous to Cohen's κ. The probability of disagreement in the upper triangle of the cross-classification, that is, the probability that Rater B (columns) selects higher scores than Rater A (rows) or the probability that fewer symptoms are diagnosed at Time 2 than at Time 1 is

$$\theta_1^t = \sum_{i<j} p_{ij} = 1 - \sum_i p_{ii} - \sum_{i>j} p_{ij}$$

where the superscript indicates that we consider the disagreement cells in the upper triangle. Under the base model of independence of the first from the second observation (or the base model of rater independence), the expected probability of finding cases in the upper triangle in the upper triangle is

$$\theta_2^t = \sum_{i<j} p_{i.} p_{.j} = 1 - \sum_i p_{i.} p_{.i} - \sum_{i>j} p_{i.} p_{.j}$$

Using θ_1^t and θ_2^t, one can define a κ-like PRE coefficient as

$$\kappa^t = \frac{\theta_1^t - \theta_2^t}{1 - \theta_2^t}$$

This coefficient also has a range of $-\infty < \kappa^t \leq 1$ (for specifics on range and special cases, see von Eye & von Eye, 2005).

To define a coefficient κ_n^t that is analogous to Brennan and Prediger's (1981) coefficient κ_n, we select the null model as the base model. This model is also used in CFA of zero

order. For θ_1^t, we use the same definition as above. For the expected probability, θ_2^t, we obtain

$$\theta_{n,2}^t = \binom{I}{2}\frac{1}{I^2} = \frac{I-1}{2\mathrm{I}}$$

and, thus,

$$\kappa_n^t = \frac{\theta_1^t - \theta_{n,2}^t}{1-\theta_{n,2}^t}$$

This coefficient has a range of $-\infty < \kappa_n^t \leq 1$ (again, for specifics on range and special cases, see von Eye & von Eye, 2005).

There are three major differences between the diagonal-half sign test proposed by Lienert and Straube (1980) and the PRE coefficients proposed by von Eye and von Eye (2005). First, the PRE coefficients can always be interpreted in units of proportionate reduction in error. That is, the PRE coefficients tell the user the increase in the percentage of cases that can be found in the upper triangle in comparison to the expected percentage. Second, the user can select from a number of base models. These models are selected with the goals of CFA in mind. Third, the effects of covariates can be made part of the analysis by estimating the expected frequencies using the model $\log \hat{m} = X\lambda + X^c\lambda^c$ instead of $\log \hat{m} = X\lambda$, where the extended model includes, in its second term, the covariate(s). The rest of the calculations remains unchanged from the case with no covariates.

To illustrate the PRE coefficients, we reanalyze the data example in von Eye and von Eye (2005; Fennig, Craig, Tananberg-Karant, & Bromet, 1994; Schuster & Smith, 2002). The data describe psychiatric diagnoses of the same 223 patients, once made by practicing psychiatrists and once in a research context. The goal of the original analyses was to determine whether there is agreement between the diagnoses provided by the service facility and research teams. The patients were rated on an ordinal 4-point severity scale with the categories 1 = severe psychosis, 2 = average severity psychosis, 3 = mild psychosis, and 4 = no clinical diagnosis. Table 20.15 gives the cross-classification of the facility with the research diagnoses.

The frequency distribution in Table 20.15 shows that the two diagnoses coincide in most cases. In each row of the cross-classification, the agreement cell (diagonal cell) contains the largest number of cases. Also in each row, the agreement cell contains more cases than expected under the base model of independent diagnoses. This is also indicated by the coefficients discussed by von Eye and von Eye (2005).

TABLE 20.15 Cross-Classification of Facility and Research Diagnoses for 223 Psychiatric Patients

Facility diagnosis	Research diagnosis								
	1		2		3		4		Totals
1	40	*18.95*	6	*13.41*	4	*11.08*	15	*21.57*	65
2	4	*10.20*	25	*7.22*	1	*5.96*	5	*11.61*	35
3	4	*10.49*	2	*7.43*	21	*6.14*	9	*11.95*	36
4	17	*25.36*	13	*17.95*	12	*14.83*	45	*28.87*	87
Totals	65		46		38		74		223

Note: Expected cell frequencies in *Italics* (base model of first-order CFA). Agreement cells underlined.
Source: Fennig et al. (Fennig et al., 1994)

Looking at the upper triangle, we obtain $\kappa^t = -0.24$. This value suggests that the proportionate reduction in these error cells is 24.14%. In other words, the upper triangle contains 24.14% fewer cases than one would expect under the assumption of independence of the two diagnoses. Proceeding from the null model, that is, the model that does not take the differences in the marginal probabilities into account, we use the expected frequency of 223/16 = 13.9375, for each cell. For the κ_n equivalent, the value of $\kappa_n^t = -0.31$ indicates that 31.30% discrepant diagnoses are made less than expected under the assumption of a uniform diagnoses distribution. The coefficient of raw disagreement for the upper triangle (this is just the proportion of cases in the upper triangle) of the disagreement cells is $ra^t = 0.18$. None of these values is significant. For example, $ra^t = 0.18$ comes with a z score of 0.10 and $p = 0.46$ (for this significance test, see von Eye, Schauerhuber, & Mair, 1997).

For comparison, we also calculate the test discussed by Lienert and Straube (1980). We obtain $w = 6 + 4 + \ldots + 9 = 40$, $b = 52$, and $z = \frac{40-52}{\sqrt{40+52}} = -1.25$. The tail probability for this value is 0.11, thus indicating that there is only an insignificant shift toward more severe ratings in the facility as compared to the research unit.

Apart from indicating nonsignificant effects, this example shows that the various coefficients are sensitive to different characteristics in the data table. Lienert and Straube's test responds to shifts toward to upper or lower triangle. Von Eye and von Eye's κ equivalents compare the observed frequencies in sectors of the cross-classification with expectancies that reflect assumptions concerning marginal probabilities and, thus, effects in the table.

Treatment Effects in Designs with Control Group

Experimental designs without a control group are deemed less informative or more biased than designs with control group. However, designs without a control group can still

TABLE 20.16 $2 \times 2 \times 2$ Table for the Comparison of Pattern Shift in Two Groups

Totals	$m_{1..}$	$m_{2..}$	$N = m_{1..} + m_{2..}$

provide information about whether or not treatment effects can be expected at all. If, in a design without a control group, results suggest that effects may exist, controlled studies can be undertaken (if they are not undertaken from the very start). Randomized clinical trials (RCTs) are necessary for a number of reasons. One is to compare treatments with each other. For example, a new form of psychotherapy is compared with an established one. Most important, in particular in psychotherapy research, RCTs are needed to distinguish spontaneous recovery, assessment reactivity, or expectancy effects from treatment effects.

CFA can be used to compare experimental groups and control groups with two-group CFA, or, when there are more than two groups, with multigroup CFA. Here, we discuss methods that allow one to compare two groups in regard to the change from one configuration to another. To explain the scenario, consider one treatment group and one control group. For both groups, Patterns A and B are observed before and after the intervention administered to the treatment group. Table 20.16 schematizes the data situation.

The goal of analysis is the comparison of the control with the treatment group in a particular change pattern. In the example in Table 20.16, there are only two change patterns, the change from $m_{.11}$ to $m_{.12}$ and from $m_{.21}$ to $m_{.22}$, where, in the table as well as here, in the text, a dot indicates the variable aggregated across. The null hypothesis for the present comparison is that the comparison groups do not differ in their change rates. Specifically, we ask whether m_{112} differs from m_{212}, or whether m_{121} differs from m_{221}. The answer to these questions is given on the basis of 2×2 cross-classifications. Table 20.17 displays this cross-classification for the first comparison.

In Table 20.17, the notation for the cell frequencies carries over from Table 20.16. Table 20.17 shows a 2×2 cross-classification in which Frequency m_{112} is compared with m_{212}, in the context of the rest of the treatment and control group samples. Tables as the one in Table 20.17 can be analyzed with marginal-dependent measures such as Pearson's X^2 or with marginal-free measures as the odds ratio (for the distinction between marginal-dependent and marginal-free measures, see Goodman, 1991, or von Eye, Spiel, & Rovine, 1995).

Data Example

In the following example, we reanalyze the data presented by Martinez-Torteya, Bogat, von Eye, Levendosky, and Davidson (Martinez-Torteya et al., 2009). The data were collected in the context of the MIS (//www.msu.edu/~mis/). As was indicated before, the study first assessed a sample of 206 women in their last trimester of pregnancy and at 2 months postpartum, and the women and their children every year until the children were 14 years old. The women in the study reported a range of experiences of intimate partner violence, from none to severe. In the example, we focus on the 93 women who reported one or more episodes of partner violence during the second year of their child's life. We ask whether frequency of violence (F) experienced during the second year of their child's life is predictive of Depression (D) and PTSD (P) in the same year. Each of these three variables was dichotomized at the median, and coded such that the value of 1 indicates a score below the median and 2 indicates a score above the median. Table 20.18 displays the $2 \times 2 \times 2$ $D \times P \times F$ cross-classification along with CFA results. We first analyze these data using a standard first-order CFA with the base model $\log \hat{m} = \lambda + \lambda^D + \lambda^P + \lambda^F$. Then, we ask whether particular comparison patterns stand out. For the CFA tests, we use the binomial approximation of the normal distribution and the Holland–Copenhaver procedure for α protection.

The overall goodness-of-fit likelihood-ratio for the base model of variable independence is $X^2 = 44.15$. For $df = 4$, this value leads us to reject of the base model ($p < 0.01$), and we anticipate that types and antitypes may

TABLE 20.18 Cross-Classification of Depression (*D*), PTSD (*P*), and Frequency of Violence (*F*)

212	3.00	13.053	−3.0011	.001345	Antitype
221	5.00	10.989	−1.9238	.027191	
222	26.00	12.237	4.2218	.000012	Type

Note: Expected cell frequencies are estimated under the base model of first-order CFA.

emerge. Indeed, Table 20.18 shows two types and two antitypes. The first type is constituted by configuration 1 1 1. These are women who report below-average frequencies of violence, along with below-average scores in Depression and PTSD. The second type is constituted by just the opposite pattern, 2 2 2. These are women who report above average frequencies of violence, along with above average Depression and PTSD. The two antitypes are constituted by Patterns 1 2 1 and 2 1 2, indicating that it is very unlikely that low frequencies of violence lead to high levels of depression but low levels of PTSD or high levels of depression but low levels of PTSD, in the presence of intimate partner violence.

To illustrate the application of the scheme shown in Table 20.17, we now consider the two levels of violence the comparison groups. The variables Depression and PTSD are crossed to form the patterns in which the two treatment groups are compared. It is important to note that the analysis we are about to illustrate is not just an extension of first-order CFA. In terms of CFA base models, the following analysis represents a 2-group CFA that is saturated in the comparison variables. Specifically, the expected frequencies are estimated using the first-order base model

$$\log \hat{m} = \lambda + \lambda^D + \lambda^P + \lambda^F + \lambda^{DP}$$

The main reason for using this base model is that types and antitypes (or discrimination types) can no longer appear just because, maybe, the discrimination variables Depression and PTSD are associated. The two treatment groups can differ in a pattern only if one or both of the discrimination variables is related to the grouping variable. We insert, for instance, Pattern $D = 1$ and PTSD = 1 into a scheme as it is shown in Table 20.17 and obtain the cross-classification in Table 20.19.

TABLE 20.19 2×2 Table for the Comparison of Two Groups in a Two-Variable Pattern

	Violence Frequency		
Patterns	Below Average	Above Average	Totals
m_{111} versus m_{211}	$m_{111} = 22$	$n_{211} = 9$	$m_{111} + m_{211} = 31$
all others combined	22	40	62
Totals	44	49	$N = 93$

The Pearson X^2 for the data in Table 20.19 is 10.44 ($df = 1$; $p < 0.01$). This result suggests that below-average frequency of violence is predictive of higher frequencies of low Depression and PTSD than above average violence.

Two points concerning the method used for analysis must be discussed, in this context. First, it is important to note that this result is not just a reformulation of the description of the first type in Table 20.18. The type suggests that the pattern low frequency of Violence–low Depression–low PTSD is *more likely than expected*. Here, we can make a comparative statement in which we contrast the two violence groups.

Second, the MIS study oversampled, on purpose, women who were victims of violence. Therefore, the marginal frequencies in Table 20.19 (as well as the univariate frequencies for tables that use the MIS data) may not reflect population characteristics. X^2 measures are known to be marginal-dependent. Thus, the result from the 2×2 cross-classification in Table 20.19 may be distorted or biased. A measure that is marginal-free is the *odds ratio*. Consider a 2×2 table with the cell frequencies m_{11}, m_{12}, m_{21}, and m_{22}. A cross-classification of this type (parallel to the one displayed in Table 20.17) is given in Table 20.20.

Table 20.20 contains the information for four odds and one odds ratio (see von Eye & Mun, 2013):

1. $\Omega_1 = p_{11}/p_{12}$: the odds of a diagnosis of the undesirable outcome versus no such undesirable outcome under treatment;
2. $\Omega_2 = p_{21}/p_{22}$: the odds of a diagnosis of the undesirable outcome versus no such undesirable outcome without treatment;

TABLE 20.20 Cross-Classification of Treatment and Outcome Pattern and Cell Frequencies

	Diagnosis of undesirable outcome	
Treatment	Yes	No
Yes	m_{11}	m_{12}
No	m_{21}	m_{22}

3. $\Omega_3 = p_{11}/p_{21}$: the odds of a diagnosis of the undesirable outcome in the treatment versus the comparison groups;
4. $\Omega_4 = p_{12}/p_{22}$: the odds of a diagnosis of no undesirable outcome in the treatment versus the comparison groups.

Each of these odds has an easy, natural interpretation, and so does the odds ratio that relates these odds to each other. Consider $\theta^T = \Omega_1/\Omega_2$. This odds ratio can be used to test the hypothesis that respondents in the treatment group are more likely to be diagnosed with the undesirable outcome than respondents who were not exposed.

It is interesting to note that there are more odds ratios that could be considered for this 2 × 2 table. However, because they all use the same information, they all have the same interpretation. Specifically, we obtain

$$\theta = \frac{\frac{p_{11}}{p_{12}}}{\frac{p_{21}}{p_{22}}} = \frac{\frac{p_{11}}{p_{21}}}{\frac{p_{12}}{p_{22}}} = \frac{p_{11}p_{22}}{p_{12}p_{21}}$$

As far as the odds ratio is concerned, one can formulate the hypothesis that the odds ratio $\theta^T = \Omega_1 / \Omega_2$ is greater than one in the population, where the superscript T indicates that the odds ratio contrasts the treatment and the comparison groups. To test this hypothesis, one can divide the logarithm (base e) of the odds ratio by its standard error (se), which can be estimated by

$$se(\log \hat{\theta}) = \sqrt{\frac{1}{m_{11}} + \frac{1}{m_{12}} + \frac{1}{m_{21}} + \frac{1}{m_{22}}}$$

The test statistic for the logarithm of the odds ratio is

$$z_\theta = \frac{\log \hat{\theta}}{se(\log \hat{\theta})}.$$

This statistic is approximately normally distributed. Applied to the data example in Table 20.19, one obtains $\hat{\theta} = 4.44$, $\log \hat{\theta} = 1.49$; $\text{se}(\log \hat{\theta}) = 0.48$; $z = 3.13$; and $p < 0.01$. We note that, in this example, the X^2 and the odds ratio analyses suggest the same conclusion. If the present X^2 result is biased, the distortion has no effect on the present result.

Single-Subject Designs

Why would one conduct research using single-subject designs when generalization of results is the main goal of scholarly activity? There are many answers to this question. Here, we focus on two answers that are of interest from a person-oriented perspective. First, in person-oriented (Bergman & Magnusson, 1997; von Eye & Bergman, 2003; von Eye, Bergman, & Hsieh, 2015) and idiographic research (Molenaar, 2004; Molenaar & Campbell, 2009; von Eye, 2004b), it has been shown that results that are based on longitudinal aggregated raw data can be trusted only under rare and unrealistic conditions such as ergodicity. What needs to be done is (1) estimation of parameters at the level of individuals and (2), if needed, aggregation of cases based on their parameters. If this research strategy is followed, one needs longitudinal single-subject designs instead of cross sectional studies.

Second, researchers can be interested in an individual in his or her own right, in a treatment study in which treatment can be extensive, or when random assignment can be ethically difficult. There can be a situation in which an individual can be different from other individuals to a degree that aggregation would bias the aggregation of parameter estimates beyond the tolerable. On the other extreme there may be an individual that is known to belong to a population and researchers are interested in how the individual responds to a new form of treatment.

A number of single-subject designs has been developed for CFA (von Eye, 2002; von Eye et al., 2010). Here, we begin with *single-subject CFA*. This is followed by *CFA of runs* and *cross-lagged CFA*.

Single-Subject CFA

When a CFA is considered for multidimensional data that stem from a single individual, the resulting cross-classification that is being analyzed does not differ in form from the cross-classification of variables across multiple individuals. Single subject data are different however, in that they were collected over multiple occasions. Consider the relationships between the three variables A, B, and C, observed over n occasions for one individual. The $A \times B \times C$ cross-classification has n entries. It allows one to test hypotheses concerning the association structure of the three variables, for that particular individual. It also allows one to search for types and antitypes that contradict a particular base model, also for the particular individual.

Data Example

To illustrate this approach, we use data from an intensive longitudinal study of self-identified alcoholics (Perrine, Mundt, Searles, & Lester, 1994). A sample of alcoholic adult men provided every morning information about their drinking the day before, as well as their subjective ratings of mood, health, and quality on the day of the interview. Here, we ask whether there are associations among mood (M) of

Respondent 3000, his subjective reports of health (H) and beer drinking (B). Data assessed from 734 consecutive days were available. Mood was rated on a 10-point Likert scale with 1 indicating "terrible mood" and 10 indicating "just wonderful." Respondent 3000 rarely endorsed the low and the high end points on this scale. Therefore, scores 4 and below were combined into a single category. Similarly, this respondent nearly never used scores 7 through 10. Therefore, scores 7–10 were also combined into a single category. The resulting scale thus ranged from 1 to 4 with 1 indicating average mood or below, and 4 indicating good or better mood. Similarly, the range of health ratings was condensed from a 10-point Likert scale to the values 1–4. The resulting scale values indicate 1 = perception of average health or below through 4 = perception of good to excellent health. The range of the numbers of beer consumed by Respondent 3000 was wide, with the extremely high numbers rarely reported. Therefore, this scale was also condensed to range from 1 = no beer consumed through 3 = three or more beers consumed in one day.

For the analysis of the resulting $4 \times 4 \times 3$ H × M × B cross-classification, we use the z-test and the Holland–Copenhaver procedure of α protection. The first base model we use is that of first-order CFA,

$$\log \hat{m} = \lambda + \lambda^H + \lambda^M + \lambda^B$$

This model can be rejected when any combination of the interactions [*B, M*], [*B, H*], [*M, H*], [*B, M, H*] exists, that is, any interaction at all.

For the base model of first-order CFA, we obtain a $\mathrm{LR} - X^2 = 89.60$ ($df = 39$; $p < 0.01$). Therefore, we anticipate that types and antitypes emerge. Table 20.21 summarizes the CFA results.

The results in Table 20.21 suggest that only one type exists and no antitype. This type indicates that comparatively low ratings of mood and health co-occur with low consumption of beer more often than expected. This result reflects an extreme case of a *local association* (Havránek & Lienert, 1984). The associations in this table of 48 cells are carried by just one cell. One could argue that cell 1 1 2 also makes a contribution. However, under the restrictions of α protection, this contribution is nonsignificant if this cell is examined by itself. If one tests whether cells 1 1 1 and 1 1 2 constitute a *composite type*, one obtains a Stouffer $Z = 6.93$, which suggests a strong deviation from the independence model for this pair of cells. This composite type suggests that health and mood ratings are at their lowest when Respondent 3000 consumed two beers or less on the day before the interview.

TABLE 20.21 First-Order CFA of the Cross-Classification of Numbers of Subjective Health (H), Mood (M), and Beer Consumed (B), for Respondent 3000

442	2.00	1.566	.3470	.364301	
443	9.00	6.049	1.2000	.115073	

We also ask whether the pairwise associations that involve mood, that is, [*B, M*], [*M, H*], allow us to explain the data. To answer this question, we estimate the log-linear model

$$\log \hat{m} = \lambda + \lambda^H + \lambda^M + \lambda^B + \lambda^{BM} + \lambda^{MH}$$

and a multinomial logit model. This model describes the data well. Specifically, we obtain a LR $- X^2 = 33.87$ ($df = 24$; $p = 0.251$). This model clearly stands by itself. It is also significantly better than the base model of first-order CFA (ΔLR $- X^2 = 55.73$; $\Delta df = 15$; $p < 0.01$). Both interactions are significant. Similarly, a multinomial logit model comes with an X^2 of 53.54, which indicates that beer consumption and subjective health can be used as predictors of mood ($df = 15$; $p < 0.01$).

This result illustrates again the difference between variable-oriented and person-oriented research. The former allows one to state that, in the present example, mood is associated with both beer consumption and subjective health ratings. The person-oriented results, however, suggest that (1) comparatively low beer consumption goes hand in hand with comparatively poor mood and low health ratings and that (2) otherwise the three variables are independent of one another.

Although interesting, the approach to single subject CFA just described lacks a developmental perspective in the sense that possible change over time is aggregated over. Therefore, we present, in the next example an approach to CFA that takes the longitudinal nature of data into account.

TABLE 20.22 Prediction CFA of the Cross-Classification of Numbers of Beer Consumed (*B*) and Subjective Health (*H*), over the First and the Second Halves of the Observation Period (*P*); for Respondent 3004

Data Example

We use data from the study on the development of alcoholics again. Instead of Respondent 3000, we now use the answers from a different participant, Respondent 3004. He provided data on 742 consecutive days. To keep the example simple, we ask whether the relationship between beer consumption (B) and subjective health (H) varies from the first to the second half of the observation period (P). Each variable was coded so that small numbers indicate low levels and high numbers indicate high levels (or perceptions indicating good levels).

This question can be answered using a base model that has two characteristics. First, the observation period is proposed to be independent of beer consumption and subjective health. Second, beer consumption is proposed to be associated with health rating. The base model is that of a Prediction CFA,

$$\log \hat{m} = \lambda + \lambda^B + \lambda^H + \lambda^P + \lambda^{BH}$$

This model can be rejected only if one or more of the following interactions exist: [*B, P*], [*H, P*], [*B, H, P*]. Each of these interactions contains the variable that indicates the first versus the second half of the observation period. If one or more of these interactions exist, the association between beer consumption and health varies over the two observation periods. For the following Prediction CFA, we use the z test and the Holland–Copenhaver procedure for α-protection. Table 20.22 displays results of CFA.

The results in Table 20.22 suggest that four pairs of prediction type/antitype exist. Each of these pairs suggests that a pattern that stands out in the first half of the observation period also stands out in the second half, but for the opposite reason. Specifically, the first antitype, constituted by configuration 1 3 1, suggests that it is very unlikely that, for this respondent, very low levels of beer consumption together with subjective ratings of average to good health are reported during the first half of the observation period. More than 66 daily instances of this pattern are expected, but it was found only for 3 days. This pattern reverses dramatically in the second half of the period. More than 67 instances of the pattern of very low levels of beer consumption and average to good health are expected, but 131 instances were found. Configuration 1 3 2 thus constitutes a prediction type.

Similarly, the second antitype, constituted by configuration 2 3 1, suggests that low beer consumption in combination with average or better subjective health is unlikely for the first half of the observation period. It constitutes a prediction antitype. In the second half, however,

this pattern is particularly likely, and constitutes a prediction type. Similarly, Pattern 3 3 (average beer consumption in tandem with subjectively average or better health) is unlikely in the first half (three instances observed versus over 15 expected) but very likely in the second half of the observation period (28 instances observed versus over 15 expected).

For Pattern 4 3, the relationship is reversed. This pattern indicates above average beer consumption in tandem with subjectively above average or better health, can be predicted to occur more often than expected for the first half of the study (331 observed versus 241 expected instances) but less often than expected in the second half (155 observed versus 244 expected instances). Pattern 4 3 is also the most frequent of all patterns for this respondent.

If the temporal aspect of the observations is not taken into account, that is, after aggregating responses over time, the $B \times H$ cross-classification (aggregated over the two periods of time; not shown here) would have contained just one type. This type suggests that drinking small amounts of beer on any given day goes hand in hand with average or better self-reported health. This type can, evidently, not be generalized over time. In the second half of the observation period, it transmutes into an antitype.

CFA of Runs

Published for the first time in the context of CFA of intensive longitudinal data, CFA of runs focuses on particular characteristics of series of data. Using runs, researchers answer the question whether there is randomness in a series of data. For a definition of *runs*, consider a series of observations. A run is defined as a pattern in this series. In general, a run is (1) an uninterrupted series of bits that share one or more characteristics that is (2) bounded on both sides by bits of different characteristics. In the following paragraphs, we give a selection of examples (for the well-known runs tests, see Stevens, 1939; Swed & Eisenhart, 1943; Wald & Wolfowitz, 1940; for runs in the context of CFA and an algorithmic perspective, see von Eye et al., 2010). The definitions involve single scores, but they can also involve two or more scores. For single scores, a run can be defined as

1. The *length*, $k > 1$, *of uninterrupted series of scores of the same value*. This is the classical definition of a run. For example, the series 1 2 3 3 3 4 4 5 6 7 contains two runs. The first involves the three 3s, that is $k_1 = 3$. The second involves the two 4s, that is $k_2 = 2$, where the subscripts index the runs. This definition of runs requires no more than nominal level scales.
2. The *length*, $k > 1$, *of an uninterrupted series of scores of increasing value*. The series 8 9 9 3 4 5 6 contains 2 runs. The first involves the first two scores, and the second involves the last four scores. For runs of series of increasing scores, one needs scales that are at least ordinal.
3. The *length*, $k > 1$, *of an uninterrupted series of scores of decreasing value*. As for runs of decreasing scores, runs of decreasing scores require no more than ordinal scales.
4. The *length*, $k > 1$, *of an uninterrupted series of scores within a pre-specified range*. For this definition, at least ordinal information is needed.
5. For pairs of scores, a run can also be defined as
6. The *length*, $k > 3$, *of an uninterrupted series of scores that go up-and-down* or *down-and-up* (Wallis & Moore's, 1941, *runs up-and-down* test). The series 1 2 5 4 6 7 6 9 contains two up-and-down runs. The first run contains the values 2, 5, and 4, and the second contains the values 6, 7, and 6. The series also contains two down-and-up runs. The first contains the values 5, 4, and 6. The second contains the values 7, 6, and 9. To describe the runs of up-and-down or down-and-up series of scores, one needs at least ordinal information.
7. The *length*, $k > 1$, *of an uninterrupted series of pairs of scores in which one particular score follows the other particular score*. Consider, for example, the series 4 1 0 1 0 1 0 6 7 8. This series contains one run of length $k = 3$ of 1s and 0s that follow each other.

More complex definitions of runs are conceivable. As was illustrated for the case of up-and-down and down-and-up runs, a series can contain runs that follow more than one definition. In most applications of runs tests, however, just one definition is used.

For use in CFA, runs information from different variables can be crossed directly, if the number of different runs is limited. This is the case when the series under study are relatively short. When series are long, many runs can result that differ in length. Therefore, for long series, researchers either create classes of runs, e.g., 'did not drink hard liquor for a week' or 'depression did not relapse for one month', or they focus on particular runs such as the longest.

The questions that CFA allows one to answer concerning runs information differ from the questions asked when runs tests are applied. With runs tests, one asks whether a series of scores or observations is random in nature. If the corresponding null hypothesis is rejected, one can entertain hypotheses concerning the processes that cause deviations from randomness. In CFA, one asks whether runs information for one variable is related to runs information

from other variables or to other variables, in general. The answers to these questions are given in terms of local deviations from CFA base models, that is, in terms of types and antitypes.

Data Example

For the following example, we use data from the Finkelstein, et al. (1994) study on the development of aggressive behavior. The authors administered a questionnaire concerning aggressive behavior to 67 adolescent girls and 47 boys at three points in time. The time intervals were two years each. The questionnaire addressed the four measures of aggression: Aggressive Impulse, Aggression-Inhibitory Response, Verbal Aggression against Peers, and Physical Aggression against Peers. In the following analyses, we use the data on physical aggression against peers (PAAP), verbal aggression against adults (VAAA), and aggressive impulses (AI). For each of the variables, three scores are available, PAAP83, PAAP85, and PAAP87, VAAA83, VAAA85, and VAAA87, and AI83, AI85, and AI87, where the numbers indicate the years in which the data were collected. When the data were collected in those years, the respondents were 11, 13, and 15 years of age, respectively. In the following example, we look at *uninterrupted series of scores of decreasing value*. The question we ask concerns the decrease in aggression in adolescents. Specifically, we ask whether there are local associations among patterns of steady decrease in the three aggression variables: physical aggression against peers (PAAP), verbal aggression against adults (VAAA), and aggressive impulses (AI).

For three observation points, there can only be increasing- or decreasing-score runs of length $k = 2$. In the present example, a run of $k = 2$ indicates a decrease in scores from 1983 to 1985 and again from 1985 to 1987. The run variables were coded as follows:

- physical aggression against peers (PAAP): the run variable for PAAP, PR, was coded as
  - PR = 1 if there was no run of decreases in PAAP scores, and
  - PR = 2 if there was a run (two consecutive decreases);
- verbal aggression against adults (VAAA): the run variable for VAAA, VR, was coded as
  - VR = 1 if there was no run of decreases in VAAA scores, and
  - VR = 2 if there was a run (two consecutive decreases);
- aggressive impulses (AI): the run variable for AI, AR, was coded as
  - AR = 1 if there was no run of decreases in AI scores, and
  - AR = 2 if there was a run (two consecutive decreases).

The 2 × 2 × 2 PR × VR × AR cross-classification can be approached with two questions. First, we ask whether there are any local associations at all. This question can be answered with the base model of first-order CFA,

$$\log \hat{m} = \lambda + \lambda^{PR} + \lambda^{VR} + \lambda^{AR}$$

This base model can fail if any interaction exists. Second, we can also ask whether association patterns are specific to adolescents who differ in their patterns of change in aggressive impulses. This question can be answered using the following base model of 2-group CFA,

$$\log \hat{m} = \lambda + \lambda^{PR} + \lambda^{VR} + \lambda^{AR} + \lambda^{PR,VR}.$$

This base model can be rejected only if interactions exist that link the run variables for physical aggression against peers and verbal aggression against adults on one side with runs of aggressive impulses on the other. These are the interactions [PR, AR], [VR, AR], and [PR, VR, AR].

Table 20.23 presents results for the base model of first-order CFA, that is, the model of variable independence. Table 20.24 presents results for two-group CFA. For both CFAs, we use the normal approximation of the binomial test and protect α using the Holland–Copenhaver procedure.

The overall goodness-of-fit likelihood-ratio for the base model of variable independence is $X^2 = 13.93$. For $df = 4$, this value leads us to reject the base model ($p < 0.01$), and we anticipate that types and antitypes may emerge. However, in this example, we encounter the rare case, in which no type or antitype emerges although the base model is rejected. Inspecting the frequency distribution in Table 20.23, we notice that, for three of the four cell pairs . . 1/. . 2, cell . . 1 contains (numerically) more

TABLE 20.24 2-Group CFA of the PR × VR × AR Cross-Classification, with AR as the Grouping Variable

	Configuration			
PR VR AR	*m*	Statistic	*p*	Type?
111	45.00			
112	6.00	2.693	.003537	Discrimination type
121	18.00			
122	3.00	1.122	.131014	
211	15.00			
212	13.00	−3.259	.000559	Discrimination type
221	9.00			
222	5.00	−1.130	.129145	

cases than expected but cell . . 2 contains (numerically) fewer cases than expected. We, therefore, conduct the 2-group CFA and expect that discrimination types emerge. Table 20.24 displays results.

The overall goodness-of-fit likelihood-ratio for the base model of 2-group CFA is $X^2 = 13.72$. For $df = 3$, this X^2 value leads to the rejection- of the base model ($p < 0.01$), and we anticipate that discrimination types may emerge. The fit of this model is only marginally better than the fit of the model of variable independence. We conclude that the interaction between the runs of physical aggression against peers and verbal aggression against adults is weak, and makes no contribution to the explanation of the frequency distribution in Tables 20.23 and 20.24.

The results in Table 20.24 show that two-group CFA identified two discrimination types. The first is constituted by configuration pair 1 1 1/1 1 2. It suggests that those adolescents who show inconsistent increases/decreases in aggressive impulses (Pattern . . 1) are more likely than those adolescents who show consistent decreases in aggressive impulses (Pattern . . 2) to also show inconsistent patterns of decreases/increases in verbal aggression against adults and physical aggression against peers. The first group contains 45 respondents, the second group contains 6 respondents. This ratio is more extreme than the group ratio, which is 74 to 27. The corresponding log odds ratio is 1.32 (se = 0.51; $z = 2.59$; $p < 0.01$).

The second discrimination type is constituted by configuration pair 2 1 1/2 1 2. This discrimination type suggests that those adolescents who show inconsistent increases/decreases in aggressive impulses (Pattern . . 1) are more likely than those adolescents who show consistent patterns of decreases in aggressive impulses (Pattern . . 2) to show consistent patterns of decreases only in verbal aggression against adults, but not in physical aggression against peers. The first group contains 15 respondents, the second group contains 13 respondents. This ratio is less extreme than the group ratio, which is 74 to 27. The corresponding log odds ratio is −1.50 ($se = 0.48$; $z = -3.12$; $p < 0.01$).

From the perspective of conducting research with CFA, we conclude:

1. Significant discrepancies between a base model and the observed frequency distribution are a necessary but not a sufficient condition for types and antitypes to emerge. Types and antitypes require, in addition, that the discrepancies between observed and expected cell frequencies are particularly strong in a few cells instead of being distributed more evenly over all cells in a table. Evidently, the distribution of discrepancies in Table 20.23 was not extreme enough.
2. Two-group CFA is able to find discrimination types in particular when the model–data discrepancies in corresponding cells go in opposite directions. This applies even when other models of CFA do not suggest that types or antitypes exist. As we said before, in this chapter, patterns of types and antitypes depend on the base model. Different base models can result in different patterns of types and antitypes (and come with different interpretations; Mellenbergh, 1996).
3. Depending on the number of groups to be compared, the number of tests performed in multigroup CFA is only a fraction of the number performed in other CFA models. Therefore, the protected α is less extreme and, thus, less prohibitive for the detection of discrimination types.

CFA of Lags

In longitudinal research, one can distinguish between *lagged values* and *current values*. Lagged values are the values of a variable from a different period. Current values are from the last observation point in time. Lags are measured in units of time (e.g., days or years), or in experimental units (e.g., trials). In the simplest case, one variable is related to itself over time. For example, one can ask whether the number of technical problems in cars produced on a Monday are predictive of problems for cars produced the following Monday, or whether the number of beers an alcoholic individual consumes on a Friday is predictive of the number of beers consumed the following Friday.

Creating data sets for the analysis of lags is relatively straightforward. All one needs to do is copy the series of scores and paste it back in with the lag of interest, shifting it by this lag. Table 20.25 displays the resulting arrangement for lags 1, 2, and 3.

TABLE 20.25 Series with Lags 1, 2, and 3

Time	Original scores	Scores with lag 1	Scores with lag 2	Scores with lag 3
1	x_1	–	–	–
2	x_2	x_1	–	–
3	x_3	x_2	x_1	-
4	x_4	x_3	x_2	x_1
5	x_5	x_4	x_2	x_2
.	.	.	.	.
.	.	.	.	.
.	.	.	.	.
$n-1$	x_{n-1}	x_{n-2}	x_{n-3}	x_{n-4}
n	x_n	x_{n-1}	x_{n-2}	x_{n-3}

TABLE 20.26 Cross-Classification of a Series of Scores with Itself, for a Lag of *k*

	Lag k series			
Original series	$i = 1$	$i = 2$	$i = 3$	Totals
$i = 1$	m_{11}	m_{12}	m_{13}	$m_{1.}$
$i = 2$	m_{21}	m_{22}	m_{23}	$m_{2.}$
$i = 3$	m_{31}	m_{32}	m_{33}	$m_{3.}$
Totals	$m_{.1}$	$m_{.1}$	$m_{.1}$	$m_{.n} = N - k$

In Table 20.25, the subscripts of the x-scores indicate the observation point. The subscripts for the lagged series show that, with increasing lags, the number of scores that can directly be compared decreases by k, the size of the lag.

When scores are categorical in nature, lagged series can be crossed with each other and subjected to methods of categorical data analysis, for example, log-linear modeling, logit modeling, or CFA. Table 20.26 displays a sample cross-classification for a variable with $I = 3$ categories.

The frequencies in the diagonal cells in Table 20.26, which are the cells with subscripts ii, indicate the number of times a category of the original series is followed by an observation of the same category, for a lag of k. The frequencies in the off-diagonal cells, which are the cells with subscripts ij, with $i \neq j$, indicate the frequency with which an observation of Category i is followed by the observation of Category j, for a lag of k.

Extensions of the approach shown in Table 20.26 can be achieved, for example, by taking stratification variables or covariates into account (gender, age, ethnic background, etc.) or by increasing the number of lagged variables. Cross-classifications such as illustrated in Table 20.26 can be analyzed using well-known methods of categorical data analysis. It is interesting to note that rater agreement tables have the exact same form as the one given in Table 20.26. Therefore, the same methods can be used for analysis (see von Eye & Mun, 2005). These methods include the estimation of coefficients of agreement and the estimation of manifest or latent variable models that reflect hypotheses concerning the pattern of agreement or disagreement (von Eye & von Eye, 2005).

The best-known coefficient of rater agreement is Cohen's κ (kappa), which is estimated from an $I \times I$ cross-classification as the one given in Table 20.26 by

$$\kappa = \frac{N\sum_{i=j} m_{ij} - \sum_{i=j} m_{i.}m_{.j}}{m^2 - \sum_{i=j} m_{i.}m_{.j}}$$

The interpretation of κ can proceed as for all PRE (proportionate reduction in error) coefficients. Specifically, κ can be interpreted as proportion of agreement beyond chance.

Data Example

For the following data example, we use data from a study of self-identified alcoholic men again (Perrine et al., 1994). We use the data from Respondent 3053 who answered the telephone survey on 800 consecutive days. The following analyses focus on the numbers of beer (B) and liquor shots (L) consumed on a given day and on mood (M) on the following day. Mood was rated on a 10-point Likert scale with 1 indicating "terrible mood" and 10 indicating "just wonderful." Respondent 3053 tended to not use the lower end points of the mood scale. Therefore, scores 4 and below were combined into a single category of 1. In addition, this respondent used scores greater than 6 rarely. Therefore, scores 6 through 10 were coded as 3. The resulting scale thus ranged from 1 to 3 with 1 indicating average mood or below, and 3 indicating good or better mood. Similarly, the range of shots of liquor consumed was condensed to include the values of 1 = no liquor consumed and 2 = 1 or more shots of liquor consumed. This respondent almost never had more than 2 shots of liquor on any given day. The range of the numbers of beer consumed by Respondent 3053 was narrow also, but he drank beer almost every day. This beer response was, therefore recoded to have values 1, 2, and 3, with 1 = one or no beer consumed through 3 = three or more beers consumed in one day.

In the following paragraphs, we ask three questions that can be answered using the data thus created.

1. Can the number of beers consumed on consecutive days be predicted?
2. Can the number of shots of liquor consumed on consecutive days be predicted?
3. Is the mood on one day predictive of the mood on the following day?
4. Is the mood on one day predicted by the numbers of beer and shots of liquor the day before?

TABLE 20.27 Cross-Classification of Beer Consumption for a Lag of One Day (Respondent 3053)

		Beer consumption lag 1			
		1	2	3	Total
Beer consumption	1	296	24	161	481
	2	30	2	15	47
	3	156	21	95	272
	Total	482	47	271	800

TABLE 20.28 Cross-Classification of Liquor Consumption for a Lag of One Day (Respondent 3053)

		Liquor consumption lag 1		
		1	2	Total
Liquor consumption	1	531	110	641
	2	110	35	145
	Total	641	145	786

The first three questions are answered using CFA as well as methods otherwise employed in the analysis of rater agreement. Specifically, considering that the tables to be analyzed are all of the form $I \times I$, we use first-order CFA for questions 1 and 3, Cohen's κ for questions 1, 2, and 3, and the odds ratio for question 2. To answer question 4, we use CFA and log-linear modeling.

Question 1: Beer consumption over a lag of one day. The cross-classification of the ordinal beer consumption scale for Respondent 3053 is given in Table 20.27.

Table 20.27 shows an interesting marginal frequency pattern. Regardless of the number of beers the respondent consumed, the first observation day is often followed by a day during which the respondent consumed only a small number of beers or none. This becomes evident by comparing the frequencies in the first column with the frequencies in the second and third columns. This pattern implies that the number of beers consumed is not strongly related to the number of beers consumed on the following day. Accordingly, the Pearson X^2 for this 3×3 table suggests a nonsignificant association ($X^2 = 3.21$; $df = 4$; $p = 0.52$). First-order CFA of the frequency distribution in Table 20.27 (not shown here) identified no types or antitypes. This is expected from the nonsignificant X^2.

Considering that the diagonal contains the largest number of cases only in the first row/column, we also expect a small and nonsignificant κ. Indeed, the $\kappa = 0.02$ indicates that the diagonal contains only 2% more cases than expected under the assumption of independence between beer consumption on one day and the next. This value is also nonsignificant ($z = 0.66$; $p = 0.51$).

Question 2: Liquor consumption over a lag of one day. The cross-classification of the ordinal liquor consumption scale for Respondent 3053 is given in Table 20.28.

Liquor consumption of respondent 3035 is not associated with itself from one day to the next. The Pearson X^2 for this 2×2 table suggests a nonsignificant association ($X^2 = 3.83$; $df = 1$; $p = 0.05$). As for beer consumption, the diagonal contains the largest cell frequency only for one cell, here in Row 1/Column 1. Also as for Table 20.27, we therefore expect κ to be small and nonsignificant. Indeed, the $\kappa = 0.07$ indicates that the diagonal contains only 7% more cases than expected under the assumption of independence between liquor consumption on one day and the next. This value is nonsignificant ($z = 1.82$; $p = 0.07$). Similarly, the odds ratio of $\theta = 1.54$ suggests that the association of liquor consumption on consecutive days is nonsignificant ($\log \theta = 0.43$; $z = 1.95$; $p = 0.052$).

Excursus: on the dependency of types and antitypes in 2×2 tables. Interestingly, it does not make much sense to perform a first-order CFA on a 2×2 cross-classification as the one given in Table 20.28. Von Weber, Lautsch, and von Eye (2003) showed that the CFA tests in 2×2 tables are completely dependent, and therefore the result of the first CFA test fully determines the results of the remaining three tests (for a discussion of type/antitype patterns in larger tables, see Krauth, 2003). To illustrate the dependency of cell-wise CFA tests in 2×2 tables, we consider the cross-classification shown in Table 20.29.

Suppose we employ the base model of variable independence. Under this base model, $m_{1.} = \hat{m}_{1.}$, $m_{2.} = \hat{m}_{2.}$, $m_{.1} = \hat{m}_{.1}$, and $m_{.2} = \hat{m}_{.2}$. Now suppose also that CFA identifies a type for cell 1 1, that is, $m_{11} - \hat{m}_{11} > 0$. We set $m_{11} - \hat{m}_{11} =$ d. Because $m_{11} + m_{12} = m_{1.} = \hat{m}_{11} + \hat{m}_{12} = \hat{m}_{1.}$, we obtain $m_{12} - \hat{m}_{12} = -$d. Accordingly, we find that $m_{21} - \hat{m}_{21} = -d$, and $m_{22} - \hat{m}_{22} = d$.

In words, in 2×2 tables for which the expected cell frequencies are estimated using the log-linear main effect

TABLE 20.29 2×2 Cross-Classification with Observed Frequencies m_{ij} and Expected Frequencies $\hat{m}_{ij}$

	Observed and expected cell frequencies		Totals
	m_{11}	m_{12}	$m_{1.}$
	$\hat{m}_{11}$	$\hat{m}_{12}$	$\hat{m}_{1.}$
	m_{21}	m_{22}	$m_{2.}$
	$\hat{m}_{21}$	$\hat{m}_{22}$	$\hat{m}_{2.}$
Totals	$m_{.1}$	$m_{.2}$	$m_{..} = N$
	$\hat{m}_{.1}$	$\hat{m}_{.2}$	N

model, there is no space for independent CFA types and antitypes. Under the main effect model (which is also the model used for X^2 testing), there is only one degree of freedom left. Therefore, if the difference between the observed and the expected cell frequency in cell 1 1 suggests the existence of a type, cells 1 2 and 2 1 will, by necessity, constitute antitypes, and cell 2 2 will, also by necessity, constitute a second type. Accordingly, if cell 1 1 constitutes an antitype, Cells 1 2 and 2 1 constitute types, and cell 2 2 constitutes a second antitype. In one word, if a type–antitype decision is made for any cell in a 2×2 cross-classification in first-order CFA, the type–antitype decisions in the remaining three cells are completely redundant. Therefore, we did not perform a first-order CFA on Table 20.28.

Question 3: Mood over a lag of one day. The 3×3 cross-classification of the ordinal mood scale for Respondent 3053 is given in Table 20.30.

Table 20.30 also shows an interesting pattern. The marginal frequencies of mood ratings are identical on consecutive days. Pearson's X^2 for this 3×3 table suggests a significant association ($X^2 = 86.18$; $df = 4$; $p < 0.01$). Only one of the diagonal cells is the largest of its row/column. This is cell 3 3. Considering that this cell frequency is the largest of the entire table, by far, we anticipate a significant κ that is larger than those for the beer and liquor consumption data. Indeed, the $\kappa = 0.22$ indicates that the diagonal contains 22% more cases than expected under the assumption of independence between mood on one day and the next. This value is significant ($z = 5.03$; $p < 0.01$).

Considering that the value of κ, although significant, is small, and that the distribution in Table 20.30 is very uneven, we now perform a first-order CFA. The base model for this analysis is that of independence of the two mood ratings, M and $M1$. The model is

$$\log \hat{m} = \lambda + \lambda^{M} + \lambda^{M1}$$

If this model is rejected, the two mood ratings must be related to each other. Types and antitypes tell us where local associations exist. Table 20.31 displays CFA results. We use the z test and the Holland–Copenhaver procedure of α protection.

TABLE 20.30 Cross-Classification of Mood Ratings for a Lag of One Day (Respondent 3053)

		Mood lag 1			
		1	2	3	Total
Mood	1	3	8	9	20
	2	6	11	38	55
	3	11	36	663	710
	Total	20	55	710	785

TABLE 20.31 First-order CFA of Mood Ratings on Consecutive Days (Respondent 3053)

	Configuration				
M M1	m	$\hat{m}$	z	p	Type/antitype?
11	3.00	.510	3.4888	.000243	Type
12	8.00	1.401	5.5744	.000000	Type
13	9.00	18.089	−2.1371	.016297	
21	6.00	1.401	3.8849	.000051	Type
22	11.00	3.854	3.6405	.000136	Type
23	38.00	49.745	−1.6653	.047929	
31	11.00	18.089	−1.6668	.047776	
32	36.00	49.745	−1.9488	.025657	
33	663.00	642.166	.8222	.205492	

The overall goodness-of-fit likelihood-ratio for the base model of independence of the mood ratings on consecutive days is $X^2 = 54.11$. For $df = 4$, this value leads us to reject the base model ($p < 0.01$), and we anticipate types and antitypes to emerge. Interestingly, only types emerge but no antitypes.

The first type is constituted by cell 1 1. This cell contains the smallest number of ratings. Still, it constitutes a type. It indicates that, although Respondent 3053 rarely indicates average to low mood on any given day, on two consecutive days, he reports average to low mood more often than expected. The second type is constituted by cell 1 2, the third-smallest cell in the table. This type signifies that although an improvement in mood from average/low to slightly above average is rare, this occurs more often than expected. The same applies to the reverse change, from slightly above average mood down to average mood (configuration 2 1). This pattern is also rare but reported more often than expected. The fourth type, constituted by configuration 2 2, suggests that two consecutive days for which Respondent 3053 reports slightly above average mood occur more frequently than expected.

The most frequent pattern (84.5%), for Respondent 3053, is 3 3. Respondent 3053 reports that his mood is above average on any two consecutive days for 84.5% of the times. We conclude that this respondent is remarkably stable and in a good mood. The observed frequency of 663 is only minimally greater than the frequency that was expected for this pattern (642.17). Therefore, configuration 3 3 does not constitute a type.

Question 4: Is the mood on one day predicted by the numbers of beer and shots of liquor the day before? It is often assumed that alcohol consumption affects mood (First & Tasman, 2004). Here, we ask whether there

are, for Respondent 3053, short-term predictive relationships of beer and liquor consumption to mood. To answer this question, we apply three methods and compare their results. First, we employ log-linear modeling. The results from this approach tell us whether there are interactions among the variables beer consumption (B), liquor consumption (L), and mood on the following day ($M1$), in general. Second, we estimate a log-linear model. The results from this model tell us whether these interactions are compatible with the hypothesis that beer and liquor consumption affects mood on the following day. Third, we perform a first-order and a prediction CFA. The results from these approaches tell us where local associations exist, if they exist. The $B \times L \times M1$ cross-classification is given in Table 20.32.

Results from Log-Linear Modeling

To create a base model that can be used for comparison, we first estimate the model of variable independence. This is the same model that will be used for first-order CFA. The overall goodness-of-fit likelihood-ratio for the base model of independence of alcohol consumption and mood ratings on the following day is $X^2 = 33.34$. For $df = 12$, this value leads us to the reject the base model ($p < 0.01$) (and we anticipate types and antitypes to emerge; see below). We then ask whether beer and liquor consumption are related to each other to the degree that this model–data discrepancy could be explained. The corresponding model is

$$\log \hat{m} = \lambda + \lambda^B + \lambda^L + \lambda^{M1} + \lambda^{B,L}$$

TABLE 20.32 First-Order CFA of Beer and Liquor Consumption and Mood Ratings on the Following Day (Respondent 3053)

Configuration					
$B\ L\ M1$	m	$\hat{m}$	z	p	Type/antitype?
111	6.00	9.777	−1.2079	.113546	
112	26.00	26.886	−.1709	.432148	
113	338.00	349.521	−.6162	.268874	
121	3.00	2.198	.5410	.294238	
122	6.00	6.044	−.0180	.492831	
123	94.00	78.574	1.7402	.040911	
211	1.00	.971	.0289	.488457	
212	4.00	2.672	.8127	.208181	
213	26.00	34.730	−1.4814	.069247	
221	2.00	.218	3.8123	.000069	Type
222	1.00	.601	.5154	.303140	
223	13.00	7.808	1.8583	.031565	
311	7.00	5.581	.6007	.274008	
312	15.00	15.347	−.0887	.464679	
313	222.00	199.515	1.5919	.055707	
321	1.00	1.255	−.2273	.410092	
322	3.00	3.450	−.2424	.404252	
323	22.00	44.852	−3.4122	.000322	Antitype

This is also the base model for the Prediction CFA that will be performed below. The overall goodness-of-fit likelihood ratio for this model of independence of alcohol consumption and the mood ratings on the following day, which incorporates the hypothesis that the two forms of alcohol consumption are related to each other, is $X^2 = 7.71$. For $df = 10$, this value leads us to the retain the model ($p = 0.66$) (and we anticipate that no prediction types and antitypes emerge). From the signs of the estimates of the interaction parameter, we conclude that the relationship between beer and liquor consumption is, for respondent 3053, negative, indicating that the more beer the respondent consumes, the less liquor he consumes, and vice versa.

From this result, we conclude that, over a lag of one day, there is no relationship of beer and liquor consumption to mood on the following day. Based on this conclusion, we also expect that the log-linear model will suggest no predictive relationship. The overall goodness-of-fit likelihood-ratio for the log-linear model is $X^2 = 28.19$. For $df = 6$, this value leads us to reject the null hypothesis of no relationship between predictors (beer or liquor consumption) and criterion (mood on the following day) ($p < 0.01$). None of the parameters of the effects that link the predictors and the criterion is significant. The Nagelkerke R^2 – equivalent is 0.01. This also indicates that close to nothing of the variability in the $B \times L \times M1$ cross-classification is explained by the model.

A log-linear model that includes the interactions between beer and mood on the following day and liquor and mood on the following day, that is, the model

$$\log \hat{m} = \lambda + \lambda^B + \lambda^L + \lambda^{M1} + \lambda^{B,M1} + \lambda^{L,M1}$$

also fails to describe the data well. The $B \times L$ interaction is needed. Evidently, the two-way interaction between beer and liquor consumption is not sufficient to explain the variability of the data that exists in Table 20.32 beyond the main effects.

Results from CFA

The results from log-linear modeling make us expect that first-order CFA will identify types and antitypes. However, the same results make us also expect that these types and antitypes only indicate where liquor and beer consumption are locally associated. As soon as the interaction between beer and liquor consumption is included in the base model, all types and antitypes can be expected to disappear. This would, again, suggest that there is no relationship between alcohol consumption and mood on the following day.

Table 20.32 displays the results from first-order CFA (the base model for this CFA was given previously). For both this run and the following Prediction CFA, we use the z-test and the Holland–Copenhaver procedure of α protection.

The overall goodness-of-fit for the base model of first-order CFA is the same as for the log-linear model of variable independence discussed previously. The base model is rejected. However, the results in Table 20.32 are, from a CFA perspective, not overly rich. We find only one type, for a cell that contains only 2 ratings, and one antitype. When the corresponding expected frequency is small, we should interpret the findings of types and antitypes quite cautiously. Specifically, as soon as an expected cell frequency is below 0.5, we do not interpret a type. Then what is left in this table is the sole antitype that is constituted by configuration 3 2 3. It indicates that, significantly less often than expected, Respondent 3053 consumed above average quantities of beer together with liquor and was in a positive mood on the next day.

From the log-linear modeling results, we already know that Respondent 3053 tended to drink predominantly either beer or liquor on drinking occasions but not both, and that his drinking had no effect on his mood on the next day. Therefore, we expect the type and the antitype to disappear when the beer × liquor interaction is taken into account. This is indeed the case (table of results not shown here).

To provide closure on the substantive part of this example, we now ask whether alcohol consumption has effects on the mood as rated for the same day. We find almost the same results. The log-linear model of variable independence is rejected ($LR - X^2 = 30.25$; $df = 12$; $p < 0.01$), and the same antitype emerges. The model that takes the beer × liquor consumption into account describes the data very well ($LR - X^2 = 3.77$; $df = 10$; $p = 0.96$), and no type or antitype emerges. We conclude that, for this respondent, there is no short-term relationship between alcohol consumption and mood.

CFA of Cross-Lagged Designs

Cross-lagged designs allow researchers to test hypotheses about the temporal relationships between two or more repeatedly observed variables. Consider the two variables, X and Y, each observed twice, that is, the four realizations $X1$, $X2$, $Y1$, and $Y2$. Figure 20.3 displays the relationships that are usually estimated.

All possible two-way relationships can be arranged in the form of a correlation matrix, as in Table 20.33.

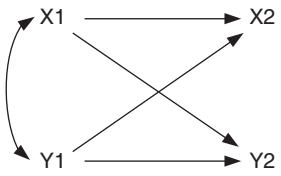

Figure 20.3 Cross-lagged relationship.

TABLE 20.33 Correlation Matrix for *X*1, *X2*, *Y*1, and *Y*2

	Variables		
Variables	*X*1	*X*2	*Y*1
*X*2	$r_{X2\,X1}$		
*Y*1	$r_{Y1\,X1}$	$r_{Y1\,X2}$	
*Y*2	$r_{Y2\,X1}$	$r_{Y2\,X2}$	$r_{Y2\,Y1}$

Five of the six relationships listed in Table 20.33 are included in Figure 20.3. The only one missing is the one between $X2$ and $Y2$. This relationship was omitted to illustrate that cross-lagged models do not necessarily involve all possible two-way relationships.

In standard, aggregate-level, variable-oriented data analysis, the paths in Figure 20.3 are estimated as regression coefficients. The paths between $X1$ and $X2$ as well as between $Y1$ and $Y2$ are called *autoregressions*, and the paths between $X1$ and $Y2$ as well as between $Y1$ and $X2$ are *cross-lagged regressions*. The relationships between $X1$ and $Y1$ as well as between $X2$ and $Y2$ are typically estimated as correlations (they could be regressions also).

These paths and correlations allow one to test hypotheses concerning

1. The *contemporaneous* associations between $X1$ and $Y1$ as well as between $X2$ and $Y2$; and
2. The *lagged* associations between $X1$ and $Y2$ as well as between $Y1$ and $X2$.

For both manifest and latent variable models, structural modeling is most suitable for estimation. Occasionally, regression analysis is still applied for manifest variable models.

One characteristic of such models that is of importance here is that all relationships are expressed at the level of aggregated raw data. That is, all relationships are expressed within a framework of variable-oriented research. In the present context, we take a person-oriented perspective for the analysis of categorical variables. That is, we do not assume that all categories of all variables carry a relationship. Instead, using the concept of *local associations* (Havránek & Lienert, 1984), we assume that, in many

cases, only some of the categories of a variable carry an association. Under this assumption, CFA is the method of choice. Therefore, we present here, for the first time, a CFA approach to cross-lagged analysis. This approach is an extension of the CFA approach to lagged relationships that was discussed and illustrated in the last section (von Eye et al., 2010).

To develop the base model for cross-lagged CFA of categorical data, we use the general definition of CFA base models. This definition states that a CFA base model contains all relationships that are *not* of interest to the researchers. If this model is rejected and types and antitypes emerge, they necessarily reflect the cross-lagged relationship under study.

To illustrate, consider the model in Figure 20.3. This model contains five of the six possible bivariate relationships. These must, therefore, not be included in the base model. In contrast, the remaining two-way relationship (the one between $X2$ and $Y2$) must be included. None of the four possible three-way interactions and the four-way interaction are part of the tested hypotheses. Therefore, they are included in the base model. In log-linear modeling notation, the nonhierarchical base model for cross-lagged CFA is

$$\begin{aligned}\log \hat{m} = \lambda &+ \lambda^{X1} + \lambda^{X2} + \lambda^{Y1} + \lambda^{Y2} + \lambda^{X2,Y2} \\ &+ \lambda^{X1,X2,Y1} + \lambda^{X1,X2,Y2} + \lambda^{X1,Y1,Y2} + \lambda^{X2,Y1,Y2} \\ &+ \lambda^{X1,X2,Y1,Y2}\end{aligned}$$

As with all other CFA base models, if any of the interactions not included in the model exist, the model is rejected and resulting types and antitypes indicate the configurations that carry the relationship. Also, as was illustrated before, the rejection of a model is a necessary condition but no guarantee that types and antitypes emerge.

It is interesting to note that the rejection of the base model of cross-lagged CFA gives no indication concerning which of the hypothesized relationships exist. Therefore, we recommend considering one of two strategies. The first involves estimating a categorical variable path model, in particular when there are more than two observation points. This can be achieved with Mplus (Muthén & Muthén, 2010) or with a specialized program for categorical data analysis such as Lem (Vermunt, 1997). The methods of functional CFA can also be used (von Eye & Mair, 2008a, 2008b, 2008c), which allow one to identify the configurations that carry the two-way interactions of the cross-lagged model.

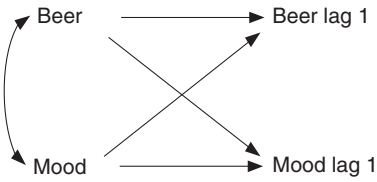

Figure 20.4 Cross-lagged relationship between beer consumption and mood.

Data Example

In the following example, we continue the analysis of the one-lag data of Respondent 3053 from the study of self-identified alcoholic men (Perrine et al., 1994). We ask whether, from one day to the next, beer consumption and mood are related to each other so that it can be described by a cross-lagged model such as the one in Figure 20.3. In this example, the model would be as shown in Figure 20.4.

We approach this model first from the variable-oriented perspective. We estimate a log-linear model that includes all the variable relations indicated in the graph. That is, we estimate the model

$$\begin{aligned}\log \hat{m} = \lambda &+ \lambda^{B} + \lambda^{B1} + \lambda^{M} + \lambda^{M1} \\ &+ \lambda^{B,M} + \lambda^{B,B1} + \lambda^{B,M1} + \lambda^{M,B1} + \lambda^{M,M1}.\end{aligned}$$

In this section, we use the same abbreviations as in the last. That is, B = beer consumption, $B1$ = beer consumption on the following day, M = self-rated mood, $M1$ = self-rated mood on the following day. This is not the CFA base model. Therefore, we hope that this model describes the data well.

If this is the case, we perform the CFA of the cross-lagged model described previously, which includes the terms that are not of interest. The base model for this CFA is

$$\begin{aligned}\log \hat{m} = \lambda &+ \lambda^{B} + \lambda^{B1} + \lambda^{M} + \lambda^{M1} + \lambda^{B1,M1} \\ &+ \lambda^{B,B1,M} + \lambda^{B,B1,M1} + \lambda^{B,M,M1} + \lambda^{B1,M,M1} \\ &+ \lambda^{B,B1,M,M1}\end{aligned}$$

If this cross-lagged base model is rejected, resulting types and antitypes indicate the interactions that are not specified in this model, which is nonhierarchical. We will know which of the interactions exist because, in this example, we estimate the log-linear model before we perform CFA. The types and antitypes will tell us where, in the cross-classification, these effects become manifest.

In the example in the last section, we used the three-category variables B and $B1$, and M and $M1$. Crossed,

these variables span a 3 × 3 × 3 × 3 cross-classification with 81 cells. For about 800 observations, this table is not too large. However, due to the very uneven frequency distribution, many cells were empty. Sparseness was so extreme that the programs we use were unable to estimate the models. Therefore, we further combined categories of the variables. Specifically, we now use for B and $B1$ the categories 1 = two or fewer beers consumed and 2 = three or more beers consumed in one day. For M and $M1$, we use the categories 1 = good mood or below, and 2 indicating better mood.

For the log-linear model, we obtain an overall goodness-of-fit likelihood-ratio of $X^2 = 7.11$. For $df = 6$, this value leads us to retain the model ($p = 0.31$), and we conclude that the higher order interactions are not needed to explain the frequency distribution shown in Table 20.34. We ask which of the five two-way interactions are significant. Table 20.35 displays the parameter estimates.

Table 20.34 shows an interesting pattern of results. Although the model, overall, describes the data well, the hypothesis that the relationships among the variables that span the cross-classification in Table 20.35 can be described by a cross-lagged model must be rejected. Of the five bivariate relationships included in this model, only one is significant. It is the one between mood on a given day and mood on the following day. We conclude that, for Respondent 3053, mood is predictive of itself over a lag of one day. In contrast, the quantities of beer consumed are hard to predict, even from one day to the next, and there seems to be no relationship between mood and beer consumption. This applies both to the contemporaneous and the lagged beer–mood and mood–beer relationships. Drinking does not seem to affect the mood of this respondent, and vice versa.

To identify the details of the relationship between mood on two consecutive days, we perform a CFA on the 2 × 2 × 2 × 2 B × M × B1 × M1 cross-classification. Considering that we already know that the M × M1 interaction exists, there is no need to create a reference model and estimate a first-order CFA. Instead, we estimate the nonhierarchical base model for cross-lagged CFA shown previously right away. If types and antitypes emerge, they will indicate the location of the association between the mood ratings on consecutive days, in this table. Table 20.35 displays the results of cross-lagged CFA. We use the z test and the Holland–Copenhaver procedure for the protection of α.

Table 20.35 suggests that, in the B × M × B1 × M1 cross-classification, three types exist and no antitype. The first type is constituted by configuration 1 1 1 1. It indicates that, more often than expected for the cross-lagged base model, average mood on one day is predictive of average mood on the following day. Please notice that we interpret the four types with reference to mood only. Neither of the two beer consumption variables is related to any of the other variables based on the log-linear modeling results. Therefore, we focus on mood. The second type is constituted by configuration 1 1 2 1. This type has the same interpretation as the first. The variable that changes score is B1. This variable is not taken into account when this type is interpreted. This applies accordingly for the third type. It is constituted by configuration 2 1 2 1. Again, it suggests that average mood is predictive from one day to the next. In all, we conclude that, for Respondent 3053, average or worse mood on a given day tends to carry over to the following day. The amount of beer consumed is not predictive of mood. Note that we cannot say that positive mood carries over as well. This result shows that it is not mood in

general that is autocorrelated over time, but it is average or negative mood that lingers over time, for this participant.

This is not the modal CFA result but, as can be seen in the examples given in this chapter, the largest cells do not always constitute types, and the smallest do not always constitute antitypes. This is the case only in zero-order CFA (Lienert & von Eye, 1989; von Eye, 2002). The largest configurations in Table 20.35 are 1 2 1 2 (small quantities of beer consumed in a good mood on both consecutive days), 1 2 2 2 (increasing quantities of beer consumed in a good mood on two consecutive days), and 2 2 1 2 (decreasing quantities of beer consumed in a good mood on two consecutive days). These configurations again illustrate that, for Respondent 3053, the quantity of beer that he consumes seems to be unrelated to his typically elevated good mood.

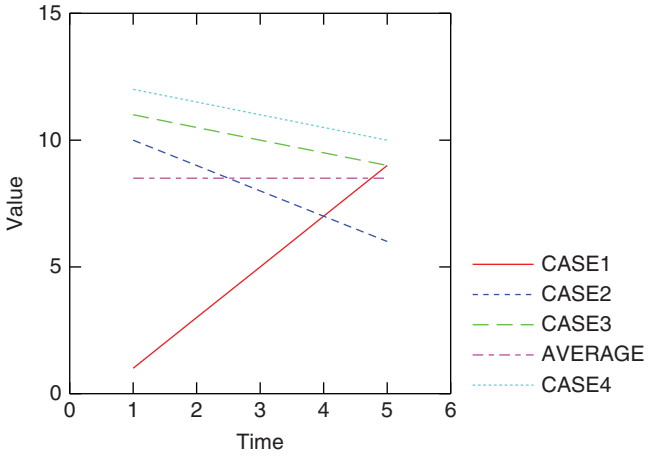

Figure 20.5 Individual and averaged developmental trajectories. See footnote 1.

Comparing Individuals' Trajectories

Comparing individuals' trajectories or, in different words, assessing interindividual differences in intraindividual change lies in the heart of person-oriented and idiographic research. Therefore, it is an important domain of data analysis with CFA. One of the main reasons for the emphasis on interindividual differences in intraindividual change is that aggregate-level descriptions of trajectories come with the high risk of missing out on developmental patterns that do not follow the overall trend. It has been repeatedly shown in the developmental literature (e.g., Baltes, Reese, & Nesselroade, 1977) and person-oriented research (von Eye & Bergman, 2003; von Eye et al., 2015) that aggregate-level estimation of parameters of developmental trajectories can miss the development of individuals completely. Here, we present two additional examples. The first uses artificial data. The second uses real data.

For the first example, consider four individuals diagnosed with obsessive-compulsive personality disorder. The therapist records the number of times they wash their hands. Whereas three of the individuals improve over the course of the therapy, one individual reports worsening symptoms. This is depicted in Figure 20.5.

Figure 20.5 shows that Cases 1, 2, and 3 improve but Case 4 gets worse. The figure also shows that the four patients, on average, do not change their behavior at all. So, based on the average trajectory, the therapy can be considered ineffective. Based on the individual trajectories, the therapy can be concluded to have the desired effects in three of the four cases.

In the real data-example, we compare the autocorrelograms of two cases from the Perrine et al. (1994) study of self-identified alcoholic men. Autocorrelograms depict the correlations among series of scores with increasing lags. The correlation for a lag of 1 is the correlation between the scores from any two consecutive days. The correlation between scores for a lag of 49 is the correlation between series of scores that are seven weeks apart. In the study of self-identified alcoholics, some of the respondents provided the researchers with responses for about 800 consecutive days. Therefore, we can compare the autocorrelograms of two respondents for longer lags, here up to $k = 50$. We use the beer consumption data from Respondents 3050 and 3053. All participants of this study started on a Sunday. Therefore, the autocorrelation patterns for these two respondents are directly comparable.

We use raw data. Specifically, the correlations are based on scales that range from 0 (no beer consumed) to 10 (10 or more beers consumed on one day). Figure 20.6 displays the autocorrelogram of Respondent 3050 in the first panel, and the autocorrelogram for Respondent 3053 in the second panel.

Not surprisingly, the two respondents differ in their autocorrelograms. Respondent 3050 shows a distinct weekday-related pattern with strong (about $r = 0.50$) positive correlations for Sundays. These correlations are significant even over a span of 7 weeks. The correlations for the days from Monday through Saturday are weak and negative. The rank order of the correlations is, over the lags, almost invariant, with the strongest negative correlations found for Wednesdays and the weakest for Saturdays.

The autocorrelation pattern for Respondent 3053 is also consistent over the lags, but the correlations decrease to the extent that, toward the longer lags, there is no correlation. The pattern is also weekday-related, with positive

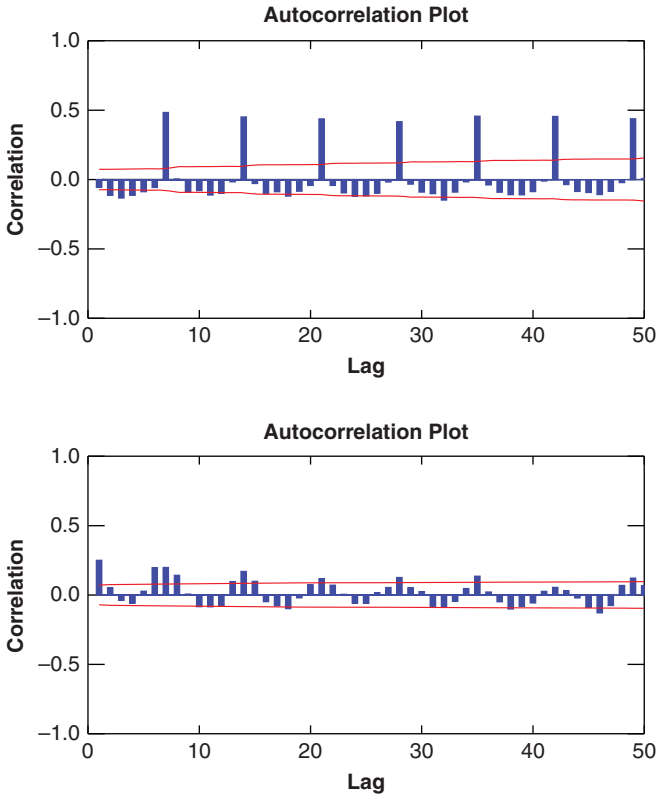

Figure 20.6 Autocorrelograms for lags between 1 and 50 for respondent 3050 (Panel 1) and 3053 (Panel 2). See footnote 1.

correlations for Saturdays, Sundays, and Mondays, and negative correlations for the other days. As for Respondent 3050, the positive correlations are stronger than the negative correlations.

In sum, the autocorrelation patterns of Respondents 3050 and 3053 show similarities in that they are weekday-related, but they also show dissimilarities in the magnitude of the correlations and the days for which positive and negative correlations are measured. In Figure 20.7, we display the autocorrelation of the aggregate of the quantities of beer that the two respondents have consumed over a span of about 800 consecutive days.

Clearly, the autocorrelation pattern for the aggregate fails to represent either individual autocorrelogram properly. Most prominent are three differences. First, it shows significant positive correlations for five of the seven days of the week. For Respondent 3050, there were six, and for Respondent 3053, there were four negative correlations for the days of the week. Second, and in correspondence with the first difference, the autocorrelogram for the aggregate shows practically no negative correlations. In contrast, for Respondent 3050, the negative correlations cease to be significant only after a lag of five weeks. For Respondent

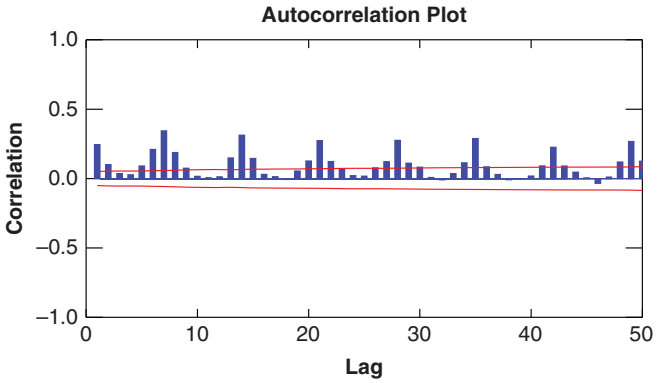

Figure 20.7 Autocorrelogram for the aggregate of respondents 3050 and 3053. See footnote 1.

3053, the negative correlations are not as strong, but there is one significant and negative correlation each for the Wednesday of the lags of six and seven weeks. Third, the autocorrelogram overestimates the magnitude of the correlations for Respondent 3053 and underestimates the correlations for Respondent 3050. This is not a surprise for aggregate statements. However, in this example, the aggregate suggests significant positive correlations for both respondents when they are nonsignificant or negative.

In the following paragraphs, we study interindividual differences in intraindividual development between Respondents 3050 and 3053 (von Eye & Mun, 2012). We take both a variable-oriented and a person-oriented perspective. For the former, we estimated a log-linear model. From the person-oriented perspective, we use CFA to answer the question concerning differences. To be able to study differences in developmental trajectories, we need a cross-classification with the following characteristics:

1. It must allow researchers to describe change at the level of the individual. Cross-classifications of the kind used for the analysis of lags, for cross-lagged analysis, and turnover tables for individuals are suitable. Based on each of these, statements are possible that relate behavior at one or more earlier points in time to behavior at one or more later points in time. These statements describe trajectories or, in more general terms, developmental change.
2. In the simplest case, we have lagged information for one variable, for two individuals. Let the variable that indicates the respondents be labeled by ID, the original observed series be labeled by O, and the lagged series by K. Then, the reference model of first-order CFA is

$$\log \hat{m} = \lambda + \lambda^{ID} + \lambda^{O} + \lambda^{K}$$

3. Cross-classifications must be available for at least two individuals. Here, it is important that cross-classifications are created that make respondents comparable. An example would be to create lagged data for series that (1) start at the same moment (2) are equal in length, and (3) have the same lag.

If the model of first-order CFA is rejected, types and antitypes suggest any kind of local associations between the variables *ID*, *O*, and *K*. More specific and pertinent to longitudinal research are the following two models. The first allows one to answer the question whether the respondents labeled by ID differ in their lag structure. The base model for this question includes the association between *O* and *K*, but proposes independence of *ID*, *O*, and *K*, or

$$\log \hat{m} = \lambda + \lambda^{ID} + \lambda^{O} + \lambda^{K} + \lambda^{O,K}$$

This model will be rejected if any of the interactions [*ID*, *O*], [*ID*, *K*], and [*ID*, *O*, *K*] exist. Types and antitypes from this model suggest that the respondents differ either in their development over time (two-way interactions of *ID* with *O* or *K*) or in the development of their patterns of constancy and change, over a lag of *K* (three-way interaction $ID \times O \times K$). In its structure, this base model is identical to the base model of two-group CFA or prediction CFA, both of which have been discussed already in this chapter (von Eye, 2002).

The second developmental model also takes into account that the two respondents may differ in their temporal pattern of behavior both in the original and the lagged string. It is the model

$$\log \hat{m} = \lambda + \lambda^{ID} + \lambda^{O} + \lambda^{K} + \lambda^{O,K} + \lambda^{ID,O} + \lambda^{ID,K}$$

If this model is rejected, only the interaction [*ID*, *O*, *K*] can exist. Types and antitypes from this base model suggest that the two respondents differ in their pattern of constancy and change over a lag of size *K*.

Data Example

In the following illustration, we resume the analysis of the alcohol consumption data of Respondents 3050 and 3053. Specifically, we examine the differences between the developmental trajectories of beer consumption, and the effects that beer consumption has on mood on the day that follows the first beer consumption. We use a lag of one day. Thus, we have four variables that span the cross-classification: (1) *B* and *B*1, the original beer consumption variable and the same variable, with a lag of one day; these variables are coded as before, with 1 indicating 0–1 beer consumed, 2 indicating 2 beers consumed, and 3 indicating 3 or more beers consumed on one day; (2) *M1*, mood on the day after the first beer consumption; this variable is coded into the two categories 1 = low or average mood and 2 = good mood or better; (3) *ID* with the categories 3050 and 3053. Together, these four variables span a $3 \times 3 \times 2 \times 2$ $B \times B1 \times M1 \times ID$ cross-classification with 36 cells. We approach this table with the following CFA base models. First, we estimate the base model of variable independence, that is, the base model of first-order CFA,

$$\log \hat{m} = \lambda + \lambda^{B} + \lambda^{B1} + \lambda^{M1} + \lambda^{ID}$$

If this model is rejected, we know that local associations exist, and we can estimate more specific developmental models. Of the many models that could be considered, we consider the hierarchical two-group model

$$\begin{aligned}\log \hat{m} = \lambda &+ \lambda^{B} + \lambda^{B1} + \lambda^{M1} + \lambda^{ID} \\ &+ \lambda^{B,B1} + \lambda^{B,M1} + \lambda^{B1,M1} \\ &+ \lambda^{B,B1,M1}\end{aligned}$$

This model is saturated in the variables *B*, *B*1, and *M*1. Therefore, types and antitypes cannot emerge because these variables might be associated with each other. This model can be rejected only if there is an interaction between *ID* and one or more of the other variables, that is, if the two respondents differ in their developmental trajectories. For both CFA runs, we use the normal approximation of the binomial test along with the Holland–Copenhaver procedure for the protection of α. In addition, to prevent convergence problems from resulting in estimates that cannot be trusted, we invoke the delta option with $\Delta = 0.01$ in both runs. Invoking the delta option has the effect that a small constant, the delta value, is added to each cell. To prevent this option from artificially increasing the sample, this constant is usually chosen to be small. In the present example, invoking $\Delta = 0.01$ results in an increase in the number of observations of $36 \cdot 0.01 = 0.36$, that is, not even half an observation. Table 20.36 displays the results of first-order CFA, and Table 20.37 shows the results of two-group CFA.

The overall goodness-of-fit likelihood-ratio X^2 of 401.90 leads us to reject the base model of first-order CFA ($df = 29$; $p < 0.01$), and we anticipate that types and antitypes emerge. Table 20.36 shows that four types and five antitypes emerge. From both, the large and significant likelihood-ratio X^2 and the types and antitypes, we conclude that local associations do exist. However, at this

point, we do not interpret the types and antitypes. They do not necessarily reflect between-respondent differences in the effects that beer consumption on one day has on beer consumption and mood on the next day. Therefore, we proceed immediately to the two-group model specified previously.

The overall goodness-of-fit likelihood-ratio X^2 of 368.756 leads us to reject the base model of two-group CFA ($df = 17$; $p < 0.01$). This model is significantly better than the base model of first-order CFA ($\Delta X^2 = 33.14$; $\Delta df = 12$; $p = 0.001$). However, there are significant model–data discrepancies, and we anticipate that types and antitypes emerge. Table 20.37 shows that 11 discrimination types emerge. To illustrate interpretation, we discuss the three most extreme discrimination types. These are the ones with the largest test statistics.

The most extreme discrimination type is constituted by configuration 1 1 2 .. Respondent 3050 reported 518 times, and Respondent 3053 reported 255 times that they consumed 0–1 beer on two consecutive days and were in good mood or better, on the second day. Although these numbers are large for both respondents, Respondent 3050 reported this pattern significantly more often than Respondent 3053.

The second-largest discrepancy was found for configuration 3 3 2 ., that is for three or more beers consumed on two consecutive days in tandem with good mood or better on the second day. Respondent 3050 reported this pattern once. In contrast, Respondent 3053 reported it 84 times.

The third most extreme pattern is 1 3 2 .. This pattern was found 65 times for Respondent 3050 and 147 times for Respondent 3053. The pattern describes an increase from

consuming 0–1 beer on one day to 3 beers or more on the following day, along with good mood or better on the second day.

Readers are invited to interpret the other discrimination types. Each of the discrimination types describes constancy or change in beer drinking from one day to the next, that go hand in hand with one of two mood levels on the second day. In all, two-group CFA shows that the two respondents differ greatly and in many configurations in constancy and change in beer consumption and mood.

Taking the variable-oriented perspective, we ask whether the association pattern of the four variables, B, $B1$, $M1$, and ID can be explained by a log-linear model. A model that describes the $B \times B1 \times M1 \times ID$ cross-classification parsimoniously and well includes all main effects and the three two-way interactions [B, ID], [$B1$, ID], and [$M1$, ID], that is, the model

$$\log \hat{m} = \lambda + \lambda^{B} + \lambda^{M1} + \lambda^{M1} + \lambda^{B,ID} + \lambda^{B1,ID} + \lambda^{M1,ID}$$

The likelihood-ratio X^2 for this model is 26.30 (df = 24; $p = 0.49$). This model suggests that the two respondents differ in all three discrimination variables, B, $B1$, and $M1$. It also suggests that there is no interaction among the discrimination variables. Based on our earlier analyses of the beer drinking data of Respondents 3050 and 3053, this result is not surprising. We had already found that, for these two individuals, mood seems to be unrelated to beer drinking. Beer drinking on one day is associated with beer drinking on the following day, but this relationship is not sufficient for an explanation of the frequency distribution of the $B \times B1 \times M1 \times ID$ cross-classification.

Extensions and Other Base Models

Depending on the aims of research, more base models are conceivable. For example, the model that includes only the two-way interactions of discriminating variables with the grouping variables, can be considered. This model would allow one to determine whether respondents differ in the main effects of the discriminating variables as well as in their interactions. This way, a model can be specified that includes person-specific marginal distributions and developmental trajectories. This model is most useful if researchers wish to determine the exact differences in developmental trajectories between respondents.

Another class of models of interest takes situational elements into account. Examples of such elements include therapy sessions, life events, the location of events, or characteristics of the people involved. A model that considers one or more of these variables can lead to *conditional types and antitypes*, that is, types and antitypes that relate developmental changes to events.

A third class of models involves estimating CFA separately for each respondent or groups of respondents. With these models, respondent-specific types and antitypes are identified. With models such as the two-group model illustrated in Table 20.37, differences between respondents' configurations can be studied. When respondents differ in a configuration, it is not implied that this configuration also constitutes a type or an antitype for either of the comparison individuals.

A fourth class of models would take covariates into account. These covariates can be once-observed variables such as gender or number of years of formal school training. However, they could also be repeatedly observed covariates such as topic covered in individual therapy sessions. The hypotheses that are asked in the context of a cross-lagged model can then be made conditional on categories of covariates.

Predicting Events

Prediction CFA (P-CFA) relates configurations on the predictor side to configurations on the outcome side. In this section, we discuss models of P-CFA that use specific outcomes. For example, one can ask whether configurations exist that make therapy success particularly likely, or whether sequences of events or trajectories exist that allow one to predict that an adolescent engages in using illicit drugs. In other contexts, one can ask whether patterns of characteristics allow one to predict which an applicant is tended a job offer, or that a student gets admitted to graduate school. In each of these examples, a particular event, such as the end point of a developmental process, is targeted. Alternatively, one can ask whether a particular starting pattern allows one to predict a particular trajectory. In this case, a series of events is predicted instead of a point in development. In the next section, we discuss CFA base models for the prediction of end points. This is followed by a discussion of CFA base models for the prediction of trajectories.

PREDICTING END POINTS OF DEVELOPMENT

As is the case throughout the entire chapter, we deal with categorical outcomes. Frequently analyzed are dichotomous outcomes such as accepted versus rejected marriage proposals or successful versus unsuccessful job applications. However, outcomes can also be multicategorical,

for example, when profiles of symptoms are used to come to a conclusion about a psychiatric diagnosis, or when a child's attachment is characterized as secure, anxious-ambivalent, anxious-avoidant, or disorganized.

To derive the base model for the configural prediction of an end point, let the descriptors of the end point be labeled by $E_1, E_2, \ldots, E_m$, and the predictors, which can be preceding or concurrent events, by $P_1, P_2, \ldots, P_m$. Then, the P-CFA base model that allows one to determine which category of the end point is more (or less) likely to occur than chance, given a particular predictor profile, includes the following terms:

1. Main effects of all variables;
2. All possible interactions among the predictor variables; and
3. All possible interactions among the outcome variables (if the end point is a profile instead of just a category); and

The corresponding log-linear base model is, thus, saturated on the predictor side as well as on the outcome side. In addition, it proposes independence of predictors and outcome variables. In the present context, we focus on outcomes that can be represented by just one variable. Multivariate outcomes can be treated in an analogous fashion. The log-linear base model for configural prediction of an outcome is

$$\log \hat{m} = \lambda + \sum_i \lambda^{E_i} + \sum_{ij} \lambda_{ij}^{E_i E_j} + \ldots + \sum_k \lambda_k^{P_k} + \sum_{kl} \lambda_{kl}^{P_k P_l} \ldots$$

where the double subscripted terms indicate two-way interactions, and the . . . indicate that all higher order interactions among the predictors and among the outcome variables are also taken into account. This model can be rejected only if relationships between predictors and outcomes exist. In other words, if this model is rejected and types and if antitypes emerge, relationships among the outcomes and the predictors must exist. In longitudinal research, predictors often are series of antecedents or series of repeatedly observed measures that are taken before the outcome occurred.

Data Example

For the following data example, we analyze data from the MIS (Bogat et al., 2004; www.msu.edu/~mis/). We use the data from the fifth year of the study. We ask whether a diagnosis of maternal clinical-level symptoms 5 years after the birth of a child can be predicted from a pattern of intimate partner violence in the fifth year and the three years before. Four variables go into the analysis. The first three are *DV*3, *DV*4, and *DV*5. These variables indicate the status of a respondent as victim (coded 2) versus not victim (coded 1) of violence that was perpetrated by an intimate partner. The fourth variable is *SX*5, the diagnosis of clinical-level psychological problems (coded 2) versus no clinical-level problems (coded 1). Crossed, these four variables span the $2 \times 2 \times 2 \times 2$ *DV*3 × *DV*4 × *DV*5 × *SX*5 cross-classification shown in Tables 20.38 and 20.39.

We analyze this table under two CFA base models. The first is the first-order CFA base model of variable independence,

$$\log \hat{m} = \lambda + \lambda^{DV3} + \lambda^{DV4} + \lambda^{DV5} + \lambda^{SX5}$$

This model can result in types and antitypes when any interactions exist. This includes interactions among the intimate partner violence indicators. These interactions are not of interest in the present context. Here, we ask whether patterns of the $DV3 \times DV4 \times DV5$ subtable are predictive of $SX5$. Therefore, we also estimate the P-CFA–type model

$$\log \hat{m} = \lambda + \lambda^{DV3} + \lambda^{DV4} + \lambda^{DV5} + \lambda^{SX5} + \lambda^{DV3,DV4} + \lambda^{DV3,DV5} + \lambda^{DV4,DV5} + \lambda^{DV3,DV4,DV5}$$

This model can be rejected only if interactions exist that link DV to SX. For both CFA runs, we use the z test and the Holland–Copenhaver procedure for the protection of α. Table 20.38 shows the results of first-order CFA, and Table 20.39 shows the results of CFA of the prediction of end points.

The overall goodness-of-fit likelihood-ratio X^2 of 94.60 leads us to reject the base model of variable independence ($df = 11$; $p < 0.01$). We, therefore, anticipate that types and antitypes emerge. Table 20.38 shows three types and no antitype. The first type is constituted by configuration 1 1 1 1. This is the modal configuration. 61 women indicated that they did not experience intimate partner violence at any time during the observation period considered for the present analysis, and they were not diagnosed as suffering from clinical-level symptoms. Only about 30 had been expected to show this pattern. We conclude that it is most likely that no clinical-level symptoms are diagnosed when women are not victimized over a span of three years, when their children are 2–5 years old. The second type is constituted by configuration 2 2 2 1. This type indicates that it can be predicted for more women than expected under the assumption of variable independence that no clinical-level symptoms are reported even if they suffer from consistent victimization, over a span of three years. In turn, the third type, constituted by configuration 2 2 2 2, suggests that more women than expected do show clinical-level symptoms. The last two types, seemingly contradictory, can be aggregated to constitute the *aggregate type* 2 2 2 ., where the dot indicates the variable aggregated over. The aggregate type suggests that more women than expected are victims of intimate partner violence in each of the three years considered here. Interestingly, the following analysis shows that no additional information than the violence pattern is needed to discriminate between the individuals with the profiles 2 2 2 1 and 2 2 2 2.

As said previously, the three types found in the $DV3 \times DV4 \times DV5 \times SX5$ cross-classification shown in Table 20.38 may simply reflect interactions among the DV measures. Therefore, we include these interactions in the base model. If types or antitypes still emerge, they reflect interactions among the DV measures and $SX5$, by necessity. The results for the P-CFA that takes all DV interactions into account are presented in Table 20.39.

The overall goodness-of-fit likelihood-ratio X^2 of 26.06 leads us to reject the base model that includes all interactions among the DC variables ($df = 7$; $p < 0.01$). We, therefore, anticipate that types and antitypes emerge. Table 20.39 shows one type and no antitype. The expected cell frequencies in Table 20.39 are, overall, much closer to the observed cell frequencies in Table 20.38. Considering that more effects and more complex effects were included in this base model, this is not surprising. The P-CFA base model for the prediction of an end point is significantly better than the base model of first-order CFA ($\Delta X^2 = 68.54$; $\Delta df = 4$; $p < 0.01$). Still, there is one significant model–data discrepancy, for configuration 2 2 2 2. This configuration—it constitutes a type—suggests that it is significantly more likely than expected that a woman who experiences intimate partner violence consistently over a span of 3 years, when her child is between 2 and 5 years old, is diagnosed with clinical-level symptoms. This applies even when all possible interactions among the DV measures across the three years are made part of the base model. The other two types that were found in first-order CFA disappeared, thus indicating that these types reflect interactions among the DV measures instead of interactions of DV measures with $SX5$.

To round out the analyses in which we predict the end point of clinical-level symptoms from a sequence of experiences of DV, we adopt a variable-oriented perspective and first estimate a path model. In this model, we predict $DV4$ from $DV3$, $DV5$ from $DV4$, and $SX5$ from $DV3$, $DV4$, and $DV5$. This model fails to describe the data ($\mathrm{LR} - X^2 = 8.34$; $df = 2$; $p = 0.015$). We, therefore, search for a parsimonious log-linear model. The model that includes all two-way and the three-way interactions among the DV measures and the two-way interactions $DX3 \times SX5$ and $DX5 \times SX5$ describes the data well ($\mathrm{LR} - X^2 = 7.45$; $df = 5$; $p = 0.19$). Each of these interactions is significant and interpretable. However, this model cannot be used to state that three consecutive years of intimate partner violence are predictive of

clinical-level psychological symptoms. For this statement, one needs CFA.

Predicting a Trajectory

There are many theories in developmental research that conceptualize turning points in development. Examples of such turning points can be found in life events. For example, when basketball player Len Bias died in 1986, at age 22, from cardiac arrhythmia that was induced by a cocaine overdose, a number of late adolescent cocaine users discontinued using the drug (Bachman, Johnston, O'Malley, & Schulenberg, 1996). On the other end of trajectories of drug use, whereas some individuals are hooked after initiation, many others do not adopt the habit of consistent and long-term drug use. Therefore, based on these and other examples, one can ask whether trajectories of development can be predicted from a particular point in time, event, or pattern of conditions.

To develop the CFA base model for the prediction of a trajectory, we proceed as in the last section (von Eye, Mair & Mun, 2010). The model we develop is also a variant of P-CFA. Let the descriptors of the potential turning point be labeled by $P_1, P_2, \ldots, P_i$, and the trajectory indicators by $Y_1, Y_2, \ldots, Y_m$. Then, the P-CFA base model that allows one to determine which trajectory is more (or less) likely to follow the potential turning point includes the following terms:

1. Main effects of all variables;
2. All possible interactions among the outcome variables; and
3. All possible interactions among the predictor variables; these are the variables that describe the potential turning point; if the turning point is described by just one variable, the main effect of this variable is included in the model (Term 1).

The corresponding log-linear base model is, thus, saturated on the side of the outcome variables as well as on the side of the variables that describe the turning point. In the present context, we focus on potential turning points that can be represented by just one variable. Multivariate potential turning points can be treated in an analogous fashion. The log-linear base model for configural prediction analysis of a potential turning point is

$$\log \hat{m} = \lambda + \sum \lambda_i^P + \sum_k \lambda_k^{Y_k} + \sum_{kl} \lambda_{kl}^{Y_k Y_l} \ldots$$

where the double subscripted terms indicate two-way interactions, and the ... indicates that all higher order interactions among variables that describe the outcome trajectory are also taken into account. This model can only be rejected if relationships between descriptors of the potential turning point and the outcome, that is, the trajectory, exist. In other words, if this model is rejected and types and antitypes emerge, relationships among the trajectory and the turning point must exist.

Data Example

For the data example of predicting a trajectory, we use the intimate partner violence data again (MIS; Bogat et al., 2004). Here, we ask whether violence experienced during the last trimester of a pregnancy is predictive of the trajectory of patterns of clinical-level psychological problems 3, 4, and 5 years after the birth of the child. We use the following variables: Violence during the last trimester of pregnancy, *DV*1, coded as 1 = no, and 2 = yes, and the indicators of maternal clinical-level problems *SX*3, *SX*4, and *SX*5, all coded as 1 = no and 2 = yes. We analyze the $2 \times 2 \times 2 \times 2$ cross-classification of these four variables under two models. To have a reference, we first estimate the first-order CFA base model of variable independence,

$$\log \hat{m} = \lambda + \lambda^{DV1} + \lambda^{SX3} + \lambda^{SX4} + \lambda^{SX5}$$

If this model is rejected, interactions among the four variables that span the table exist. To determine whether the interactions among *DV*1 and the trajectories constitute types and antitypes, we also estimate the P-CFA model of the prediction of trajectories,

$$\log \hat{m} = \lambda + \lambda^{DV1} + \lambda^{SX3} + \lambda^{SX4} + \lambda^{SX5} + \lambda^{SX3,SX4} + \lambda^{SX3,SX5} + \lambda^{SX4,SX5} + \lambda^{SX3,SX4,SX5}$$

If this model is rejected and types or antitypes emerge, *DV* during pregnancy is predictive of particular trajectories of clinical-level psychological symptoms. For both CFA runs, we use the normal approximation of the binomial test and protect α using the Holland–Copenhaver procedure. Table 20.40 summarizes the CFA results for the CFA base model of variable independence.

The overall goodness-of-fit likelihood-ratio X^2 of 80.48 leads us to reject the base model of variable independence ($df = 11$; $p < 0.01$), and we expect types and antitypes to emerge. Table 20.40 shows that first-order CFA identifies two types and no antitype. The first type, constituted by

configuration 1 1 1 1, suggests that women who do not suffer from intimate partner violence during pregnancy show, more often than expected, no clinical-level psychological symptoms in years 3, 4, and 5 after the birth of the child. In parallel, the second type, which is constituted by configuration 2 2 2 2, suggests that women who did suffer from intimate partner violence during pregnancy show clinical-level psychological symptoms in years 3, 4, and 5 after the birth of the child at higher rates than expected.

These two types are plausible and easy to interpret. However, they can, in theory, be the results of interactions among *DX*3, *DX*4, and *DX*5. Therefore, we estimate the model of prediction of trajectories that was specified previously. For the present purposes, we do not simply ask whether types and antitypes emerge (readers are invited to confirm that, although this base model is also rejected, no types or antitypes emerge; the overall goodness-of-fit LR-X^2 for this base model is 17.26; $df = 7$; $p = 0.02$). Instead, we ask whether the women who do versus do not suffer from intimate partner violence during pregnancy differ in the occurrence rates of particular trajectories. In other words, we analyze the data using the aforementioned base model from the perspective of a 2-group analysis. Table 20.41 summarizes the results.

The results in Table 20.41 indicate that victims of intimate partner violence differ from nonvictims in particular in the occurrence rate of a trajectory of no clinical-level psychological problems, that is, in configuration 1 1 1 .. This pattern is significantly more likely in the group of nonvictims than in the group of victims. The table gives equal observed cell frequencies, and one might conclude that the occurrence rates are the same. However, one has to take into account that the group of victims is, in the present sample, larger than the group of nonvictims (116 victims of intimate partner violence vs. 77 nonvictims), and that the estimation of the expected cell frequencies takes this proportion as well as the possible interactions among the three *SX* measures into account. The expected cell frequency for the nonvictims is 47.08 (below the observed frequency), and the expected cell frequency for the victims is 70.92 (above the observed frequency).

We conclude that the base model of CFA for the prediction of a trajectory is not only significantly better than the base model of first-order CFA ($\Delta X^2 = 63.22$; $\Delta df = 4$; $p < 0.01$), it also allows one to identify a difference in occurrence rate of the trajectory of no clinical-level psychological symptoms. The difference goes in the expected direction: nonvictims of intimate partner violence show this pattern significantly more often than victims.

DISCUSSION

This chapter introduces CFA as a method for the analysis of developmental processes, and illustrates various applications using real data. There are several unique aspects that distinguish CFA from more variable-oriented approaches.

We first discuss these differences broadly and then move to implications of these characteristics more specifically for translational research.

Unique Characteristics of CFA

The first characteristic that sets CFA apart from other approaches to research in developmental psychopathology is that CFA allows one to answer the same questions, but with individuals in mind instead of variables. Findings from variable-oriented research are difficult to translate into prevention or intervention practices given that effects of covariates cannot be isolated or removed in an individual. Similarly, it is difficult to estimate the cost-effectiveness of prevention and intervention programs based on variable-oriented research because of the co-occurrence of problems and associated contextual conditions observed in individuals. It is not surprising that cost-effectiveness of well-known prevention/intervention programs are gauged per individual, not per problem or desirable outcome (see also Mun, Bates, & Vaschillo, 2010). Likewise, when clinical practitioners make observations that can shed new light on etiological pathways, CFA can be utilized to see if the new discovery can be found in other populations or settings before more controlled, variable-oriented experimental studies can be conducted.

Based on CFA, results are stated in terms of profiles (configurations) that were observed more often or less often than expected and, therefore, contradict a particular hypothesis. This hypothesis is formulated such that the effects the researchers are interested in must exist when the hypothesis is rejected, for the individuals who exhibit a particular profile. The CFA base model incorporates these hypotheses. When using CFA, one typically hopes that the base model is rejected and types and antitypes emerge that illuminate the phenomenon of interest. If this is the case, the hypotheses of interest prevail. In general, the probability with which particular profiles occur allows one to make decisions about the hypotheses that are reflected in the CFA base model. This way, one of the chief goals of psychological research can be reached, that is, the goal of making statements about people.

Second, researchers who use CFA do not assume that variable relationship always include all categories of a variable. Instead, they assume that particular effects exist in particular sectors of the data space, for select groups of cases. In other words, CFA is more attuned to detecting subgroups than variable-oriented methods in which analysis for interactions or subgroups need to be explicitly specified. The difference between the two broad approaches is that in the former, finding subgroups or unusual patterns, via detecting types and antitypes, is the goal of application, but the opposite is true in the latter. Thus, for research in developmental psychopathology where the existence of subgroups can provide important clues to the etiology, treatment, and prognosis of a problem, CFA is a user-friendly, analytic tool.

A third major difference between CFA and other methods of analysis is that CFA allows one to make statements about sectors of the data space that are comparatively sparsely populated or even empty. This is done in the form of CFA antitypes. Talking about sectors in the data space that contain fewer cases than expected based on theory or prior knowledge can be of utmost importance in many research domains. Consider, for example, research on the effects of neuroleptic drugs. Some of these drugs are known to come with high risks of lowered life expectancy, extrapyramidal effects on motor control, or decrease in brain volume. Imagine a new drug that is being tested in patients. One domain of comparison with existing drugs concerns these side effects. An antitype for the new drug could indicate that, in comparison with existing drugs, certain side effects are particularly unlikely in a group of patients with a particular profile.

CFA and Translational Research

As discussed in the previous section, and illustrated in the examples in this chapter, application of CFA proceeds under the assumption that relations among variables are not necessarily valid across the entire range of admissible scores (when variables are metric) or all categories (when variables are categorical). As implied by this assumption, researchers use CFA to create statements that apply to individuals who exhibit a particular profile, that is, a particular pattern of scores or categories.

Interestingly, this assumption seems to closely correspond with the language used to describe results of developmental psychopathological research. For example, we read, in the context of research on the long-term effects of insecure attachment, that "one such outcome may be conduct disorder, in a child who has the genetic and neurobiological diathesis, who has an insecure representational model of the self, and who faces extremes and additional stress in the form of a violent home and/or community environment in conjunction with minimal support or nurturance from caregivers" (Cicchetti & Toth, 2008, p. 18; see also Richters & Cicchetti, 1993). This statement describes a profile of scores and categories. Children covered by this statement have four characteristics. They (1) possess the

genetic and neurobiological diathesis; (2) have an insecure representational model of the self; (3) face extreme and additional stress in the form of a violent home and/or community environment; and (4) face extreme and additional stress because of minimal support or nurturance from caregivers.

Regardless of whether some or all of these characteristics are necessary, or some or all are sufficient for the development of conduct disorder, it is important to realize that this pattern of characteristics, that is used to predict conduct disorder cannot be created using such methods as regression analysis, hierarchical linear modeling, or, more generally, structural modeling (the disconnect discussed in the introduction). Each of these methods creates statements on variable relations that include the entire range of scores of categories. In the previous example profile, only a selection of scores and categories is used. This implies either that no statement is made about the remaining scores or categories or that the outcome will not be observed when the remaining scores or categories are observed. In brief, this statement applies to a selection of individuals only.

Relating this basic characteristic of CFA to the desideratum of translational research, we note that this type of research is designed to "address how basic behavioral processes inform the diagnosis, prevention, treatment, and delivery of services for mental illness . . . ", or vice versa (National Advisory Mental Health Council, 2000, p. iii). It is one of the key characteristics of CFA that it suggests that these processes are not the same for individuals who differ in behavioral and neuropsychological profiles, or who live under different conditions. CFA also suggests that translational research, as well as the delivery of services must be tailored to individuals or subpopulations, that is, those who can benefit in particular from services. For example, dose–response models must be created that take characteristics of clients into account, type, and delivery of therapy must be tailored to the specific pattern of illness, or the combination of drugs and psychotherapy must take the interplay between diagnosis and other patient characteristics into account. The same drug, the same dose, and the same type of psychotherapy can have effects that are specific to the client in need of help, but also his or her living conditions, age or partner situation.

The statistical method of CFA is uniquely suited to point researchers as well as applied scholars to those patterns that are most promising, but also to those patterns that are least promising for intervention measures. The methods is, therefore, of great interest for basic, translational, and applied research.

Limitations

In spite of all the encouraging characteristics of CFA, there are limitations. Here, we discuss three most important ones. First, to perform CFA when variables are metric, researchers often resort to reducing the number of possible values to a small, manageable number of categories. The reason for this is obvious. Crossing variables and examining individual profiles would result in exorbitantly large numbers of profiles, tables of sizes that can no longer be analyzed, and most profiles would not be observed at all or observed just once. In other words, to enable researchers to analyze profiles statistically, the number of categories must be small, and the sample of cases must be large.

Naturally, when the number of possible values is reduced, information is bound to disappear. This issue has been discussed at length in the methodological literature (e.g., MacCallum et al., 2002). However, we maintain that (1) researchers do not always have a choice when they analyze data with CFA, log-linear models, or latent class analysis, (2) not always will this loss of information result in distorted results (for an example, see von Eye & Mair, 2011), and (3) because of measurement error, dichotomization of metric response variables can provide even better, unbiased results by reducing errors in measurement (Shentu & Xie, 2010). Likewise, cutting-edge medical research is typically conducted using dichotomized or binary outcomes. Results from this type of variables can be easier to communicate with nonacademic, important stake holders (Mun et al., 2010).

Outlook. Methods of CFA are still in need of further development. Although visible progress has been made (e.g., von Eye et al., 2010), there are still domains that CFA has yet to enter. Two domains are of note. The first domain is that of causality research. Recently, considerable progress has been made in the development of statistical methods that allow one to test hypotheses that are compatible with assumptions of causal relations (see Dodge & Rousson, 2001; von Eye & DeShon, 2012; von Eye & Wiedermann, 2013). The development of CFA methods in this domain is at its beginning (von Eye & Brandtstädter, 1997, 1998; von Eye, Wiedermann, & Mun, 2013). The most important aspect of these developments is that the idea that carries CFA, that not all categories of variables are necessarily involved in relations, be translated into the domain of causal relations.

Second, this idea needs to be translated into the universe of latent variables. To date, there exist no configural approaches to latent variables analysis. One would hope that CFA models be developed that allow researchers to

analyze composite variables without inflating the table under study beyond the tractable.

Value Added

To conclude this chapter, we summarize the value added by CFA.

1. CFA allows researchers to make statements about people instead of variables.
2. These statements are valid for particular groups of individuals, but not for others.
3. These statements are based on selections of categories, not all categories of variables.
4. CFA allows one to test very specific hypotheses.
5. CFA allows one to identify typical developmental trajectories and atypical developmental trajectories. This option is of particular importance in research on the development of pathological behavior.

INTRODUCTION

In 1986, Reuben Baron and David Kenny published their classic article on the distinction between mediator and moderator variables in social psychological research (Baron & Kenny, 1986). This particular paper has been incredibly influential on the way data have been analyzed in the social sciences and, according to the Web of Science, has been cited more than 24,000 times to date. In fact, this is the most highly cited paper written by any social psychologist (Nosek et al., 2010), and its citation count is still climbing by more than 1000 each year. This particular article has even spawned its own spinoff literature, with a number of recent articles including Baron and Kenny in their titles, specifically written in response to and elaborating upon the initial Baron and Kenny work, including *Reconsidering Baron and Kenny* (Zhao, Lynch, & Chen, 2010), *Reflections on the Baron and Kenny Model of Statistical Mediation* (Pardo & Román, 2013), and two additional works with *Beyond Baron and Kenny* in their titles (Hayes, 2014; Krause et al., 2010).

Perhaps the popularity and influence of this particular paper is due to that fact that it strives to distinguish between *mediation* and *moderation*, two "often-confused

functions of third variables" (Baron & Kenny, 1986, p. 1173), both conceptually and in terms of the analyses necessary to test them. Both mediation and moderation involve systems of three variables. Each has an initial or focal predictor variable (which we will refer to as *X*) and an outcome or criterion variable (which we will refer to as *Y*). In addition, there is a third variable—the mediator (*M*) or moderator (*Z*)—involved in the system. Baron and Kenny (1986) state that a moderator "is a qualitative . . . or quantitative . . . variable that affects the direction and/or strength of the relation between an independent or predictor variable and a dependent or criterion variable" (p. 1174) and that it "partitions a focal independent variable into subgroups that establish its domains of maximal effectiveness in regard to a given dependent variable" (p. 1173). In other words, a moderator affects the association between two variables such that the impact of the predictor on the criterion varies depending on the level or value of the moderator (Holmbeck, 1997). Baron and Kenny (1986) stated that a mediator, on the other hand, "represents the generative mechanism through which the focal independent variable is able to influence the dependent variable of interest" (p. 1173). The key features defining such a mediator model are that (1) the predictor influences the mediator, and (2) the mediator, in turn, influences the outcome variable (Holmbeck, 1997; MacKinnon & Dwyer, 1993).

In the nearly 30 years since the publication of the Baron and Kenny article, the analytic literatures on both mediation and moderation have continued to grow. For example, recommendations for the post hoc probing of moderated effects have been extensively developed (Aiken & West, 1991), as have optimal methods for statistical testing and finding confidence intervals for mediated effects (MacKinnon, Fritz, Williams, & Lockwood, 2007; MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002; MacKinnon, Lockwood, & Williams, 2004; Preacher & Hayes, 2004, 2008). In addition, the collection of longitudinal data has become more prevalent as new analytic approaches well-suited to such data have been developed and researchers have come to realize the benefit of investigating how individuals change across time (Willett, 1997). In this chapter, we will discuss how both mediation and moderation can be explored in longitudinal data in which the focal predictors, outcomes, and moderators and mediators are repeatedly measured over time.

We will begin by discussing how the concepts of mediation and moderation feature in developmental psychopathology research and outlining the typical analysis methods used to identify moderation and mediation in cross sectional data. Because these methods and their application in particular literatures has been covered extensively elsewhere (e.g., Dearing & Hamilton, 2006; Frazier, Tix, & Baron, 2004; Gogineni, Alsup, & Gillespie, 1995; Rose, Holmbeck, Coakley, & Franks, 2004) our discussion will be relatively brief. Then we will explain the possible benefits of collecting longitudinal observations and discuss two analytic frameworks—multilevel modeling and structural equation modeling—that are often used to model longitudinal data. Then we will bring these together and discuss in detail various models designed to test moderation and mediation hypotheses in longitudinal data, including a lag-as-moderator approach, *interactions* between time and time-varying covariates in multilevel models, a mediation *change over time* model, autoregressive and latent growth models (as well as a combination of the two), a latent change score approach, and an exponential decay model. This is followed by a discussion of how modern methods of determining causal inference may be applied and extended in the longitudinal context. Finally, we conclude with a section on promising directions for future research on mediation and moderation in longitudinal data.

THE ROLE OF MODERATION AND MEDIATION ANALYSES IN DEVELOPMENTAL PSYCHOPATHOLOGY RESEARCH

Several of the foundational ideas in developmental psychopathology involve the types of associations that can be appropriately tested with models that include moderated and mediated effects. A primary goal—if not *the* primary goal—of developmental science is to understand how processes unfold over time, and it is precisely this idea of *process* that guides methodology designed to detect mediation. In fact, one of the earliest presentations of methodology to detect longitudinal mediation effects described the procedure as process analysis (Judd & Kenny, 1981). The Judd and Kenny article is particularly important as it describes the importance of longitudinal mediation relations, while the Baron and Kenny article does not. The often used geographic analogy of *developmental pathways* implies that earlier variables affect later variables in series and readily maps onto mediational logic where initial variables predict mediators that, in turn, predict outcomes. The sort of sequential effects in a mediation analysis could also be used to model the spreading influence across domains or systems in developmental cascades (Masten & Cicchetti, 2010) and chain

reactions (Rutter, 1999). In addition, mediation analyses can be useful in exploring how interventions designed to change or prevent maladaptive behavior achieve their effects. Intervention versus control is the initial variable, constructs that are targeted by the intervention are the mediators, and the behavior is the outcome in such an analysis.

The idea that contextual effects influence individual development is a natural fit for a moderation framework, which can model how characteristics of the individual interact with aspects of the physical and social environment to produce adaptive and maladaptive behavior. The emphasis on risk and resilience that features prominently in the developmental psychopathology literature also suggests an analytic framework involving moderator variables. Vulnerabilities and protective factors from multiple domains serve as moderators and interact with stressors to produce a range of behavioral outcomes. Any particular outcome is probably not a simple function of a single isolated factor but rather the result of a combination of multiple biological, social/cultural, and psychological factors, and a framework that can accommodate such interactions is necessary to model such influences appropriately. The concept of multifinality—the idea that a given risk factor could lead to a variety of different outcomes depending on other aspects of the system (Cicchetti & Rogosch, 1996)—is necessarily going to involve some moderator variables that determine the manner in which the risk factor is ultimately expressed behaviorally.

Indeed, modeling a process as complex as human development may ultimately require models that combine aspects of both mediation and moderation. Viewing the individual as a complex system with variables at multiple levels exerting mutual and potentially reciprocal effects might lead to models that examine the effects of change at one level of the system on mediators at other levels that ultimately affect behavioral outcomes. One might also test whether the effects of focal variables at one level might depend upon the state of moderator variables at other levels. Adding to this the longitudinal aspect of processes unfolding over time results in an incredibly intricate framework of influences that will require careful consideration, clever study design, and sophisticated analytical tools to explore and ultimately understand. The focus of this chapter is to provide developmental psychopathology researchers with information about analytic techniques involving mediation and moderation in longitudinal data that might prove useful in understanding how developmental processes result in adaptive and maladaptive behavior.

ECLS-K DATA EXAMPLES

The various moderation and mediation analyses described in this chapter will be illustrated with examples drawn from the Early Childhood Longitudinal Study–Kindergarten Cohort (ECLS-K) data. This data set includes a wealth of information on a nationally representative sample of children who entered kindergarten in the 1998–1999 school year and were followed through the eighth grade. ECLS-K participants were selected via a multistage probability sampling design (U.S. Department of Education, National Center for Educational Statistics, 2009). One hundred geographical areas consisting of counties or groups of counties were initially selected, and a total of 1,280 public and private schools were sampled from within these areas. A target of approximately 24 kindergarteners enrolled at each school were then selected for the study. In total, the original sample at kindergarten fall included 21,260 children.

Study participants were assessed at kindergarten fall and spring, first grade fall and spring, third grade spring, fifth grade spring, and eighth grade spring. Because the first grade fall assessment involved only a small subsample of participants and many of the measures of interest here were not assessed at eighth grade spring, we focus on the remaining five assessments. For analyses in which equally spaced time points are desirable, we will focus on the first through fifth grade assessments, which occurred every 2 years. At each assessment, data were gathered from children, parents, and teachers. Our illustrative analyses utilize demographic information, child academic assessments, and teacher questionnaire data.

To further unify the illustrative analyses, we will focus on mediation and moderation effects involving attention-deficit/hyperactivity disorder (ADHD). A number of research efforts have examined ADHD in the ECLS-K data set (e.g., Barnard-Brak & Brak, 2011; Morgan, Staff, Hillemeier, Farkas, & Maczuga, 2013; Schneider & Eisenberg, 2006; Stone, Brown, & Hinshaw, 2010). Several of these have focused primarily on diagnoses of ADHD within the sample. We focus instead on reported ADHD symptom levels, which provide different (and, some would argue, better) information than diagnosis indicators (Currie & Stabile, 2006, 2009; Fletcher & Wolfe, 2008).

A modified version of the Social Rating Scale (adapted by ECLS-K with permission; Gresham & Elliott, 1990) was administered to teachers at each time point to assess children's social and behavioral functioning in the classroom. Four of the five subscales of the Social Rating Scale are used in our illustrative analyses: Approaches to Learning

(LEARN, six items), Externalizing Behavior (EXTERN, five items), Interpersonal Skills (INTERP, five items), and Internalizing Behavior (INTERN, four items). These subscales are highly reliable, with split half reliabilities ranging from .76 (EXTERN at third grade spring) to .92 (INTERN at fifth grade spring; Tourangeau, Nord, Lê, Sorongon, & Najarian, 2009). A detailed examination of the associations between these subscales and ADHD diagnosis measures in the ECLS-K data set showed that approaches to learning and externalizing behavior were the strongest predictors of diagnosis (Elder, 2010). The Approaches to Learning subscale includes items that rate the child's attentiveness, task persistence, eagerness to learn, learning independence, flexibility, and organization. The Externalizing Behavior subscale includes items that indicate the frequency with which a child argues, fights, gets angry, acts impulsively, and disturbs ongoing activities. Thus, we will use these particular variables as proxies for the inattentive (LEARN) and impulsive/hyperactive (EXTERN) symptoms of ADHD.

The ECLS-K data includes a number of academic performance measures. We utilize the IRT theta estimates for age-graded reading (READ) and mathematics (MATH) performance. The reliability of these scores ranged from .91 (for math at kindergarten fall) to .96 (for reading at kindergarten spring; Tourangeau et al., 2009).

Our illustrative analyses in the ECLS-K data will examine a number of moderation and mediation effects involving ADHD that have been previously identified in the literature. For example, we will examine how the association between ADHD symptoms and academic performance changes over time (or, alternately, as children grow older; Frazier, Youngstrom, Glutting, & Watkins, 2007; Kawabata, Tseng, & Gau, 2012). We will also examine potential moderating effects of gender on the association between ADHD and negative academic and social effects (Gaub & Carlson, 1997; Gershon & Gershon, 2002; Lahey et al., 2007; Lee, Lahey, Owens, & Hinshaw, 2008; Owens, Hinshaw, Lee, & Lahey, 2009).

Our primary mediation example is drawn from a recent article examining possible mediators of the association between ADHD and depression (Humphreys et al., 2013). Specifically, we will examine whether interpersonal skills and academic performance in reading and math mediate the association between our two ADHD symptom measures and depression. Such a mediated effect has been suggested as an explanation for the comorbidity between ADHD and depression that fits within a developmental psychopathology perspective (Drabick & Kendall, 2010). ADHD may lead to difficulties in social and academic functioning, and over time, failure to achieve success in these areas may lead to depression. Interpersonal skills and depression will be measured by the appropriate subscales of the Social Rating Scale. The Interpersonal Skills subscale (INTERP) rates a child's skill in forming and maintaining friendships, getting along with people who are different, comforting or helping others, expressing feelings and ideas in positive ways, and showing sensitivity to the feelings of others. The Internalizing Behavior subscale (INTERN) includes items rating the apparent presence of anxiety, loneliness, low self-esteem, and sadness. Admittedly, this is a confounded measure of depression, but it is the best proxy for this construct in the public use data set.

Because we wish to focus the reader's attention on similarities and differences between different methods of estimating longitudinal moderation and mediation, our analyses of the ECLS-K data are somewhat oversimplified. In particular, they do not address the complexly multilevel nature of the data, and they do not include sampling weights. Our analyses of the longitudinal ECLS-K data incorporate the nesting of multiple observations over time within individuals, but they do not explicitly model higher levels of nesting, for example individuals nested within classrooms, classrooms nested within schools, and schools nested within the counties that make up the primary sampling units of the study. Moreover, we did not make use of the multiple weights included in the ECLS-K data set designed to adjust for oversampling of Asians and Pacific Islanders and survey nonresponse (Tourangeau et al., 2009) to produce estimates that characterize the U.S. population of kindergarteners from the 1998–1999 cohort. As a consequence, similarity among students within classes and schools may produce some downward bias in the standard errors reported here, and our results are not necessarily representative of the whole of the U.S. population of students.

BASIC MODERATION

A situation in which the effect of one predictor varies depending on the value of another defines moderation. Moderation hypotheses are common in the social sciences and can be tested using a number of different frameworks, including one-way analysis of variance (ANOVA), regression, and structural equation modeling. ANOVA-based methods for testing moderation were developed prior to those in other areas; however, these methods are appropriate only for categorical predictors. Application of ANOVA-based methods to continuous predictors requires artificial dichotomization of the continuum into high and low groups, which is not ideal because it unnecessarily

reduces the power to detect the moderated effect and because it can produce spurious main and moderated effects under certain conditions (Maxwell & Delaney, 1993). Hence we will focus here on moderation within the regression framework.

The most typical approach to testing moderation effects with regression simply represents the synergistic effect between two predictors as a cross-product term and includes the cross-product in a regression equation simultaneously with its lower order component vectors. If we wish to test whether the effect of a predictor variable X on an outcome variable Y is moderated by Z, we would fit an equation:

$$Y = b_0 + b_1X + b_2Z + b_3XZ + e \qquad (21.1)$$

and examine the test of the b_3 coefficient to determine whether the effect of X on Y is moderated as predicted. The analysis is carried out in the same way regardless of whether X and Z are continuous measures or measured dichotomies. If one or more of the predictors is a categorical variable with more than two levels, a series of coded vectors will be required to represent it, and the test of the moderated effect will involve more than a single vector. In such a case, each vector coding the first predictor will need to be multiplied by each vector coding the second predictor, and the whole set of cross-products should be tested using a hierarchical regression approach to determine the R^2 change associated with the addition of the cross-products to the model (Cohen, Cohen, West, & Aiken, 2003).

Because cross-product vectors created to represent moderation effects are often highly collinear with their component vectors, it is typically recommended that the researcher center continuous predictor variables at their means prior to creating the cross-product. This will reduce the correlation between the vectors by eliminating what is known as nonessential collinearity (Aiken & West, 1991) among the predictor vectors, while leaving the associations between the predictors and the outcome unaltered. This can improve estimation as well as provide meaningful interpretations for lower order coefficients in the regression analysis. For example, if we left both X and Z in their raw metric in equation 21.1, the intercept of equation 21.1 would represent expected Y values for a subject with zeros on both the X and Z measures. Zero might not represent a particularly meaningful value on the X and Z scales, and it might actually be off-scale (e.g., if X and Z were 1–7 Likert-type measures). Similarly, the b_1 coefficient in equation 21.1 would represent the expected change in Y associated with a one unit increase in X when $Z = 0$ and the b_2 coefficient would represent the expected change in Y associated with a one unit increase in Z when $X = 0$. If we were to center each of the two predictors around their respective means, however, and create the cross-product from these centered variables, the intercept will represent the expected outcome for an "average" subject with mean values on both X and Z, the b_1 coefficient would represent change associated with X when Z is at its mean, and b_2 would represent change associated with Z when X is at its mean.

In the ECLS-K data, we tested whether the association between teachers' ratings of ADHD symptoms (LEARN and EXTERN, the predictors) and interpersonal skill (INTERP), reading (READ) and math performance (MATH), and internalizing behavior (INTERN) outcomes at kindergarten fall might be moderated by child gender (GENDER). The ADHD symptom predictors were centered at their means, and GENDER was coded such that males = 0 and females = 1. Regression results are reported in Table 21.1. As the coefficient b_1 indicates the association between the ADHD symptom predictor and the outcome at GENDER = 0 (male), the second column of Table 21.1 was labeled as the ADHD symptom effect for males (e.g., b_1 $\text{LEARN}_{\text{Male}}$). The coefficient b_2 in the third column (e.g., b_2 Gender) represents the difference between females and males in the outcome variable at the mean of the ADHD symptoms.

The fourth column of Table 21.1 presents the tests of the b_3 interaction coefficients in each of the various analyses. Only 2 of the 8 interactions were significant. Specifically, LEARN and EXTERN interacted with GENDER to predict READ and INTERP, respectively. These significant coefficients associated with the cross-product terms indicate that, in fact, the association between attentive symptoms and reading performance and the association between impulsive/hyperactive symptoms and interpersonal skill ratings is different for boys and girls. Both effects are slightly stronger for girls than for boys.

Higher order interactions involve synergistic effects among three or more variables. For example, we might predict that an XZ interaction is significant at only one of the two levels of a dichotomous variable W. Or if W is a continuous variable, we might hypothesize that the XZ interaction becomes more pronounced at higher levels of W. We would fit

$$Y = b_0 + b_1X + b_2Z + b_3W + b_4XZ + b_5XW + b_6ZW + b_7XZW + e \qquad (21.2)$$

and examine the test of the b_7 coefficient associated with the three-way interaction to determine whether the interactive effect of XZ, in fact, varies depending on the value of W. Tests of whether the two gender interactions identified above might differ for families with varying incomes in the ECLS-K data found no significant three-way interactions when income was represented continuously (using the natural log of the WKINCOME variable) or dichotomously (using a median split on the WKINCOME variable), suggesting that the interactive effects remained stable across the range of income.

Significant interactions are typically followed by post hoc tests of simple effects. These examine the effect of one variable at particular values of the other. When both variables involved in the interaction are categorical, the post hoc analyses involve splitting the sample into groups defined by the levels of one variable and examining the effect of the other variable within each of these groups. Tests are typically conducted using model sums of squares produced in the group-specific analyses and residual sums of squares from the full model in which the interaction was initially estimated (Pedhazur, 1997). If one variable is continuous and the other categorical, the data splitting approach could be used to examine the effect of the continuous predictor within the various groups defined by the levels of the categorical variable, or the effect of the categorical variable could be examined at particular values of the continuous predictor. The Pothoff extension of the Johnson-Neyman technique can be used to find the ranges of the continuous predictor where the categorical variable has a significant effect, or specific values on the continuum can be selected at which to test the significance of the categorical distinction using a recentering strategy. Both approaches are discussed in detail in Aiken and West (1991).

When both variables involved in the interaction are continuous, the appropriate post hoc analyses involve testing the simple slope of one variable at particular values of the other. Ideally the simple slopes would be calculated and tested at meaningful points along the continuum of the other continuous variable. Often simple effects are simply examined at the mean and values ±1 standard deviation from the mean of a variable, which might be considered average, high, and low levels of the construct. Some care should be taken with this approach, however, as it is possible that one of the extreme values might fall outside the range of actual values if the variable is highly skewed.

The various terms in equation 21.1 can be regrouped as

$$Y = (b_0 + b_2Z) + (b_1 + b_3Z)X + e \qquad (21.3)$$

to show that that $b_1 + b_3Z$ provides an estimate of the simple slope of Y on X at a particular value of Z. The coefficient b_1 estimates the simple slope of Y on X when $Z = 0$, which will be at the mean of Z if centered predictors were used in the regression analysis. Values of Z (or centered Z, if centered predictor variables were used) can simply be substituted into equation 21.3 to calculate simple slopes at high and low Z values. The standard error of these simple slopes can be calculated using the typical equation for a linear combination of coefficient values:

$$SE_{b1+b3} = \sqrt{s_{b1}^2 + 2Zs_{b1,b3} + Z^2s_{b3}^2} \qquad (21.4)$$

where s^2_{b1} is the sampling variance of b_1, s^2_{b3} is the sampling variance of b_3, and $s_{b1,b3}$ is the sampling covariance between b_1 and b_3 (Aiken & West, 1991). The matrix of sampling covariances of the coefficient estimates can be obtained from most statistical programs that estimate ordinary least squares (OLS) regression. The square roots of the diagonal elements of this matrix are the standard errors of the coefficients reported in typical regression output.

We examined simple effects associated with the previously identified significant gender interactions in the ECLS-K data using a recoding strategy. Examination of the lower order coefficient for b_1 in Table 21.1 shows that the effect of approaches to learning on reading performance for boys (i.e., when GENDER = 0) is 0.2966, which is significant at $p < .0001$. This indicates that for every 1-point increase in the approaches to learning subscale score, we should expect a 0.2966 point increase in reading performance. We can then calculate the effect for girls by combining the b_1 and b_3 coefficients: $b_1 + b_3 = 0.2966 + 0.0314 = 0.3280$. So for girls, for every 1-point increase in the approaches to learning subscale score, we should expect a 0.328 point increase in reading performance. The significance of this value could be tested by computing the standard error of the linear combination $b_1 + b_3$ as described in equation 21.2. Alternately, GENDER could be recoded such that females = 0 and males = 1, the cross-product recomputed and the analysis rerun to produce an estimate of the LEARN effect for girls as the b_1 coefficient, shown in column 5 of Table 21.1. The standard error of this simple effect for girls is .0082 and the effect is significant at $p < .0001$. Similarly, we see that the simple effect of externalizing on interpersonal skill is –0.5217 for boys and –0.5757 for girls, both significant at $p < .0001$.

BASIC MEDIATION MODEL

The basic framework of a single mediator model at a single time point (i.e., a cross sectional mediation model) is shown in the two panels of Figure 21.1. The top panel shows the path diagram for a single predictor variable *X* and its effect on an outcome variable *Y*. The coefficient *c* on the path linking *X* to *Y* represents the total effect of the predictor on the outcome variable. The lower panel of Figure 21.1 shows the path diagram for this association when including the mediator variable. The coefficient *a* represents the effect of the predictor *X* on the mediator *M*, and the coefficient *b* represents the effect of the mediator *M* on the outcome *Y*,

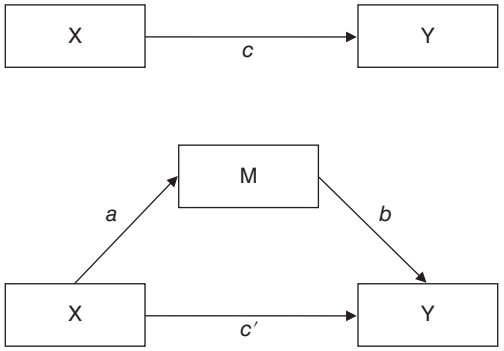

Figure 21.1 Path diagrams for the mediation model.

over and above the effect of the predictor. The coefficient c' on the path linking *X* to *Y* represents the direct effect of the predictor on the outcome variable, over and above the effect of the mediator.

The estimates of the path coefficients in these diagrams can be straightforwardly obtained through a series of three OLS regression analyses or equivalently through fitting two structural equation models to the manifest variables. The regression model corresponding to the top panel of Figure 21.1 would be

$$Y = b_0 + cX + e \tag{21.5}$$

The coefficient associated with the *X* predictor in this equation estimates the *c* path coefficient representing the total effect of *X* on *Y*. Two regression analyses are necessary to produce estimates of the coefficients in the lower panel of Figure 21.1. The first of these predicts the mediator variable from the initial predictor:

$$M = b_0 + aX + e \tag{21.6}$$

The coefficient associated with the *X* predictor in this equation estimates the *a* path coefficient linking the predictor to the mediator. The second regression equation predicts the outcome variable from the predictor and the mediator simultaneously:

$$\mathrm{Y} = b_0 + c'X + b\,M + e \tag{21.7}$$

The coefficient associated with the *X* predictor in this equation estimates the c' path coefficient representing the direct effect of *X* on *Y*. This is the effect of the predictor on the outcome that *cannot* be attributed to the mediator. The coefficient associated with the *M* mediator in this equation

estimates of the b path coefficient linking M to Y, over and above the effect of X.

Baron and Kenny's (1986) steps approach to testing mediation specifies a number of conditions that must be met to establish mediation:

1. The independent variable must affect the mediator.
2. The predictor must affect the outcome.
3. The mediator must affect the outcome.
4. The effect of the predictor on the outcome must be less when the mediator is present in the analysis than when it is absent.

Each of these steps involves coefficients from the three regression equations specified above. Step 1 requires examination of the significance of the a path coefficient from equation 21.6. Step 2 requires examination of the significance of the c path coefficient for the total effect from equation 21.5. Step 3 requires examination of the significance of the b path in equation 21.7. Then Step 4 involves comparing the c and c' coefficients from equations 21.5 and 21.7. If $|c'| < |c|$, the final step has been met, and according to this approach, mediation has been identified. Once mediation has been established, the significance of the c' coefficient in equation 21.7 can be examined to determine whether mediation is complete (i.e., no significant direct effect once the mediator has been taken into account) or partial (a significant direct effect persists).

Two point estimates of the mediated or indirect effect can be produced from the set of coefficient estimates in equations 21.5–21.7. The first such point estimate is that implied by Step 4 of the Barron and Kenny approach: $c - c'$. Using this difference as a point estimate of the mediated effect makes intuitive sense: when the effect of X on Y not due to the mediator (i.e., the direct effect or the c' estimate) is subtracted from the total effect of X on Y (i.e., the c estimate), the difference logically must be the effect of X on Y that is due to the mediator. A second point estimate of the mediated effect is the product of the a and b path coefficients. Using this product as a point estimate of the mediated effect makes intuitive sense for this function as well: if the a path coveys the influence of X on M and the b path similarly conveys the influence of M on Y, their product naturally conveys the influence of X (at the beginning of the system) to Y (at the end of the system). With simple single-level data and continuous M and Y measures, these two point estimates are algebraically equivalent (MacKinnon, Warsi, & Dwyer, 1995).

Several researchers have pointed out flaws in the steps approach to mediation. The first of these is that Step 2, which specifies that the total effect of X on Y must be significant, is not strictly necessary (MacKinnon et al., 2002; Zhao et al., 2010) for a mediated or indirect effect to be present. There are situations where the direct and indirect effects might have different signs (inconsistent mediation or suppression, see MacKinnon, Krull, & Lockwood, 2000), which might combine to produce a nonsignificant total effect that would not meet the criteria for Step 2. Such a situation may also prove problematic for Step 4, which specifies that the direct effect must be smaller in magnitude than the total effect. Consider, for example, a situation in which $a = 2$, $b = -1$, and $c' = 2$. The total effect c would be equal to the sum of the indirect effect ab and direct effect c'. This would be $c = ab + c' = 2 * -1 + 2 = 0$, and the condition of Step 2 would not be met. Moreover, in this case $|c'| > |c|$, as $2 > 0$, and the condition of Step 4 would also not be met, and a researcher applying the steps approach would erroneously conclude that no mediation was present.

Another apparent difficulty of strictly applying the steps approach is that at Step 4, any difference in the appropriate direction could be deemed evidence of mediation, but given ever-present sampling variability, a stricter criterion requiring a significant difference seems more appropriate. An approximate standard error can be derived via first-order Taylor series expansion or the multivariate delta method (MacKinnon, 2008):

$$s_{ab} = \sqrt{b^2 s_a^2 + a^2 s_b^2} \tag{21.8}$$

where s_a^2 and s_b^2 are the sampling variances of the regression estimates of a and b. These can be obtained by squaring the standard errors of a and b produced in all standard regression output or by examining the diagonal elements of the co/variance matrix of the estimates which can generally be requested as additional output in statistical software for regression estimation. This particular form of the standard error of the mediated effect is often referred to as the Sobel standard error (Sobel, 1982, 1986). Baron and Kenny (1986) suggested a slightly more complex approximate standard error, which can be derived via second order Taylor series expansion and represents the exact variance under the condition of independence:

$$s_{ab} = \sqrt{b^2 s_a^2 + a^2 s_b^2 + s_a^2 s_b^2} \tag{21.9}$$

A statistical test of the mediated effect can be conducted by dividing either the ab or the equivalent $c - c'$ estimate of

the mediated effect by the selected approximate standard error. This should be distributed as a z in large samples, and thus values more extreme than ±1.96 would be considered significantly different from zero at $p < .05$. However, this large sample z test assumes that the product ab is normally distributed, and the ab estimate of mediation generally is not (MacKinnon et al., 2007). This test has been found to be overly conservative (i.e., to have low power) in simulation studies (MacKinnon et al., 2002). This may or may not be problematic, depending on the particular circumstances in which the test is employed. If a researcher uses this test in an existing data set and finds a significant mediated effect, the fact that the test is conservative and therefore somewhat underpowered does not diminish the significance of the finding in any way, although a confidence interval formed around the significant point estimate of the mediated effect will still be too wide and indicate more uncertainty in the value than is truly warranted. In contrast, a nonsignificant result might indicate a null effect or might simply be the result of an underpowered test. In addition, using this test to determine the necessary number of subjects for a future study in an a priori power analysis would result in an unnecessarily large sample size recommendation.

Because of this distributional difficulty, several alternative approaches have been suggested. One such alternative involves looking not at the distribution of ab, but at the product $z_a z_b$, where z_a and z_b are z scores formed as the ratios of the coefficient estimates to their standard errors. The $z_a z_b$ product is known to have a complex nonnormal distribution, but values obtained in such an analysis can be compared to tabled values (Meeker, Cornwell, & Aroian, 1981) and asymmetric confidence limits can be obtained from software written especially for this purpose (MacKinnon et al., 2007; Tofighi & MacKinnon, 2011). An alternate approach involves a resampling technique known as bootstrapping. Bootstrapping involves repeated resampling with replacement (Efron & Tibishirani, 1993). For example, if a researcher is bootstrapping cases from a sample of 100, many (typically over 1000) new samples of 100 cases are drawn from the original sample. These samples may differ from the original in that a given case may appear more than once in each bootstrap sample. Then the statistic of interest may be calculated for each bootstrap sample. These are ordered and values of the statistic associated with the desired percentiles (often the 2.5th and 97.5th for a 95% confidence interval) define the lower and upper limits of a confidence interval. This procedure may be refined using a procedure known as bias correction to adjust for the fact that the statistic obtained in the original analysis may not fall at the 50th percentile of the distribution of bootstrap values (Efron & Tibishirani, 1993). In the case of a mediated effect, the cases themselves are resampled and ab estimates produced from regressions involving X, Y, and M in each of the new bootstrap samples are obtained (MacKinnon et al., 2004; Preacher & Hayes, 2004).

The simple single-mediator model in Figure 21.1 can be expanded to multivariate situations that include multiple predictors and multiple mediators. With multiple predictor and mediator variables, it is common to run an initial set of analyses examining mediated effects of each predictor–mediator pairing individually, then to run a combined model to examine the *unique* effects of each variable over and above the others. For example, if we were to expand Figure 21.1 to include three mediators, equation 21.5 examining the effect of the single predictor on the single outcome would remain unchanged, producing a single estimate of the total effect c. The X to M associations examined with equation 21.6 would require three separate regression equations, each predicting a single mediator from the predictor X, producing three unique a coefficients, a_1, a_2, and a_3. Equation 21.7 would need to include all three mediators simultaneously along with the predictor to produce three unique b coefficients b_1, b_2, and b_3 and a single estimate of the direct effect c'. The $c - c'$ point estimate of mediation in this case represents the total mediated effect and the a_1b_1, a_2b_2, and a_3b_3 point estimates represent specific mediated effects unique to each of the three mediators.

A set of cross sectional mediation analyses was conducted in the ECLS-K data. These analyses tested whether the effect of ADHD symptoms on depression was mediated by academic performance and interpersonal skill at the initial kindergarten fall assessment. Specifically, teacher ratings of approaches to learning and externalizing behavior were treated as initial predictor variables, theta scores on math and reading and teacher ratings of interpersonal skill served as mediators, and teacher ratings of internalizing behavior were the outcome. Regression equations similar to those in equations 21.5 to 21.7 were first fitted to each predictor–mediator pair separately, then all predictors and mediators were entered simultaneously into a multiple mediator model. The results of these analyses are summarized in Table 21.2.

The third and fourth columns of Table 21.2 present a and b coefficient estimates, with their standard errors below in parentheses. The results of these analyses show that both approaches to learning and externalizing behaviors significantly predict each of the three mediators, and each of the three mediators significantly affects the internalizing

outcome. The *ab* point estimates and the Sobel standard errors of each mediated effect appear in the fifth column of the table. When examined in separate analyses, each of these mediated effects is significant. In this particular case, the bootstrap 99% confidence intervals in the sixth column of the table are very close to those that would be computed using the normal theory and Sobel standard error provided in the previous column. The fact that zero is not included in any of these confidence intervals indicates significance at $p < .01$ and corresponds to the *z* test results.

The remaining columns of the table present the results of a multiple predictor–multiple mediator analysis in which all predictors and mediators were analyzed simultaneously. A path diagram for this particular model is shown in Figure 21.2. The two initial predictor variables, approaches to learning and externalizing behavior, are highly negatively correlated ($r = –.50$, $p < .0001$). The two academic mediators are strongly positively correlated (.77, $p < .0001$), and these two measures are moderately positively correlated with interpersonal skill (.27 for math and .25 for reading, both *p*s < .0001). The *a* path estimates representing the unique effects of each of these predictors (over and above the others) on each of the three mediators appear in column 7 of Table 21.2, and all six of these remain significant, though the effects of externalizing behavior seem somewhat attenuated (when compared with the separate analyses reported in column 3 in the table), and the effects of externalizing on reading and math have, in fact, changed sign. The *b* path estimates representing unique effects of a particular mediator are provided in column 8. When all variables are in the model simultaneously, the path representing the unique effect of reading on internalizing is not significant (over and above the effects of math, interpersonal skill, approaches to learning, and externalizing behavior). The *b* paths from interpersonal skill and math to internalizing have also reversed sign in the analyses that simultaneously include the externalizing predictor. The *z* tests of point estimates of the mediated effects in column 9 and the bootstrap confidence intervals in column 10 indicate that the effects of approaches to learning and externalizing behavior on internalizing behavior are significantly—and uniquely—mediated by math and interpersonal skill but not reading.

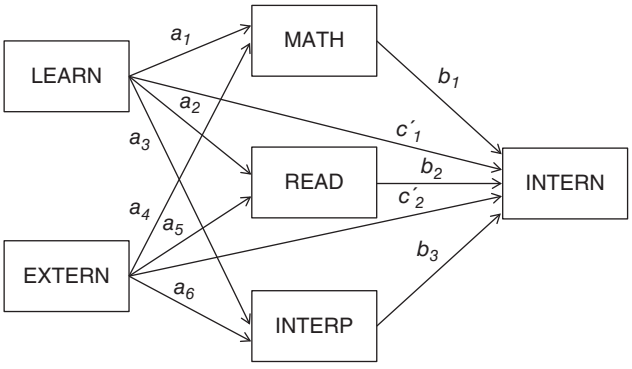

Figure 21.2 Path diagram for the two-predictor, three-mediator in the ECLS-K data.

COMBINING BASIC MEDIATION AND MODERATION

Several researchers have described approaches that combine moderation and mediation into a single framework to examine more complex associations among sets of variables (e.g., Edwards & Lambert, 2007; Fairchild & MacKinnon, 2009; Hayes, 2013; MacKinnon, 2008; Muller, Judd, & Yzerbyt, 2005; Preacher, Rucker, & Hayes, 2007). Such approaches typically consider situations involving both

moderated mediation and mediated moderation. Moderated mediation, or moderation of an indirect effect (Fairchild & MacKinnon, 2009), is moderation of the *ab* estimate of a mediated effect by a fourth variable, *Z*. *Z* could exert its moderating influence on the *a* path from *X* to *M*, on the *b* path from *M* to *Y*, or both (though it should be noted that circumstances exist when moderation of both paths does not necessarily imply moderation of the *ab* product). Mediated moderation, or the mediation of a moderator effect (Fairchild & MacKinnon, 2009), involves an exploration of the mechanism through which an interaction between two predictors *X* and *Z* (i.e., the *XZ* cross-product) exerts its effect on *Y*.

The framework described in Fairchild and MacKinnon (2009) attempts to unify the various proposed approaches by providing a single comprehensive presentation that subsumes the specific differing approaches as special cases. Figure 21.3 presents the path diagram for this combined framework. The regression equations necessary to produce the various path coefficients are straightforward generalizations of each of the three regression equations necessary for a simple mediation analysis. For example, equation 21.5 in which the outcome is regressed on the focal predictor becomes

$$Y = b_0 + c_1 X + c_2 Z + c_3 XZ + e \tag{21.10}$$

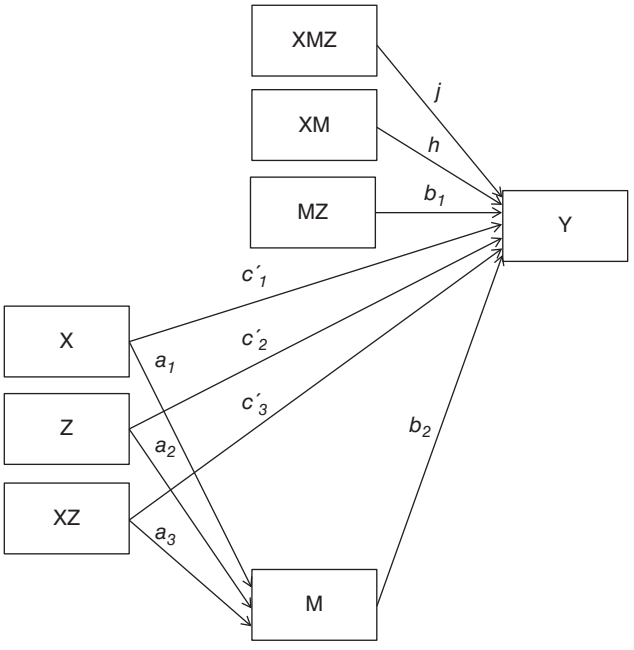

Figure 21.3 Path diagram of the Fairchild and MacKinnon (2009) approach to moderated mediation and mediated moderation.

The *c* coefficients in this equation thus provide total effect analogs for each of two predictors, *X* and *Z*, as well as their interaction *XZ*. The coefficient c_1 is the effect of *X* on *Y* when $Z = 0$, the coefficient c_2 is the effect of *Z* on *Y* when $X = 0$, and the coefficient c_3 is the interaction of *X* and *Z* on the outcome. Typically, all predictor variables in such an analysis would be centered around their means prior to estimation, which would make the c_1 and c_2 coefficients the average effects of *X* and *Z* on the outcome, respectively.

The generalization of equation 21.6 is

$$M = b_0 + a_1 X + a_2 Z + a_3 XZ + e \tag{21.11}$$

This equation provides *a* path coefficient estimates for *X*, *Z*, and their interaction. The coefficient a_1 is the average effect of *X* on the mediator *M*, the coefficient a_2 is the average effect of *Z* on the mediator, and the coefficient a_3 is the interaction of *X* and *Z* on the mediator variable.

The generalization of equation 21.7 is

$$Y = b_0 + c'_1 X + c'_2 Z + c'_3 XZ + b_1 M + b_2 MZ + hXM + jXMZ + e \tag{21.12}$$

The c' coefficients in this equation provides direct effect analogs for *X*, *Z*, and their interaction *XZ*. The coefficients c'_1 and c'_2 are the average direct effects of *X* and *Z* on the outcome, and the coefficient c'_3 is the direct effect of the *XZ* interaction on the outcome. The b_1 coefficient is the average effect of *M* on *Y*, and the remaining paths b_2, *h*, and *j* estimate possible moderation of this effect by *Z*, *X*, and the *XZ* interaction, respectively.

Moderation of an indirect effect, in this framework, would involve the a_3 or b_2 coefficients. Fairchild and MacKinnon (2009) suggested that a joint test of these two coefficients may be acceptable to identify moderated mediation (i.e., mediation is deemed significant if both the *a* and *b* paths are significant). When the moderator is dichotomous, this effect can be more rigorously tested by calculating the *ab* point estimate of the mediated effect within each group and testing the significance of the difference between them using a pooled standard error. Details of this procedure as well as that for a continuous moderator are discussed in Fairchild and MacKinnon (2009). Mediation of a moderator effect could be estimated as the $a_3 b_1$ product.

Table 21.3 presents the results of six analyses examining whether (1) the mediated effects of ADHD symptoms on internalizing behavior through academic performance and

interpersonal skill might be moderated by gender, and (2) the moderation effect of gender on the association between ADHD symptoms and internalizing might be mediated by academic performance and/or interpersonal skill. The a_3 and b_2 coefficients that suggest moderated mediation appear in columns 3 and 4, and the statistical test appears in column 8. The joint test would suggest moderation of the mediated effect by gender for the effect of LEARN on INTERN through READ and the effect of EXTERN on INTERN through INTERP. The test of the difference between the *ab* estimates of mediation for boys and girls indicates that the latter effect is significant at $p < .001$, but the former is only marginally significant. The a_3 and b_1 coefficients that comprise the a_3b_1 estimate of mediated moderation appear in columns 3 and 5 of Table 21.3, and the test of mediated moderation is provided in column 9. These results indicate that the interactive effect of LEARN and GENDER on INTERN is mediated by reading performance, and the interactive effect of EXTERN and GENDER on INTERP is mediated by interpersonal skill.

LONGITUDINAL DATA

The discussion of methods to detect mediation and moderation above are specific to cross sectional data. The introduction of longitudinal data, with repeated measurements of the same variables over time, provides several benefits that may help to elucidate the associations of interest to a researcher. Many of these are discussed in MacKinnon (2008), with attention to how these are relevant to mediated effects in particular. First, longitudinal data provide information about the temporal precedence of the variables involved in the association. This is especially salient when the researcher wishes to establish causal pathways in a mediation model. Causes must precede their effects, and mediation models necessarily involve either implicit or explicit causal claims. In cross sectional data, if the initial predictor is randomly assigned (e.g., randomization to treatment and control groups), then logic dictates that *X* precedes *M* and *Y* in the model. For nonrandomly assigned variables and for the *M* to *Y* relation, however, it is often difficult to establish the ordering of the variables, and thus it is common to acknowledge the possibility of reverse or reciprocal causation in such situations. With repeated measurements of the various constructs in longitudinal data, however, the researcher can explore lagged associations and changes in variables over time. If *X* at Time 1 predicts *M* at Time 2, which in turn predicts *Y* at Time 3, it is more likely that the earlier measures cause the later measures than vice versa (though it is still possible that some third variable causes both the earlier and later measures). Testing moderation does not necessarily involve ordering variables as in a mediation model, but here still it can be useful to explore lagged associations and change over time. If an interaction between two variables at Time 1 predicts an outcome at a later time point or change in the outcome over time, this makes a stronger argument for possible causality than examination of all variables cross sectionally.

A second benefit of the repeated measurement of constructs in longitudinal data is that it allows the researcher to disentangle processes occurring within and between individuals. In cross sectional data, the only differences that can be detected are those between different individuals at the single time point. With two or more observations, however, it is possible to calculate intraindividual change, as well as differences between individuals. It may well be that the predictors of individual change are quite different from the

predictors of differences between individuals, hence disentangling the within-person and between-person effects will provide a more fully accurate model of how real-world processes operate to produce their effects on behavior.

A third benefit of longitudinal data is that having repeated measurements of variables allows the researcher to rule out some possible alternative explanations for the effect of one variable on another. In cross sectional data, it is possible to argue that virtually any association between two variables is, in fact, due to an unmeasured and omitted third variable that affects them both. With longitudinal data, however, a researcher can covary previous measures of an outcome construct when predicting the current measure of that construct. This sort of autoregressive effect essentially removes the influence of any stable person characteristics that might influence the current outcome measure, as each individual serves as his or her own control. While one could still argue that some characteristic of the individual influences both the Time 1 and Time 2 measurement of a construct, it would be difficult to assert that this stable characteristic influences change in the construct over time. However, it is still possible that some time-varying confound provides a reasonable alternative account of a significant effect, so though use of a longitudinal design guards against some kinds of third variable explanations, it is not a universal panacea.

Another benefit of longitudinal data was noted by Gollob and Reichardt (1991), who point out that the effect that one variable has on another may not be instantaneous. It may take some time for certain types of variables to exert their effects, which cross sectional data may not be able to capture. Examining lagged associations in longitudinal data or changes over time may be more illuminating in such cases.

The concepts of stability, stationarity, and equilibrium are helpful in describing longitudinal data, longitudinal relationships, and the models used to examine them. Stability refers to the extent to which some feature of the data stays the same across time. That feature may be a variable mean, a rank ordering of variable values, a trend over time, or a periodic process. Stationarity refers to the extent to which relations between variables stay the same across time. Equilibrium refers to the extent to which the pattern of variances and covariances among variables stays the same over time. Equilibrium is related to both stability and stationarity, but a stable and stationary model is not necessarily at equilibrium (Cole & Maxwell, 2003). A cross sectional model can accurately assess relations among variables only after equilibrium has been reached (Maxwell & Cole, 2007). In longitudinal data, stability can be assessed by measuring the dependency of an observation at a given time point on its value at the previous time point; stationarity can be evaluated by assessing invariance of relations among variables across time points; and some information about equilibrium can be obtained by examining the variance–covariance matrix among the variables across time points (MacKinnon, 2008).

The analysis of longitudinal data requires an analytic framework that can accommodate the unique features of such a data structure, most importantly the dependence that arises from the within-person stability of repeated measurements of an outcome measure assessed at multiple time points. Such dependence violates assumptions regarding independent errors that are necessary for many traditional statistical model techniques (e.g., GLM), resulting in downwardly biased standard errors, inflated test statistics, and inflation of the Type I error rate when such methods are improperly applied to longitudinal data. Two alternative analytic frameworks—multilevel modeling and structural equation modeling—are able to appropriately model the within-person similarity and thus are frequently used to analyze data from developmental studies. Below we briefly discuss these two frameworks, how cross sectional moderation and mediation are incorporated into each, and what types of models are commonly used to analyze longitudinal data with each approach.

MULTILEVEL MODELING

When data are nested or clustered, application of standard regression analysis techniques can be problematic. For example, when individual subjects are nested within groups, it is quite possible that outcome measures for individuals within the same group may be more similar than a random grouping of individuals would be. This similarity could arise from a number of different sources, including shared group experiences (e.g., students within the same elementary school classroom all share the same teacher), interaction among group members (e.g., students within the classroom talk to each other, which might result in more similar attitudes), or nonrandomly distributed background variables (e.g., students within a school may all live in the surrounding neighborhood, which may be relatively homogeneous in terms of socioeconomic status). Such data would have a positive intraclass correlation (ICC). Such within-group similarity (or between-group mean differences) would not be modeled within a single-level regression analysis, resulting in downwardly biased standard errors and overly large

test statistics, ultimately increasing the probability of making a Type I error (alpha inflation) and concluding that a significant effect exists more often than warranted (Barcikowski, 1981). Multilevel models—also known as mixed models (Laird & Ware, 1982), random coefficient models (Longford, 1993), or hierarchical linear models (Raudenbush & Bryk, 2002)—are explicitly designed to accommodate such nested data structures.

A multilevel model can be conceptualized as a series of models at the various levels of the data. For students nested within schools, the lower level (L1) model for students would be specified as

$$\text{L1:} \qquad Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + r_{ij} \tag{21.13}$$

where Y_{ij}, X_{ij}, and r_{ij} are the outcome score, predictor score, and residual, respectively, for individual i within school j. β_{0j} and β_{1j} are intercept and slope values for school j. Thus, one can think of this part of the model as a series of regressions within each of the j groups.

Each of the coefficients of the L1 model is treated as a criterion measure in higher or upper level (L2) models. In the students within schools example, these would be specified at the school level:

$$\begin{aligned} \text{L2:} \qquad \beta_{0j} &= \gamma_{00} + u_{0j} \\ \beta_{1j} &= \gamma_{10} + u_{1j} \end{aligned} \tag{21.14}$$

The β_{0j} intercept for school j is a function of the overall intercept for the sample (γ_{00}) plus a group-specific deviation u_{0j}. Similarly the β_{1j} slope of Y on X is a function of the overall slope for the sample (γ_{10}) plus a group specific deviation u_{1j}. Including error terms at both L1 (r_{ij}) and L2 (the u's) appropriately models the within-group similarity, thus providing accurate tests of significance of predictor effects.

The multiple equations at L1 and L2 may be algebraically combined into a single equation:

$$Y_{ij} = \gamma_{00} + \gamma_{10}X_{ij} + u_{0j} + u_{1j}X_{ij} + e_{ij} \tag{21.15}$$

The single-equation form of the model is typically estimated using an iterative procedure that alternates between generalized least squares estimates of fixed effects (γ_{00} and γ_{10}) and maximum likelihood estimates of the variance components. The L2 u error terms are assumed to be distributed $\sim \boldsymbol{N}(\mathbf{0}, \boldsymbol{\tau})$, and thus the variance components include τ_{00} (the variance of u_{0j}), τ_{11} (the variance of u_{1j}), τ_{01} (the covariance between u_{0j} and u_{1j}), as well as σ^2 (the variance of r_{ij}). Estimating the combined equation rather than performing the two-step procedure implied by the multiple equation form (known as slopes and intercepts-as-outcomes; see Burstein & Miller, 1980) allows for more appropriate weighting of large versus small groups in the analysis and permits estimation even when some groups are rank deficient (i.e., when some groups contain too few individuals to run the within-group regression analysis). This particular analysis, also known as a random coefficient regression model (Raudenbush & Bryk, 2002), essentially describes the distribution of intercepts and slopes across groups, estimating an average intercept γ_{00}, the variability of intercepts τ_{00}, an average slope γ_{10}, and the variability of slopes τ_{11}. These averages are not the simple arithmetic averages that one could obtain from the two-step procedure but rather an Empirical Bayesian weighting that shrinks less reliable estimates (i.e., those from smaller groups) toward common group estimates to obtain a more representative measure of central tendency.

Another common application of multilevel modeling involves repeated measures data where the same constructs are assessed on multiple occasions for a set of individuals. In this scenario, L1 is the repeated measures (within-person) level, and L2 is the individual (between-person) level. The multiple outcome measurements provided by a given individual are more likely to be similar than a random grouping of measurements, and thus we would expect a positive ICC value. When the repeated measurements are considered simple replications and no systematic trend across time is expected, the multilevel framework discussed above can be readily adapted. Such analyses are common, for example, in daily diary studies (see Bolger & Laurenceau, 2013) where days are nested within individuals. Often no trends are necessarily expected across the relatively brief spans of such studies; the multiple days are included simply to obtain many measures of predictor and outcome variables and to allow the researcher to distinguish between within- and between-person effects.

The data for a multilevel analysis of repeated measures is typically organized as a long file with one observation for each of the assessments. The multiple-equation form of the model would be

$$\begin{aligned} \text{L1:} \qquad Y_{ti} &= \pi_{0i} + \pi_{1i}X_{ti} + e_{ti} \\ \text{L2:} \qquad \pi_{0i} &= \beta_{00} + r_{0i} \\ \pi_{1i} &= \beta_{10} + r_{1i} \end{aligned} \tag{21.16}$$

One might think of the first equation as a regression across timepoints t for each individual i, providing individual-specific intercept and slope coefficients that serve as outcomes in the individual-level L2 equations.

The single-equation form of the model is

$$Y_{ti} = \beta_{00} + \beta_{10}X_{ti} + r_{0i} + r_{1i}X_{ti} + e_{ti} \tag{21.17}$$

This model provides estimates of the overall expected value of the outcome measure when the X predictor is equal to zero (β_{00}), the variance in this value across individuals ($\tau_{00} = \text{var}(r_{0i})$) the overall association between X and Y (β_{10}), the variance in this association across individuals ($\tau_{11} = \text{var}(r_{1i})$), as well as the residual variance among time points within an individual ($\sigma^2 = \text{var}(e_{ij})$).

Moderation in Multilevel Models

The aforementioned multilevel equations could be expanded to accommodate a higher level predictor of both intercepts and slopes. This would be a group-level predictor in the scenario with individuals nested within groups and an individual-level predictor in the repeated measures scenario. Going forward with the repeated measures case, the lower level equation would remain unchanged:

$$\text{L1:} \qquad Y_{ti} = \pi_{0i} + \pi_{1i}X_{ti} + e_{ti} \tag{21.18}$$

and each of the L2 equations would be expanded to incorporate the individual-level predictor:

$$\begin{aligned} \text{L2:} \qquad \pi_{0\text{i}} &= \beta_{00} + \beta_{01}W_i + r_{0i} \\ \pi_{1i} &= \beta_{10} + \beta_{11}W_i + r_{1i} \end{aligned} \tag{21.19}$$

The single-equation form of the model becomes

$$Y_{ti} = \beta_{00} + \beta_{01}W_i + \beta_{10}X_{ti} + \beta_{11}W_iX_{ti} + r_{0i} + r_{1i}X_{ti} + e_{ti} \tag{21.20}$$

This model estimates four fixed effects. The β_{00} estimate is the expected value of the outcome when both the L1 and L2 predictors are equal to 0. The β_{01} estimate is the effect of the individual-level predictor W on the outcome when the repeated measures predictor X is equal to 0 (i.e., the simple effect of W). The β_{10} estimate is the overall effect of the repeated measures predictor X on the outcome when the individual-level predictor W is equal to 0 (i.e., the simple effect of X). The β_{11} estimate is the cross-level interaction between the repeated measures predictor X and the individual level predictor W. Thus this estimate represents (1) the extent to which the association between X and Y changes for each unit increase in W, and/or (2) the extent to which the association between W and Y changes for each unit increase in X. Cross-level interactions are not entirely unique to multilevel models, but they arise most naturally within the multiple equation form within this framework. The t test of the β coefficient associated with the cross-product (i.e., β_{11}) is thus often an appropriate test of moderation when predictor and moderator variables are assessed at different levels of a hierarchical data structure.

In addition to cross-level interactions, multilevel models can accommodate single-level interactions at either the lower or the higher level of the data structure. The techniques involved are essentially identical to the cross-product methods used in single-level regression models. Moderation of the effect of a repeated measures variable by another repeated measures variable would require expanding the L1 equation to include the second variable and the L1 cross-product vector:

$$\text{L1:} \quad Y_{ti} = \pi_{0i} + \pi_{1i}X_{ti} + \pi_{2i}Z_{ti} + \pi_{3i}X_{ti}Z_{ti} + e_{ti} \tag{21.21}$$

and additional L2 equations would need to be specified for the two new L1 coefficients:

$$\begin{aligned} \text{L2:} \qquad \pi_{2i} &= \beta_{20} + r_{2j} \\ \pi_{3i} &= \beta_{30} + r_{3j} \end{aligned} \tag{21.22}$$

The β_{20} coefficient represents the simple effect of the Z predictor when X equals 0, and the test of the β_{30} coefficient tests the overall moderated effect. Note that if an L2 predictor was added to the L3 equation for π_{3i}, the associated coefficient would represent the three-way interaction among L1 X, L1 Z, and the L2 predictor. The fact that this is a three-way interaction would be apparent in the single-equation form of the model.

Single-level moderation at L2 would involve expanding (at least) the first of the L2 equations (which predicts the L1 intercept) to include the second individual-level predictor and the cross-product vector:

$$\text{L2:} \quad \pi_{0i} = \beta_{00} + \beta_{01}W_i + \beta_{02}Z_i + \beta_{03}W_iZ_i + r_{0i} \tag{21.23}$$

The β_{02} coefficient represents the simple effect of Z when W equals 0, and the test of the β_{03} coefficient tests the moderated effect. Note that if the individual-level Z predictor and the WZ cross-product are added to other L2 equations

(which predict L1 slope coefficients associated with particular L1 variables) the associated coefficients would represent three-way interactions among L2 *W*, L2 *Z*, and the particular L1 variable whose L1 parameter estimate serves as the outcome for the L2 equation. Calculation, testing, and plotting simple slopes for interactions in multilevel models is carried out in exactly the same way as in single-level regression models.

The issue of centering, which features prominently in discussions of interactions within the single-level regression framework, is no less important when considering multilevel models. Centering serves the same two purposes, providing meaningful interpretations of lower order coefficients and increasing the stability of model estimation. In fact, the latter probably provides greater benefit in multilevel models than in single-level regression analyses, as estimation is much more difficult in the multilevel case. When considering an interaction between two L2 predictor variables, centering is essentially carried out just as in single-level regression: subtracting the mean of each L2 predictor from each observation of that predictor and creating the cross-product from these centered variables reduces nonessential collinearity and allows interpretation of lower order effects of one variable at the mean of the other. One slight wrinkle does emerge: the analyst must decide whether to calculate the mean of the L2 variable to use in the centering as a simple unweighted function, counting each L2 score equally, or as a weighted function which adjusts for the number of L1 units within each L2 unit (i.e., individuals within groups or observations within individuals). Of course, there will be no difference between the two when the number of L1 units per L2 unit is identical across all groups/individuals.

When one or both of the variables involved in the interaction is at L1, however, centering becomes a slightly more complex issue. Consider first the situation with individuals nested within groups. Kreft, de Leeuw, and Aiken (1995) discussed two possible means to use in centering L1 predictors. Centering around the grand mean (CGM) simply involves subtracting the single grand mean value of the L1 predictor from each predictor observation. Centering within contexts (CWC) involves subtracting the mean of each group from the predictor observations within each group. Thus while GGM is a simple linear transformation of the raw variable score, CWC is not. Both provide meaningful (though different) zero points at which to interpret lower order coefficients, and both confer some computational advantage, though this is typically greater for CWC, which orthogonalizes effects at L1 and L2. Additional discussion of centering issues for multilevel models with individuals nested within groups can be found in Hofmann and Gavin (1998) and Enders and Tofighi (2007). Repeated measurements of time-varying predictors can be centered with CGM or CWC analogs that subtract the mean value of the L1 predictor for the entire sample or a person-specific mean from each observed score. Hoffman and Stawski (2009) explain how such centered L1 variables can be entered into multilevel models that simultaneously include the means as L2 predictors to disentangle between-person and within-person effects in repeated measures data.

Mediation in Multilevel Models

Mediation in multilevel models is tested in essentially the same matter as for single-level regression models. Each of the three regression models necessary for producing the coefficients for a mediation analysis may be recast as a multilevel model, including an L2 intercept error term to appropriately model clustering of individuals within groups or repeated measures within individuals. Details are provided in Krull and MacKinnon (1999, 2001). The multiple equation forms of such models would differ depending on the level of measurement of *X* and *M*. Krull and MacKinnon (2001) adopted a model naming convention related to the sequential ordering of variables in a mediation model, where $X \rightarrow M \rightarrow Y$. In a $1 \rightarrow 1 \rightarrow 1$ model, the *X*, *M*, and *Y* variables would each be measured at the lower level of the data hierarchy. So the initial variable, the mediator, and the outcome variable would all be characteristics of individuals in multilevel data with individuals nested within groups or time-varying characteristics measured on multiple occasions over a period of time in multilevel data with repeated measures nested within individuals. In a $2 \rightarrow 1 \rightarrow 1$ model the initial predictor would be a L2 variable, while the mediator and outcome would be L1 constructs. In a $2 \rightarrow 2 \rightarrow 1$ model, both the initial predictor and mediator are measured at L2, while the outcome is at L1. Models including a link from a lower level to a higher level are not estimable within a multilevel modeling framework, but these could potentially be handled within a multilevel structural equation model (Preacher, Zyphur, & Zhang, 2010).

Fitting a $2 \rightarrow 2 \rightarrow 1$ mediation model would involve running a regression model on L2 data to obtain an estimate of the *a* path linking predictor to mediator and a multilevel model of the form

$$\begin{aligned} \text{L1:} \quad & Y_{ij} = \beta_{0j} + e_{ij} \\ \text{L2:} \quad & \beta_{0j} = \gamma_{00} + c' X_j + b M_j + u_{0j} \end{aligned} \tag{21.24}$$

to obtain an estimate of the *b* coefficient. These would be multiplied to produce the *ab* estimate of the mediated effect, and this can be tested using the Sobel standard error described earlier for single-level mediation models or more precisely by developing bootstrap confidence intervals (Pituch, Stapleton, & Kang, 2006).

For a $2 \rightarrow 1 \rightarrow 1$ model, the multilevel model equations for obtaining the *a* path are

$$\begin{aligned} &\text{L1:} \quad \mathrm{M}_{ij} = \beta_{0j} + e_{ij} \\ &\text{L2:} \quad \beta_{0j} = \gamma_{00} + \mathrm{a}X_j + u_{0j} \end{aligned} \tag{21.25}$$

And the equations for the *b* path are

$$\begin{aligned} &\text{L1:} \quad \mathrm{Y}_{ij} = \beta_{0j} + \beta_{1j}M_{ij} + e_{ij} \\ &\text{L2:} \quad \beta_{0j} = \gamma_{00} + c\prime X_j + u_{0j} \\ &\qquad\quad \beta_{1j} = b \end{aligned} \tag{21.26}$$

Note the similarity in form for the *b* path in the $2 \rightarrow 2 \rightarrow 1$ model and the *a* path in the $2 \rightarrow 1 \rightarrow 1$ model, both of which involve $2 \rightarrow 1$ links.

For a $1 \rightarrow 1 \rightarrow 1$ model, the multilevel equations for the *a* path are

$$\begin{aligned} &\text{L1:} \quad \mathrm{Y}_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + e_{ij} \\ &\text{L2:} \quad \beta_{0j} = \gamma_{00} + u_{0j} \\ &\qquad\quad \beta_{1j} = a \end{aligned} \tag{21.27}$$

And the multilevel equations for the *b* path are

$$\begin{aligned} &\text{L1:} \quad \mathrm{Y}_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + \beta_{2j}M_{ij} + e_{ij} \\ &\text{L2:} \quad \beta_{0j} = \gamma_{00} + u_{0j} \\ &\qquad\quad \beta_{2j} = b \end{aligned} \tag{21.28}$$

Again, note the similarity between the multilevel equations for these paths and those for the *b* path in the $2 \rightarrow 1 \rightarrow 1$ model, which also involves a $1 \rightarrow 1$ link. Equations for producing *c* path estimates are not provided here but can be found in Krull and MacKinnon (2001).

Two complications arise when working with multilevel rather than single-level equations for estimating the various paths in a mediation model. The first is that the two alternate point estimates of the mediated effect, *ab* and $c - c'$, are generally not identical in the multilevel case. The reasons for this are discussed in Krull and MacKinnon (1999). The differences are usually quite small and become smaller with increasing sample size. The second complication is unique to the $1 \rightarrow 1 \rightarrow 1$ model. The previously specified equations allow for random intercepts to accommodate within group similarity, but slopes of all other L1 coefficients are specified as fixed. It may, in fact, be that the effects of the initial predictor on the mediator (i.e., the *a* path) or the effect of the mediator on the outcome (i.e., the *b* path) vary across L2 units. This would mean that different groups have different *a* and/or *b* paths in multilevel data with individuals nested within groups or that different individuals have different *a* and/or *b* paths in multilevel data with repeated measures nested within individuals. To appropriately model such data, it will be necessary to include random errors on the L2 equations predicting the L1 slope coefficients.

If it should be the case that both the *a* path and the *b* path in a $1 \rightarrow 1 \rightarrow 1$ model randomly vary across L2 units, it is possible that these *a* and *b* coefficients might covary. In this case, the point estimate of the mediated effects is not equal to *ab* but rather

$$Med = ab + \sigma_{ab} \tag{21.29}$$

which involves the covariance between the *a* and *b* estimates (Kenny, Korchmaros, & Bolger, 2003). Moreover, the approximate standard error is not equal to equation 21.8 but rather

$$s_{Med} = \sqrt{b^2\sigma_a^2 + a^2\sigma_b^2 + \sigma_a^2\sigma_b^2 + 2ab\sigma_{ab} + \sigma_{ab}^2} \tag{21.30}$$

which involves the covariance between the *a* and *b* estimates as well as the sampling variance of the covariance estimate (Kenny et al., 2003).

Finding an estimate of the covariance between the *a* and *b* estimates is challenging because these are typically produced in two completely separate analyses. Bauer, Preacher, and Gil (2006) presented a method that fits both the *a* and *b* paths in a single analysis, which allows the covariance and its corresponding sampling variance to be estimated. Their approach involves stacking the data so that each L1 unit has two observations with identical predictors and creating a generic outcome variable. The outcome variable is set equal to the *M* variable on the first observation for each L1 unit, and the outcome variable is set equal to the *Y* variable on the second observation. Then two selection variables (S_m and S_y) are created to distinguish between the first ($S_m = 1,\ S_y = 0$) and second

($S_m = 0,\ S_y = 1$) observations for each case. A multilevel model with a L1 equation of the form:

$$\begin{aligned} \text{L1: } Z_{ti} &= S_{mti}(1 + a_i X_{ti}) + S_{yti}(1 + b_i M_{ti} + c_i' X_{ti}) + e_{Zti} \\ &= S_{mti} + a_i S_{mti} X_{ti} + S_{yti} + b_i S_{yti} M_{ti} \\ &\quad + c_{ti}' S_{yti} X_{ti} + e_{Zti} \end{aligned} \tag{21.31}$$

is then fit to the stacked data, and each of the five L1 coefficients is allowed to vary randomly at L2. This model essentially fits multilevel models for the *a* path and the *b* and *c*′ paths simultaneously. To model the error variance appropriately, it will be necessary to allow the estimation of two separate values, corresponding to the observations with different values on one of the two indicator variables. Further details on how to implement the Bauer et al. (2006) method in a number of statistical software programs can be obtained from the website of the article's first author. More information on implementation of the model in the Mplus programming language is also available (MacKinnon, 2008; Preacher et al., 2010). The multilevel mediation model is summarized in MacKinnon and Valente (2014) and a Bayesian formulation for the multilevel mediation model is in Yuan and MacKinnon (2009).

MULTILEVEL MODELING APPROACHES FOR LONGITUDINAL DATA

The dominant multilevel model for the analysis of longitudinal data is the multilevel growth model (Hox, 2010; Raubenbush & Bryk, 2002; Singer & Willett, 2003). Growth in this sense refers to any sort of change over time, including increasing values, decreasing values, or trends that change direction. For longitudinal data that involve an intervention delivered at a particular point in time, an exponential decay model might provide a useful alternative that is especially well-suited for examining the change that follows the delivery of the intervention. Both approaches are discussed in detail below.

Multilevel Growth Modeling

A multilevel growth model is very similar to the two-level model for repeated measurements nested within individuals shown in equations 21.16 and 21.17. The primary difference is that the growth model includes at least one variable representing time at L1. If a single time variable is linearly coded and no covariates are included in the model, the multiple equation specification for the model would be

$$\begin{aligned} \text{L1:} \quad & Y_{ti} = \pi_{0i} + \pi_{1i} time_{ti} + e_{ti} \\ \text{L2:} \quad & \pi_{0i} = \beta_{00} + r_{0i} \\ & \pi_{1i} = \beta_{10} + r_{1i} \end{aligned} \tag{21.32}$$

where $time_{ti}$ is the time relevant variable. Each individual-specific growth parameter π is a function of the overall estimate of the growth parameter β in the sample and individual specific deviation r from that value. The single-equation form of the model is

$$Y_{ti} = \beta_{00} + \beta_{10} time_{ti} + r_{0i} + r_{1i} time_{ti} + e_{ti} \tag{21.33}$$

β_{00} estimates is the overall intercept, which is the expected value of the outcome variable when time is at its zero point. β_{10} estimates the overall linear slope estimate. The τ matrix contains the variances and covariances of the L2 errors *r*, and thus τ_{00} is the variance of individual-specific intercepts, τ_{11} is the variance of individual-specific slopes, and τ_{01} is the covariance between them. This particular parameter estimate is more often interpreted in growth models than in other multilevel models that do not involve time, because it can indicate whether individuals are becoming more similar (compensatory growth) or different (fan-spread growth) in their outcome variable scores.

More complex forms of growth can be modeled by adding additional variables coding time information to the L1 model. For example, higher order polynomial trends can be fitted by adding powered functions of the linear time variable. Piecewise models can also be fitted by adding additional coded vectors to produce models that estimate either (1) the slopes of the different time segments, or (2) one slope and the difference between slopes (Raudenbush & Bryk, 2002). Both individual and time-varying covariates can be added to the model. Individual covariates are added to the L2 specification as predictors of intercepts and/or slopes. For example, a gender variable could be added to the L2 equations in 21.32 to test whether intercepts and slopes of the outcome variable differed for males and females. A time-varying covariate could be added to the L1 specification either to adjust for its effect when estimating growth or to examine its effect over and above growth. A decision would need to be made about whether the effect of this variable would vary across individuals (in which case the L2 equation associated with this variable

would include an r error term) or would be assumed fixed (no L2 error term).

Most information relevant to multilevel models in general applies equally to multilevel growth models, with just a couple of notable exceptions. First, the time variable in a growth model is typically "centered" on a meaningful value—often the initial time point of the study—rather than on the mean per se. Centering time at its mean would simply put the zero point in the middle of the study period, which may not be the most substantively meaningful point at which to evaluate effects. Second, typical independence and homoscedasticity assumptions about L1 errors may not be realistic in longitudinal data. L1 error variances may increase or decrease over time, and values measured at later time points may depend on previous values measured at earlier time points. Most multilevel modeling software includes options for specifying heteroscedastic and autoregressive error structures that might be better suited for growth models.

Multilevel Exponential Decay Model

In considering models for longitudinal data, a primary issue is the shape of the trajectory across time. As discussed by Fritz (2014), often when researchers encounter data that exhibit any nonlinearity, a quadratic growth model is chosen without regard for the implications to the underlying variables or theory. For longitudinal psychological data, especially following an intervention or treatment, Fritz suggests that an exponential decay model has several advantages over a quadratic model. First, the exponential decay function is more realistic for many variables in psychology because it approaches an asymptote. One can imagine many scenarios where an individual is given a treatment, causing a change in the individual's underlying construct, which slowly returns to the individual's pretreatment level over time. At the same time, the individuals in the control group remain unchanged, a scenario illustrated in Figure 21.4. If the treatment had a lasting effect on the individual, the individual's score would still likely decrease across time, but not back to his or her pretreatment level (i.e., the construct would asymptote at a different value than the pretreatment level). While a quadratic growth model can approximate the exponential decay present in the figure, a quadratic function at some point must reach a minimum and then begin to grow towards infinity, an unlikely scenario given most variables in psychology. For this reason, many researchers have already used an exponential decay function (e.g., Blozis, 2004, 2007; Blozis, Conger, & Harring, 2007; Browne, 1993; Cudeck, 1996).

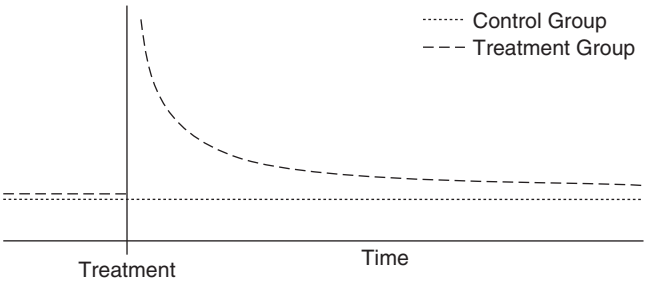

Figure 21.4 Illustration of a treatment group decaying exponentially across time while the control group remains constant.

Another reason for choosing an exponential decay model is that exponential decay is a parsimonious function requiring the estimation of three parameters:

$$Y_i = \beta_2 + (\beta_0 - \beta_2)\exp[\beta_1 t] + r_i \tag{21.34}$$

where t is time, β_0 is the initial state value at $t = 0$, β_2 is the asymptote value as time goes to infinity, and β_1 is the rate of change value, which is constrained to be less than zero to ensure that the asymptote exists (Pinheiro & Bates, 2000). While a quadratic model also contains three parameters, the interpretations of the coefficients from the exponential decay model are likely to be more useful to a researcher than those from a quadratic model.

Analyzing longitudinal data using an exponential decay model requires the use of a nonlinear multilevel model. Using notation from Raudenbush and Bryk (2002; see also Davidian & Giltinan, 1995), the exponential decay model is

$$\begin{aligned}
\text{L1:} \quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i} t] + r_{ti} \\
\text{L2:} \quad & \beta_{0i} = \gamma_{00} + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + u_{2i}
\end{aligned} \tag{21.35}$$

where $time_i$, β_{0i}, β_{1i}, and β_{2i} have the same interpretation as in equation 21.34, r_{ti} are the Level 1 residuals, and the u_{ji}'s are random effects distributed $\sim \boldsymbol{N}(\mathbf{0}, \boldsymbol{\tau})$. As in linear multilevel models, time-varying predictors can be added at L1, while time-invariant predictors are added at L2. The inclusion of L2 predictors may be especially interesting for exponential decay because they test whether variance in the initial value, rate of change, and asymptote values can be predicted by another variable. Two of the most widely used software packages for estimating nonlinear multilevel

models in the social sciences are NLME (R Development Core Team, 2013) and SAS PROC NLMIXED (SAS Institute, 2014), although many other statistical packages for linear multilevel models also allow the estimation of nonlinear multilevel models.

STRUCTURAL EQUATION MODELING

Structural equation modeling is a multivariate analytic technique for exploring patterns of association among variables. A typical structural equation model (SEM) has two components: (1) a measurement model that specifies how observed indicator variables are related to unobserved latent constructs; and (2) a structural model that specifies how the various observed and latent variables are related to one another. Structural equation modeling employs a matrix representation to specify a number of simultaneous equations that denote the associations among observed and latent variables, and the model can be fitted using estimation methods that maximize the fit between the observed covariance matrix of the variables and the covariance matrix implied by the model. In depth treatment of this topic can be found in a number of texts, including Bollen (1989) and Kline (2011).

Diagrams are often used to depict the variables and relations specified in an SEM. By convention, observed variables are typically represented as squares or rectangles, and latent variables are typically represented as circles or ovals. Single-headed arrows represent directional causal relations between variables and double-headed arrows represent nondirectional correlational associations. The estimates produced in an SEM typically include factor loadings relating observed indicators to latent factors, path coefficients relating variables and factors to one another, variances and covariances of errors/disturbance terms. It is also possible to estimate means of latent variables, although these parameters are not typically part of standard SEM estimation. Mean structure can be indicated in SEM diagrams by arrows from a triangle representing a constant value of 1, though often such effects are not noted in the diagrams. In addition to parameter estimates, SEM programs provide a number of absolute and relative fit indices that allow researchers to examine how well the proposed model fits the data. These include a chi-square test of overall model fit, the root mean square error of approximation (RMSEA; Steiger, 1990), and the comparative fit index (CFI; Bentler, 1990). Particular aspects of the model can be tested by examining the size of the estimated coefficients relative to their standard errors or by comparing the fit of a series of models in which specific parameters, originally freely estimated, are systematically constrained.

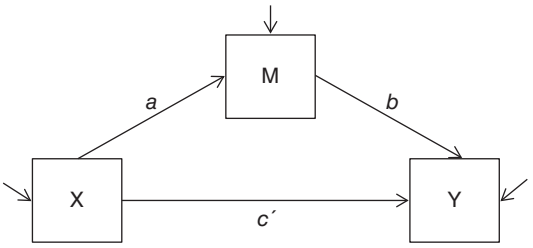

Figure 21.5 SEM mediation model for manifest *X*, *M*, and *Y* variables.

Mediation in SEM

Specification and estimation of mediation in SEM is straightforward. Figure 21.5 depicts a simple SEM for a single mediator model. All three variables in this model are observed, and thus this particular SEM is a simple path analysis and does not include a measurement model. Fitting the model produces estimates of the *a* and *b* path coefficients and their standard errors. These can be used to test mediation in much the same way as with regression analysis. Some SEM programs offer specific options for testing mediated (or indirect) effects, using either delta standard error method tests or bootstrapping methods.

If variables are measured with multiple indicators, SEM can be used to examine mediation among the underlying latent constructs. A measurement model can be specified to define the initial, mediator, and outcome factors from their various observed indicator variables (as shown in Figure 21.6), and the structural model specifies the appropriate paths between the latent constructs to test the mediated effect. The latent constructs are theoretically error-free, and the path coefficients will not suffer from the attenuation that occurs in estimated associations between observed measurements. Thus the mediated effects among latent constructs should be stronger and more easily detected than mediation among observed variables.

Moderation in SEM

There are a number of different approaches for examining moderation within an SEM. If the moderating variable is observed and categorical, the typical method involves fitting a multiple group model (Jöreskog, 1971). Such a model essentially fits a separate SEM within each level of the categorical moderator. For example, to examine

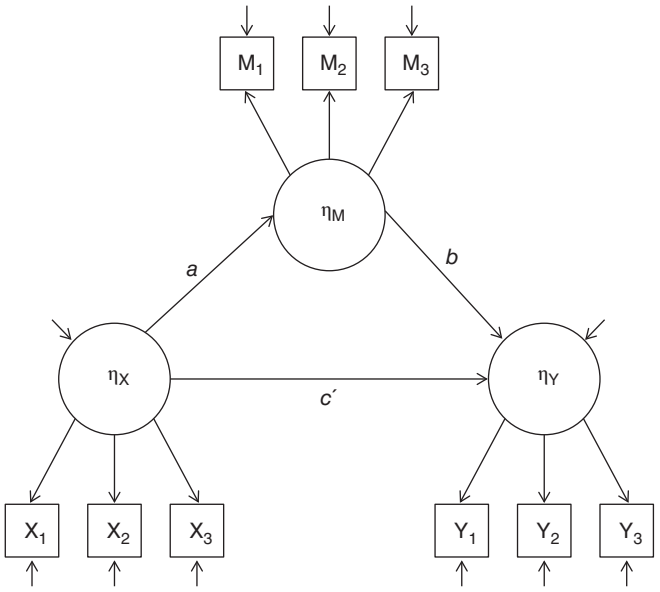

Figure 21.6 Mediation model with latent *X, M*, and *Y* variables.

whether the association between impulsive/hyperactive symptoms and interpersonal skill is moderated by gender, an SEM that allows different coefficients for the EXTERN → INTERP path would be fitted. The chi-square value for this model would be compared with that from a nested model that constrained the coefficients in the two groups to be equal. A significant chi-square difference would indicate that model fit improves when the two coefficients differ, supporting the hypothesis that the association is moderated by gender.

If the two variables involved in the moderated effect are observed, but neither is categorical, a multiplicative cross-product variable can be created and entered as an additional observed variable in the SEM. This cross-product variable then (1) is allowed to covary with the two component variables from which it was produced, and (2) predicts the outcome variable as shown in Figure 21.7. A significant path coefficient from the cross-product variable to the outcome measure would indicate moderation.

A moderated effect involving latent variables is somewhat more difficult to model. The most common approach to representing a latent variable interaction involves specifying an additional latent variable—essentially the cross-product of the two latent variables of interest—with cross-products of the original variable indicators serving as indicators of the interaction construct. This latent cross-product variable represents the interactive effect on the outcome measure when fitted with the two original latent variables simultaneously in the model. Specification

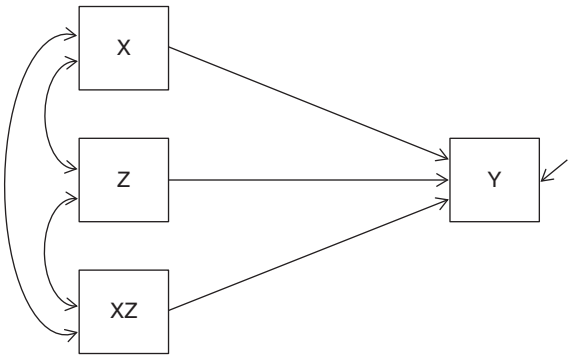

Figure 21.7 An SEM with an interaction between manifest variables.

and fitting of this model can be difficult, as it may involve complex nonlinear constraints, include many highly correlated variables, and violate normality assumptions. A number of different methods have been proposed to address these issues, but no clear consensus as to the best method for analyzing latent variable interactions has emerged. The various issues and proposed solutions are summarized in Kline (2011, Ch. 12).

STRUCTURAL EQUATION MODELS FOR LONGITUDINAL DATA

When longitudinal data are to be used in an SEM, the data set is typically organized in wide format (as opposed to the long format necessary for multilevel modeling), with one line of data per individual subject and multiple uniquely named variables representing the repeated measures of each construct. A number of different types of SEMs can be used to model longitudinal data, including autoregressive panel models, latent growth models, and latent change models. It is also possible to fit an exponential decay model within the SEM framework.

Autoregressive Model

In an autoregressive panel model (Duncan, 1969; Humphreys, 1960; Jöreskog, 1979; Wiley & Wiley, 1970), a measure of a given construct at a particular time point is presumed to be a function of value of that construct at the previous time point. The top series in Figure 21.8 illustrates an autoregressive model for an X variable, and the lower series illustrates a similar model for a Y variable. The arrows from time t to $t + 1$ within each series (i.e., X_1 to X_2 and X_2 to X_3; Y_1 to Y_2 and Y_2 to Y_3) are the autoregressive coefficients representing stability

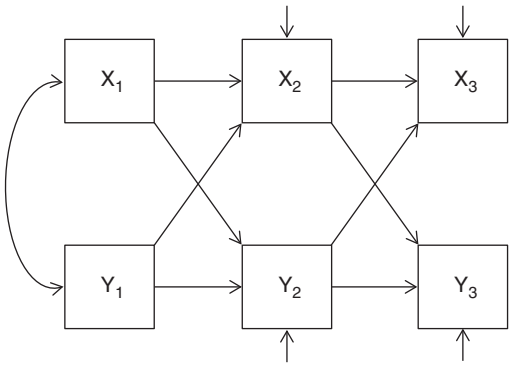

Figure 21.8 Autoregressive model with cross-lagged paths.

over time. Such models can be estimated with a series of OLS regression models or in a single simultaneous SEM. Autoregressive models for particular variables can be combined to form more complex models. For example, Figure 21.8 includes two types of cross-lagged paths: (1) paths from earlier measures of *X* to later measures of *Y*, and (2) paths from earlier measures of *Y* to later measures of *X*. Testing such a cross-lagged model—usually by fitting a series of SEMs that constrain particular sets of paths to be equal to zero or equal to each other (see Martens & Haase, 2006)—can allow a researcher to determine whether one set of effects leads the other or if there is reciprocal causality between the two constructs.

Latent Growth Curve Model

Another common SEM for longitudinal data is the latent growth curve (LGC) model (Duncan, Duncan, & Strycker, 2006). In such a model, multiple measurements of a given construct over time serve as indicator variables for latent growth factors. While typical SEM measurement models estimate the factor loadings that relate the latent variable to the observed indicators, the loadings in a latent growth model are fixed to define the shape of the growth trajectories. For example, Figure 21.9 presents a linear growth trajectory modeled based on three measurement time points. The factor loadings on the intercept factor are set to 1. The factor loadings on the linear slope factor are set to represent the amount of time elapsed since the first measurement occasion while setting the loading for the time point represented by the intercept factor to 0. Therefore, in the ECLS-K data, if we model linear growth from the kindergarten fall to fifth grade spring with kindergarten fall as the intercept, the first loading would be set equal to zero (essentially erasing the arrow) for the kindergarten fall assessment and the second loading would be set equal to .5, indicating that, on average, half of a year has elapsed

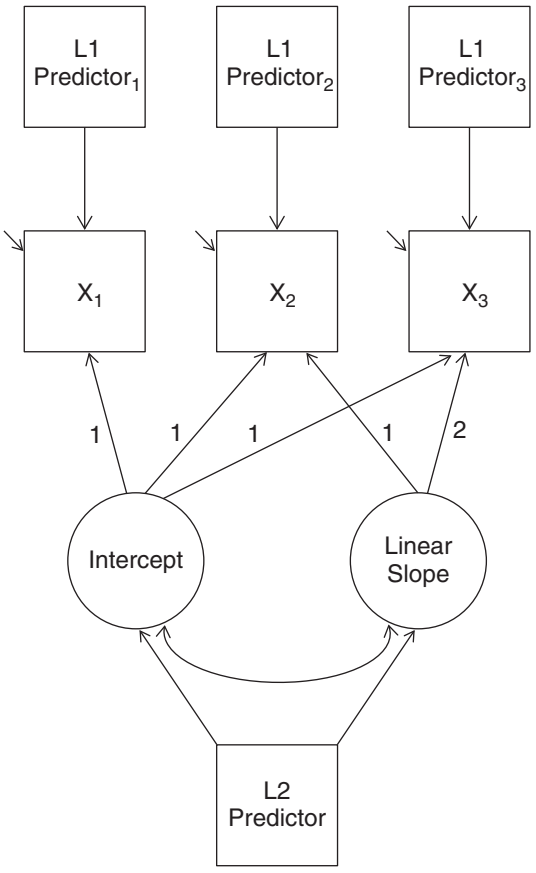

Figure 21.9 SEM latent growth curve model with L1 and L2 predictions.

at kindergarten spring. The other loadings would be set equal to 1.5, 3.5, and 5.5 to represent elapsed time at the first, third, and fifth grade spring assessments. If we model a quadratic growth trajectory, another growth factor, a quadratic growth factor, is added to the linear growth model in Figure 21.9, with the factor loadings equal to the squared linear values: 0, .25, 2.25, 12.25, and 30.25.

Estimating an SEM for a latent growth model produces means and variances for each of the latent growth factors. The means describe the normative growth trajectory. In a linear growth model, means of the intercept and linear growth factors would represent the expected value of the construct at the initial time point and the linear growth rate, respectively. The estimated variances of the growth factors represent differences between individuals in intercepts and linear rates of change. The covariance between intercepts and linear slopes is also estimated, along with an estimate of the error variance associated with the measurement of the outcome variable at each time point.

Both time-varying and individual (invariant over time) covariates can be added to a latent growth model.

Individual covariates are added as predictors of the latent growth factors, as shown in the lower portion of Figure 21.9. A time-varying covariate measured at a given time point can be added as a predictor of the outcome construct at that time point, as shown in the upper portion of Figure 21.9. Alternately, a researcher could let a time-varying covariate measured at an earlier time point predict the outcome construct measured at later time point, introducing an aspect of temporal precedence and a prospective lagged effect.

SEM and multilevel models can produce equivalent estimates of growth model parameters (Curran, 2003). However, the two modeling frameworks differ somewhat in their defaults for model specification and estimation, and thus results from the two approaches may initially appear to differ. Specifically, multilevel models estimate a single L1 variance component (assuming homogenous error variances across time points), while SEMs usually estimate time point-specific error variances. Also, multilevel programs will usually constrain negative variance estimates to zero, while SEM programs will allow the negative estimate. However, if program defaults are appropriately changed to reflect common settings, results produced with multilevel models and SEMs will be essentially identical.

Latent Change Model

Another type of latent variable model for investigating longitudinal data is the latent change score (LCS) model, also referred to as the latent difference score model (Ferrer & McArdle, 2003; McArdle, 2001; McArdle & Hamagami, 2001; McArdle & Nesselroade, 2003). An example of a four-wave LCS model is shown in Figure 21.10, where the η variables represent the error-free true score for each measurement wave, the Δ variables represent the latent change scores, and the ξ_1 variable is a second-order slope variable that represents the change in the latent change scores over time or, in other words, the change in the rate of change in score over time. Because each η variable is represented by only one observed score, the paths between all of the observed Y variables and the η variables are constrained to be equal to 1. A measurement model can be added to the LCS model to incorporate multiple indicators; Figure 21.11 shows an example of a four-wave multiple-indicator LCS model.

McArdle and Hamagami (2001) described the Δ variables as being a rate of change for a given time lag such that for a time lag of 1,

$$\Delta_t = \eta_t - \eta_{t-1} \tag{21.36}$$

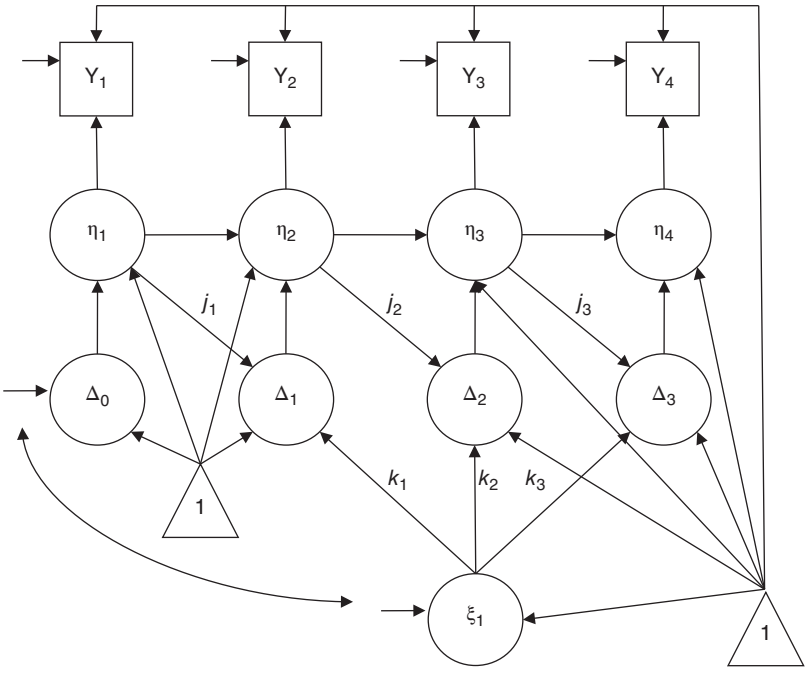

Figure 21.10 A four-wave latent change score model.

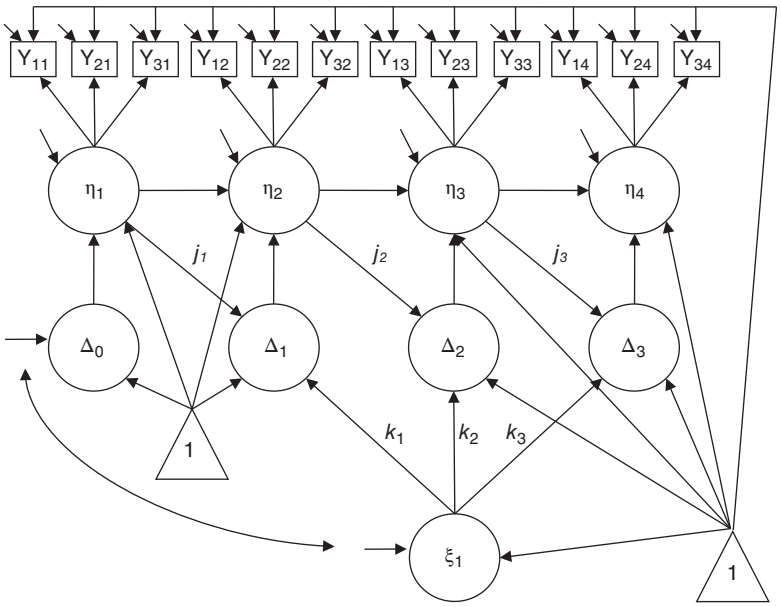

Figure 21.11 Multiple-indicator latent change score model.

except for Δ_0. An individual latent change score is then equal to

$$\Delta_t = k_t\xi_1 + j_t\eta_{t-1} \tag{21.37}$$

where j_t is the loading between the latent change score at time t to the latent construct score at time $t - 1$, and k_t is the loading of the latent change score on the ξ_1 variable. Assuming equally spaced measurement, the values of k_t are usually constrained to be equal across waves, as are the values of j_t, but unequal spacing of measurements can be taken into account by adjusting these constraints to reflect the actual spacing. In addition, Ferrer and McArdle (2003) described a cross-lagged version of the LCS model where the change score at time t predicts the observed score at time $t + 1$.

Equation 21.37 shows that the latent change score Δ_t is proportional to the score at the previous time point, $j_t\eta_{t-1}$, and the latent slope, $k_t\xi_1$. That is, an individual's change score at time t is a function of the overall change across time and the individual's score at the previous time point, which is why McArdle and Hamagami (2001) called this model a dual change score model. Constraining either the j paths, k paths or both to be equal to 0 changes the interpretation of the model. For instance, if the k paths are set to 0, the model becomes a proportional change score model because an individual's change score at time t only depends on their score at the previous time point, which will not be the same for each individual or time point. Alternatively if the j paths are set to 0, the model becomes a constant change score model because an individual's score at time t only depends on the latent slope, which is the same for all individuals across all time points. If the k and j paths are both set to 0, then the latent change score is not proportional to the previous score or related to the latent slope. When this occurs, there is no change in the construct scores across time, so the model becomes a no-change score model.

Much like a linear LGC model, the mean of Δ_0 can be considered as a latent intercept because it is the average score across individuals at baseline and the mean of ξ_1 can be considered a latent slope because it is the average change in change scores across time. Overall model fit can be determined by typical SEM fit indices such as the chi-square goodness of fit test, the RMSEA, and the CFI. Stationarity in the LCS model can be investigated by comparing models that constrain the autoregressive paths, j paths, and k paths of the model to be equal across waves with models where the constraint is lifted, using a series of nested model chi-square change tests.

Exponential Decay Structural Equation Model

A latent variable version of the exponential decay nonlinear mixed effects model can be specified using the general method for nonlinear latent variable growth curve models described by Browne (1993; see also Blozis, 2004, 2007;

Blozis et al., 2007). The nonlinear LGC model for exponential decay is similar to the LGC model and is of the form

$$\mathbf{X} = \boldsymbol{\tau}_{\mathbf{x}} + \boldsymbol{\Lambda}_{\mathbf{x}}\boldsymbol{\xi} + \boldsymbol{\delta} \tag{21.38}$$

where the vector $\boldsymbol{\xi}$ contains the latent growth parameters, the paths in the loading matrix $\boldsymbol{\Lambda}_{\mathbf{x}}$ are constrained to specific values, and the $\boldsymbol{\tau}_{\mathbf{x}}$ vector contains the means of the observed variables. Also present is the vector $\boldsymbol{\kappa}$, which contains the means of the latent variables, in this case the growth parameters. The difference between a linear LGC model and one for exponential decay is in the interpretation of the means of the latent variables and in the values of the constrained path loadings in the $\boldsymbol{\Lambda}_{\mathbf{x}}$ matrix.

To construct an exponential decay LGC model using Browne's (1993) method, illustrated in Figure 21.12, the loadings in the $\boldsymbol{\Lambda}_{\mathbf{x}}$ matrix must be set equal to the first partial derivatives of the exponential decay function

$$\lambda_{0t} = \frac{d}{d\beta_0} f(t, \boldsymbol{\theta}) = Exp[t\beta_0] \tag{21.39}$$

$$\lambda_{1t} = \frac{d}{d\beta_1} f(t, \boldsymbol{\theta}) = (\beta_0 - \beta_2) t Exp[t\beta_1] \tag{21.40}$$

$$\lambda_{2t} = \frac{d}{b\beta_2} f(t, \boldsymbol{\theta}) = 1 - Exp[t\beta_2] \tag{21.41}$$

where

$$f(t, \boldsymbol{\theta}) = \beta_2 - (\beta_0 - \beta_2) Exp[t\beta_1]$$

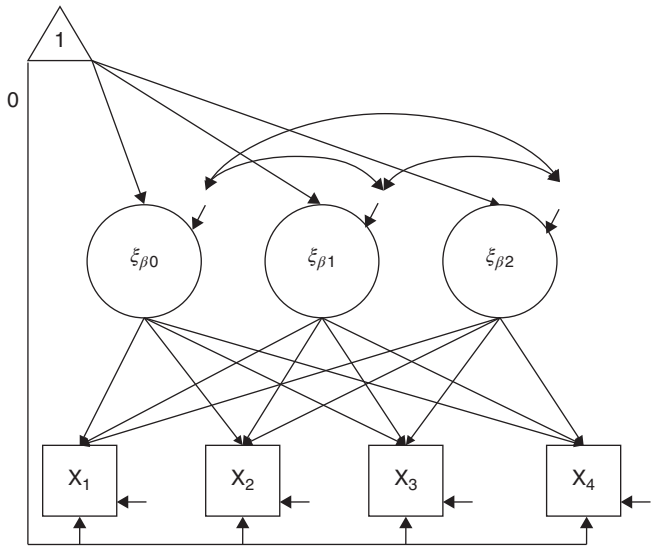

Figure 21.12 A four-wave exponential decay latent growth curve model.

This defines the vector of latent variables to be $\boldsymbol{\xi} = [\xi_{\beta 0} \ \xi_{\beta 1} \ \xi_{\beta 2}]'$ and the vector of means for the latent variables to be $\boldsymbol{\kappa} = [\beta_0 \ \beta_1 \ \beta_2]'$ where β_0, β_1, and β_2 have the same interpretations as in equation 21.34.

The latent exponential decay model created using the Browne (1993) method has two problems that arise during estimation. The first is that the mean of one of the latent variables must be constrained to be equal to zero. The second problem is that, as shown in equations 21.39 to 21.41, to constrain the loadings in the $\boldsymbol{\Lambda}_{\mathbf{x}}$ matrix correctly, the values of the means of the latent variables must already be known prior to estimating the model. Both of these problems may be circumvented, however, by setting β_1 equal to 0 and then simultaneously estimating the path loadings and the means of the latent variables using nonlinear constraints, for example using the MODEL CONSTRAINT command in Mplus.

MODELS FOR MODERATION AND MEDIATION IN LONGITUDINAL DATA

The next section of the chapter describes several models that incorporate mediation and moderation into the analysis of longitudinal data. Most employ the multilevel and SEM frameworks for model specification and estimation. Some of these approaches (e.g., the lag as moderator model, time-varying covariate interactions within multilevel models, and the mediation over time model) make use of the repeated measurements to explore how certain effects and associations change over time. Other approaches, especially those examining mediation using the SEM framework, focus more on the inherently time-ordered aspect of longitudinal data to establish the temporal precedence of effects necessary to make a causal argument about how predictor variables exert their effects on the outcomes of interest.

Lag as Moderator Model

Selig, Preacher, and Little (2012) developed a moderator model unique to longitudinal data. Specifically, they propose the lag as moderator (LAM) approach to examine time-dependent associations. It is possible that the strength of the association between two variables assessed at different occasions will depend on the length of time elapsed between the occasions. Their presentation assumes just a single measurement of two variables for each subject, but variability of the time lag between the two measurements across subjects.

The general approach involves using the length of the lag between measurement occasions as a predictor in a regression model. If the focal variables are X (predictor) and Y (criterion), the model would include X, the lag, and the interaction between X and the lag as predictors:

$$\hat{Y} = b_0 + b_1 X + b_2\, Lag + b_3 \tag{21.42}$$

In this equation, the b_1 coefficient represents the association between X and Y when Lag = 0 (i.e., simultaneous estimation), the b_2 coefficient represents the expected change in Y for a 1 unit increase in the length of the lag, and b_3 represents the linear change in the association between X and Y that accompanies a 1 unit increase in the length of the lag. Strategic centering of the lag variable can change the meaning of the b_1 coefficient to test the association between X and Y if a particular lag is believed to be particularly important.

Selig et al. pointed out that in many cases, change in the X–Y association as a function of the lag will not be linear. This nonlinearity might be captured with a straightforward polynomial specification (here, a quadratic form):

$$\hat{Y} = b_0 + b_1 X + b_2 Lag + b_3 Lag^2 + b_4 XLag + b_5 XLag^2 \tag{21.43}$$

or with a more complex nonlinear parameterization:

$$\hat{Y} = b_0 + \left[\alpha_{Y \cdot X} - \left(\alpha_{Y \cdot X} - \alpha_0\right)\left(\frac{Lag}{\alpha_{Lag}} - 1\right)^2\right] X \tag{21.44}$$

Though the latter expression requires nonlinear regression techniques for the estimation of its parameters, it provides estimates with more meaningful interpretations than those of the quadratic model (Cudeck & du Toit, 2002). α_0 is the expected association between X and Y when Lag = 0, α_{Lag} is the value of the lag at which the maximal X-Y association is obtained, and $\alpha_{X \cdot Y}$ is that maximum association. Alternately, an exponential model might be specified:

$$\hat{Y} = b_0 + (ae^{bLag})X \tag{21.45}$$

to represent a functional relationship that approaches an asymptote rather than symmetric form (i.e., any increase to a maximum must necessarily be followed by a decrease) implied by a quadratic specification.

Selig et al. provide an empirical example illustrating the LAM approach using variables from the Early Head Start Research and Evaluation study (Department of Health and Human Services, Administration for Children and Families, 1996–2001; available from the Inter-university Consortium for Political and Social Research website: www.icpsr.org/). As is often the case, the original intention was to collect the observational data at a single fixed lag; however, practical difficulties resulted in variation in time elapsed between measurement occasions across subjects. The LAM analysis examined effect of lag length on the association between the quality of stimulation provided to a child in his or her home at approximately 14 months and a measure of cognitive, language, and social development at approximately 24 months of age. Though the nominal lag between the 14-month and the 24-month observations was 10 months (and, in fact, the average lag was 10.08 months), there was considerable variability in the actual length of the lag, which ranged from 2.95 to 16.98 months (SD = 1.74 months).

Initial examination of the data consisted of a series of scatterplots windowing different lag lengths and estimation of a regression slope within each window. A plot of these slope values against the average lag for each window showed a clear decrease in the strength of association with longer lags. To capture this change, Selig et al. fit a linear and an exponential LAM model, and both showed significant lag moderation. The two models seemed to fit the data equally well for the range of lags actually present in the data, but the authors pointed out that for even longer lags the linear model predicts a negative association between the two variables while the exponential model predictions approach a lower asymptote of zero. They cautioned, however, that their example data did not involve random assignment of the lag length, and thus interpretations must be circumspect.

We used the LAM model to examine the effect of the lag between the measurement of ADHD symptoms at kindergarten fall and measurement of interpersonal skills, academic performance, and internalizing behavior at kindergarten spring. The lag between the two assessment occasions ranged from 3.8 to 9.3 months, with an average of 6.1 months. Linear and quadratic effects of lag length were tested. Only two interactions between predictor values and lag length emerged, both linear. The negative association between kindergarten fall EXTERN and kindergarten spring INTERP was stronger for shorter than for longer lags ($b_3 = 0.3340$, SE = 0.1177, $p < .01$), and the positive association between kindergarten fall EXTERN and kindergarten spring INTERN was stronger for longer than for shorter lags ($b_3 = 0.2268$, SE = 0.1063, $p < .05$).

Selig et al.'s LAM approach was designed for a very specific data structure, with only two observations of

measurement per subject, each variable assessed at only one of the measurement occasions, and variation in the lag between measurement occasions across subjects either produced intentionally (e.g., through random assignment of lag lengths) or as the result of vagaries in the implementation of a fixed-lag design. The single-level regression estimation that they recommend, whether linear or nonlinear, requires a single outcome observation for each subject. It should be possible, however, to adapt their framework for estimation as a multilevel model, which will widen the range of data structures to which the LAM approach might be applied. Moreover, such applications would convert what Selig et al. acknowledge as an interindividual approach to what is often an intraindividual question into an appropriately matched intraindividual analysis.

When the predictor variable is time-invariant but the criterion is assessed at multiple later time points, each subject shows intraindividual variation in the predictor-criterion lag. The single equation form of a multilevel model would closely parallel those specified by Selig et al., simply adding L2 error terms to model the potential unmeasured similarity among the repeated criterion observations obtained from a given individual. At L1 (the repeated measures level), the equation would be

$$Y_{ti} = \beta_{0i} + \beta_{1i}\text{Lag}_{ti} + e_{ti} \tag{21.46}$$

and at L2 (the individual level), we would have

$$\begin{aligned}\beta_{0i} &= \gamma_{00} + \gamma_{01}X_i + u_{0i}\\ \beta_{1i} &= \gamma_{10} + \gamma_{11}X_i + u_{1i}\end{aligned} \tag{21.47}$$

The γ_{11} coefficient captures the lag moderation effect in this model.

Results of fitting such models in the ECLS-K data are provided in Table 21.4. These models predicted kindergarten spring through fifth grade spring assessments of interpersonal skills, academic performance, and internalizing behavior from kindergarten fall measures of ADHD symptoms. Initial models included interactions between ADHD symptoms and both linear and quadratic lag variables. If the interaction between the ADHD symptoms variable and the quadratic lag was not significant, the model was refitted with only the interaction involving the linear lag. Most of the final models included significant interactions with the quadratic lag function; however, the model predicting READ from EXTERN included only an interaction with linear lag. All of the models indicated that the strongest effects of the kindergarten fall ADHD symptoms variables were the contemporaneous ones on the outcome variables at kindergarten fall with Lag = 0. The magnitude of the association between kindergarten fall EXTERN and READ declined linearly through the fifth grade spring assessment. For the other predictor/outcome combinations, the magnitude of the association declined quickly at the kindergarten spring and first grade spring assessments and gradually leveled off. Some of the models, in fact, indicate a reversal of the original trend near the fifth grade assessment, but this seems more likely an artifact of the necessary symmetry in quadratic models than a real pattern in the data, suggesting that exponential models might be a more appropriate choice for modeling some of these particular associations.

Multilevel Growth Models with Time-Varying Covariate Interactions

The multilevel growth model presents an interesting opportunity for examining a particular kind of moderation in longitudinal data. This is moderation of the effect of a L1 predictor variable on a L1 outcome variable by time. That is, one can test whether the association between repeatedly measured predictor and outcome constructs changes systematically over the course of a longitudinal study. Many theories would predict change in the strength of association between two variables during the course of development or when transitioning from one developmental stage to another. Judicious coding of time trends and modeling interactions between predictors and the time-related variables will allow such effects to be directly tested.

For example, consider a simple linear multilevel growth model

$$\begin{aligned} \text{L1:} \quad & Y_{ti} = \beta_{0i} + \beta_{1i} time_{ti} + e_{ti} \\ \text{L2:} \quad & \beta_{0i} = \gamma_{00} + u_{0i} \\ & \beta_{1i} = \gamma_{10} + u_{1i} \end{aligned} \tag{21.48}$$

Combined:

$$Y_{ti} = \gamma_{00} + \gamma_{10} time_{ti} + u_{0i} + u_{1i} time_{ti} + e_{ti}$$

This model estimates the linear trend in the outcome variable over time. If a researcher is interested in the effect of a time point-specific predictor variable (X_{ti}, a time-varying covariate), it can be added to the L1 specification

$$\text{L1:} \quad Y_{ti} = \beta_{0i} + \beta_{i1} time_{ti} + \beta_{2i} X_{ti} + e_{ti} \tag{21.49}$$

with an associated L2 equation

$$\text{L2:} \quad \beta_{2i} = \gamma_{02} \tag{21.50}$$

Combined:

$$Y_{ti} = \gamma_{00} + \gamma_{10} time_{ti} + \gamma_{02} X_{ti} + u_{0i} + u_{1i} time_{ti} + e_{ti} \tag{21.51}$$

With this specification, the time trend (γ_{01}) is adjusted for variation in the time-varying predictor and γ_{02} represents the effect of the predictor over and above the time trend.

Now consider adding the interaction between the L1 predictor and the linear time variable:

$$\begin{aligned} \text{L1:} \quad & Y_{ti} = \beta_{0i} + \beta_{i1} time_{ti} + \beta_{2i} X_{ti} \\ & \qquad + \beta_{3i} X_{ti} time_{ti} + e_{ti} \\ \text{L2:} \quad & \beta_{3i} = \gamma_{30} \end{aligned} \tag{21.52}$$

Combined:

$$\begin{aligned} Y_{ti} = {} & \gamma_{00} + \gamma_{10} time_{ti} + \gamma_{02} X_{ti} + \gamma_{03} X_{ti} time_{ti} + u_{0i} \\ & + u_{1i} time_{ti} + e_{ti} \end{aligned}$$

As Singer and Willett (2003, p. 171) noted, the coefficient associated with the interaction between a time-varying predictor and the time variable (here, γ_{03}) can be interpreted in two ways. One interpretation is that the rate of change over time in the outcome variable depends on the level of the time-varying predictor. The second interpretation, and the one that we will focus on here, is that the effect of the time-varying predictor on the outcome changes over time. The equation above specifies linear change in the association between the time-varying predictor and the outcome, but (as discussed in the original Baron and Kenny (1986) paper), a more (e.g., quadratic) or less (e.g., step) complex function could be used to model a hypothesized pattern of change.

Hedeker (2004) discussed such an effect in the context of a longitudinal psychiatric study originally described in Reisby et al. (1977). This study examined the association between imipramine and desipramine plasma levels (the time-varying predictors) and clinical response (the outcome variable) over time in a sample of depressed inpatients. Because the effectiveness of antidepressants is not immediate but develops over time, an exploration of such moderated effects seems warranted. The model included a linear time trend, main effects of the imipramine and desipramine plasma levels, and interactions between linear time and the plasma levels. The model including the two interactions fit better than the model without the interactions. Examination of specific coefficients showed that the imipramine level by time interaction was not significant in this sample, but the desipramine interaction was significant, indicating that, in fact, the effect of this particular antidepressant on clinical response became more pronounced over the course of the 5-week study.

Table 21.5 reports the results of analyses in the ECLS-K data that included interactions between time-varying predictors and time. In particular, we explored whether the effects of the two ADHD symptoms variables on interpersonal skill, academic performance, and internalizing behavior change between fall of kindergarten and spring of fifth grade. Multilevel growth models incorporating an interactions between an ADHD symptoms variable and functions of the time variable were fitted for each possible pairing of LEARN and EXTERN with INTERP, MATH, READ, and INTERN. In each model, the base growth curve for the outcome construct was allowed to be quadratic with random effects for all growth parameters, and any nonsignificant variances were trimmed.

As Table 21.5 shows, the interaction between LEARN and linear time on INTERP is significant. This indicates that the contemporaneous positive association between the approaches to learning score and interpersonal skill ratings become stronger over time. For example, as indicated in column 3 of Table 21.5, the expected association between these two variables at kindergarten fall (i.e., when

Time = 0) is .6365 and can be interpreted in much the same way as an unstandardized regression coefficient: for each one unit increase in LEARN at kindergarten fall, the expected value of interpersonal skill at that time point increases by .6365 points. For each additional year that passes, the contemporaneous association is expected to increase by .0070 points (column 4). So at fifth grade spring, the expected value of interpersonal skills increases by .6750 (i.e., .6365 + .0070 ∗ 5.5) for each one unit increase in LEARN. Similarly, Table 21.5 shows that the negative effects of LEARN on INTERN and the negative effects of EXTERN on MATH become significantly more pronounced over time. The predicted associations between the ADHD predictor variables and the outcome variables at each time point correspond fairly well—but not perfectly—to coefficients produced via OLS regressions conducted on data from each time point separately. Although this model may not precisely reproduce the regression coefficients at each time point, it does allow for a single parameter test of the change in such coefficients across time that is not available from analyses conducted on data from each measurement occasion separately.

Five of the eight analyses presented in Table 21.5 involve a significant interaction between the time-varying ADHD symptoms predictor and the quadratic time function, and for all of these, the interactions involving the linear and quadratic time functions are of opposite sign. This indicates that the initial changes in the magnitude of the ADHD symptoms variable and the outcome will eventually change direction. For example, the coefficients for the effect of LEARN on MATH in columns 3 and 4 of Table 21.5 indicate a positive association at kindergarten fall that initially decreases in magnitude over time. However, because of the positive sign of the quadratic interaction in column 5, this trend reaches a minimum around third grade spring, and the magnitude of the association increases thereafter. The maxima or minima for the other four associations with quadratic time interactions, however, reach their minima or maxima much closer to the end of the grade range included in the data. Care should be taken to ensure that these reversals are a true feature of the data and not just an artifact of the necessarily symmetric time function used in this particular example.

The model specification in equation 21.50 as well as those in Hedeker (2004) and the previous ECLS-K analyses assume that the effects of the time-varying covariates are fixed. That is, the association between the time-varying covariate and the outcome measure is the same for all subjects. Moreover, the extent to which the covariate's association with the outcome changes over time is also assumed to be the same for all subjects. However, with a sufficiently large sample, it may be possible to explore whether, in fact, these effects differ across individuals. This can be accomplished by adding error terms u_{2i} and u_{3i} to the L2 equations predicting the β_{2i} and β_{3i} coefficients, respectively. Then the variance of u_{2i} estimates (τ_{22}) indicates the extent to which individuals vary in the association between their predictor and outcome values when time is at its zero point, and the variance of the u_{3i} estimates (τ_{33}) indicates the extent to which individuals vary in how much this association changes over time.

Mediation Change over Time Model

The mediation change over time (M-COT) model builds upon the idea of creating interactions between predictors and the explicit time variable in a multilevel growth model to examine possible change in both the *a* and *b* paths of a mediation model over time. In contrast to other longitudinal mediation models that will be presented below, the focus of this model is not on establishing the temporal precedence of effects necessary for causal pathways. Rather, the M-COT model is largely descriptive and explores how the various paths in the basic model of Figure 21.1, specifically the *a* path from *X* to *M* and the *b* path from *M* to *Y*, change over the course of a longitudinal study. The $X \rightarrow M$ and $M \rightarrow Y$ relations within the model might be cross sectional, or *X* might be assessed prior to *M*, and *M* might be assessed prior to *Y*. In the former case, the M-COT model would simply describe how the contemporaneous associations between variables

change over time. In the latter case, the M-COT model would describe how the lagged relations among variables change as time progresses.

This discussion will concentrate on the M-COT model for exploring cross sectional mediation in longitudinal data. This model is appropriate for data with repeated measures of the outcome variable Y. The initial variable X and the mediator variable M could also be measured repeatedly or could be time-invariant individual variables. The following model assumes a $1 \rightarrow 1 \rightarrow 1$ model with all three variables measured repeatedly at the same time points. The M-COT model can be specified as a two-level random coefficient (i.e., multilevel) model with time points nested within individuals (Arruda & Krull, 2013). For a simple model that examines linear change over time in the a and b paths, the multiple equation form of the model to estimate a paths would be:

$$\begin{aligned} \text{L1:} \quad & M_{ti} = \beta_{0i} + \beta_{1i} time_{ti} + \beta_{2i} X_{ti} \\ & \quad + \beta_{3i} time_{ti} X_{ti} + e_{ti} \\ \text{L2:} \quad & \beta_{0i} = \gamma_{00} + u_{0i} \qquad \beta_{2i} = \gamma_{20} \\ & \beta_{1i} = \gamma_{10} + u_{1i} \qquad \beta_{3i} = \gamma_{30} \end{aligned} \tag{21.53}$$

and the single-equation form would be

$$\begin{aligned} M_{ti} = {} & \gamma_{00} + \gamma_{10} time_{ti} + \gamma_{20} X_{ti} + \gamma_{30} time_{ti} X_{ti} \\ & + u_{0i} + u_{1i} time_{ti} + \mathrm{e}_{ti} \end{aligned} \tag{21.54}$$

In this particular model, the γ_{20} coefficient estimates the association between X and M when time is at its zero point. The γ_{30} coefficient estimates how much this association changes for each additional unit of time.

The multilevel equation to generate β path estimates would be:

$$\begin{aligned} \text{L1:} \quad & Y_{ti} = \beta_{0i} + \beta_{1i} time_{ti} + \beta_{2i} X_{ti} + \beta_{3i} time_{ti} X_{ti} \\ & \quad + \beta_{4i} M_{ti} + \beta_{5i} time_{ti} M_{ti} + e_{ti} \\ \text{L2:} \quad & \beta_{0i} = \gamma_{00} + u_{0i} \quad \beta_{2i} = \gamma_{20} \quad \beta_{4i} = \gamma_{40} \\ & \beta_{1i} = \gamma_{10} + u_{1i} \quad \beta_{3i} = \gamma_{30} \quad \beta_{5i} = \gamma_{50} \end{aligned} \tag{21.55}$$

in the multiple equation form, and

$$\begin{aligned} \mathrm{Y}_{ti} = {} & \gamma_{00} + \gamma_{10} time_{ti} + \gamma_{20} X_{ti} + \gamma_{30} time_{ti} \mathrm{X}_{ti} \\ & + \gamma_{40} M_{ti} + \gamma_{50} time_{ti} \mathrm{M}_{ti} + u_{0i} + u_{1i} time_{ti} + \mathrm{e}_{ti} \end{aligned} \tag{21.56}$$

in the single equation form. The γ_{40} coefficient in this particular model estimates the association between M and Y when time is at its zero point. The γ_{50} coefficient estimates how much this association changes for each additional unit of time.

Combining the appropriate coefficients from the two models provides an expression for how the mediated effect ab changes over time (Arruda & Krull, 2014a). The additional subscripts M and Y in the following equations indicate whether a given coefficient came from the first multilevel equation (M) regressing M on X or the second multilevel equation (Y) regressing Y on X and M simultaneously. The combined expression is simply the product of the terms relevant to the a effect in equation 21.54 and those relevant to the β effect in equation 21.6:

$$ab_{ti} = (\gamma_{20M} + \gamma_{30M} time_{ti})(\gamma_{40Y} + \gamma_{50Y} time_{ti}) \tag{21.57}$$

Manipulating and rearranging this expression gives

$$\begin{aligned} ab_{ti} = {} & \gamma_{20M}\gamma_{40Y} + (\gamma_{20M}\gamma_{50Y} + \gamma_{30M}\gamma_{40Y}) time_{ti} \\ & + \gamma_{30M}\gamma_{50Y} time_{ti}{}^2 \end{aligned} \tag{21.58}$$

The first term in this expression, $\gamma_{20M}\,\gamma_{40Y}$, estimates the mediated effect (i.e., the product of the a and b paths) when time is at its zero point. The second term, $\gamma_{20M}\,\gamma_{50Y} + \gamma_{30M}\,\gamma_{40Y}$, estimates the instantaneous linear change in the mediated effect when time is at its zero point. The third term, $\gamma_{30M}\gamma_{50Y}$, estimates the quadratic change in the mediated effect over time and indicates how the instantaneous linear change in the mediated effect itself changes over time.

Approximate standard errors for the three terms in equation 21.58 can be obtained via the multivariate delta method (Arruda & Krull, 2014a). Specifically, the standard errors are as follows:

$$SE(\gamma_{20M}\gamma_{40Y}) = sqrt(\gamma_{20M}{}^2\sigma^2{}_{\gamma 40Y} + \gamma_{40Y}{}^2\sigma^2{}_{\gamma 20M}) \tag{21.59}$$

$$\begin{aligned} SE(\gamma_{20M}\gamma_{50Y} + \gamma_{30M}\gamma_{40Y}) = {} & sqrt(\gamma_{20M}{}^2\sigma^2{}_{\gamma 50Y} \\ & + \gamma_{50Y}{}^2\sigma^2{}_{\gamma 20M} + \gamma_{40Y}{}^2\sigma^2{}_{\gamma 30M} + \gamma_{30M}{}^2\sigma^2{}_{\gamma 40Y}) \\ & + (2 * (\gamma_{20M}\gamma_{30M}\sigma_{\gamma 40Y\gamma 50Y}) + (\gamma_{40Y}\gamma_{50Y}\sigma_{\gamma 20M\gamma 30M})) \end{aligned} \tag{21.60}$$

$$SE(\gamma_{30M}\gamma_{50Y}) = sqrt(\gamma_{30M}{}^2\sigma^2{}_{\gamma 50Y} + \gamma_{50Y}{}^2\sigma^2{}_{\gamma 30M}) \tag{21.61}$$

These standard errors can be used to conduct hypothesis tests or develop confidence intervals for each of the terms in equation 21.58. Thus we can explicitly test the trend in *ab* over time.

One useful way to think about this model is to consider the ultimate form of change in the *ab* estimate of the mediated effect that will result from combining different trends in *a* and *b*. As currently specified, three types of trends are possible for the *a* path: the *a* path could be zero (both the γ_{20M} and γ_{30M} coefficients are nonsignificant), a nonzero constant over time (the γ_{20M} coefficient is significant but the γ_{30M} coefficient is nonsignificant), or a linearly increasing function of time (the γ_{30M} coefficient is significant, regardless of the significance of the γ_{20M} coefficient). The same three trends are also possible for the *b* path (i.e., zero—both the γ_{40Y} and the γ_{50Y} coefficients are nonsignificant, constant—the γ_{40Y} coefficient is significant but the γ_{50Y} coefficient is nonsignificant, or linearly changing—the γ_{50Y} coefficient is significant, regardless of the significance of the γ_{40Y} coefficient). Then there are nine possibilities for the multiplicative combination, as shown in Table 21.6. Of course, whenever the nature of either of the two paths is zero, the multiplicative function *ab* will also be zero. Thus five of the nine combinations ultimately produce no mediated effect. Only four combinations produce nonzero values for the *ab* function over time, and these correspond to the four terms in equation 21.58.

With this limited set of possibilities (i.e., allowing only zero, constant, and linear trends for *a* and *b*), the only way that the *ab* product could indicate a constant mediated effect over time is if both *a* and *b* are nonzero constants. There are two ways that *ab* could show a pattern of linear change over time, specifically (1) if *a* is a nonzero constant and *b* changes linearly over time, or (2) if *b* is a nonzero constant and *a* changes linearly over time. The product *ab* will change quadratically over time only if both *a* and *b* change linearly.

By substituting each of the unique time values into the equation, it is possible to calculate the estimated mediated effect *ab* at each time point. Standard errors of these time point-specific estimates can be calculated using the multivariate delta method. Simulation studies (Arruda & Krull, 2013, 2014b) comparing the time point-specific estimates of *ab* from the M-COT model with those generated by fitting a series of OLS regression models to the data from each time point found that both approaches generated unbiased estimates of *ab* at each time point. When the data generating process for *a* and *b* was truly linear over time (i.e., when the analysis model form matched the true model), however, time point-specific estimates produced by the M-COT model had smaller standard errors than those generated using standard regression techniques to estimate mediated effects at each time point separately. Thus the M-COT approach is more highly powered than the regression approach. Across the range of simulated conditions, the standard errors of mediated effects at specific time points were 14-47% smaller in the M-COT model, resulting in 25-89% more power to detect nonzero effects than using standard regression techniques (Arruda & Krull, 2014b).

The M-COT model was used to assess changes in mediated effects over time in the ECLS-K data. Results of separate analyses in which the ADHD symptoms variables predicted interpersonal skill and academic performance mediators and an internalizing behavior outcome are presented in Table 21.7. The negative effect of LEARN on INTERN through INTERP has a negative linear trend and no significant quadratic trend, so this effect become increasingly pronounced over time. Similar patterns hold for the effects on LEARN on INTERN through READ and MATH, but these include a significant positive quadratic component, so the increasingly negative mediated effects level off at later grades for these academic performance mediators. The effects of EXTERN on INTERN through the three mediators all show similar patterns, with positive mediated effects at kindergarten fall and significant linear and quadratic trends. This indicates that the mediated effects become stronger over time, and the rate of increase speeds up at later grades.

The M-COT model is unique among techniques designed to assess mediation in longitudinal data because it assesses mediation cross sectionally, but the cross sectional associations are not necessarily stable over time. It is assumed that there is some short-term process that has reached equilibrium at each measurement occasion, but a longer-term process that is not stationary. This model might prove useful in explaining conflicting results in developmental studies that have examined mediation at different ages or across different timespans. The model specified here is a $1 \rightarrow 1 \rightarrow 1$ mediation model, but the general framework could be easily adapted to accommodate individual-level predictor and mediator variables at L2. The model was also limited to linear trends over time for both the *a* and *b* paths. A simulation study is currently underway to examine more complex trends for *a* and *b* as well as ideal methods for determining the form of the *a* and *b* trends in real world data where the true data generating process is not known. The current model allows intercepts and time trends to vary across individuals but assumes that the *a* and *b* paths are fixed. If the data warrant, these assumptions could be removed by incorporating methods similar to those of Bauer et al. (2006). Finally, critiques about assessing mediation cross sectionally could be addressed by estimating lagged relations among variables (e.g., $X1 \rightarrow$ M2 $\rightarrow$ Y3; $X2 \rightarrow$ M3 $\rightarrow$ Y4; $X3 \rightarrow$ M4 $\rightarrow$ Y5) rather than the cross sectional associations as shown here.

Longitudinal Mediation in Autoregressive Panel Models

When *X*, *M*, and *Y* are measured repeatedly over time, autoregressive panel data models can be extended to the three variable case to investigate longitudinal mediation. When the autoregressive mediation model involves two waves of data, fitting the autoregressive models to estimate mediation effect is somewhat limited, in that either the relation between *X* and *M* or the relation between *M* and *Y* is contemporaneous. Gollob and Reichardt (1991) argued that it takes time for a cause to have an effect and thus, at least $k + 2$ waves of data are needed to estimate indirect effects in a model with a chain of *k* mediators. Thus, with a single mediator, data should ideally be collected at least across three waves or time points, so *X* can affect *M* and *M* can affect *Y* in time. Otherwise, some parameter constraints or assumptions are needed, based on theory and prior knowledge (Gollob & Reichardt, 1991), such as assumptions of stationarity and knowledge of test-retest reliability.

Figure 21.13 presents an example of the autoregressive mediation model with two waves of data, where the effect of *X* on *M* and the effect of *M* on *Y* are specified as lag-1 effects in an SEM. The autoregressive models described in this section are based on the observed variables, ignoring the measurement errors. With inclusion of multiple

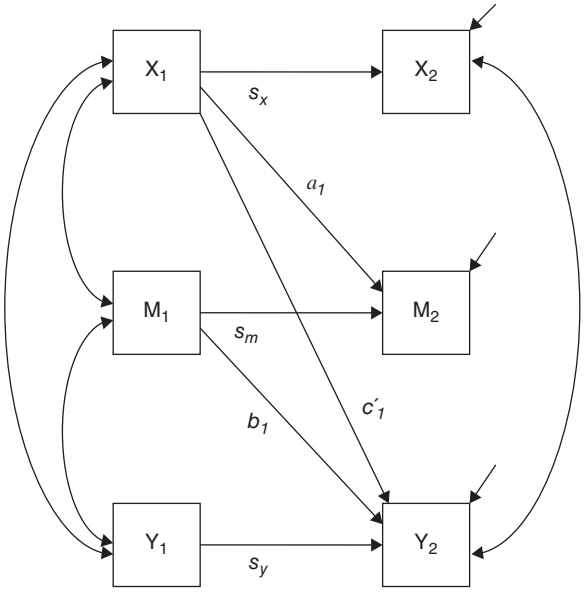

Figure 21.13 An autoregressive model with longitudinal mediation across two waves.

indicators, the repeated measures of X, M, and Y can be modeled as latent variables and the indirect effects can be estimated based on the lagged effects between the latent variables. The model in Figure 21.13 can be described by equations 21.62 to 21.64.

$$X_2 = i_{x2} + s_x X_1 + e_{x2} \tag{21.62}$$

$$M_2 = i_{m2} + a_1 X_1 + s_m M_1 + e_{m2} \tag{21.63}$$

$$Y_2 = i_{y2} + b_1 M_1 + c'_1 X_1 + s_y Y_1 + e_{y2} \tag{21.64}$$

where the variables measured at time 1 are treated as predetermined as follows:

$$X_1 = i_{x1} + e_{x1} \tag{21.65}$$

$$M_1 = i_{m1} + e_{m1} \tag{21.66}$$

$$Y_1 = i_{y1} + e_{y1} \tag{21.67}$$

where i_{x1}, i_{m1}, and i_{y1} are the means of X_1, M_1, and Y_1, respectively, and e_{x1}, e_{m1}, and e_{y1} are deviations from the means. Typically, X_1, M_1, and Y_1 are specified to be correlated. As described previously, i_{m2} and i_{y2} in equations 21.63 and 21.64 are regression intercepts, and e_{m2} and e_{y2} are residuals. The coefficients a_1 and b_1 represent the effect of X_1 on M_2 and the effect of M_1 on Y_2, respectively, while the coefficient c'_1 denotes the direct effect of X_1 on Y_2. The product of the estimates of the coefficients a_1 and b_1, i.e., $a_1 b_1$, is the estimated longitudinal indirect effect. Although the coefficient b_1 represents the relation between M and Y before X affects M, the $a_1 b_1$ estimator would be a reasonable estimate of the longitudinal indirect, because under the stationarity assumption the relation between M_1 and Y_2 (b_1) would be equal to the relation between M_2 and Y_3 that would have been measured after the second wave (Cole & Maxwell, 2003). The standard error of the estimated indirect effect can be obtained using the formulas described earlier based on the relevant path coefficients and their standard errors to conduct the significance test and compute confidence intervals.

Another example of the autoregressive mediation model with two wave data is the model in Figure 21.14 (Mackinnon, 2008). The relations relevant to the mediational pathways can be expressed by the following equations 21.68 and 21.69:

$$M_2 = i_{m2} + a_1 X_1 + a_2 X_2 + s_m M_1 + e_{m2} \tag{21.68}$$

$$Y_2 = i_{y2} + b_1 M_1 + b_2 M_2 + c'_1 X_1 + c'_2 X_2 + s_y Y_1 + e_{y2} \tag{21.69}$$

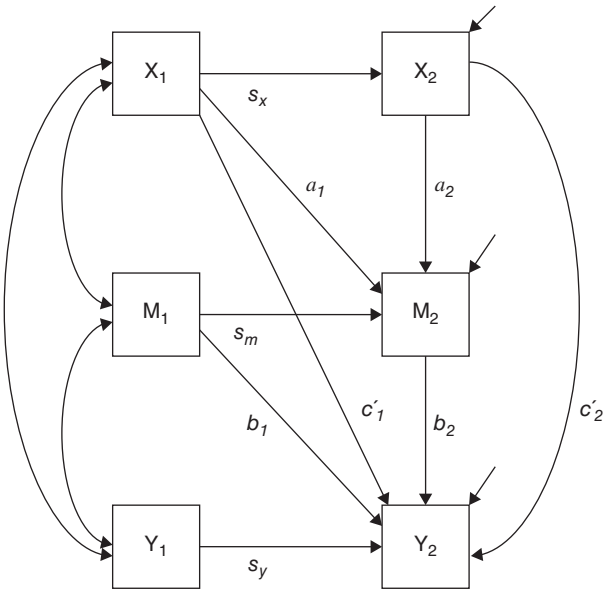

Figure 21.14 An autoregressive mediation model with longitudinal and contemporaneous mediation across two waves.

With the addition of the contemporaneous relations (a_2, b_2, and c'_2) to the previous model in Figure 21.13, the coefficient a_1 in the above model represents the effect of X_1 on M_2 after controlling for the effects of X_2 and M_1, while the coefficient a_2 represents the effect of X_2 on M_2 after controlling for the effects of X_1 and M_1. Similarly, the coefficients b_1 and b_2 indicate the effect of M_1 on Y_2 after controlling for the effects of X_1, X_2, M_2, and Y_1 and the effect of M_2 on Y_2 after controlling for the effects of X_1, X_2, M_1, and Y_1, respectively. There are several ways to estimate mediated effects in the model in Figure 21.14: $a_1 b_1$, $a_2 b_2$, and $a_1 b_2$. As described earlier, the indirect effect $a_1 b_1$ is based on the across-time or lag-1 relations, while the indirect effect $a_2 b_2$ is estimated based on the contemporaneous relations among the variables measured at time 2. The indirect effect $a_1 b_2$ is based on the across-time relation between X_1 and M_2 and the contemporaneous relation between M_2 and Y_2. Cole and Maxwell (2003) recommend the $a_1 b_1$ estimator, because the estimates $a_2 b_2$ and $a_1 b_2$ involve cross sectional relations and are likely to be biased when time is needed for the cause to exert its effect on the outcome (Gollob & Reichardt, 1987).

In the two-wave autoregressive mediation models, information on stability, stationarity, and equilibrium is quite limited, in that we cannot actually test whether these properties hold across time. However, estimating autoregressive effects is beneficial for avoiding omitted variable bias. An autoregressive effect is defined as the effect that a variable has on itself at a later time (Gollob & Reichardt, 1987) and

is denoted by the coefficients s_x, s_m, and s_y in the above models. These coefficients also estimate the stability of a variable across time (Kenny, 1979). When the dependent variable at time t is predicted by the predictors at time $t - 1$, the levels of the dependent variable at time $t - 1$ may represent unmeasured variables that are correlated with the predictors and estimating autoregressive relations can control for such unmeasured variables (Gollob & Reichardt, 1991). Without controlling for those omitted variables or confounders, the causal effects will be biased. Thus, the estimates of a_1 and a_2 in Figures 21.13 and 21.14 will be less biased when estimating s_m and so will b_1 and b_2, when estimating s_y. These less biased coefficients in the mediational pathways will result in the indirect effect that is closer to the true effect size.

When X, M, and Y are measured repeatedly over three or more occasions, the parameterizations in the autoregressive models become more flexible. For example, the effect of M_2 on Y_3 that relied on the stationarity assumption in the two wave data (b_1 in Figures 21.13 and 21.14) can now be estimated. With three or more waves of data, estimating lag effects according to the causal order of X to M to Y is possible, although timing of measurements is a remaining issue, because it is difficult to predict how long it takes for one variable to have its optimal effect on another. Having more waves of data also provides opportunities to examine when stability, stationarity, and equilibrium are reached. It may take a long time for a system of X, M, and Y to achieve stability, stationarity, or equilibrium and sometimes it may be achieved beyond the time span the data cover. While these characteristics can only be assumed in the cross sectional or two wave designs, researchers can check these assumptions with more waves of data by testing equivalence of parameter estimates across waves. Finally, time specific indirect effects can be estimated across multiple waves. The magnitude of effect, either the autoregressive effects or the lagged effects, may vary across time (Cole & Maxwell, 2003). The effect of X_1 on M_2 may be larger or smaller than the effect of X_2 on M_3 and the resulting indirect effects may differ depending on which time points are involved (Cole & Maxwell, 2003; Gollob & Reichardt, 1987, 1991). It might be an interesting research task to detect when the significant indirect effect arises, holds, and desists.

Figure 21.15 shows an example of the autoregressive mediation model with four waves of data, in which the relations among X, M, and Y are specified as lag-1 effects. The model in Figure 21.15 can be described in the following equations:

$$\mathrm{X}_2 = i_{x2} + s_{x1}\mathrm{X}_1 + e_{x2} \tag{21.70}$$

$$\mathrm{X}_3 = i_{x3} + s_{x2}\mathrm{X}_2 + e_{x3} \tag{21.71}$$

$$\mathrm{X}_4 = i_{x4} + s_{x3}\mathrm{X}_3 + e_{x4} \tag{21.72}$$

$$\mathrm{M}_2 = i_{m2} + a_1\mathrm{X}_1 + s_{m1}\mathrm{M}_1 + e_{m2} \tag{21.73}$$

$$\mathrm{M}_3 = i_{m3} + a_2\mathrm{X}_2 + s_{m2}\mathrm{M}_2 + e_{m3} \tag{21.74}$$

$$\mathrm{M}_4 = i_{m4} + a_3\mathrm{X}_3 + s_{m3}\mathrm{M}_3 + e_{m4} \tag{21.75}$$

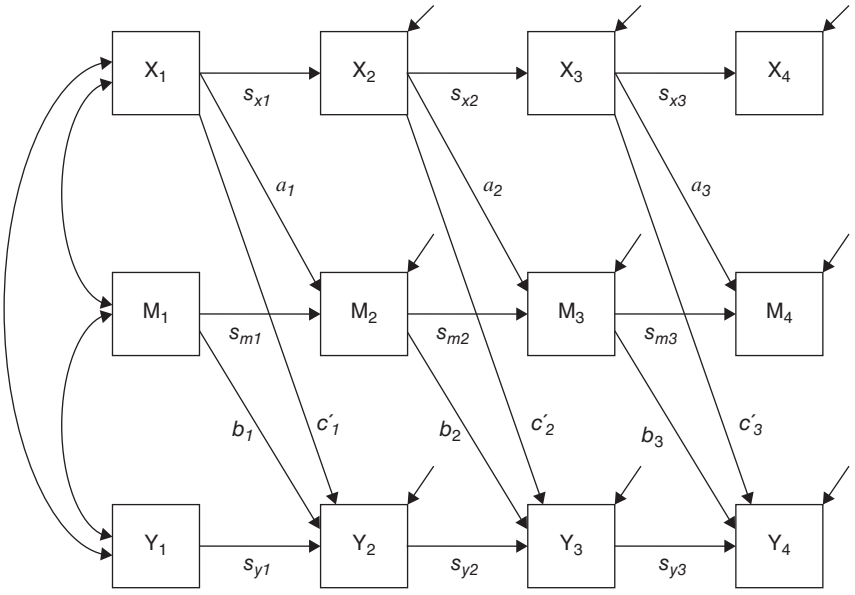

Figure 21.15 An autoregressive mediation model with longitudinal mediation across four waves.

$$\mathrm{Y}_2 = i_{y_2} + b_1\mathrm{M}_1 + c'_1\mathrm{X}_1 + s_{y_1}\mathrm{Y}_1 + e_{y_2} \quad (21.76)$$

$$\mathrm{Y}_3 = i_{y_3} + b_2\mathrm{M}_2 + c'_2\mathrm{X}_2 + s_{y_2}\mathrm{Y}_2 + e_{y_3} \quad (21.77)$$

$$\mathrm{Y}_4 = i_{y_4} + b_3\mathrm{M}_3 + c'_3\mathrm{X}_3 + s_{y_3}\mathrm{Y}_3 + e_{y_4} \quad (21.78)$$

Again, the variables measured at time 1 are predetermined in the same way as in equations 21.65 to 21.67. With more than two waves of data, the effect of X on M and the effect of M on Y are represented by more than one path coefficient. In Figure 21.15 and equations 21.70 to 21.78, the coefficients a_1, a_2, and a_3 all represent the time-specific effect of X on M. Similarly, the coefficients b_1, b_2, and b_3 represent the time-specific effect of M on Y controlling for X, although the coefficients b_2 and b_3 are the effects of M that were affected by X, while b_1 is the effect of M before X exerts its effect on M. The coefficients c'_1, c'_2, and c'_3 reflect the time-specific direct effects of X on Y.

The indirect effects for the model in Figure 21.15 can be estimated in several ways. As we did for the two wave data, one can estimate the indirect effect for each lag such as a_1b_1, a_2b_2, and a_3b_3. Another option is to estimate the indirect effect reflecting the temporal ordering of X, M, and Y, such as a_1b_2 and a_2b_3. The indirect effect and its standard error can be obtained following the formulas described earlier and can be used for significance testing and construction of confidence limits. If the stationarity assumption holds across 4 waves, all the a paths will be equivalent and so will the b paths. In such case, the estimated indirect effects (i.e., a_1b_1, a_2b_2, a_3b_3, a_1b_2, a_2b_3) will be the same. On the other hand, if the path coefficients vary across waves, the indirect effects will be different depending on the time points involved and specific indirect effects can be examined. For example, if four measurement occasions span across different developmental phases, the indirect effect observed at the earlier phase may differ from the indirect effect at the later phase. Differences in the indirect effects across different phases may be an interesting research question. If the autoregressive mediation model is estimated in an SEM framework, the equivalence of path coefficients across time can be tested and the parameters can be constrained accordingly before obtaining the indirect effect.

In addition to the indirect effects listed already that are based on the two longitudinal relations between $X_t \rightarrow M_{t+1}$ and $M_t \rightarrow Y_{t+1}$ (e.g., a_1b_1, a_2b_2, a_3b_3, a_1b_2, a_2b_3), there are other time-specific indirect effects in the model in Figure 21.15, such as $s_{x1}a_2b_3$ and $a_1b_2s_{y3}$. These individual indirect effects are time-specific indirect effects, as they represent causal mechanisms from X to M to Y for specific time intervals. Gollob and Reichardt (1991) argued that these individual time-specific indirect effects may be of less interest to researchers because mediation may evolve gradually over the course of time, rather than occurring at a specific time point. The overall indirect effect may then provide a better estimate for the indirect effect. The *overall indirect effect* is defined as the sum of all the *individual time-specific indirect effects,* i.e., all the indirect effects from X at time 1 to Y at the last time point mediated by M at any time between the first and the last time points (Gollob & Reichardt, 1991). In the model in Figure 21.15, there are three such individual time-specific indirect effects: (1) $X_1 \rightarrow X_2 \rightarrow M_3 \rightarrow Y_4$ ($s_{x1}a_2b_3$), (2) $X_1 \rightarrow M_2 \rightarrow M_3 \rightarrow Y_4$ ($a_1s_{m2}b_3$), and (3) $X_1 \rightarrow M_2 \rightarrow Y_3 \rightarrow Y_4$ ($a_1b_2s_{y3}$). Computing the total indirect effect and its standard error, as well as the total direct effect and its standard error, is available in most SEM software programs, including EQS (Bentler & Wu, 2006), LISREL (Jöreskog & Sörbom, 2006), Proc CALIS in SAS (SAS Institute, 2014), and Mplus (Muthén & Muthén, 2014). It is worth noting that the accuracy of the total indirect effect would rely on the specified mediation model, however. For example, if the mediation model in Figure 21.15 is a true model but the measurement at time 2 is omitted, resulting in the model with data measured at time 1, 3, and 4, the estimated total indirect effect will not equal the true overall indirect effect. See Gollob and Reichardt (1991) for illustration.

We fit an autoregressive panel SEM with longitudinal mediation paths to first, third, and fifth grade ECLS-K data. Though it is possible to fit autoregressive models with unequal lags between time points (Voelkle, Oud, Davidov, & Schmidt, 2012), for the sake of simplicity, only the first, third, and fifth grade measures with constant 2-year lags are used in this example. Table 21.8 presents

coefficients and standard errors for a, b, and the longitudinal mediated effect from ADHD symptoms at first grade through interpersonal skills and academic performance at third grade on internalizing behavior at fifth grade. The results indicate significant longitudinal mediated effects of LEARN on INTERN through both READ and MATH (but not INTERP) and longitudinal effects of EXTERN on INTERN through all three mediators. However, CFI and RMSEA values indicated that these models did not fit the data well.

Another type of autoregressive mediation model is shown in Figure 21.16 with the mediational pathways described in equations 21.79 to 21.84:

$$M_2 = i_{m2} + a_1 X_1 + a_4 X_2 + s_{m1} M_1 + e_{m2} \quad (21.79)$$

$$M_3 = i_{m3} + a_2 X_2 + a_5 X_3 + s_{m2} M_2 + e_{m3} \quad (21.80)$$

$$M_4 = i_{m4} + a_3 X_3 + a_6 X_4 + s_{m3} M_3 + e_{m4} \quad (21.81)$$

$$Y_2 = i_{y2} + b_1 M_1 + b_4 M_2 + c'_1 X_1 + c'_4 X_2 + s_{y1} Y_1 + e_{y2} \quad (21.82)$$

$$Y_3 = i_{y3} + b_2 M_2 + b_5 M_3 + c'_2 X_2 + c'_5 X_3 + s_{y2} Y_2 + e_{y3} \quad (21.83)$$

$$Y_4 = i_{y4} + b_3 M_3 + b_6 M_4 + c'_3 X_3 + c'_6 X_4 + s_{y3} Y_3 + e_{y4} \quad (21.84)$$

In addition to the longitudinal relations between X, M, and Y specified in Figure 21.15, the model in Figure 21.16 includes the contemporaneous relations among X, M, and Y at each wave. These relations are estimated by the coefficients a_4, a_5, and a_6 for the relations between X and M at Time 2, Time 3, and Time 4, respectively, and the coefficients b_4, b_5, and b_6 for the relations between M and Y. The product of path coefficients for the contemporaneous relations, such as a_4b_4, a_5b_5, and a_6b_6, provide the estimates of the contemporaneous indirect effect. When X and M have immediate effects, the longitudinal relations may miss the real effects due to the time lag between measurements. In such cases, the contemporaneous indirect effects may be closer to the true indirect effects (MacKinnon, 2008).

We fit models including both longitudinal and contemporaneous mediation pathways to the ECLS-K first through fifth grade data. The results are summarized in Table 21.9. These models fit the data better than the previous set that included only the longitudinal pathways (all CFIs > .95), but RMSEA values were in the .08–.10 range, which is still larger than desired for optimal fit. Longitudinal mediated paths (X1 → $M3$ → $Y5$) involving the INTERP and READ (but not MATH) mediators were significant or marginally significant and in the expected direction. Several mediated effects involving contemporaneous a or b paths were also significant in models including the INTERP mediator and READ mediators.

Although having more than two waves for the autoregressive models may allow for the flexibility in model specification and the opportunities to obtain more detailed information about the indirect effects, it may introduce

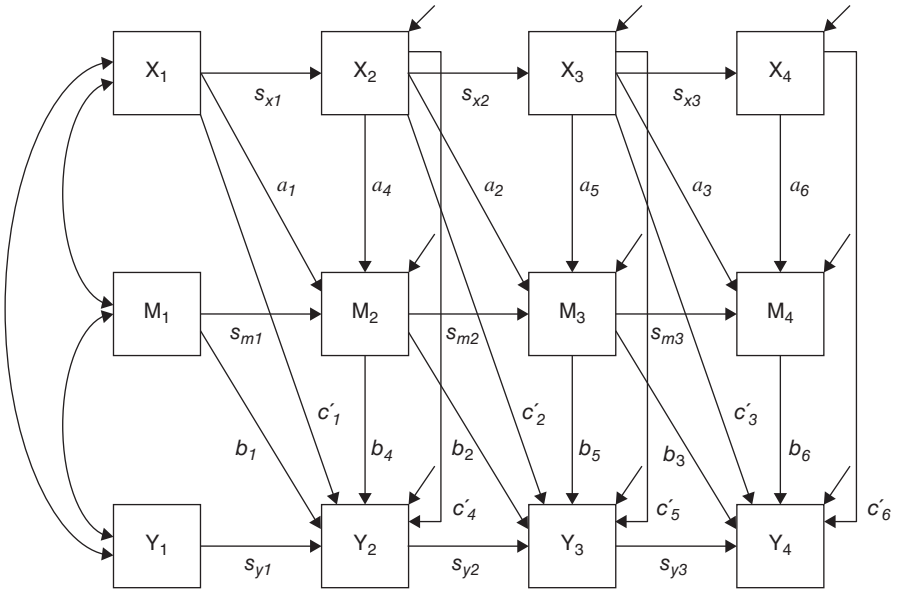

Figure 21.16 An autoregressive mediation model with longitudinal and contemporaneous mediation across four waves.

complexity of parameterization. For example, a variant of the model in Figure 21.16 may include cross-lagged effects among X, M, and Y by adding the direct effects from M_{t-1} to X_t and Y_{t-1} to M_t based on the temporal sequence in which the variables are measured. Specifying these cross-lagged relations may reflect data more reasonably than the models in Figure 21.15 and 21.16, because X, M, and Y are related to each other. However, this model violates the causal sequence of X to M to Y specified by the mediation model because of the reversed paths from M to X and Y to M. As expected, choosing a correct model can be a tricky task with more parameters to be estimated. When the models are estimated in the SEM framework, it would be appropriate to estimate a series of nested models and conduct a series of chi-square difference tests to choose a model that better reflects the data, as well as the theory. In addition, equality of path coefficients, such as paths for the effects of X on M (i.e., a_1, a_2, and a_3) can be also tested by comparing the models with and without the equality constraints.

Latent Growth Curve Mediation Models

The latent growth curve (LGC) modeling (Meredith & Tisak, 1990; Muthén & Curran, 1997; Willett & Sayer, 1994) is another approach that can be used to evaluate longitudinal mediation models when X, M, and Y are repeatedly measured across three or more time points (Cheong, 2011; Cheong, MacKinnon, & Khoo, 2003; Mackinnon, 2008). Unlike the autoregressive mediation models, where the indirect effect is based on the differences among the study participants, the indirect effect in

the LGC mediation model is conceptualized in terms of within-individual changes. In the autoregressive mediation models, the indirect effect is interpreted as the expected effect of X on Y at time t through M at time $t-1$, if there was one unit change in X prior to time $t-1$. Here, the changes in X, M, and Y are assumed equivalent to differences among participants in those variables. In LGC mediation models, individuals' trajectories of X, M, and Y are estimated using the repeated measures across multiple measurement time points and the indirect effect is determined based on the relations between the within-individual changes in X, M, and Y.

The capability of modeling mediation in terms of within-individual changes is important in developmental research, where the core research questions center on development, which is typically defined as within-individual change, and individual differences in development (Nesselroade, 1991). Using difference scores in a two-wave design is the simplest way of measuring individual change; however, difference scores contain minimal information about individual change (Rogosa, 1988; Rogosa, Brandt, & Zimowski, 1982; Willett & Sayer, 1994). The change patterns may follow nonlinear (e.g., quadratic or exponential) patterns or fluctuate in level between the two measurement time points. Growth curve modeling is considered a better method for investigating longitudinal within-individual changes and individual differences in those changes (Rogosa, 1988; Rogosa et al., 1982). Although growth curve models can be formulated both in the multilevel modeling framework (Raudenbush & Bryk, 2002; Goldstein, 1995) and in the SEM framework (Meredith & Tisak, 1990; Muthén & Curran, 1997; Willett & Sayer, 1994), we focus on the SEM approach in this section.

In the LGC approach to mediation, the mediation process is typically modeled using a parallel process model (Muthén & Curran, 1997; Stoolmiller, 1994). The repeated measures of X, M, and Y are modeled as distinctive growth processes and the mediation is specified in the relations among the growth factors. As it is recommended that researchers investigate the longitudinal pattern of change in each variable before examining the longitudinal relations between the variables (Raudenbush, 2001; Rogosa, 1988), the estimation of growth trajectories that best describe the changes in X, M, and Y should precede modeling mediation based on the relations among the latent growth factors. In this approach, the growth trajectories of X, M, and Y are modeled in the measurement model, where the repeated measures relate to the latent growth factors according to the specified time scale. Once the growth trajectory shape is appropriately modeled for each X, M, and Y, the full parallel process model is specified to model the mediation process in the structural model among the latent growth factors.

Figure 21.17 shows an example of the LGC mediation model, where the growth trajectories of X, M, and Y are modeled as linear, based on repeated measures obtained with equal intervals across three waves. According to the specified time scales, the intercept factors (i.e., η_1, η_3, and η_5) represent the level of each variable at time 1, i.e., the initial status. The slope factors (i.e., η_2, η_4, and η_6) represent the change or growth rate of each variable per time unit. The mean and the variance of the intercept factor estimate the average level of initial status of each variable and the individual differences in the initial status. The mean and the variance of the latent slope factor estimate the average growth rate of each variable and the individual differences in the growth rates. Details of model specifications for LGC models can be found elsewhere (e.g., Muthén & Khoo, 1998; Willett & Sayer, 1994). The mediation process is specified in the relations among the latent factors shown in the middle of the model in Figure 21.17. More specifically, the individual differences in the initial status and the growth rates of M and Y are modeled as functions of the individual differences in the initial status and the growth rates of X and M.

The relations among the latent factors in Figure 21.17 are described in the following equations:

$$\eta_{3i} = \pi_{0\mathrm{m}} + d_1\eta_{1i} + e_{3i} \tag{21.85}$$

$$\eta_{4i} = \pi_{1\mathrm{m}} + a\eta_{2i} + d_2\eta_{1i} + e_{4i} \tag{21.86}$$

$$\eta_{5i} = \pi_{0\mathrm{y}} + d_3\eta_{1i} + d_5\eta_{3i} + e_{5i} \tag{21.87}$$

$$\eta_{6i} = \pi_{1\mathrm{y}} + b\eta_{4i} + c'\eta_{2i} + d_4\eta_{1i} + d_6\eta_{3i} + e_{6i} \tag{21.88}$$

where η_{1i}, η_{3i}, η_{5i} are the intercept factors and η_{2i}, η_{4i}, η_{6i} are slope factors for the trajectory of X, M, and Y, respectively, varying across individuals indicated by the subscript i. In the previous equations, $\pi_{0\mathrm{m}}$, $\pi_{0\mathrm{y}}$, $\pi_{1\mathrm{m}}$, and $\pi_{1\mathrm{y}}$ are the regression intercepts of the growth factors and e_{3i}, e_{4i}, e_{5i}, and e_{6i} are residuals of the growth factors. Equations 21.85 and 21.87 describe the intercept factors of M and Y, respectively, as functions of the intercept factors of X and M. These directional paths in Figure 21.17 are based on the causal theory of X to M to Y. If the first measures of X, M, and Y are obtained simultaneously, they can be specified as covariances. Equation 21.86 models the slope factor of M as a function of the intercept and the slope factors of

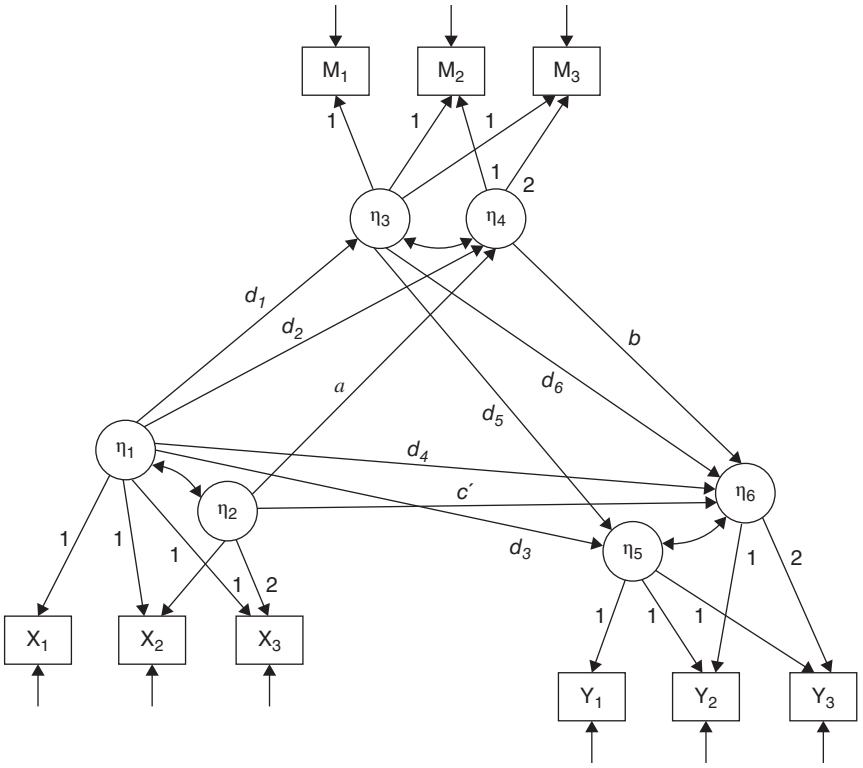

Figure 21.17 A latent growth curve mediation model across three waves.

X, while equation 21.88 specifies the slope factor of *Y* predicted by the intercept and the slope factors of *X* and *M*. Although there are several possible indirect effects that can be of interest in this model, the main focus is on the relations among the slope factors, as the benefit of the LGC approach is the capability of modeling mediation in terms of within-individual changes in *X*, *M*, and *Y*. The coefficient *a* represents the effect of the growth rate of *X* on the growth rate of *M*. The coefficient *b* represents the effect of the growth rate of *M* on the growth rate on *Y*. The product of the two coefficients (i.e., *ab*) provides the estimate of the indirect effect that is based on the within-individual changes, determined by the extent to which the change in *X* affects the change in *M* (*a*) and the extent to which the change in *M* affects the change in *Y* (*b*). The standard error of the indirect effect and its standard error can be obtained in the same way described earlier and used for the significance test of the indirect effect.

We fit a series of simple LGC mediation models to ECLS-K data from all 5 waves. Though preliminary models suggested that growth models did not fit the ADHD symptoms, interpersonal skill, and internalizing behavior data well, we nonetheless proceeded with the mediation models for the sake of illustration, specifying linear trajectories for the *X*, *M*, and *Y* variables. Unsurprisingly, we encountered frequent convergence problems; estimation of the variance of the slope of the mediator trajectory seemed particularly problematic. This variance was estimated as negative in the LEARN → INTERP → INTERN model and was very close to zero in the LEARN → READ → INTERN and EXTERN → MATH → INTERN models. It was necessary to constrain this parameter (and its covariance with the intercept of the mediator trajectory) to zero to achieve convergence in the LEARN → MATH → INTERN and EXTERN → INTERP → INTERN models. The EXTERN → READ → INTERN model did not converge, even with this constraint. Both the CFI and RMSEA indicate poor fit for all models. Tests of the mediated effects involving predictor, mediator, and outcome slopes are reported in Table 21.10. For all models that converged, the estimate of the *a* path relating the slope of the predictor to the slope of the mediator was significant, though the relation between the slopes of LEARN and MATH was counterintuitively negative. Only two *b* path estimates were significant: the slope of READ was negatively related to the slope of INTERN, and the slope of INTERP was counterintuitively positively related to the slope of INTERN. Tests of the *ab* estimates of mediated effects show significant mediation in the LEARN → READ → INTERN and EXTERN → INTERP → INTERN models, but the

mediated effect in the latter model is in a counterintuitive direction. Though LGC mediation models can be very useful in explicating mediation effects in longitudinal data, this particular technique does not seem appropriate for this particular data, as a growth framework is not well suited to capture change over time in most of the variables. As mentioned earlier, it is required to inspect the pattern of change in the study variables carefully before putting the trajectories together in a comprehensive LGC mediation model.

When the measures of *X*, *M*, and *Y* across waves are concurrent, the relations between the slope factors in the mediation model may be interpreted as correlational because the growth rates are estimated based on the measures across the same time span. However, this is less problematic than purely cross sectional data, because the growth rates are estimated based on the entire time span that the data cover and the effects of the changes in the predictors at earlier waves would be reflected in the changes in the outcome variables at later waves. An alternative method is to estimate growth trajectories in two-stage piecewise growth curve models (Raudenbush & Bryk, 2002; Khoo, 2001), where distinct growth trajectories are specified for early and later phases and the time ordering of the growth trajectories of *X*, *M*, and *Y* can be modeled accordingly. The indirect effects then can be estimated for different phases, such as the indirect effect via the earlier growth of *M* on the earlier growth of *Y*, the indirect effect via the earlier growth of *M* on the later growth of *Y*, and the indirect effect via the later growth of *M* on the later growth of *Y*.

Estimating LGC Mediation as a Multilevel Model

The LGC mediation models discussed in the previous section were estimated using structural equation modeling techniques. The SEM framework is ideally suited for such analyses, as its ability to estimate a number of simultaneous equations allows for the estimation of predictive and outcome effects of the same variable within a single analysis. For example, in a mediational analysis, the mediator serves as an outcome variable when examining the *a* path and as a predictor variable when examining the *b* path. It is relatively simple within this framework to have one arrow pointing to a variable (i.e., that variable is an outcome) and another pointing from that variable (i.e., that variable is a predictor of another variable) in an SEM diagram and to create the appropriate equations to estimate both effects simultaneously.

The mediated effect involving latent slope parameters in Figure 21.17 could potentially also be tested within a multilevel modeling framework. The difficulty here is that latent growth in *X* is a predictor of latent growth in *M*, and that latent growth in *M* is a predictor of latent growth in *Y*. In a single multilevel model, it is simple to allow a variable to predict the growth parameter—just include that predictor in the L2 equation predicting that parameter—but there is no obvious way to expand the model to allow the growth parameter itself to predict another variable. However, after running a multilevel model, a researcher can obtain Empirical Bayesian (EB) estimates of growth parameters for each individual. These estimates combine individual-specific information from a single subject's own data and the normative trajectory for the entire sample to produce stable and reliable estimates of person-specific effects (Candel & Winkens, 2003). The EB estimates of intercepts and slopes of the *X* variable can be entered as L2 predictors of the growth parameters in a multilevel growth analysis of the mediator variable to produce estimates of the d_1, d_2, and *a* parameters in Figure 21.17. Similarly, EB estimates of intercepts and slopes can be obtained when running the growth analysis for the mediator variable, and these (along with the EB estimates of intercepts and slopes from the first analysis) can be entered as L2 predictors of the intercept and slope parameters in the multilevel growth analysis of the outcome variable to produce the

remaining coefficients in Figure 21.17, including the b coefficient that relates the mediator slope to the outcome slope. Conducting multiple multilevel analyses seems a bit less elegant than the single comprehensive SEM, but equivalent estimates are produced, and thus longitudinal mediation can be assessed in either framework.

Another possibility for recasting the LGC mediation model in the multilevel framework involves including all three variables (X, M and Y) in a single multivariate multilevel model (Hox, 2010; Raudenbush & Bryk, 2002). One way of conceptualizing such a model is as a three-level framework, with the variables distinguished at L1, repeated measures at L2, and individual subjects at L3. With three measurement occasions as shown in Figure 21.17, the data set would be organized with nine lines of data per subject, one for each of the X, M and Y variables at each of the three time points. The actual X, M, and Y values would be entered into a single generically named variable, V. Three dummy variables (D_1, D_2, and D_3) would be created to identify which observations were associated with each of the three variables, and these dummies, in conjunction with a variable indicating the time point of measurement, would uniquely identify each of the nine unique values.

The L1 model would consist of the three dummy variables, two of which will be zero for any given observation:

$$\text{L1:}\quad V_{vti} = \pi_{1ti}D_{1ti} + \pi_{2ti}D_{2ti} + \pi_{3ti}D_{3ti} \qquad (21.89)$$

for variable v at time point t for subject i. Notice that there is no intercept and no error term in this equation. An intercept would imply that predictors could affect all observations equally, and we wish to keep X, M and Y distinct in this model. An error term is unnecessary because this level of the model simply sorts the variables by type, which should involve no error.

The L2 models would be:

$$\begin{aligned}\text{L2:}\quad \pi_{1ti} &= \beta_{10i} + \beta_{11i}time_{ti} + r_{1ti}\\ \pi_{2ti} &= \beta_{20i} + \beta_{21i}time_{ti} + r_{2ti}\\ \pi_{3ti} &= \beta_{30i} + \beta_{31i}time_{ti} + r_{3ti}\end{aligned} \qquad (21.90)$$

and at L3:

$$\begin{aligned}\text{L3:}\quad \beta_{10i} &= \gamma_{100} + u_{10i} \quad \beta_{11i} = \gamma_{110} + u_{11i}\\ \beta_{20i} &= \gamma_{200} + u_{20i} \quad \beta_{21i} = \gamma_{210} + u_{21i}\\ \beta_{30i} &= \gamma_{300} + u_{30i} \quad \beta_{11i} = \gamma_{310} + u_{31i}\end{aligned} \qquad (21.91)$$

These equations at each level can be algebraically combined to give the single-equation form of the model:

$$\begin{aligned}V_{vti} = {} & D_{1ti}(\gamma_{100} + \gamma_{110}time_{ti} + r_{1ti} + u_{10i} + u_{11i}time_{ti})\\ & + D_{2ti}(\gamma_{200} + \gamma_{210}time_{ti} + r_{2ti} + u_{20i} + u_{21i}time_{ti})\\ & + D_{3ti}(\gamma_{300} + \gamma_{310}time_{ti} + r_{3ti} + u_{30i} + u_{31i}time_{ti})\end{aligned} \qquad (21.92)$$

This is exactly the same as running three separate multilevel growth models on the X, M, and Y variables, but all three equations are combined into a single analysis. The advantage of the single analysis is that the L3 variance–covariance matrix of the u's will be 6×6 and will contain off-diagonal elements that represent associations between growth in X and growth in M (a correlational version of the a path in Figure 21.17) and between growth in M and growth in Y (a correlational version of the b path in Figure 21.17).

Because there is no error term at L1, this multivariate analysis could alternately be specified as a two-level model. This is actually the more practical specification, as it is quite difficult to suppress the L1 error term or constrain it to zero in most multilevel software packages. In separate equation form, the L1 model would be

$$\begin{aligned}\text{L1:}\quad V_{ti} = {} & \beta_{10i}D_{1ti} + \beta_{11i}D_{1ti}time_{ti} + \beta_{20i}D_{2ti}\\ & + \beta_{21i}D_{2ti}time_{ti} + \beta_{30i}D_{3ti}\\ & + \beta_{31i}D_{3ti}time_{ti} + r_{1ti} + r_{2ti} + r_{3ti}\end{aligned}$$

Again, the specification contains no explicit intercept. The three dummy variables represent intercepts for their specific variables. Moreover, the time variable is entered in interaction with each of the dummy variables. These interactions represent the three slopes associated with the X, M, and Y variables. In addition, this equation includes three distinct error terms. This model could be estimated, for example, in SAS Proc Mixed (SAS Institute, 2014), which has the facility to estimate multiple L1 error terms corresponding to the distinct levels of a L1 variable with the group = option. A single variable distinguishing X, M, and Y with uniquely coded values would need to be created to accomplish this. The L2 specification for this model would be identical to the L3 specification of the three-level multivariate model and thus the single-equation forms of both models are identical.

In the general multivariate multilevel model, associations among slopes are correlational and thus nondirectional. Mediation analyses, however, typically involve

directional hypotheses ($X \rightarrow M$ and $M \rightarrow Y$). Examining such directional effects in the longitudinal mediation model requires the ability to include latent variables on the predictor side of the equation. The HLM program incorporates just such facility into the HLM2, HLM3, MLM, and MLM2 modules (Raudenbush, Bryk, Cheong, Congdon, & du Toit, 2011). The HLM manual provides an example in which a latent intercept is used to predict a latent slope. The method described in the manual could easily be expanded to simultaneously estimate growth parameters for more than one outcome variable and allow the slope of one to predict the slope of another. However, the latent variable modeling window in HLM currently allows each latent variable to be used as either a predictor or an outcome, but not both. So in a multivariate model including multiple measurements of X and M, this program could allow the slope of X to predict the slope of M, producing a coefficient and standard error for the a path in Figure 21.17. However, because M cannot simultaneously serve as both an outcome (on the a path from the X slope) and a predictor (on the b path to the Y slope), it would still be necessary to run a second multivariate multilevel analysis with multiple measurements of X, M, and Y to allow the slopes of X and M to predict the slope of Y to produce the b and c' coefficients in Figure 21.17. So directional coefficients can be produced, and a mediated effect can be computed and tested from these, but incorporating the entire process into a single analysis will need to wait for further development of multilevel software.

Autoregressive Latent Trajectory Mediation Models

Integrating the unique strengths of the autoregressive models and the LGC models, Bollen and his colleagues (Bollen & Curran, 2004; Bollen & Zimmer, 2010) proposed the autoregressive latent trajectory (ALT) model. The ALT model parameterizes autoregressive relations between the repeated measures as in the autoregressive models, while simultaneously estimating the growth trajectories based on the pattern of changes across time. The multivariate application of the ALT model allows for parameterization of the autoregressive relations within each variable, the lagged relations between variables at specific measurement occasions, and the relations between the within-individual changes in those variables. Applying ALT models to investigation of mediation, researchers may be able to capture time-specific indirect effects as well as indirect effects based on the growth trajectories that are estimated across the entire time span the data cover.

In the ALT model, the measures of X, M, and Y at time 1 are treated as predetermined and including this predetermined time 1 measure takes care of the biases resulting from omitted variables prior to the time span the data cover. Individual trajectories in the ALT model are estimated based on the measures from time 2 to time t. The autoregressive relations within each variable are specified between the repeated measures from time 1 to time t. Thus, the measure at time t for $t \geq 2$ is specified as the function of the variable itself measured at time $t - 1$ and the trajectory components (i.e., intercept and slope factors) estimated based on the variable measured from time 2 to time t. For example, X_2 is determined by X_1 and the intercept factor, while X_3 is determined by X_2, the intercept factor, and the slope factor. The intercept factor in the ALT model captures the portion of the measure at time 2 that remains unexplained by the time 1 measure and the slope factor represents the growth rate estimated based on time 2 to time t measures. For an ALT model to be identified, four or more waves of data are needed (Bollen & Curran, 2006). Details about the ALT model specifications can be found elsewhere (Bollen & Curran, 2004; Bollen & Zimmer, 2010).

The model in Figure 21.18 depicts an example of the ALT mediation model, where X, M, and Y are measured across four time points. The lag-1 effects between X, M, and Y at each wave are shown in the middle of the figure relating X_{t-1} to M_t to Y_{t+1}. The mediation relations among the individual trajectories are represented by the dotted lines connecting directionally between the intercept factors and the slope factors of X, M, and Y. The time specific indirect effects are estimated based on the lagged effects between the repeated measures of X, M, and Y (e.g., $X_1 \rightarrow M_2$ and $M_2 \rightarrow Y_3$) as in the autoregressive mediation models and the indirect effect based on the within-individual changes in X, Y, and M is estimated in the relations between the slope factors (i.e., $\eta_2 \rightarrow \eta_4 \rightarrow \eta_6$) as in the LGC mediation models. These two different types of indirect effects are independent of each other, as the autoregressive and the lagged effects are net of individual trajectory components in the ALT models. As expected, model specification can be complicated and it may take several steps to determine the appropriate final model; however, the ALT models can provide unique opportunities to simultaneously estimate and separate out the time-specific and the within-individual change based indirect effects in one comprehensive model. Given the difficulties encountered in estimating the LGC mediation models in the ECLS-K data, we did not explore ALT models for our particular example.

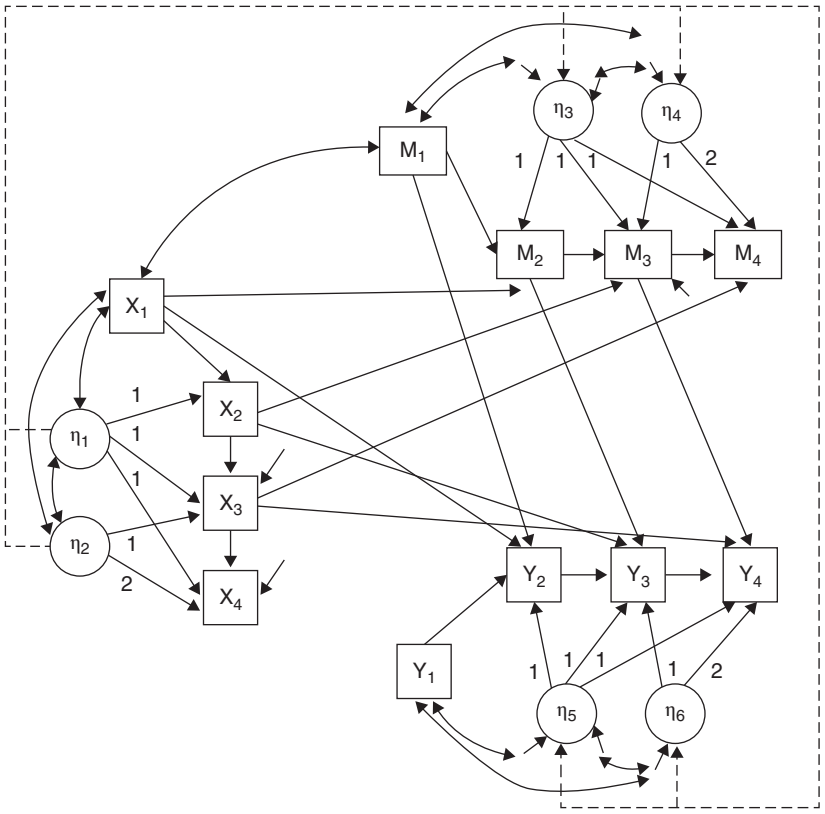

Figure 21.18 An autoregressive latent trajectory mediation model across four waves.

Latent Change Score Models for Moderation and Mediation

Before describing moderation and mediation in latent variable difference score models, a brief word is needed about manifest variable difference score models for longitudinal data. With two waves of data, MacKinnon (2008) suggests forming change scores for *X*, *M*, and *Y*, substituting the difference scores into the equations for the single mediator, and then testing for mediation using one of the cross sectional tests of mediation mentioned earlier. For three or more waves of data, difference scores may be computed and placed into an OLS autoregressive model to test for mediation. Although the steps for fitting the model and testing for mediation are the same as in the autoregressive mediation model, the interpretation of the results is quite different. Instead of a variable at one wave influencing another variable at a later wave, now it is the difference in scores on a variable across two waves influencing the difference in the scores of another variable across two later waves.

With a categorical moderator variable, the simplest method to test for moderation in a LCS model would be to run a multiple group analysis and compare the parameter estimates in the different groups. Depending on the model constraints, this would test whether the proportional or constant change between groups was different or could even test whether one group changed proportionally while another changed constantly or did not change. For observed continuous time-invariant predictors, the latent change score parameters can be regressed onto both predictors and the interaction term. Interactions between latent time-invariant predictors or between a latent time-invariant predictor and a latent change score parameter are possible as well, but require more advanced methods; Marsh, Wen, and Hau (2006) provided an overview of some of these methods.

There are several ways an LCS model can be incorporated into a mediation model. Figure 21.19 shows one example of a LCS longitudinal mediation model where the mediated effect is composed of the slopes of the individual LCS models. That is, the slope of the change in *X* predicts the slope of the change in *M*, which in turn affects slope of the change in *Y*. This is comparable to the parallel process LGC model described by Cheong et al. (2003) because the processes are occurring at the same time. If the processes were measured after one another, the then a serial process LCS model could be specified.

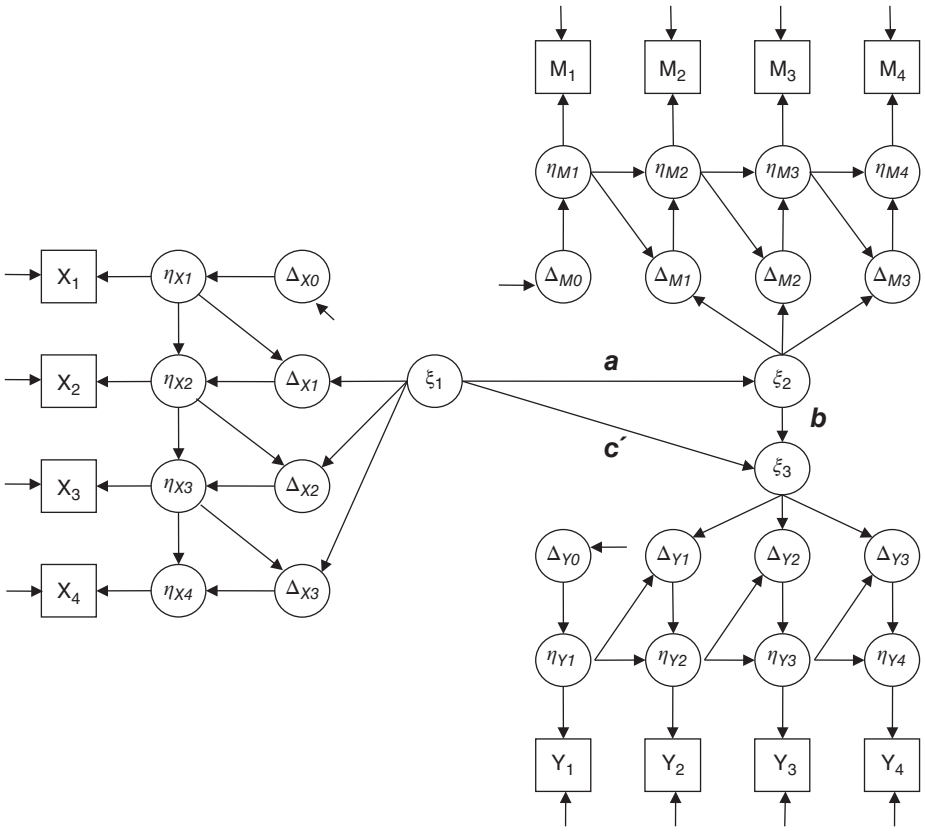

Figure 21.19 Parallel process latent change score mediation model.

MacKinnon (2008) described a different LCS longitudinal mediation model, shown in Figure 21.20. In this model, rather than have the slopes of the change in individual variables predict one another, the error-free true score η variables from one variable predict the latent change scores, Δ, in the other variable. For instance, η_{x1} predicts Δ_{m1} and η_{m2} predicts Δ_{y3}. This model is closer to an autoregressive model, because the variables only affect other variables at later waves. Note that the mean structure has been omitted from Figures 21.19 and 21.20 for ease of presentation. Additionally, an LCS model with *a* paths linking change in the predictor to change in the mediator (i.e., from Δ'_xs to Δ'_ms) and *b* paths linking change in the mediator to change in the outcome (i.e., from Δ'_ms to Δ'_ys) could plausibly be used to test longitudinal mediation.

The process of fitting the LCS mediation models in Figures 21.19 and 21.20 is similar to fitting a LGC mediation model (MacKinnon, 2008). The first step is to fit the individual LCS models for *X*, *M*, and *Y*. This allows the researcher to specify the best fitting LCS model for each variable, such as determining whether a dual change or proportional change model fits better. The second step is to add the mediation paths using the structural model. As in the LGC mediation models, other paths may be appropriate, such as a path from η_{x1} to the Δ_{y2}, which is similar to the lag 1 direct effects from the autoregressive model. The Chi-square goodness of fit test, the RMSEA, and the CFI may be used to assess overall model fit.

Testing for mediation can be accomplished in several ways. First, the joint significance test could be used by examining the significance of each of the individual paths. Second, specific indirect paths can be examined by using a MODEL INDIRECT command in the Mplus program and requesting bootstrap confidence intervals. As with the autoregressive models and LGC, the overall indirect effect can be examined using EQS, SAS PROC CALIS, and LISREL, but only Mplus will test specific indirect effects for significance. For in depth examples of fitting LCS models with LISREL see McArdle (2001) and Ferrer and McArdle (2003).

We fit LCS mediation models to the first, third, and fifth grade ECLS-K data. Table 21.11 presents the results of the parallel process analysis similar to Figure 21.19. All six

models included significant *j* and *k* coefficients for *X*, *M*, and *Y*, indicating both proportional and constant change over time for all constructs. RMSEA and CFI values for all models indicated less than ideal fit, particularly for models with interpersonal skills as the mediator. The tests of mediation in Table 21.11 indicate that the slopes of change in interpersonal skills and reading performance significantly mediated the association between the slope of change in approaches to learning and internalizing behavior. Also, the slopes of change in both academic performance variables mediated the association between the slope of change in externalizing behavior and the slope of change in internalizing behavior. The direction of the mediated effect, however, was counterintuitive for three of the four mediated pathways.

A second series of LCS mediation models was fitted to the first through fifth grade ECLS-K data in which true scores predicted latent change as in Figure 21.20. The results are reported in Table 21.12. Because three time points were included in the analysis, two distinct *a* and two distinct *b* paths were estimated in each model. a_1 and b_1 examine effects of first grade true scores on latent change from first to third grade, and a_2 and b_2 examine effects of third grade true scores on latent change from third to fifth grade. RMSEA and CFI values indicated less than ideal fit in all models, especially for those involving the interpersonal skills mediator. The tests of mediation in Table 21.12 indicate a significant a_1b_1 estimate of mediation

for LEARN → INTERP → INTERN, but the temporally ordered a_1b_2 estimate was nonsignificant. All three possible estimates of mediated effects for EXTERN → INTERP → INTERN were significant. The a_2b_2 estimate in the EXTERN → READ → INTERN model was the only significant mediated effect involving the academic performance variables.

Moderation and Mediation in Exponential Decay Models

Similar to standard multilevel models, moderation in an exponential decay multilevel growth model is accomplished by adding the moderating variable and appropriate interaction term at the correct level. If the moderator is a time-varying predictor, Z_{ti}, and interacts with another time-varying predictor, X_{ti}, that is not time, then both the predictors and the interaction term, $X_{ti}Z_{ti}$, would be added at L1 in equation 21.35.

$$
\begin{aligned}
\text{L1:}\quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] \\
& \quad + \beta_{3i}X_{ti} + \beta_{4i}Z_{ti} + \beta_{5i}Z_{ti}X_{ti} + r_{ti} \\
\text{L2:}\quad & \beta_{0i} = \gamma_{00} + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + u_{2i} \\
& \beta_{3i} = \gamma_{30} + u_{3i} \\
& \beta_{4i} = \gamma_{40} + u_{4i} \\
& \beta_{5i} = \gamma_{50} + u_{5i}
\end{aligned}
\tag{21.93}
$$

Because of the nonlinear relation between time and the outcome variable, a linear interaction between time and a time-varying covariate is difficult to conceptualize and will not be discussed for the multilevel or latent variable exponential decay models.

If the moderator is a time-invariant predictor, Z_i, of one of the growth parameters, for example β_0, and interacts with another time-invariant predictor of the same growth parameter, X_i, then both the predictors and the interaction, X_iZ_i, between these predictors would be added to the corresponding L2 equations in equation 21.35.

$$
\begin{aligned}
\text{L1:}\quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] + r_{ti} \\
\text{L2:}\quad & \beta_{0i} = \gamma_{00} + \gamma_{01}X_i + \gamma_{02}Z_i + \gamma_{03}X_iZ_i + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + u_{2i}
\end{aligned}
\tag{21.94}
$$

L2 interactions may be of more interest for the exponential decay model as they test whether the effect of a time-invariant predictor on the initial value, rate of change, and asymptote value is dependent on the value of the moderator. For the latent variable exponential decay model with a time-invariant categorical moderator variable, the simplest method to test for moderation would be to run a multiple group analysis and compare the parameter estimates in the different groups. This would test whether the initial value, rate of change, and asymptote value were the same for the different groups. For observed continuous time-invariant predictors, the latent growth parameters can be regressed onto both the predictors and the interaction term. As with the LCS model, interactions between latent time-invariant predictors or between a latent time-invariant predictor and a latent growth parameter are possible for the latent exponential decay model, but require more advanced methods described by Marsh et al. (2006).

If one of the variables is a time-varying predictor, X_{ti}, and the other is a time-invariant predictor, Z_i, then

a cross-level interaction can be estimated by including the time-varying predictor at L1 and including the time-invariant variable as a predictor of the time-varying variable in the L2 equation in equation 21.35.

$$\begin{aligned}
\text{L1:}\quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] + \beta_{3i}X_{ti} + r_{ti} \\
\text{L2:}\quad & \beta_{0i} = \gamma_{00} + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + \gamma_{21}Z_i + u_{2i} \\
& \beta_{3i} = \gamma_{30} + \gamma_{31}Z_i + u_{3i}
\end{aligned} \tag{21.95}$$

This also allows for interactions between time-invariant predictors and time if Z_i is added as a predictor of β_1. Note that the time-invariant predictor must also be included as an L2 predictor of β_2 in order for the first-order effect Z_i to be estimated in the model, which is necessary for the correct estimation of the interaction term $X_{ti}Z_i$.

Though not technically an interaction, differential effects based on the relations between the growth parameters can be examined using the off-diagonal elements of the covariance matrix of the random effects, $\boldsymbol{\tau}$. For example, if higher initial values were associated with higher asymptote values, then τ_{02} would be positive and significantly different from zero. The same association can be examined in the latent variable exponential decay using the covariances in the $\boldsymbol{\Phi}$ matrix.

The first step in constructing an exponential decay multilevel mediation model is to rewrite the equations from the linear single mediator model in the form of equation 21.35. When M and Y decay exponentially and X is a continuous variable, X is added at L1 of equation 21.35 and the effect of X on M becomes

$$\begin{aligned}
\text{L1:}\quad & M_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] + a_iX_{ti} + r_{ti} \\
\text{L2:}\quad & \beta_{0i} = \gamma_{00} + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + u_{2i} \\
& a_i = \gamma_{30}
\end{aligned} \tag{21.96}$$

where γ_{00}, γ_{10}, and γ_{20} represent the mean values across subjects for the initial value, rate of change, and asymptote for M partialling out the effect of X, respectively, and γ_{30} is the effect of X partialling out the effect of time (i.e., the natural exponential decay of M). Because M is also continuous, X and M are added at L1 of equation 21.35 and the effect of X and M on Y becomes

$$\begin{aligned}
\text{Level1:}\quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] + b_iM_{ti} \\
& \qquad + c'_iX_{it} + r_{ti} \\
\text{Level2:}\quad & \beta_{0i} = \gamma_{00} + u_{0i} \\
& \beta_{1i} = \gamma_{10} + u_{1i} \\
& \beta_{2i} = \gamma_{20} + u_{2i} \\
& b_i = \gamma_{30} \\
& c'_i = \gamma_{40}
\end{aligned} \tag{21.97}$$

where γ_{00}, γ_{10}, and γ_{20} represent the mean values across subjects for the initial value, rate of change, and asymptote for Y partialling out the effects of X and M, respectively, γ_{30} is the effect of M partialling out the effects of time (i.e., the natural exponential decay of Y) and X, and γ_{40} is the effect of X partialling out the effects of time and M. Krull and MacKinnon (2001) call this a $1 \rightarrow 1 \rightarrow 1$ model because all three variables occur at L1.

Here the three mediation parameters, a_i, b_i, and c'_i, have all been treated as fixed effects, meaning that the mediation effects do not vary between individuals. Adding random effects for these three paths would not change the interpretations of the coefficients, but it would indicate that the effect differs among individuals, an indication of the presence of moderation. For example, if an L2 predictor was added that predicted b_i, such as a baseline value of M, this would create a cross-level interaction between that predictor and M, meaning the predictor of b_i is a moderator of the effect of M on Y. For more information on moderation of a mediated effect see Fairchild and MacKinnon (2009); for more information on mediation at different levels see Bauer et al. (2006), Kenny et al. (2003), Krull and MacKinnon (2001), and Preacher et al. (2010).

When X is a time-invariant variable, such as random assignment to a treatment, instead of entering X as an L1 covariate, X must be entered into the multilevel model at L2. The multilevel equations for the model of X on M then change from equation 21.95 to

$$\begin{aligned}
\text{L1:}\quad & M_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i})\exp[\beta_{1i}t] + r_{ti} \\
\text{L2:}\quad & \beta_{0i} = \gamma_{00} + a_0X_i + u_{0i} \\
& \beta_{1i} = \gamma_{10} + a_1X_i + u_{1i} \\
& \beta_{2i} = \gamma_{20} + a_2X_i + u_{2i}
\end{aligned} \tag{21.98}$$

Assuming X is a dichotomous dummy coded variable, then γ_{00}, γ_{10}, and γ_{20}, are estimates of the initial value, rate of change, and asymptote of M for the group coded 0, respectively, and a_0, a_1, and a_2 are the differences between the two groups in X such that $\gamma_{00} + a_0$, $\gamma_{10} + a_1$, and $\gamma_{20} + a_2$ are the initial value, rate of change, and asymptote of M for the group coded 1, respectively.

The effects of M and X on Y change from equation 21.96 to

$$\begin{aligned}
\text{L1:} \quad & Y_{ti} = \beta_{2i} + (\beta_{0i} - \beta_{2i}) \exp[\beta_{1i} t_t] + b_i M_{ti} + r_{ti} \\
\text{L2:} \quad & \beta_{0i} = \gamma_{00} + c_0' X_i + u_{0i} \\
& \beta_{1i} = \gamma_{10} + c_1' X_i + u_{0i} \\
& \beta_{2i} = \gamma_{20} + c_2' X_i + u_{0i} \\
& b_i = \gamma_{30}
\end{aligned} \tag{21.99}$$

Again assuming X is a dichotomous dummy coded variable, γ_{00}, γ_{10}, and γ_{20}, are estimates of the initial value, rate of change, and asymptote of Y for the group coded 0, partialling out the effect of M, respectively, c_0', c_1', and c_2' are the differences between the two groups in X partialling out the effect of M, such that $\gamma_{00} + c_0'$, $\gamma_{10} + c_1'$, and $\gamma_{20} + c_2'$ are the asymptote value, initial value, and rate of change of Y for the group coded 1, respectively, and γ_{30} is the effect of M partialling out the effect of time (i.e., the natural exponential decay of Y) and the effect of X on the exponential decay of Y. Krull and MacKinnon (2001) call this a $2 \rightarrow 1 \rightarrow 1$ model because X is at L2 while M and Y are at L1.

Adding M as a time-varying predictor in at L1 so that the model estimates the relation between M and Y at the same point in time violates the temporal precedence assumption. An alternate method would be to introduce a lag such that M predicts Y at later time points. With a lag of one wave, M_{it} in equation 21.98 would change to $M_{(t-1)i}$, so that each measurement of M predicts the measurement of Y at the next time point. Then b_i would be the average relation across time between M at time t and Y at time $(t + 1)$, partialling out the effect of time. One issue with lags is that M must be measured prior to Y. Also, although the model makes no assumption that the measurements of M or Y are equally spaced, when the relation between M and Y is lagged, if the measurements are not equally spaced, b_i will represent the average effect across different amounts of time. For example, if M and Y were measured at 1, 3, and 12 months, introducing a lag of one wave would mean that $M_{1\text{month}}$ would predict $Y_{3\text{months}}$, a lag of 2 months, while $M_{3\text{months}}$ would predict $Y_{12\text{months}}$, a lag of 9 months, an undesirable situation.

The value of M immediately following an intervention could also be entered as an L2 predictor of the rate of change and asymptote of Y. If X had a significant effect on the initial value of M, which in turn predicted the rate of change and asymptote of Y, then the effect of X on the rate of change and asymptote of Y would be mediated through its initial effect on M. This does not satisfy temporal precedence since the initial value of Y is used to estimate the rate of change and asymptote of Y, but it does make a stronger case for mediation than in equation 21.98.

Using the exponential decay model shown in equations 21.95 and 21.96, when X and M are added to the model at Level 1, mediation can be tested using the joint significance test by testing a and b for significance. The mediated effect $a_i b_i$ can also be tested by dividing it by the standard error

$$\begin{aligned}
Var(\widehat{ab} + \hat{\sigma}_{aj,bj}) = {} & b^2 Var(\hat{a}) + a^2 Var(\hat{b}) + Var(\hat{a}) Var(\hat{b}) \\
& + 2ab Cov(\widehat{ab}) + Cov(\widehat{ab})^2 + Var(\hat{\sigma}_{aj,bj})
\end{aligned} \tag{21.100}$$

that includes the covariance of the a and b parameters (Bauer et al., 2006; see also Kenny et al., 2003; Krull & MacKinnon, 1999, 2001; MacKinnon, 2008). However, this assumes that the distribution of the mediated effect is normal, which is often not the case. For this reason, creating a confidence interval around the mediated effect using the percentile bootstrap may be preferred.

Testing for mediation when X is entered at L2 such as in equations 21.97 and 21.98 is slightly different than for the continuous L1 X variable model in equations 21.95 and 21.96 as there are now three individual effects of X on M, a_0, a_1, and a_2. Each of these parameters represents a different effect of X on M, and because of this, three different mediated effects can be estimated, $a_0 b_i$, $a_1 b_i$, and $a_2 b_i$, all of which may be tested for significance using one of the methods described earlier. As discussed during the presentation of autoregressive models, each of these mediated effects represents a specific indirect effect, any or all of which may be of substantive interest.

Several different exponential decay mediation models are possible when using an LGC approach. The first is a direct extension of the model in equations 21.95 and 21.96. Illustrated in Figure 21.21, this model begins by fitting separate exponential decay LGC models for X, M, and Y. Then the observed M variables are regressed on the observed X variables and the observed Y variables are

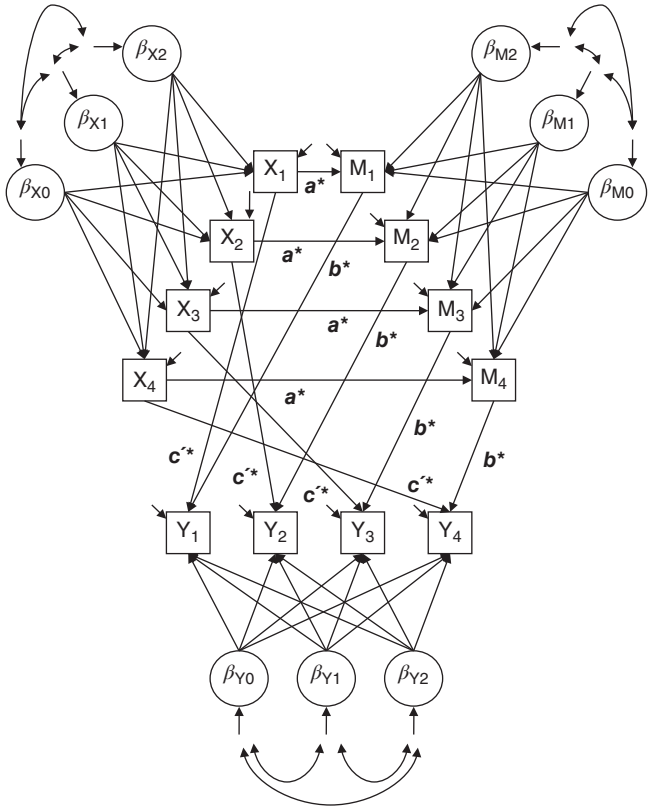

Figure 21.21 An exponential decay latent growth curve model with a continuous X variable and direct paths between observed variables.

regressed on the observed X and M variables, constraining all of the paths between sets of observed variables to be equal. For the dichotomous X variable model in equations 21.97 and 21.98, separate exponential decay LGC models are fit for M and Y, and the observed Y variables are regressed on the observed M variables, again constraining these paths to be equal. The latent growth parameters from M and Y are then regressed onto X.

Another form of exponential decay LGC mediation model is a parallel process model. As was described earlier, an exponential decay LGC model is equivalent to a linear LGC model, only with an exponential decay trajectory across time. Hence, the individual linear LGC models in the parallel process LGC mediation model may be replaced with exponential decay LGC models to form a parallel process LED mediation model, as shown in Figure 21.22.

The parallel process mediation model in Figure 21.22 only contains paths between the rate of change growth parameters. However, depending on the theory behind the model, other paths may be appropriate. For instance, if X were dichotomous and had an effect on the initial value of M, then it may be of interest to include a path between the initial value of M and the rate of change of Y. Or, continuing with the dichotomous X example, if M reached asymptote before Y, it could be of interest to investigate whether the asymptote of M had an effect on the asymptote of Y. Testing for mediation would be conducted similarly to the parallel process LGC by testing the significance of individual paths or by testing specific indirect paths for significance. In addition, various fit indices given by most structural equation modeling software can be used to assess overall model fit.

Testing for mediation in the exponential decay LGC model is similar to testing for mediation in the multilevel exponential decay model in that the meditational parameters are tested for significance or individual indirect effects are directly tested for significance. One advantage of the latent variable framework is the addition of fit indices, which are provided by most SEM software packages and provide valuable information about the overall fit of the model and the presence of a significant mediated effect. Another advantage is the ability to model measurement error and have multiple indicators for a variable. Finally, the latent variable framework allows for the correlation of residuals and growth parameters as well as the ability to relax the equality constraints for the mediation parameters (e.g., the effect of M_1 on Y_1 does not have to equal the effect of M_2 on Y_2).

Because the ECLS-K variables in our example do not include a treatment or intervention, we did not fit illustrative exponential decay models to this data.

Moderated Mediation in SEM

Sometimes a researcher may wish to test a hypothesis about whether longitudinal mediation effects differ depending on the value of a particular variable, i.e., moderated longitudinal mediation. If the longitudinal mediation is modeled using one of the SEM approaches outlined above, an appropriate test of such moderation can be conducted using techniques for incorporating moderation into this framework, the nature of which depend on the type of moderator involved. If the moderator Z represents a categorical variable with a relatively small number of levels, such as clearly defined group membership (e.g., sex, religion, grouping on age), the multiple group approach (i.e., stacked analysis) in SEM (Jöreskog, 1971) can be used for investigating the moderated mediation effects (Little, 2013; MacKinnon, 2008). Since the independent variable and the mediator may display differential effects in the different groups, stacking groups together allows for comparisons of the parameters, with some parameters

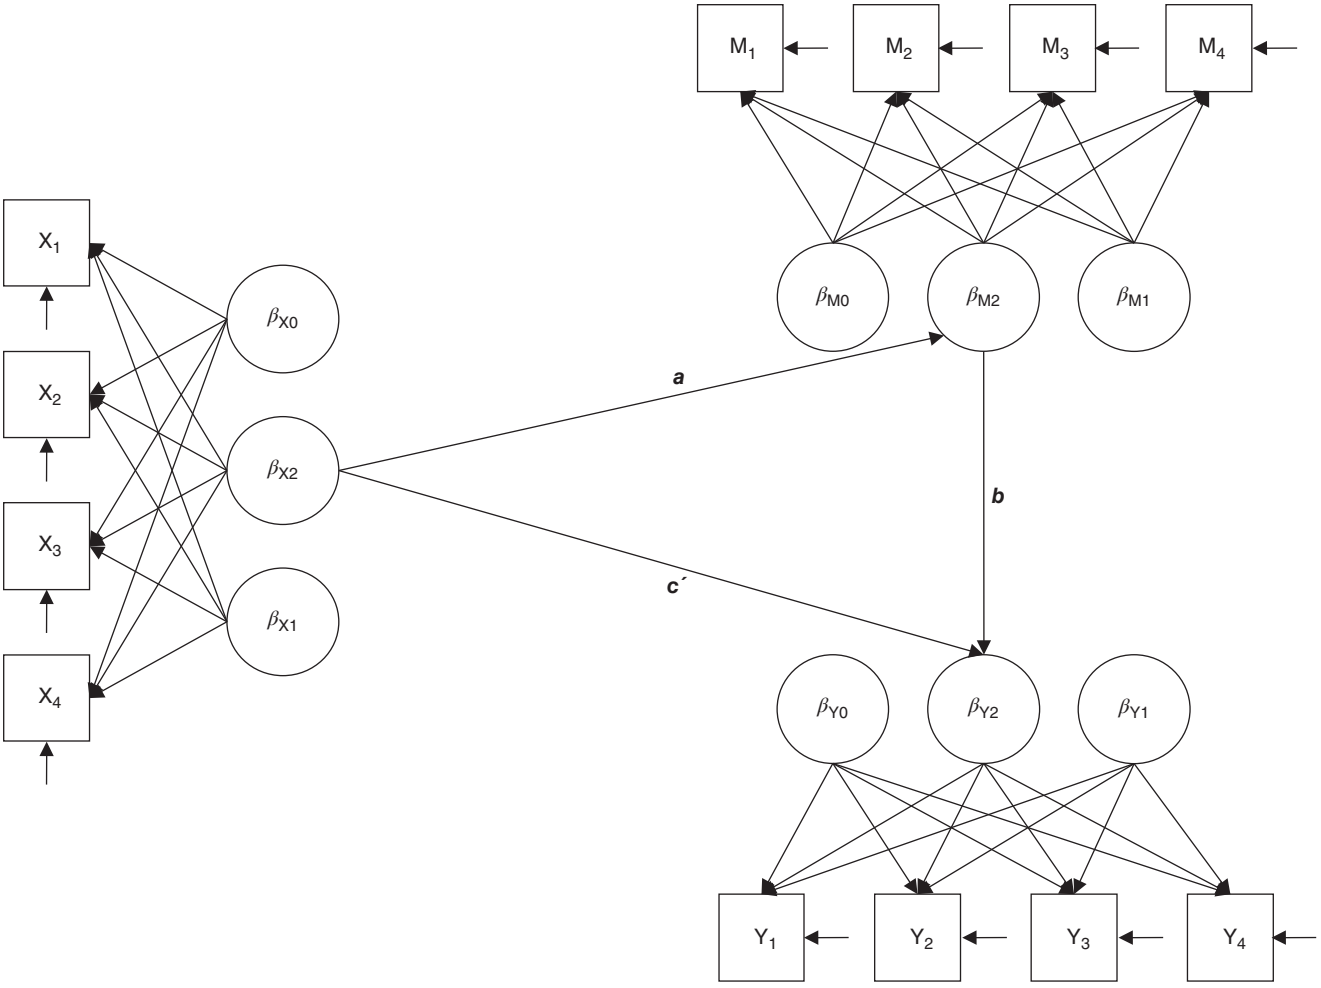

Figure 21.22 A parallel process exponential decay latent latent growth curve model with a dichotomous *X* variable and direct paths between latent growth parameters.

constrained to be equal, while other parameters specified to vary between the stacked groups. The parameters that differ between the groups indicate interactions between the variable providing the group membership and the variables in the model, such as *X* and *M*.

Typically, it is assumed that the same mediation model holds for the stacked groups and the equality of parameter estimates for the relations between *X* and *M* (i.e., *a* paths), *M* and *Y* (i.e., *b* paths), or *X* and *Y* (i.e., *c*′ paths) are examined. Bollen (1989) suggested that researchers start with the model without restricting any parameters across the groups. A satisfactory fit would indicate that the same form of model holds across the stacked groups and provide a rationale for further testing the equivalence of the parameters. The moderated mediation can be investigated from the final model where the equivalent parameters are constrained and nonequivalent parameters are freely estimated. This approach can be applied to structural equation models with observed variables and also models with latent variables for estimating the interaction effect between the latent variable and the categorical group variable (Rigdon, Schumacker, & Wothke, 1998). When *X*, *M*, or *Y* are latent variables, a series of hierarchical tests for invariance should be conducted for the measurement models before examining the equality of the structural relations, to assure that the measures used for the latent variables *X*, *M*, and/or *Y* are equivalent across the groups. If the growth trajectories of *X*, *M*, and *Y* are estimated for the LGC mediation, researchers should inspect if the trajectory shapes are equivalent or different across the stacked groups before testing the moderated mediation. The steps for testing measurement invariance can be found elsewhere (Horm & McArdle, 1992; Jöreskog, 1971; Meredith, 1993).

In a stacked model for moderated mediation, several hypotheses can be tested, including a test of the equality of the relation between *X* and *M* (i.e., *a* paths), a test of the

equality of the relation between M and Y (i.e., b paths), or a test of the equality of the relation between X and Y (i.e., c' paths) across the groups. More importantly, further analysis to test the equality of the indirect effects (i.e., ab estimators) is needed. While the tests of the equality of the relations among X, M, and Y may provide the information on the source of differential indirect effects across the groups, it is possible that the estimated indirect effects obtained in the stacked groups may not statistically differ even when the magnitude of the a paths or the b paths differ across groups. The equality of the path coefficients can be tested by comparing a series of nested models where the relevant paths are constrained to be equal across groups. The equality of the estimated indirect effects can be tested by a t test by dividing the difference in the mediated effects by the pooled standard error of the mediated effect as follows:

$$t_{a_1b_1-a_2b_2} = {}^{(a_1b_1-a_2b_2)}/\sqrt{s^2_{pooled}} \qquad (21.101)$$

In equation 21.100, a_1b_1 and a_2b_2 are the estimated indirect effects from each of the stacked groups and $\sqrt{s^2_{pooled}}$ is the pooled standard error of the mediated effect in each group (MacKinnon, 2008). The equality tests described for the two-group case in this section can be easily extended to cases with more than two groups. The analysis procedures described above can be carried out for each pair of groups to locate the sources of the moderation by group membership.

When the moderator Z is a continuous observed variable interacting with an observed X or M variable, the moderated mediation can be examined using the product term created to reflect the moderation of Z in the relations between X and M (i.e., a path), between M and Y (i.e., b path), or between X and Y (i.e., c' path). Again, the two variables involved in the product term (e.g., X and Z) need to be centered with respect to their means (e.g., $X - \overline{X}$ and $Z - \overline{Z}$) before creating the product term, because a product term based on the uncentered variables will be highly correlated with the first-order effect terms and the high correlations between the predictors may introduce collinearity problems (Aiken & West, 1991; Marquardt, 1980). Centering the variables will minimize or remove the correlations between the product term and the first-order effect terms. The centered variables and their product term are then entered in the model to predict M or Y to test the moderation by Z in the specific relations in the mediation model. With significant interaction effects, further probing of the interaction patterns can be conducted by obtaining simple slopes at different levels of the moderator Z as described earlier in this chapter. Some SEM software programs such as Mplus (Muthén & Muthén, 2014) calculate the indirect effects at different levels of Z and produce the plots of indirect effects corresponding to particular values of Z.

When the moderator is a latent variable interacting with other latent variables in the model, the moderated mediation model can be investigated using the latent interaction variable. Since the use of latent variables in SEM has many advantages, including the capability of controlling for measurement errors that could obscure the interaction effects, various approaches to estimating interactions between latent variables (Arminger & Muthén, 1998; Bollen & Paxton, 1998; Jöreskog, 1998; Kenny & Judd, 1984; Klein & Moosbrugger, 2000; Marsh, Wen, & Hau, 2004; Wall & Amemiya, 2000) have been proposed in the past years. These approaches commonly specify the indicators of the latent interaction variable with the product of the indicators of the two latent variables, but they differ in the ways they specify the nonlinear constraints used for the factor loadings and variance associated with the latent interaction variable. As expected, the modeling process of these approaches may be complicated and unwieldy, and this may be the reason why such methods have not been frequently applied to the substantive research (Rigdon et al., 1998). However, the latent interaction variable approaches have the potential to be applied to estimating moderated mediation, although more research is warranted to investigate the applicability of these approaches for the models with more than one interaction term (Marsh et al., 2004).

To illustrate a basic moderated longitudinal mediation analysis, we fit a multiple groups SEM for boys and girls using the autoregressive mediation model including both lagged and contemporaneous a and b paths (as in Figure 21.16 and Table 21.9) for the LEARN → INTERP → INTERN pathway, which was the best fitting longitudinal mediation model in the first to fifth grade ECLS-K data. Comparisons of the fit of nested models revealed that several parameter estimates differed by gender. Specifically, the autoregressive path from LEARN at third grade to LEARN at fifth grade and both autoregressive paths involving the INTERP mediator were larger for boys than for girls. In addition, boys had larger error variances and disturbance variances than girls for all three variables at all time points. The only mediation effect parameters that differed by gender were the lagged a paths. Boys had stronger associations between first grade LEARN and third grade INTERP ($a_{boys} = -0.1786$, SE = 0.0142, $p < .0001$ vs. $a_{girls} = -0.1272$, SE = 0.0150, $p < .01$) and between third grade LEARN and fifth grade INTERP than girls ($a_{boys} = -0.1686$, SE = 0.0152, $p < .0001$ vs. $a_{girls} =$

–0.1250, SE = 0.0155, $p < .01$). The test of the difference between boys' and girls' *ab* estimates for the temporally ordered $X1 \rightarrow M3 \rightarrow Y5$ mediation effect was significant ($a_1b_1 - a_2b_2 = -0.0019$, SE = 0.0010, $p < .05$), indicating that the effect of approaches to learning on internalizing behavior mediated by interpersonal skill was, in fact, stronger for boys than for girls.

MODERN CAUSAL INFERENCE AND LONGITUDINAL MEDIATION MODELS

There has been a dramatic increase in research on causal inference related to mediation analysis over the last decade (Imai, Keele & Tingley, 2010; MacKinnon, 2008; Pearl, 2012, Valeri & VanderWeele, 2013). In the psychology literature, causal inference has primarily focused on the need for longitudinal rather than cross sectional relations to demonstrate mediation (Cheong et al., 2003; Cole & Maxwell, 2003, Judd & Kenny, 1981; MacKinnon, 2008; Maxwell & Cole, 2007). These articles emphasize the central role of demonstrating temporal precedence such that *X* occurs before and causes later change in *M* and *M* occurs before and causes later change in *Y*, as discussed in a recent article (Maxwell, Cole, & Mitchell, 2011) and commentary on this topic (West, 2011). Temporal precedence refers to the demonstration that for a variable to be a cause of an effect, it must occur before the effect.

The mediation model is a longitudinal model such that *X* causes *M* and *M* causes *Y*, so evidence for this longitudinal causal process is ideally obtained from longitudinal data. Mediation relations between variables measured at one time represent associations between levels of the variables such that a person with high scores on *X* also has higher scores on *M* and *Y*, as an example. In some situations, temporal order between the variables is reasonable such as when *X* represents random assignment to an intervention or measures of *M* are taken before measures of *Y*. Cole and Maxwell (2003) demonstrated algebraically the bias that can result when cross sectional relations are treated as if they are longitudinal relations. The notion that relations between levels of variables at a single time point differ from relations across time applies to any difference across any period of time. For example, the mediated effect for measures that differ one minute in time may differ from measures that differ by one year in time. It is not necessarily the cross sectional versus longitudinal nature of measures that is important. It is the match between when change occurs between variables in the true population mediation model and whether the variables are measured when this mediation relation can be detected (MacKinnon, 2008).

Another important causal inference topic related to temporal precedence is the influence of omitted variable bias on mediation relations (MacKinnon & Pirlott, 2015). There has been an early and sustained focus of attention in the social sciences that accurate estimation of mediation depends on the consideration of other variables that may explain or alter a mediation conclusion from a research study (James, 1980, Judd & Kenny, 1981). In the medical and epidemiology literature, causal inference for mediation has primarily addressed the issue of how confounder variables may bias mediation estimation. Omitted variable bias and confounder bias are considered synonyms in this chapter representing unmeasured variables that influence mediation relations. The potential outcome model provides a way to define causal mediation analysis in the context of confounders or omitted variables. The potential outcome model for causal inference is relevant for many fields and its application has steadily grown. The beginnings of the potential outcome approach for mediation in the social sciences can be traced to an influential paper by Holland (1988). Holland applied the Rubin causal model (Rubin, 1974) to demonstrate the challenges of identifying causal mediation effects even when *X* represents randomization to conditions (see also Sobel, 2008). In epidemiology, Robins and Greenland (1992) described the restrictive assumptions necessary for identification of causal mediation. Pearl (2001) described and developed a solution discussed in Robins and Greenland (1992) to obtain causal mediation effects that serves as the source for a series of important recent papers on causal mediation from the potential outcome perspective (Imai, Keele & Tingley, 2010; Imai, Keele, & Yamamoto, 2010; Lynch, Cary, Gallop, & Ten Have, 2008; Pearl, 2012; Ten Have et al., 2007; Valeri & VanderWeele, 2013; VanderWeele & Vansteelandt, 2009; Vansteelandt, 2009). These new papers provide some practical guidance and software for researchers to use. All of these previous papers have focused primarily on the cross sectional mediation case of measurement of *X*, *M*, and *Y*, and not the longitudinal case.

The purpose of this section is to describe potential outcome model approaches for investigation of mediation effects in the context of longitudinal data. First the potential outcome model for evaluating intervention data is described, followed by applications of this model to the case of mediation. Mediation and moderation relations are described for this potential outcome model. Additional information regarding the potential outcome model for longitudinal data is outlined followed by the estimation

of causal estimators from data. Other approaches to longitudinal mediation from a modern causal inference perspective are briefly described.

Potential Outcomes Model

The potential outcomes approach to estimating causal effects (Holland, 1986, 1988; Pearl, 2009; Rubin, 1974) distinguishes between an individual's observed and counterfactual outcomes. A counterfactual outcome is an outcome for a participant in a research condition in which that participant did not serve (the condition contrary to actual condition they did serve in). For the case of two groups, let variable X be an intervention with level x ($x = 1$ for the intervention, $x = 0$ for the control) and variable Y be the outcome variable. The potential outcomes framework considers all conditions that an individual could serve in, including both intervention and control conditions, even though observed data can only be obtained for one of the two groups. In other words, these models consider all potential outcomes, so if an individual is assigned to the intervention group, the potential outcome $Y(1)$, is the observed outcome Y. The counterfactual outcome for that individual is the value for the outcome variable if that person was assigned to the control group, $Y(0)$. The individual causal effect is equal to $Y(1) - \mathrm{Y}(0)$, even though the value in the control group cannot be observed for a participant in the intervention group. Because it is not possible for the same individual to simultaneously serve in both intervention and control groups, the individual causal effect is not estimable—a problem called the fundamental problem of causal inference. However, assuming that participants are exchangeable, then it is possible to compute a causal effect averaged across individuals in each group and this average causal effect is computed as $\mathrm{E[Y(1) - Y(0)]}$, or the expected average difference between intervention and control groups. This average causal effect is a causal estimator under certain assumptions, primarily that individuals have been randomized to the two conditions.

The potential outcome approach applied to mediation introduces a mediating variable M with level m that mediates the relation between X and Y. The potential outcome approach to mediation demonstrates several complexities in the estimation of mediation. The additional complexity is shown in the additional effects that are now relevant when including the mediator, M, in causal sequence from X to M to Y (Hogan & Lancaster, 2004; Jo, 2008; Pearl, 2001, 2012; Robins & Greenland, 1992; VanderWeele & Vansteelandt, 2009). In addition to the average causal effect now called the total effect (TE) of X on Y, there are five additional causal effects: the controlled direct effect (CDE) which is the direct effect of X on Y at a certain value m of M, a direct effect in the control group called the pure natural direct effect (PNDE), a direct effect in the intervention group called the total natural direct effect (TNDE), the indirect effect in the control group called the pure natural indirect effect (PNIE), and the indirect effect in the intervention group called the total natural indirect effect (TNIE). Use $Y(x, m)$ to denote the potential outcome for an individual under the intervention level x and mediator level m. X takes the value $x = 0$ for the control group, and $x = 1$ for the intervention group. If the actual value of M is m for an individual, then the counterfactual value of M for that individual is denoted as m'.

The *controlled direct effect* of intervention X on outcome Y is the direct effect of the intervention on the outcome at a fixed level m of the mediator M:

$$\mathrm{CDE} = Y(1, m) - Y(0, m) \tag{21.102}$$

The *natural direct effect* of X on Y is different from the CDE in that M is set to the level $M(x)$, the level that would have naturally occurred under one of the conditions of X, so there are now two natural direct effects corresponding to intervention and control groups. In the case of $M(0)$, the PNDE is the effect of intervention X on outcome Y when X did not influence the mediator M (or the participants were assigned the mediator level under the control condition).

$$\mathrm{PNDE} = Y1, M(0) - Y(0, M(0)) \tag{21.103}$$

In the case of $M(1)$, the TNDE is the effect of intervention X on outcome Y when X did not influence the mediator M (or the participants were assigned the mediator level under the intervention condition).

$$\mathrm{TNDE} = Y1, M(1) - Y(0, M(1)) \tag{21.104}$$

Following the same approach, the *pure natural indirect effect* is the effect of the intervention on Y when changing the level m of M in the control condition. In other words, the PNIE is the effect of the intervention on outcome when the level of M is changed when X is set to 0.

$$\mathrm{PNIE} = Y0, M(1) - Y(0, M(0)). \tag{21.105}$$

The *total natural indirect effect* (TNIE) is the effect of the intervention Y when changing the level of M in the

intervention condition. In other words, the TNIE is the effect of intervention on outcome when the level of M is changed when X is set to 1.

$$\text{TNIE} = Y1, M(1) - Y(1, M(0)) \tag{21.106}$$

The total effect is equal to the sum of the pure natural direct effect plus the total natural indirect effect, and the total effect is also equal to the sum of the pure natural indirect effect plus the total direct effect. Because there are different effects for intervention and control groups, an interaction is included in this model insomuch as the direct and indirect effects may differ in the two groups. The direct and indirect effects are different in the two groups if the interaction between X and M in the prediction of Y is nonzero. If the interaction is zero, then the two direct effects are equal and the two indirect effects are equal and these results reduce to the traditional estimator of the direct and indirect effects. Importantly, Pearl (2001) demonstrates that the decomposition of the total effect into the natural direct and indirect effects holds even in models with interactions and nonlinear models such as logistic regression (i.e., the pure natural direct effect plus the Total Natural Indirect Effect equals the total effect).

These estimators described already are estimators of causal effects under certain assumptions. Two assumptions are required for controlled direct effect to be identified (Pearl, 2001; VanderWeele, 2010):

1. No unmeasured confounders for the relation between X and Y.
2. No unmeasured confounders for the relation between M and Y.

Two additional assumptions are required for natural direct and indirect effects to be identified:

3. No unmeasured confounders for the relation between X and M.
4. No measured or unmeasured M to Y confounders are affected by intervention.

Assumptions (1) and (3) refer to the ignorability of intervention (i.e., the intervention independent of potential outcomes for the mediator and outcome) given observed pretreatment confounders. This assumption is satisfied with randomization of X.

Assumption (2) refers to the ignorability of the mediator and the potential outcomes for Y given the observed intervention and pretreatment confounders. This ignorability of the mediator assumption may be difficult to satisfy in actual research because randomization of M is usually not plausible for many studies. In other words, the value of the mediator is not randomly assigned to participants but is self-selected. Even when conditioning on observed confounders for the relation between M and Y, there can still be unobserved confounders that would lead to violation of this assumption. This assumption is strong and is often ignored in studies even though a causal interpretation of a mediated effect is not possible without its existence (VanderWeele & Vansteelandt, 2009; MacKinnon, 2008). Methods described in this article hold that assumption 3 is true and methods to investigate this assumption are only starting to be developed (Coffman & Zhong, 2012). Assumption 4 states that there are not confounders affected by the intervention that confound the M to Y relation. One goal of multiple mediator models is to assess these additional posttreatment confounders in a way that allows for causal estimation. However, approaches to deal with multiple mediators are an active area of current research in causal inference (VanderWeele & VanSteelandt, 2013). And in the application of the potential outcome model for longitudinal mediation, effects of earlier waves on later waves could be postintervention confounders that violate assumption 4.

The assumptions described above have also been described as sequential ignorability assumptions in the research literature on causal mediation (Imai, Keele, & Tingley, 2010; Pearl, 2001; VanderWeele & Vansteelandt, 2009). The linear regression approach as well as potential outcome methods including the natural direct and indirect effects assumes *sequential ignorability*, which consists of the ignorability of the intervention assignment and the ignorability of the mediator. In other words, random assignment of X ensures that c and a represent causal effects (with assumptions 1 and 2) but b and $c\prime$ do not have a causal interpretation without further assumptions (Holland, 1988). For instance, given that the individuals are randomly assigned to conditions of an intervention, there are not confounders of the X to Y and X to M relations. However, because participants are not randomly assigned to values of M, the relation between M and Y, b, is not a causal effect because there can be confounders that account for the effect of M on Y.

Comparison of Traditional and Potential Outcome Mediation Analysis

For the case of continuous M and Y as in most social science studies, there is a direct correspondence between the

estimators of the direct and indirect effects in traditional and the potential outcome methods. If all assumptions are satisfied, traditional and potential outcome methods come to the same conclusion about direct and indirect effects if the interaction of X and M on Y is zero. So the traditional estimators of ab and c' correspond to the natural indirect and natural direct effects causal estimators. When the interaction between X and M is included in the statistical analysis, the natural indirect effects correspond to simple mediation effects in the traditional analysis where the simple mediation effects are at specific values of the mediator. However, typically the interaction of X and M is included in traditional analysis as a way to test the assumption that the causal relation of M to Y does not differ across levels of X. If the interaction is nonsignificant, it is often not included in traditional mediation analysis mainly because the relation of M to Y is often based on prior research. To clarify, if the interaction is included in the statistical model then there are simple mediation effects in traditional analysis corresponding to different b paths in the statistical analysis. These effects would reflect the mediated effect at different values of the mediator. There are corresponding effects in the potential outcome approach that refer to the effects for the control group called the pure effects and the effects for the intervention group called the total effects. For the potential outcome approach, the interaction of X and M is included in the analysis to calculate the different direct and indirect effects in each group.

Moderation in the Potential Outcome Model

A described already, the potential outcome model has different direct and indirect effects in the intervention and control groups. These additional estimators are only present if the interaction of X and M is nonzero. In this potential outcome framework, an interaction of indirect effects corresponds to testing the equality of the natural indirect effect in the two groups. Similarly, moderation effects could be obtained by testing the causal effects across subgroups where each subgroup could have different natural direct and indirect effects. A statistical test of the interaction across subgroups could be accomplished by dividing the difference between natural indirect effects across groups by a multivariate delta method standard error for the difference between the causal effects or by using a resampling method such as the bootstrap to create a confidence interval for the difference between the effects and testing whether zero is in the interval.

Potential Outcome Mediation Model with Longitudinal Data

The causal perspective on longitudinal mediation elucidates a problem in the regression analysis of data with more than one wave. The description of this problem in the causal inference literature is in the context of time-varying interventions or situations in which earlier waves of data predict later treatment and later values of the outcome (Robins & Hernan, 2009). The problems with longitudinal data from a causal inference perspective are illustrated here using a study of the effects of loneliness on depression as described in VanderWeele, Hawkley, Thisted, and Cacioppo (2011). There is evidence that loneliness and depression are separate constructs and that loneliness leads to increased depression (see VanderWeele et al., 2011) but it would be useful to estimate the size of this effect. Say that depression at the fourth time of measurement is the focus of the analysis. Depression at the fourth time point is predicted by the following variables: depression at the first, second, and third times and loneliness at the first, second, and third times. All of these variables are likely to have some effect on Time 4 depression, but there is a problem with estimating all of these effects at once. Depression at Time 2 is on the pathway from loneliness at Time 1 to depression at Time 4, so it may mediate the effect of loneliness on later depression thereby reducing the total effect of loneliness on later depression. In other words, depression at Time 2 could be a mediator of the relation of Time 1 loneliness on depression at Time 4. Because depression at Time 2 is a potential mediator, it would not be ideal to adjust effects if a researcher was interested in estimating the total effect of earlier loneliness on later depression. Depression at Time 2 is also related to both depression and loneliness at Time 3 so it is also a confounder of these variables on Time 4 depression. Because it is a possible confounder, depression at Time 2 must be adjusted to get an accurate estimate of the relation of loneliness and depression at Time 4. So depression at Time 2 should be adjusted for to remove confounding, and it should also not be adjusted for so that it does not block the total effect of loneliness at Time 1 on depression at Time 3. The correct analysis would both adjust and not adjust for Time 2 depression, which is not possible with regression analysis. Robins, Hernan, and Brumback (2000) proposed a solution to this problem by conducting an analysis that removes confounder effects so the true effects can be estimated. In this context, a model called a marginal structural model removes effects of variables that may serve as a confounder to estimate the effects of

loneliness on depression at later waves of measurement. The approach uses a weighting method to render an unconfounded data set.

In terms of an intervention, *X*, and a mediation model with two waves of data for *M,* *M*1 and *M*2, and *Y,* *Y*1 and *Y*2, say we are looking at the effect of the intervention, *X*, on the outcome *Y*2. If control is made for a variable that is a consequence of the intervention, the mediator *M*2, then the relation of *X* to *Y*2 will be biased. By doing this, part of the effect of the intervention is blocked. For the mediation relation, *X* to *M*2 to *Y*2, control for *X* is needed to get the correct relation of *M*2 to *Y*2, that is *X* is a confounder of the *M*2 to *Y*2 relation. It is not possible with a single regression model to obtain an unbiased estimate of *X* on *Y*2 because it must simultaneously control for *M*2 and not control for *M*2. With a structural equation model, it is possible to estimate relevant indirect effects for effects from *X* to *Y*2 when *X* is uncorrelated with *M*1 and *Y*1 because the level of *X* is randomized to groups. The single mediated effect in this model corresponds to *X* to *M*2 to *Y*2. With the marginal structural model and a nonrandomized *X*, the time 1 measures *M*1 and *Y*1 (before the intervention is delivered) are used to weight *M*2 to remove confounding and then a weighted analysis is used to estimate the causal effect of the unconfounded *M*2 variable on *Y*2. A similar approach is illustrated below.

Inverse Probability Weighting with Longitudinal Data

An approach to obtaining effects adjusted for confounders in longitudinal mediation models is to use observed covariates to measure confounder effects and adjust analyses to remove the confounder bias (Robins et al., 2000). The goal of these analyses is to create a pseudo-population of data in which confounder bias has been removed and then conduct analyses on this new confounder-free data set. This new confounder-free data set avoids the problem of simultaneously adjusting for and not adjusting for an intermediate variable that is also a confounder. It accomplishes the goal by separately estimating the confounder effect and other effects. A weighting strategy is used to weight observations based on how much the observations are confounded to create an unconfounded data set. A statistical model is first developed for the prediction of the mediator based on covariate information from baseline measures. These baseline measures can be the measure of *M* and *Y* at baseline as well as other available variables. The weights for each participant are obtained from the residuals of two models (1) a statistical model in which only *X* predicts the mediator, and (2) a statistical model in which *X* and all covariates are used to predict the mediator. A weight is formed by dividing the probability of the residual in the first model by the probability of the residual in the second model. A weighted regression model is used in the analysis to predict *Y* with *M* and *X* (Coffman, 2011; Coffman & Zhong, 2012; Robins, Hernan, & Brumbeck, 2000; Toh & Hernan, 2008). The coefficient relating *M* to *Y* is the *b* coefficient with confounder bias removed and sandwich estimators of standard errors are used to create confidence intervals for the effect. This method assumes that all measures of confounder bias have been measured and included in the analysis to create the weights (thereby leading to accurate estimation of the relation of *M* to *Y*, i.e., by adjustment for potential confounders). If there are repeated measures of *X*, *M*, and *Y*, then weights are obtained for each predicted value of *M* at each time with prior values of *X* included as covariates to adjust for confounder bias. The weights in the final analysis for the prediction of *Y* are the product of the weights obtained for the prediction of each wave of *Y*. Weights that adjust for missing data can also be included.

Clearly, a substantial assumption of this method is that there are no unmeasured confounders, which may be difficult to satisfy in some situations. One important check for the model is to assess the extent to which there is enough overlap in the weights in each group with plots and tables to investigate the balance of the weighting procedure. To date the marginal structural model has not been widely used in psychology but it is more common in epidemiology and the health sciences. It is among the most straightforward of causal inference methods to apply. As described already, VanderWeele et al. (2011) applied the marginal structural model method to investigate the effect of loneliness on depression across five waves.

There are several methods to estimate weights for inverse probability weighting that may be especially useful when the weights vary a great deal from very small to very large (Cole & Hernan, 2008). The weights for each participant represent how much that participant's data are used in the final regression of *X* and *M* on *Y*. If the denominator in the weight equation becomes extremely small, the weights for some persons may be excessively large so that one person may overly influence the results of the analysis. One method to deal with this problem is the use of truncated weights to avoid some subjects having too much or too little influence on the analysis. A relative alternative approach avoids calculation of the weights by creating new data sets where confounder effects are removed using a method called *g-estimation*. G-estimation is not described here but is available in several sources (Loeys et al., 2014; Vansteelandt, 2009).

Causal Estimators for the ECLS-K Data Set

To illustrate the causal estimates, three variables were selected from the ECLS-K data set, an independent variable measure of externalizing behavior at first grade, a mediating measure of reading performance at time third grade, and an outcome measure of internalizing behavior at fifth grade. These measures were used as indicators of a mediating process such that externalizing behavior reduces reading performance, which then increases later depression. Covariates included the kindergarten fall and spring measures of externalizing, reading, and internalizing variables along with gender and age to adjust for potential confounding. The goal of the analysis was to estimate causal effects across waves adjusted for possible confounders where the confounders were measured at the first two waves of measurement. The program described in Valeri and VanderWeele (2013) was used to estimate the natural direct and indirect effects described earlier. To simplify the analysis, only complete cases were used in the analysis for a total of 7,355 individuals. First, the interaction of first grade externalizing behavior and first grade reading performance was not statistically significant in the prediction of Y (.011, SE = .032, $p < .5$) so separate estimates of direct and indirect effects at different levels of first grade externalizing behavior were not computed. In other words, the two different causal estimators of effects were not necessary because the nonsignificant interaction indicated that effects did not differ across levels of the mediator. As a result there is one natural direct effect (NDE = .046, SE = .007, LCL = .033, UCL = .059), one natural indirect effect (NIE = .004, SE = .0008, LCL = .002, UCL = .005) and the sum of these effects equals the total effect (TE = .049, SE = .007, LCL = .036, UCL = .062). All of the effects are statistically significant, which is perhaps not surprising given the large sample size. The metric of the effects is in terms of a one standard deviation change (.540 units) in externalizing at first grade. Dividing the indirect effect by the standard deviation of Y, suggests that a standard deviation change in externalizing led to an indirect effect via reading performance of about .04 standard deviations in internalizing symptoms.

FUTURE DIRECTIONS

There are many potentially fruitful directions for future research regarding longitudinal moderation and mediation. For example, Bayesian analysis of longitudinal data is one particular area where the development of new analytic methods may produce better estimates of hypothesized effects and produce tests that more appropriately reflect substantive theory. Bayesian estimation allows researchers to incorporate prior information into the analysis, which can potentially produce more efficient estimates of moderation and mediation effects (Yuan & MacKinnon, 2009). Moreover, while many traditional estimation techniques rely on large-sample theory, Bayesian estimation is exact, making this approach particularly suitable for data with small samples (Ozechowski, 2014). This aspect of Bayesian analysis is also particularly relevant to mediation effects. Maximum likelihood estimation provides estimates of parameters and standard errors and assumes normal distributions based on large sample theory. However, the *ab* estimate of the mediated effect is known to be nonnormal (MacKinnon et al., 2007), and this problematic violation often necessitates the use of specialized techniques (e.g., bootstrapping or the application of the distribution of the product) for hypothesis testing. However, Bayesian analysis produces the whole (skewed) posterior distribution of the mediated effect and requires no such assumption. Muthén and Asparouhov (2012) presented a Bayesian approach to structural equation modeling, which could potentially include both mediation and moderation. Yuan and MacKinnon (2009) described a Bayesian approach to modeling multilevel mediation, and Ozechowski (2014) demonstrated the use of Empirical Bayes methods for testing mediation in a small sample.

Another possible focus of future research is person-centered moderation and mediation. While more typical variable-centered approaches concentrate on examining relations among variables, person-centered approaches examine patterns of responses for individuals. The person is the unit of analysis (Bauer & Shanahan, 2007), and analytic techniques such as cluster analysis, latent profile analysis, latent class analysis, and latent transition analysis can be used to empirically sort individuals into distinct groups according to their patterns of variable values and associations. For example, individuals might be classified as showing patterns either consistent or inconsistent with mediation. Collins, Graham, and Flaherty (1998) demonstrated such an analysis and show that under particular conditions, variable-centered approaches might detect mediation when there are, in fact, no differences in the proportion of individuals showing patterns consistent with mediation in control and treatment groups. Bauer & Shanahan (2007) illustrate how a person-centered approach can be used to model complex moderated effects.

The recent rapid development of new technology and methods for collecting intensive longitudinal data has resulted in a need for analytic methods suitable for

examining moderation and mediation in such large data sets. For example, current technology allows the collection of intensive ecological momentary assessment (EMA) data, where subjects repeatedly report on key variables while they go about their daily lives. An EMA data set might include hundreds of observations obtained via smartphone from a given individual over the course of a few days or perhaps just one observation per day for several weeks, months, or an entire year. Fitness tracking devices might record several physical activity and condition variables repeatedly for a period of several hours. fMRI data contain activation information about multiple voxels over the time course of an experimental session. Analysis of such rich data sets with traditional techniques can prove cumbersome (Baraldi, Wurpts, MacKinnon, & Lockhard, 2014). As the collection of such data becomes increasingly frequent, there is a clear need for the development of specific methods to explore moderation and mediation in such big data applications. Baraldi et al. (2014) described particular multilevel models that can be used to address relevant questions in EMA data and to explore the effects of personalized, technologically delivered ecological momentary interventions. Lindquist (2012) presented an extension of the mediation model for fMRI data that allows the mediating variable to be a continuous function rather than a single scalar measure and includes causal estimators of effects. The combination of intensive longitudinal data and a person-centered analytic approach may potentially allow the examination of research questions that could not be easily addressed with smaller data sets and traditional variable-centered analytic techniques. For example, groups of subjects who confirm or do not confirm the pattern of mediation at different phases of time during a study (e.g., confirming mediation at early versus later phases) could be identified and their transition patterns over the course of time can be examined to predict their status on an outcome variable.

There is also a clear need for more research on temporal design issues. Every researcher designing a longitudinal study needs to make a number of explicit decisions about the data collection schedule. This audience would benefit from clear recommendations regarding the ideal number as well as the frequency and spacing of observations for various types of research scenarios. Some research in this area has, in fact, been conducted for univariate and bivariate growth models where interest centers on testing the effects of treatment on growth (e.g., Raudenbush & Liu, 2001) or variabilily in growth across individuals and covariation among growth rates (e.g., Rast & Hofer, 2014). However, similar work focusing on the power to detect moderation and mediation effects has yet to be conducted.

In the interest of developing models that more accurately reflect developmental processes, future research should also focus on methods to parsimoniously represent nonlinear effects. Polynomial trends are, by far, the most common functions currently used to represent change over time, and linear models are the more frequently employed of these. However, most growth is probably not strictly linear (Fritz, 2014). Adding higher order polynomial terms may increase the realism of the model, but these additional factors are often difficult to interpret and incorporate into more complex analyses (such as those involving mediation and moderation). Cudeck and Harring (2007) described a number of nonlinear functions and discuss the considerations involved in choosing a particular nonlinear form to represent change. In addition to such nonlinear trends in an outcome variable over time, it is also possible that mediation or moderation effects might themselves be nonlinear. Our models typically assume that the moderated or mediated effect operates identically throughout the range of the predictor variable. However, such an assumption may be overly simplistic, and developing methods and recomendations for testing these effects would be a useful contribution to the literature. Semiparametric and related generalized additive modeling approaches are important directions in this work (Hastie & Tibshirani, 1990; Keele, 2008; Shen, Chou, Pentz, & Berhane, 2014).

Though the methods described in this chapter focus primarily on interinterdividual analysis, it is potentially useful to distinguish between intra- and interindividual processes. Most psychologcal studies are focused on variation between cases (Molenaar, 2004), and explaining intraindividual processes through reference to interindividual findings is a simple generalization of the ecological fallacy (Robinson, 1950). Molenaar (2004) defines the conditions under which the structure of intra- and interindividual variation will be analogous and argues that these will rarely if ever be met in real psychological processes. If a researcher wishes to explore within-person mediation, using a $1 \rightarrow 1 \rightarrow 1$ mulitilevel mediation model (e.g., Krull & MacKinnon, 2001), combined with judicious decisions regarding the centering of the various predictors in the model, can help to disentangle these processes. To date, however, very little work has focused on ideal methods for exploring intraindividual effects and how best to approach such questions in real world data sets.

The combination of mediation and moderation into a single analytic framework is another area that would benefit from future quantitative research and application in substantive data. Currently the most frequent method for exploring whether mediated effects might, in fact, be

moderated by a fourth variable is the rather simplistic approach of creating subgroups based on the moderator and conducting a multiple group SEM. Such an approach is well suited when the moderator is truly categorical, but artificially categorizing a continuous variable so that it can be forced into such an analysis is far from ideal. Dichotomizing a continuous variable via a median split has many undesirable consequences, including loss of power and spurious main effects and interactions (MacCallum, Zhang, Preacher, & Rucker, 2002). The development and application of more sophisticated techniques that avoid such inappropriate treatment of variables will result in much better tests of hypotheses involving mediated moderation and moderated mediation in longitudinal data. These might involve continuous variable approaches to moderation within an SEM or incorporation of person-centered methods that empirically identify subgroups of subjects based on patterns of multiple variables.

Finally, causal inference approaches in general and for mediation in particular are also being rapidly developed. Several books are now appearing that should help disseminate these methods (Hernan & Robins, in press; Morgan & Winship, 2007; Pearl, 2009), though longitudinal mediation modeling has not been widely addressed in these books. There are some recent applications with longitudinal data (Ertefaie & Stephens, 2010; Lindquist, 2012; O'Malley, 2012). Some interesting recent work attempts to combine both dynamic mediation models and modern causal inference (Aalen, Roysland, & Gran 2012; Aalen, Roysland, Gran, Kouyos, & Lange, 2014). Aalen et al. (2012) described two overlapping approaches to causal inference with longitudinal mediation corresponding to interventionist and mechanistic viewpoints. The interventionist approach focuses on estimating causal effects when there is randomization or the evaluation of the status of a system when there is and when there is not an intervention. Typically this approach focuses on the potential outcomes model as described already, although some approaches do not require counterfactuals (Dawid, 2000). The mechanistic approach focuses on how effects come about rather than how an intervention would cause effects. As described by Aalen et al. (2012, p. 832) the "mechanisms in the structure of the world are present whether humans are there to intervene or not, and hence seem to be the more fundamental part." As a compromise between interventionist and mechanistic positions, Aalen et al. (2012, p. 843) stated, "Now our modest suggestion is as follows: if a direct effect cannot reasonably be defined as a controlled or natural direct effect in the counterfactual sense because the required hypothetical manipulation of the mediator is inconceivable, then we can alternatively view these effects as being represented by flow in a dynamic system, so that the direct effect corresponds to the flow not passing through the mediator. The indirect effect can similarly be understood as that passing through the mediator." Aalen et al. went on to describe a stochastic differential equation model for mediation that includes dynamic models for X, M, and Y processes including a dynamic model for how X, M, and Y are related. Aalen et al. apply this idea to mediation in survival analysis data. Other recent work also addresses dynamic change based on functional data analysis and mediation (Lindquist, 2012), though this approach also targets the estimation of natural and controlled effect causal estimators described previously. More application of these methods to actual data is an important future direction of this research in psychology.

Because development is longitudinal by definition, and because so many of the hypotheses developmental psychopathologists seek to test involve multiple variables interacting and affecting each other in sequence, the concepts of longitudinal moderation and mediation are particularly important in this area of research. The various analytic models presented in this chapter test how effects change over time or the mechanisms through which earlier causes produce their later effects. Application of these methods in longitudinal data will help to advance the field and achieve better understanding of the complex processes that unfold over time to produce adaptive and maladaptive behavior.

CORE THEORETICAL PRINCIPLES OF DEVELOPMENTAL PSYCHOPATHOLOGY AND LATENT GROWTH MODELING APPROACHES

In this chapter, variations of latent growth modeling and their applications in developmental psychopathology are reviewed. In each section, we first discuss developmental methodology and quantitative techniques for studying developmental trajectories in developmental psychopathology, focusing on latent growth modeling. We begin by reviewing core principles of developmental psychopathology, which is conceptualized as an evolving interdisciplinary science that studies the interplay among the biological, psychological, and social-contextual aspects of normal and abnormal development across the lifespan (Cicchetti, 2010, 2015). Developmental psychopathology posits the following important questions: What are the causes of a particular disorder? What are the transformations in behavioral (or phenotypic)

manifestation? Where do changes happen in the pathway to psychopathology?

Within the developmental psychopathology perspective, maladaptation is viewed as evolving through the successive adaptations in the person's environment. That is, maladaptation is the complex result of a myriad of risk and protective factors operating over time; and it is not some sort of trait a person has or an expression of a pathogen (Sroufe, 1997). Accordingly, key research questions in developmental psychopathology focus on (1) discovery of factors that place individuals on *pathways* probabilistically leading to later disturbances, and (2) *processes,* which maintain individuals on such pathways once enjoined.

Developmental psychopathology is a perspective that is especially applicable to the investigation of critical transitional turning points in development across the life span. Empirical research in developmental psychopathology involves knowing about the trajectories and pathways of disorders across the life span and asking the following questions: What happened before the onset of the disorder? How does it progress? Do the manifestations of the symptoms continue or stop at some point? As disorders may appear at any point in the life span, it is imperative to examine the course, phases, and sequelae of disorders. The goals of developmental psychopathology are broad and integrative, seeking to understand adaptation and maladaptation across the life course, and to comprehend the complex interplay among multiple levels of functioning including biological, psychological, and social processes in the development.

Next, a few core theoretical principles of developmental psychopathology guide our reviews of empirical studies using latent growth modeling.

The Pathways Framework

The premise of developmental psychopathology is that the same laws that govern normal development also govern pathological development (Cicchetti, 2015). Therefore, pathology is viewed in terms of developmental deviation and a significant deviation in adaptation represents an increased probability of problems in dealing with (negotiating) subsequent developmental issues. A particular adaptational failure at any point in time is best viewed as placing an individual on a pathway (or trajectory) potentially leading to disorder. For example, anxious attachment (maladaptive pattern of attachment) is not viewed as psychopathology per se, but in terms of developmental risk for disturbance. Developmental psychopathology also believes that change is possible at any points on the pathway. Even when a maladaptive pathway is enjoined, return to positive functioning often remains possible. Thus, this perspective emphasizing the concept of pathways is closely related to the concept of resilience.

Developmental psychopathology also emphasizes that the same rules of development do not necessarily apply to all children and families. In this regard, two theoretical concepts are relevant. First, *equifinality* suggests that there are multiple pathways to similar manifest outcomes. For example, a pattern of maladaptation that has many features in common, such as depressive mood, lack of social engagement, and low self-esteem, may be the result of distinctly different developmental pathways, one rooted in alienation, and one rooted in anxiety and helplessness. Second, *multifinality* suggests that a single pathway can lead to multiple outcomes. For example, not all maltreated children develop similar disorders or any disorders. Some maltreated children show depression, others show conduct disorder, and still others show substance use problems. Yet there still are some maltreated children who do not show any critical psychopathology.

Resilience

Developmental psychopathologists are interested in studying pathways to competent adaptation despite exposure to conditions of adversity because the results will help obtain a better understanding of both normal development and psychopathology. Resilience refers to the fact that some children facing adversity nonetheless do well or return to positive functioning following a period of maladaptation (Sroufe, 1997). Resilience is shown in the positive end of the distribution of developmental outcomes among individuals at high risk. These resilient individuals maintain adaptive functioning in spite of serious risk hazards (Rutter, 1990). Developmental psychopathologists see resilience as a dynamic process encompassing positive adaptation within the context of significant adversity.

According to Luthar, Cicchetti, and Becker (2000), two critical conditions are implicit in this notion: (1) exposure to significant threat or severe adversity; and (2) the achievement of positive adaptation despite major assaults on the developmental process. Luthar and colleagues (2000) further differentiated diverse developmental processes determined by protective and vulnerability factors. Protective factors have direct ameliorative effects at both high- and low-risk conditions. Thus, protective effects are exhibited when the main overall effects on the at-risk individuals are promoting their positive functioning. Such main effects of protective factors can be described as

protective-stabilizing processes where individuals with the attribute show stability in competence despite increasing risk, whereas individuals without the attribute decrease in competence. Protective factors may operate to have interactive or moderating effects. First, protective-enhancing processes may be seen when the attribute (moderator) allows individuals to interact with stress in such a way that their competence is augmented with increasing risk. Second, protective-reactive processes may be described when the attribute generally confers advantages but less so when risk is high.

In contrast to protective factors, vulnerability factors are identified when the main overall effects on the at-risk individuals are negative, thus demoting their positive functioning. Those individuals with the attribute are expected to manifest greater maladjustment at both high- and low-risk conditions. Such main effects of vulnerability factors are described as vulnerable-stable processes, where the general disadvantages of individuals with the attribute remain stable despite changing levels of stress. Interactive or moderating effects of vulnerability factors can be shown in vulnerable and reactive processes where the overall disadvantage linked with the attribute is heightened with increasing levels of stress. Overall, these vulnerability and protection processes illustrate that the impact of stress on competence levels depends on protective or vulnerability factors.

Indeed, prior research in developmental psychopathology suggests that many risk factors do not have direct, additive effects but rather indirect, interactive effects. Rutter (1990) demonstrated that risk factors did not lead to an increased rate of psychiatric disorder if they occurred truly in isolation. Rather, the rate was increased if there were two or more concurrent risk variables. For example, family discord has an adverse effect only when it is accompanied by other adversities. Research on the impact of parental divorce suggests that divorce accompanies many stressors that may take a toll on children, including economic hardship (decreased income for the single-mother family) and maternal depression (Hetherington, Bridges, & Insabella, 1998). Researchers in developmental psychopathology should be reminded that one should consider the impact of a particular risk factor in the presence of other independent or related risk factors. This perspective is related to the multiple level approach principle in developmental psychopathology discussed in the following section.

Multiple Levels of Analysis

Most developmental psychopathologists will agree that singular, linear cause of psychopathology will rarely be obtained. More often, adequate prediction of either disturbance or resilience requires considering multiple risks and protective factors and their interplay (Cicchetti & Sroufe, 2000). In addition, within a developmental psychopathology perspective, the development of psychopathology is viewed as unfolding along different developmental pathways among different individuals. Thus, it is expected that relevant causal processes vary among individuals who show the same pattern of disorders (i.e., equifinality), and that there is heterogeneity in the expression of disorders (i.e., multifinality) (Cicchetti, 2010; Cicchetti & Rogosch, 1996). Therefore, in studying developmental pathways and processes of psychopathology, it is important to investigate simultaneously different psychopathological outcomes as well as individuals' functioning in multiple domains of development and across multiple settings.

Developmental psychopathology studies involving multiple levels of analyses have been increasing. For example, recent empirical studies of resilience have incorporated neurobiological and molecular genetic analyses in addition to the traditional measures of psychosocial contributors (Cicchetti & Curtis, 2007). The integrated knowledge gained by employing multiple biological and psychological levels of analyses is particularly beneficial for contributing to the ability to design individualized preventive interventions to facilitate the development of resilient functioning (Cicchetti & Toth, 2006).

Contextual factors play an important role in shaping the processes of maladaptation, psychopathology, and resilience. For example, prior research demonstrates that social-contextual experiences can influence neurobiological structure and functioning (Cicchetti & Tucker, 1994; Grossman et al., 2003). Within a developmental psychopathology perspective, researchers are goaded to move away from the search for single pathogens and to move toward the search for a complex of influences that initiate a developmental pathway that is probabilistically associated with disturbances. Thus, systematic examination of multiple levels of contexts, including community-, institutional-, and societal-level influences, is encouraged in developmental psychopathology research (Cicchetti & Rogosch, 1999).

Normality and Psychopathology

Why do developmental psychopathologists study atypical, high-risk populations? It is because they believe not only that knowledge from the investigation of normal development can inform the study of high-risk conditions and psychopathology but also that the investigation of

risk and pathology can enhance our comprehension of normal development (Cicchetti, 2010, 2015). Developmental psychopathology is studying how individuals function through examinations of extremes in the distribution. For example, as will be illustrated later, studies of maltreatment indicate that children who have experienced the extremes of dysfunction in parenting tend to show a broad range of psychological maladaptation. Such a finding indicates the criticality of adaptive parenting practices in the development of normal populations.

Developmental Analysis

In developmental psychopathology research, it is necessary to examine the relationships between predictors and problem behaviors over time and across ages (Cicchetti, 2015; Cicchetti & Rogosch, 1999). Accordingly, longitudinal research beginning even prior to the onset of disorder is important since such research is necessary for untangling causal mechanisms and processes. Some variables may have stronger links with onset of problems, while others may be more tied to persistence or desistance of the symptoms. Only longitudinal research can identify risk and protective factors associated with different stages in the progression of psychopathology. More importantly, examining longitudinal trajectories (as opposed to a snapshot) is essential for identifying developmental pathways to maladaptation, psychopathology, and resilience, as well as understanding diversity in process and outcomes of maladaptation, psychopathology, and resilience. As such, the core theoretical principles of developmental psychopathology demand empirical evaluation based on longitudinal data.

BASIC ASSUMPTIONS AND LONGITUDINAL DESCRIPTIVE ANALYSES

Primary Goals of Longitudinal Research

In their seminal paper, Baltes and Nesselroade (1979) described the history and rationale for conducting longitudinal research. In their work, they outlined five rationales for collecting longitudinal data, which could be studied only with longitudinal, repeated-measures data: identifying (1) intraindividual change; (2) interindividual variability in intraindividual change; (3) interrelationships among intraindividual changes; (4) determinants of intraindividual change; and (5) interindividual variability in the determinants of intraindividual change. Additionally, Baltes and Nesselroade indicated that the primary reason for collecting longitudinal data was the identification of intraindividual change. Since their seminal paper, the primary approach used to evaluate and model intraindividual change is the latent growth model (McArdle, 1986; Meredith & Tisak, 1984, 1990).

The latent growth model not only allows for the study of intraindividual or within-person change but also allows for the study of interindividual variability in intraindividual change (or between-person differences in within-person change) and determinants of intraindividual change (or causes/mechanisms of within-person change). The latent growth model has grown out of several modeling traditions, but is now dominated by the structural equation modeling (SEM) and multilevel modeling (MLM; also referred to as the mixed-effects and random coefficient model) frameworks. The SEM and MLM frameworks each have benefits and limitations (Ghisletta & Lindenberger, 2004); however, over time, the two frameworks have grown to be more similar, and the relative advantages of each approach have been minimized.

Planning and Sampling in a Longitudinal Study

The study of intraindividual change should be approached with careful planning and design. The design of a longitudinal study requires thoughtful consideration regarding the sampling of individuals, the sampling of measurement occasions, and the sampling of constructs (Cattell, 1952). The sampling of individuals is a first obvious consideration when designing any research study; however, additional considerations need to be made when planning a longitudinal study because the sampling of individuals can impact the time metric (sampling of measurement occasions) as well as the sampling of constructs.

In a longitudinal study, the time metric, the time scale over which change has occurred, can be referenced by the beginning of the study. Example time metrics may be *measurement occasion* number (e.g., 1, 2, 3) and *chronological time* (e.g., 1 month, 12 months, 24 months). Such time metrics are common in psychopathology when studying intraindividual change subsequent to the beginning of an intervention (e.g., baseline, 1 month follow-up, 12-month follow-up). Alternatively, the time metric can be referenced at the individual level. Example time metrics may be chronological time since birth (age), time since an individual event (e.g., birth of child, marriage, death of family member), and time to an individual event (e.g., time to crawling, time until death). When planning of structuring change over an individual time metric, the sampling of individuals requires careful thought.

For example, a study of intraindividual changes in depression during adolescence could be structured as a cohort-based study where 11-year-olds are sampled at the first occasion and then followed for the next five years at regular or irregular intervals. Alternatively, a sample of 11-year-olds, 12-year-olds, and 13-year-olds can be sampled at the first occasion and the followed for the next 3 years at regular or irregular intervals. This type of accelerated longitudinal study (Bell, 1954) requires a different sampling of individuals.

The sampling of individuals also influences the sampling of constructs and the scales intended to measure the construct. Often, researchers will choose scales that are appropriate for measuring interindividual differences within the sample at the first measurement occasion without considering whether the scales are sensitive to expected intraindividual changes or whether the scales will be appropriate for the sample at the conclusion of the study. Measures must be sensitive to intraindividual change over the time period studied; however, most psychological measures are not evaluated for this ability—the majority of scales are psychometrically evaluated with a cross sectional sample. It is important to note that reliable and valid measures for studying interindividual differences are not necessarily reliable and valid for measuring intraindividual change.

A second consideration for the sampling of scales is to look for scales that remain appropriate for the sample at the conclusion of the study. Often, the same measurement scales are utilized over the entire course of the study because researchers want to use the observed changes in the scores as a dependent variable. If this is done, it is important for the measures to be valid and reliable for all individuals at all time points and sensitive to change over the entire range of the time that the scale is utilized. For example, utilizing a child behavior problem scale for 3- to 5-year-olds may not be optimal when studying development from ages 4 to 7 because the sample ages out of the age range for which the scale was developed.

Alternatively, researchers can plan for changes in the measurement of constructs over the course of the study. For some studies, it is unreasonable to have measures that are reliable, valid, and sensitive to intraindividual change over the entire course of the longitudinal study due to the length of the study and the sample characteristics and how the sample characteristics are expected to change over the course of the study. For example, studies of lifespan development may need to utilize different assessments over the course of the study as the sample ages (e.g., McArdle et al., 2009). In these cases, it is essential to build in scale and/or item overlap across time to create scores that are quantitatively comparable. If this is not done, another approach is to use a separate sample to do equating/linking. There are upsides (e.g., do not over burden longitudinal sample) and downsides (e.g., inability to examine invariance within longitudinal sample) of this approach.

Thoughtful consideration for the sampling of measurement occasions is also key to gaining the most information from the longitudinal study. The sampling of measurement occasions includes the number of measurement occasions as well as the timing or spacing of measurement occasions. However, a third consideration is whether or not the number of measurement occasions and the timing of assessments is the same or varies over individuals (McArdle & Woodcock, 1997). For this we simply note that much can be gained by intentionally building flexibility and variability into the measurement schedule of individuals and note that all aspects of the sampling of measurement occasions can be studied through simulation prior to any data collection (see Ferrer & Grimm, 2012). The sampling of measurement scales was discussed above, so here we simply reiterate the importance of utilizing measurement instruments that are sensitive to change over the planned data collection period and that many validated instruments may be unable to track the growth and changes taking place within the individual.

Key Issues in Latent Growth Modeling

Primary issues to the successful application of latent growth models include issues related to the measurement of the outcome of interest and issues related to the time scale over which the developmental process occurs and over which change is statistically modeled (Grimm & Ram, 2011).

Measurement

Latent growth models are typically applied to repeated-measures data obtained from multiple individuals. Among the first questions when approaching such data are how the construct was measured. Specific questions that arise are as follows:

1. What are the measurement properties of the instrument?
2. Are the measurement properties equivalent over time?
3. Was the instrument sensitive to and able to capture within-person change?
4. Are there distributional issues that need to be considered, such as ceiling effects, floor effects, skew, and

whether the variable provides limited information (e.g., binary, ordinal variables)?

5. Most importantly, is the instrument measuring the same construct in the same metric across time?

Ideally, the measurement instrument should have strong measurement properties (reliability and validity) at each measurement occasion. Additionally, the measurement instrument should be sensitive to change over the time scale of the study and at the level of aptitude (ability, trait-level) of the population. For example, utilizing the Woodcock-Johnson Applied Problems subtest may be useful for measuring changes in mathematics-related skills over a 2-year period for a sample of third to fifth grade students. However, the same measure is inappropriate for measuring mathematics-related skills over a 2-month period in a sample of preschool children. The reasons for the difficulty level of the test and the implied level of aptitude of the samples as well as the time span of the study must be thoughtfully considered. Moreover, certain instruments that are ideal for measuring relatively large changes in aptitude are poor at measuring relatively small changes in aptitude.

A check on the distribution of scores from the instrument over time can highlight potential issues when approaching the data from a modeling standpoint. Ideally, scores will be more or less normally distributed at each measurement occasion or point along the time metric (e.g., each grade, each year). Deviations from normal distributions can indicate potential issues as well as potential opportunities. Truncated distributions, such as those with floor or ceiling effects, may require statistical adjustment when modeling. Depending on the nature of truncation, models can be fit to account for the truncation—for example, ceiling or floor effects can be statistically modeled as well as zero-inflated distributions (see Olsen & Schafer, 2001). If these distributional anomalies are not accounted for within the statistical model, incorrect solutions and conclusions can be drawn (Wang, Zhang, McArdle, & Salthouse, 2008). Nonnormal distributions, such as those that arise from count data (e.g., How many cigarettes smoked within the last 2 weeks?) or binary data (e.g., Have you smoked within the past 2 weeks?) should be modeled with the appropriate statistical distribution (e.g., Poisson, logit). Otherwise, model fit and parameter estimates can be biased. Alternatively, a skewed distribution may indicate the need for a mixture distribution (McLachlan, & Peel, 2000), which can arise because the sample is actually comprised from multiple subpopulations. In these situations, a growth mixture model (Muthén & Muthén, 2000; Muthén & Shedden, 1999) or latent class trajectory model (Nagin, 1999) is needed.

One of the most important considerations is that the instrument measures the *same construct* in the *same metric* at each point along the time metric. This enables the scores obtained from the instrument to be compared quantitatively. Thus, intraindividual change can be tracked. The question of whether the *same construct* was measured in the *same metric* is a question of measurement invariance (Meredith, 1964a, 1964b, 1965, 1993). Statistically, this question can be examined through fitting a series of item factor analyses or item response models (see Meredith & Horn, 2001; Widaman & Reise, 1997). However, when a single score is obtained from an instrument, measurement invariance is often assumed without thorough investigation. In these cases, researchers run the risk of drawing incorrect conclusions. It is not appropriate to assume measurement invariance holds simply because the same questions were asked at each measurement occasion; however, this is often done. Additionally, it is incorrect to assume measurement invariance does not hold when different questions were asked at different measurement occasions (see McArdle et al., 2009).

Time Metrics

A second key issue for understanding intraindividual change is the time metric, over which intraindividual change is thought to occur and the time scale for statistically tracking longitudinal change. Within the growth curve model, there is a single dominant time scale used to track intraindividual change. This dominant time scale serves as a proxy for tracking the time over which the underlying change process occurs (Grimm & Ram, 2011). Examples of time scales are chronological age, gynecological or maturational age, time since the beginning of the study, measurement occasions, time until death or other event (e.g., marriage, graduation), and grade in school. To further illustrate this point, we have plotted physical height for a sample of females from the National Longitudinal Survey of Youth–Children and Young Adults (NLSY-CYA; Center for Human Resource Research, 2004) in Figure 22.1 with different time scales. We chose the NLSY-CYA because this study began in 1986 with a sample of children from mothers who participated in the National Longitudinal Survey of Youth in 1979 (NLSY-79). Thus, children were different ages in 1986, and children were also added to the study as the study progressed. Furthermore, we chose physical height because its developmental progression is strongly influenced by chronological and maturational age.

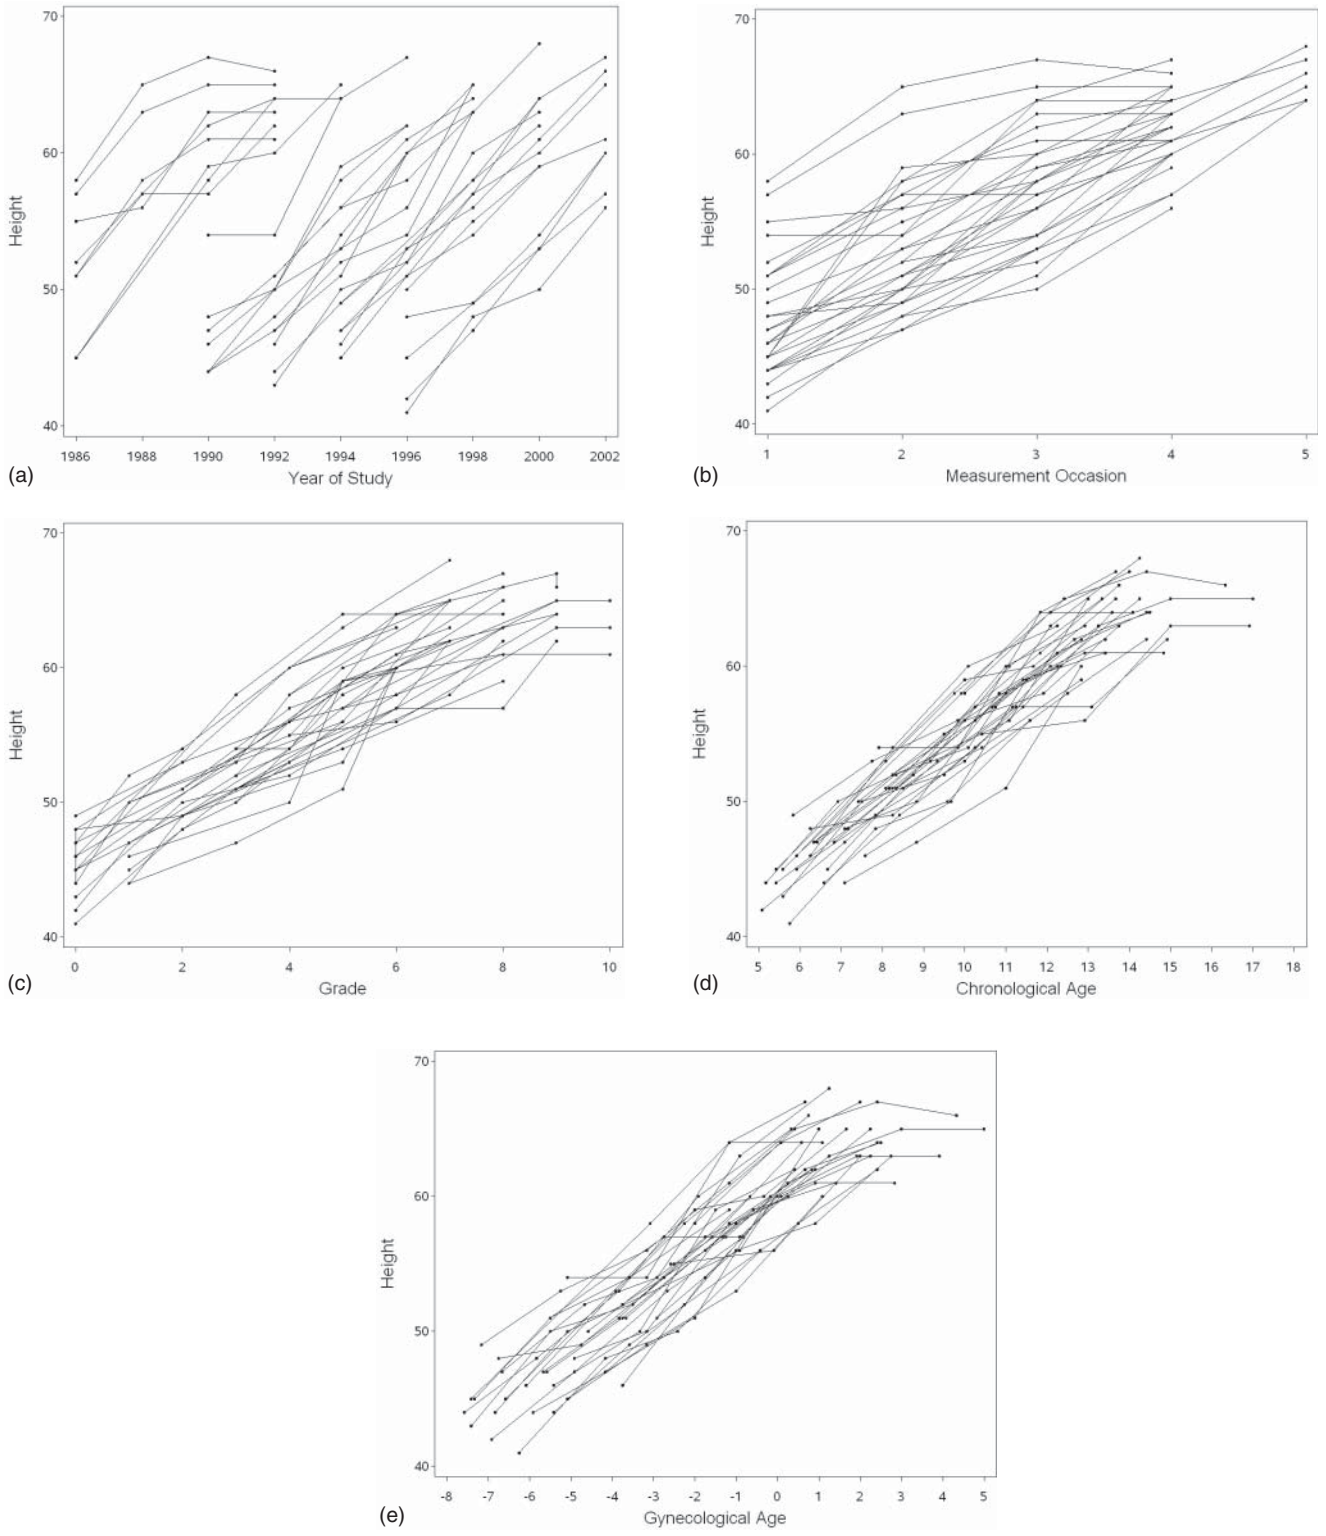

Figure 22.1 Longitudinal plots of individual changes in height based on different time metrics for a sample of female participants of the National Longitudinal Survey of Youth–Children and Young Adults. *Source*: Bureau of Labor Statistics, U.S. Department of Labor, and National Institute for Child Health and Human Development. Children of the NLSY79, 1979–2010. Produced and distributed by the Center for Human Resource Research, The Ohio State University. Columbus, OH: 2012.

Figure 22.1a is a plot of physical height against year in study from 1986 through 2002. This is obviously an inappropriate time scale to model changes in physical height given what we know about the developmental process and given the lack of systematicity in the individual trajectories of the longitudinal plot. At the same time, this plot is helpful because it highlights how different participants began the study in different years. Figure 22.1b is a plot of the same data against measurement occasion. Measurement occasion is a commonly utilized time scale for many longitudinal studies; however, for modeling changes in physical height in the NLSY-CYA, it is also inappropriate because participants entered the study at different ages. Additionally, measurement occasion, as a researcher-defined time scale, is unlikely to be the time scale over which intraindividual change is dependent upon (Grimm & Ram, 2011). On the positive side, this plot highlights how participants have a different number of measurement occasions.

Figure 22.1c is a plot of physical height against year in school or grade. Grade is closely aligned with chronological age and maturational age, but is also inappropriate for studying individual changes in physical height. One issue that is evident in this plot is that children may repeat a grade (or two) and this can be seen as vertical lines within an individual trajectory. That is, the value of the time scale remains the same at two different measurement occasions. Obviously, grade could be measured more finely, such as grade plus the percent of school completed since the beginning of the school year or the amount of time since the child began kindergarten for the first time. Ideally, the chosen time metric will accurately represent the amount of time that has elapsed between assessments. For these data, year in school or grade does not adequately do this.

Figure 22.1d is a plot of physical height against chronological age. Here, we see that children began the study at different ages and begin to see the developmental process that we know—stable increases in height during childhood, rapid increases during the pubertal years, and little to no changes in height during late adolescence/early adulthood. This is the time metric often utilized when modeling changes in physical height (see Grimm et al., 2011). We note that chronological age is a common time-metric when studying intraindividual changes in many types of biological and psychological constructs; however, other scalings of age may be as, or even more, appropriate (Nesselroade & Featherman, 1997). As a final illustration relevant to this point, we have plotted physical height against gynecological age in Figure 22.1e. Gynecological age was defined as time to or time since the individual's age of menarche. In this figure, we see that changes in physical height were somewhat more rapid near age of menarche (gynecological age = 0) compared with changes that occurred after or before menarche. Certain research questions and theories posit alternative scalings of age as the ideal time scale to model intraindividual change and these should be utilized to the extent possible (e.g., terminal decline; Gerstorf et al., 2008).

Ideally, the chosen time metric will adequately represent the amount of time that has passed between assessments as well as represent a dominant reason why the intraindividual changes have occurred as they have. One approach is to consider the time metric, which is able to align participants, such that the shape of developmental changes is most similar. In practice, we recommend examining multiple feasible time metrics before proceeding with analyses. This can be done with a series of plots, as in Figure 22.1, and done conceptually and theoretically. In the majority of situations, we acknowledge that multiple ongoing time metrics are likely to impact intraindividual change (Grimm & Ram, 2011). For example, changes in depression over adolescence may be related to schooling demands and peers, which change with *year in school*, as well as demands at home, which are likely associated with *chronological age*, as well as biological changes taking place within the individual associated with *maturational age*. These time metrics are strongly associated with one another (highly collinear), forcing researchers to choose between them or model them jointly and deal with the presence of collinearity. We refer readers to McArdle and Bell (1954), Ram et al. (2010), and Wohlwill (1973) for discussions regarding the choice of time metric in latent growth curve models.

Modeling Intraindividual Change

Once the time metric is decided upon, the next step is to determine, at the individual level, how the observed trajectories are associated with the chosen time metric. The majority of applications in growth curve modeling focus on simple functional forms of change, such as linear and quadratic change functions. However, the true underlying change process is likely to be more complicated. Here, a balance must be struck between the complexity of the model and the amount of information present in the data.

There are several approaches to choosing an appropriate individual change model. The first, and most common, approach is to begin with simple change functions and progress through a series of viable alternatives chosen based upon an individual plot, such as those presented in Figure 22.1. The simplest change function is a no-change, no-growth, or intercept-only model, where each individual

has an intercept score that is maintained across the observation period. This is often a model researchers would like to reject, but is a common starting point because of its simplicity and because the model yields fit statistics that can be statistically compared with more complex models because the intercept only model is nested under most growth models. Next, a linear model is fit, which is followed by a quadratic model and higher order polynomials if necessary. Finally, a few inherently nonlinear models (e.g., exponential, Gompertz, logistic) are fit that may be able to mimic the observed overall change pattern (see Grimm & Ram, 2009).

A second approach is to consider the important characteristics of the developmental process and fit a model with those properties, and if this model fits the data well then use the model. For example, important aspects (or parameters where individuals are likely to differ) in the developmental process related to changes in physical height may be rates of change in infancy, childhood, and adolescence along with the timing of puberty and a final adult height. Preece and Baines (1978) derived multiple functional forms with many of these important aspects and applied them to longitudinal height data and evaluated model fit (see also Grimm et al., 2011). We do, however, acknowledge that this approach is challenging when considering the range of psychological constructs and the general lack of strong theories describing important changes in such constructs.

A third approach is to model intraindividual change patterns with a series of splines (see Cudeck & Klebe, 2002; Ram & Grimm, 2007)—a series of lines or simple curves (e.g., quadratic) that connect at specific points in time (knot points) that can be chosen by the researcher or estimated from the data. These models are sometimes referred to as *multiphase* models because the various splines can represent phases of development that have beginning and end points. These models are especially useful when the underlying developmental process is thought to be guided by shifts or when the developmental process is interrupted by an external event, such as a death in the family. In this situation, changes prior to the event and after the event can be thought of as having distinct developmental processes.

A fourth approach is to let the data speak. There is a variety of what we would call exploratory approaches for modeling change (see Grimm, Steele, Ram, & Nesselroade, 2013). For example, Meredith and Tisak (1990) fit a latent basis or unstructured growth model, where an ideal structure of change was derived from the data. Functional forms of change that mimicked this derived change pattern were fit to the data and evaluated. Grimm et al. (in press) advocated a completely exploratory approach to growth modeling where a series of models are fit with an increasing number of latent variables. The associations between the time-metric and the observed trajectories are unstructured (similar to the latent basis model). Thus, in this approach the number of latent variables and the individual patterns of change are unknown, which is similar to how exploratory factor analysis models are fit to cross sectional multivariate data. This approach can yield an appropriate number of latent variables as well as potential forms of change that may be suitable for the data. Additional exploratory approaches are based upon principal component analysis (Davison, 2008; Tucker, 1958, 1966), multidimensional scaling (Ding, Davison, & Petersen, 2005), and smoothing spline models (Guo, 2002).

Interindividual Variability in Intraindividual Change

In latent growth curve models, the intraindividual change pattern or the functional form of change is invariant over participants. For example, if a linear model is chosen as the intraindividual change function, then all individuals are expected to follow a linear change pattern. Interindividual variability in intraindividual change, within the latent growth modeling framework, enters in the parameters, which describe the individual change pattern. That is, even though individuals follow the same functional form (e.g., linear), the parameters of the functional form (e.g., intercept and slope) are allowed to vary over individuals. Allowing the parameters of the functional form to vary over individuals provides for a wide variety of potential developmental patterns, especially with a functional form with multiple parameters (e.g., cubic and spline models).

Theoretically, any parameter of the intraindividual change function can vary over individuals (e.g., intercept and slope of linear model are allowed to vary over individuals); however, there are situations where theory or a lack of information from the data leads certain parameters to be invariant over individuals such that interindividual variability is not manifested. One of these situations was evident when studying intraindividual changes in reading ability (Grimm, Ram, & Estabrook, 2010). The chosen intraindividual change model was a Gompertz model. The Gompertz model has four parameters: a lower asymptote, an upper asymptote, the location of the inflection point, and a rate of change from the lower to the upper asymptote. For reading ability, the lower asymptote is the predicted reading ability when time approached negative infinity. Theoretically, it is logical that interindividual differences in reading ability at this point in time were minimal or nonexistent. Thus, this parameter was not allowed to vary over individuals. Ideally, theoretical notions of the

developmental change process should drive and inform the nature and location of interindividual variability in intraindividual change; however, again we recognize the limitations of the data that are brought to the analysis.

Determinants of Intraindividual Change

As mentioned earlier, one of the rationales for collecting longitudinal data proposed by Baltes and Nesselroade (1979) is the identification of determinants of intraindividual change. The latent growth curve model accommodates this rationale by allowing for interindividual difference variables (e.g., gender and intervention type) to predict the parameters of the growth curve, which describe interindividual variability in intraindividual change. Ideally, these associations will indicate the degree to which the interindividual difference variables are associated with the rate of intraindividual change; however, this is not necessarily the case with complex models that have multiple parameters impacting intraindividual change (Grimm, Castro-Schilo, & Davoudzadeh, 2013). Finally, we note that the identification of *causes* of interindividual differences in intraindividual change can only be identified with appropriate controls, such as random assignment.

THE LATENT GROWTH MODELING

Historical Development

Early work in the modeling and understanding of intraindividual change was very descriptive before the rise of fitting mathematical models to individual-level data. In this approach, linear and a variety of complex nonlinear models were considered and the researchers had multiple goals. A first goal was to minimize the size of the residuals. Models with smaller residuals better represented to data and were seen as superior. A second goal was to have a mathematical function with parameters that had meaning in relation to the intraindividual change process under consideration. These, sometimes contrasting, goals are evident in the study of physical height where certain mathematical models were specified to capture key aspects of development, such as the timing of puberty (e.g., Preece & Baines, 1978), whereas other models were developed to simply map onto the observed data with little attention paid to the interpretability of parameters (e.g., reference). This phase along the developmental continuum, is often referred to as *individual growth modeling* (Willett & Sayer, 1994), continued for a number of years with few modifications (e.g., Berkey, 1982), and remains a useful approach to studying intraindividual change. Furthermore, interindividual variability in intraindividual change could be examined by relating parameters of the mathematical function to between-person variables (e.g., Wishart, 1938).

During the *individual growth modeling* phase, alternative approaches to understanding intraindividual change surfaced. For example, Tucker (1958, 1966) fit principal component analysis models to the matrix of sums of squares and cross-products to decompose the matrix into *generalized learning curves* and individual weights. The *generalized learning curves* represent dominant trends within the data and the individual weights represented the extent to which an individual's trajectory was impacted by each *generalized learning curve*. Tucker used the term *generalized learning curves* due to his work with learning data; however, this approach can be applied to a variety of types of data and is commonly referred to as *Tuckerized curves* (see Grimm, Steele, et al., 2013; Meredith & Tisak, 1984).

Rao (1958) described several approaches for understanding intraindividual change and interindividual variability in intraindividual change. First, Rao (1958) discussed calculating an average rate of change—in essence decomposing the repeated measures into an initial state and a rate of change. In this approach, he also discussed transformations of the time scale to make changes more or less constant (linear change). Rao (1958) also discussed the possibility of using factor analytic methods, specified the growth curve model, and utilized principal components analysis of the uncorrected sum of squares and products matrix to estimate a model. This last routine is equivalent to Tucker's (1958) *generalized learning curves* and was developed independently at the same time.

In 1984, Meredith and Tisak presented their paper, *Tuckerizing curves*, at the International Meeting of the Psychometric Society. In the presentation, Meredith and Tisak described the *latent curve model* and how the model can be specified within the SEM framework. They discussed multiple types of latent growth models including the free curve or latent basis model as well as a negative exponential model and this work was published in 1990 (Meredith & Tisak, 1990). During this time, McArdle expanded on Meredith and Tisak's work by exploiting the flexibility of the structural equation modeling framework (McArdle & McDonald, 1984) to specify combinations of latent growth curves and behavior genetic models (McArdle, 1986), multivariate latent growth models (McArdle, 1988), and multiple group latent growth models (McArdle & Hamagami, 1996). Additionally, Browne and du Toit (1991) and Browne (1993) highlighted how the SEM framework could be used to approximate growth models that followed inherently nonlinear mathematical functions.

At a similar time, Laird and Ware (1982) published a paper in biometrics on random-effects models for longitudinal data describing models for growth and for repeated measures. An early article that reached psychologists was written by Bryk and Raudenbush (1987), who published a *Psychological Bulletin* article on the use of hierarchical linear model (i.e., multilevel model, mixed-effects model, and random coefficient model) to assess change. This spawned the use of this framework for studying growth within the psychological and educational disciplines. The work that followed was focused on how the mixed-effects modeling framework could be used to study inherently nonlinear processes. This work appeared in books by Davidian and Giltinan (1995), Littell et al. (1996), and Pinheiro and Bates (2000). Additional work by Singer (1998) and Willett and Sayer (1994) was prominent in the development of latent growth models and spread the use of the multilevel approach to studying change.

By the late 1990s, it was clear that multilevel models for assessing change and structural equation models for assessing change were equivalent in many cases (Curran, 2003; McArdle & Hamagami, 1996), especially for the most commonly fit models (e.g., polynomial models). Papers followed describing the various ways to fit latent growth models (e.g., Ferrer, Hamagami, & McArdle, 2004) and the relative advantages and disadvantages of each approach (Ghisletta & Lindenberger, 2004). At first, the multilevel model had advantages related to individually spaced measurements and the flexibility of fitting inherently nonlinear models, whereas the structural equation modeling approach had advantages related to indices of model fit, flexibility in the residual structure, and the inclusion of measurement models. Several of these relative advantages have been reduced because each framework has increased in flexibility. Furthermore, general modeling programs (e.g., WinBUGS) have further blurred the differences between the multilevel and structural equation modeling approaches for understanding change.

In the late 1990s and early 2000s, there were two additional important expansions of the general latent curve modeling framework. The first development was the introduction of the growth mixture model by Muthén and Shedden (1999). The growth mixture model allowed for an exploration of growth trajectories and for an additional way to incorporate between-person differences in growth. The growth mixture model combined the finite mixture model and the latent growth model and allowed researchers to cluster individuals based upon their individual growth trajectories. Thus, between-person differences in growth were allowed to manifest themselves by different classes and between-person differences within each class. Additionally, we note a similar development appeared in the latent class trajectory model, which was introduced by Nagin (1999). The difference between the growth mixture model and the latent class trajectory model was that between-person differences were allowed for within each latent class in the growth mixture model but not in the latent class trajectory model.

The second development was the introduction of the latent difference or latent change score modeling framework by McArdle and Hamagami (2001; see also McArdle, 2001). The latent change score model allowed for dynamic associations between multiple outcomes while simultaneously modeling growth trajectories. This model placed an emphasis on time-sequential within-person change and led to subsequent developments in differential models (see Boker, Neale, & Rausch, 2004) and latent acceleration models (Hamagami & McArdle, 2007).

More recently there have been developments that combine several of the models discussed above. For example, Grimm and Ram (2009b) proposed the second-order growth mixture model—a combination of the second-order growth model (McArdle, 1988) and the growth mixture model (Muthén & Shedden, 1999). Grimm, Zhang, Hamagami, and Mazzocco (2013) combined the latent difference score model (McArdle & Hamagami, 2001) with the estimation of inherently nonlinear growth models within the SEM framework (Browne & du Toit, 1991), which allowed for an emphasis on within-person change when modeling nonlinear growth trajectories. Grimm (2006) combined the latent difference score model with the finite mixture model, and Grimm, Ram, and Estabrook (2010) presented a combination of the finite mixture model and the estimation of inherently nonlinear growth models within the SEM framework to examine clustering of nonlinear growth trajectories. Finally, Zhang, McArdle, and Nesselroade (2011) presented growth rate models—rotations of growth models where a latent variable representing the rate of change at a given time point is included in the model to highlight the individual rate of change in nonlinear growth models.

Latent Growth Curve as a Structural Equation Model

Within the SEM framework, the latent growth curve is fit as a restricted common factor model. The growth factors (e.g., intercept and linear slope in a linear growth model) of the growth model are latent variables within the SEM framework. In the specification that follows and all model specifications included in this chapter, we use Greek letters for parameters that are fixed or estimated (e.g., factor

loading matrix) and Latin letters for entities that are not estimated nor fixed (e.g., factor scores).

The general latent growth model can be expressed as

$$\mathbf{Y}_i = \Lambda \mathbf{h}_i + \mathbf{u}_i \tag{22.1}$$

where $\mathbf{Y}_i$ is a $T \times 1$ vector of the repeatedly measured observed scores for individual i;, where T represents the number of repeated assessments based on the chosen time metric; Λ is a $T \times R$ factor loading matrix, which serves to define the growth factors of the growth curve (e.g., intercept and slope); R is the number of growth factors; $\mathbf{h}_i$ is an $R \times 1$ vector of latent factor scores (e.g., intercept and slope scores) for individual i; and $\mathbf{u}_i$ is a $T \times 1$ vector of unique scores for individual i.

The latent factor scores can be written as deviations from the sample-level mean written as

$$\mathbf{h}_i = \boldsymbol{\alpha} + \mathbf{d}_i \tag{22.2}$$

where $\boldsymbol{\alpha}$ is an $R \times 1$ vector of latent variable means, and $\mathbf{d}_i$ is an $R \times 1$ vector of mean deviations for individual i. The covariance matrix of mean deviations is $\boldsymbol{\psi}$, an $R \times R$ matrix indicating the magnitude of between-person differences in the latent growth factors as well as the degree of linear association among the latent growth factors.

The unique scores have expected means equal to 0 (i.e., $E(\mathbf{u}_i) = 0$) and covariance matrix $\boldsymbol{\Theta}$ (i.e., $\text{COV}(\mathbf{u}_i) = \boldsymbol{\Theta}$), where is a $T \times T$ matrix. Often, only the diagonal elements of are estimated, which forces the unique scores to be time-specific. However, additional types of structures of can be examined, such as first-order autoregressive and block-diagonal (see Kwok, West, & Green, 2007). Additionally, many researchers force the diagonal elements to be equal across time (i.e., $\boldsymbol{\Theta} = \mathbf{I}\theta$, where is a $T \times T$ identity matrix and is a scalar).

The latent growth model places a set of expectations on the repeated measures and it is important to understand these expectations to evaluate model fit and misfit. Additionally, understanding model expectations can guide the use of model modifications. The model expectations of observed variables based upon the latent growth model is

$$\boldsymbol{\mu} = \Lambda \boldsymbol{\alpha}$$
$$\sum = \boldsymbol{\Lambda} \boldsymbol{\psi} \Lambda' + \boldsymbol{\Theta} \tag{22.3}$$

where is an $T \times 1$ vector of expected means and is a $T \times T$ expected covariance matrix. The expected mean structure for the latent growth model is simply the factor loading matrix multiplied by the mean vector of the latent variables, and the expected covariance structure follows the common factor analysis model of the latent variable covariance matrix pre and post multiplied by the factor loading matrix plus the residual or unique covariance matrix.

A path diagram of a latent growth curve model with two latent variables is given in Figure 22.2. In such diagrams, squares represent observed variables, circles represent latent variables, and the triangle denotes the constant. One-headed arrows represent directional relationships, such as regression paths and two-headed arrows represent nondirectional or symmetric relations, such as covariances. The labels of the paths in the path diagram are derived from the previous specification. With the path diagram in Figure 22.2 and the path tracing rules derived by Wright (1921), model expectations can be calculated, which replicate the matrix algebra given already.

Common Latent Growth Models

To further show how the SEM framework can be used to specify latent growth models, we present a series of specific latent growth models that are commonly considered in psychology and psychopathology. In each description, we present specifications of the required matrices. In all specifications, we assume there are four equally spaced measurement occasions ($T = 4$).

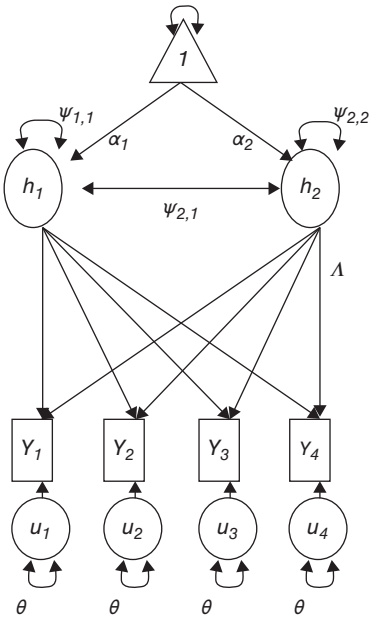

Figure 22.2 A latent growth curve model.

Linear Change

The linear change model is the most commonly fit growth curve in applied research. The linear change model has two latent variables ($R = 2$): an intercept, often centered at the first measurement, and a linear slope representing the individual constant rate of change over the observation period. The intercept and linear slope are allowed to vary over persons and allowed to covary with each other. Conceptually, the linear growth model is similar to fitting a linear regression model to each individual's data, retaining individual parameters for the intercept and slope, and summarizing those estimated parameters to calculate their means to get a sense of the average growth trajectories as well as their variances and covariance to understand between-person differences in the growth parameters and their degree of linear association. The linear growth model is specified as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & \frac{1-k_1}{k_2} \\ 1 & \frac{2-k_1}{k_2} \\ 1 & \frac{3-k_1}{k_2} \\ 1 & \frac{4-k_1}{k_2} \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.4}$$

where the repeated measures for individual i is a product of the factor loading matrix multiplied by the factor scores for individual i, plus the unique scores for individual i. In the factor loading matrix, the first column contains fixed values set equal to 1 to define the intercept factor, h_1, and the second column will contain fixed values set equal to change linearly with time to define the linear slope, h_2. The constants are chosen to center the intercept and scale the slope. Often, is set to 1 to center the intercept at the first occasion and is set to 1 to scale the slope in terms of the unit of time used in the selected time metric.

Quadratic Change

The quadratic change model is commonly considered when curvature is evident in the growth pattern and when the linear model does not adequately capture the intraindividual change pattern. The quadratic growth model is specified as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 1/2 \\ 1 & 2 & 2 \\ 1 & 3 & 9/2 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \\ h_3 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.5}$$

The quadratic model has three latent variables, an intercept, h_1, a linear slope, h_2, and a quadratic slope, h_3. The factor loadings for the intercept are all fixed at 1, the factor loadings for the linear slope change linearly with time, and the factor loadings for the quadratic slope are simply the square of the factor loadings for the linear slope divided by 2 (this is done to scale the quadratic slope in terms of acceleration). We note the same potential to center the intercept and scale the linear and quadratic slope. In this example, the centering and scaling constants, and k_2, are both set equal to 1. With this centering, the intercept represents the predicted value of the outcome at the first occasion; the linear slope represents the individual rate of change at the first occasion; and the quadratic slope represents acceleration, curvature, or how quickly the rate of change is changing, which is constant across time.

The quadratic model is often considered; however, the parameters of the quadratic model can be difficult to map onto theoretical notions of change (Cudeck & du Toit, 2002) and difficult to interpret in isolation because both the linear and quadratic slopes impact the intraindividual rate of change (see Grimm, Castro-Schilo, & Davoudzadeh, 2013). To combat these issues, Cudeck and du Toit (2002) reparameterized the quadratic model to emphasize the time when the maximum (or minimum) value is reached and the maximum (or minimum) value. These parameters are easily interpretable, highlighting interesting aspects of quadratic curve. Unfortunately, Cudeck and du Toit's (2002) approach is rarely considered when fitting the quadratic growth model in applied settings.

Transformations of Time

Polynomial transformations of time, such as in the quadratic model described above, are common in the application of latent growth models but are not the only viable transformations of time. For example, square root or log transformations of time may yield useful results concerning the growth of the construct under study. In essence, the growth process may be linear with respect to a different time scale. If this alternative time scale is utilized, then the process would conform to a linear growth model (see also Rao, 1958). As an example, we present the square root growth model, which can be specified as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & \sqrt{2} \\ 1 & \sqrt{3} \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.6}$$

where the first column of the factor loading matrix defines the intercept and the second column defined the linear slope in square root time. Additionally, if the second column of the factor loading matrix was divided by $\sqrt{3}$, then the slope can be discussed as the amount of change the has occurred from the first to the last measurement occasion; however, the shape of intraindividual change would still follow square root time.

Latent Basis or Unstructured Change

The latent basis or unstructured change model is a very flexible model that borders on exploratory change because the pattern of change is derived from the data. That is, instead of imposing a structure on change, such as linear or quadratic, within the factor loading matrix, the factor loading matrix has elements that are freely estimated. The latent basis model can be written as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & \lambda_{2,2} \\ 1 & \lambda_{3,2} \\ 1 & 1 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.7}$$

The first column of the factor loading matrix is set equal to 1 to define the intercept latent variable. The second column, on the other hand, has two fixed elements and two estimated elements. The first element is set equal to 0, the second and third are estimated from the data, and the last element is set equal to 1. This pattern of loadings define, what most call, a *shape* factor because the estimated factor loadings define the structure or individual change pattern and this pattern of change can vary greatly in shape. The two fixed factor loadings are needed for identification; however, their values and locations within the second column are arbitrary. This configuration centers the intercept at the first measurement occasion and scales the *shape* factor in terms of change from the first to the last occasion. Additionally, the estimated factor loadings represent the proportion of total change that has occurred since the first measurement occasion. Such interpretations are straightforward when change is monotonic; however, the latent basis model can structure change that is not monotonic (e.g., rise and fall). Even though the interpretation of the estimated factor loadings remain, changing the identification constraints to emphasize change to the maximum (or minimum) point can make interpretation more straightforward (see Ram & Grimm, 2007). Finally, we note that the latent basis model has been considered a model that optimizes the rescaling of time due to the estimated factor loadings.

Inherently Nonlinear Change Patterns

An additional collection of latent growth models follows patterns of change that are inherently nonlinear. In such models, a parameter is contained within the function of time—usually in an exponent or raised to an exponent. That is, within the factor loading matrix a nonlinear function is specified where an estimated parameter is contained within that function. Such models have several benefits because of the wide variety of shapes of development that can be modeled and the flexibility for modeling between-person differences in the shape of development (Burchinal & Appelbaum, 1991; Grimm, Ram, & Hamagami, 2011). Two such inherently nonlinear models are the power model and the exponential growth model. The power model can be expressed as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & \beta^0 & -1 \\ 1 & \beta^1 & -1 \\ 1 & \beta^2 & -1 \\ 1 & \beta^3 & -1 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.8}$$

where the factor loading matrix has a series of ones in the first column to define the intercept and the second column defines a power function where an estimated parameter β is raised to the power of time (0, 1, 2, 3) and then one is subtracted from this value. The variety of developmental patterns is determined by the estimated value of β. The exponential model can be written as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 1 - \exp(-\beta \cdot 0) \\ 1 & 1 - \exp(-\beta \cdot 1) \\ 1 & 1 - \exp(-\beta \cdot 2) \\ 1 & 1 - \exp(-\beta \cdot 3) \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.9}$$

where the second column of the factor loading matrix now changes as a function of $1 - \exp(-\beta \cdot t)$, where β is an estimated parameter and t is the value to time based upon the chosen time scale. In the power model and the exponential model, we note that the factor loadings are not fixed values as in the linear, quadratic, or square root models but are also not freely estimated as in the latent basis model. Instead, the values are structured to change according to a specific function.

The utility and flexibility of inherently nonlinear models is shown when allowing the parameters within the factor loading matrix to vary over individuals. This type of model is not directly estimable within the SEM framework; however, this type of model can be approximated and in many

cases the approximation is very good (see Browne, 1993; Browne & du Toit, 1991; Grimm, Ram, & Hamagami, 2011, for details on this approximation).

Multiphase Change

Multiphase change models (see Cudeck & Klebe, 2002) are a type of latent growth model where the repeated measures data are compartmentalized and change is more or less modeled within discrete phases of time. These models also go by the name spline or piecewise growth models. Change within each phase can be modeled with any of the above mentioned growth models; however, relatively simple models, such as a linear or quadratic change model, are often fit within each phase. For example, a bilinear model can be specified as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \\ 1 & 1 & 2 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \\ h_3 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \tag{22.10}$$

where the first column of the factor loading matrix defines the intercept, which is centered at the first measurement occasion; the second column defines the first linear phase, which represents intraindividual change during the first two measurement occasions; and the third column defines the second linear phase, which represents intraindividual change from the second to fourth measurement occasions. These multiphase models can accommodate a variety of nonlinear change patterns and tend to have parameters that are easily interpretable.

MULTILEVEL MODELING FOR STUDYING DEVELOPMENTAL TRAJECTORIES

The multilevel model for studying developmental trajectories was presented by Laird and Ware (1982) and Bryk and Raudenbush (1987). Growth models can be fit in the multilevel modeling framework as a two-level model because the repeated measurements are nested within individuals. There are several ways to present the multilevel model—we present two common approaches, highlight how the specifications are equivalent, and how the specifications can map onto the structural equation modeling approach for latent growth analyses.

Following Laird and Ware (1982), the multilevel model for change can be specified as

$$\mathbf{Y}_i = \mathbf{X}_i\boldsymbol{\alpha} + \mathbf{Z}_i\mathbf{d}_i + \mathbf{e}_i \tag{22.11}$$

where $\mathbf{Y}_i$ is a $n_i \times 1$ vector of observed scores for individual i, $\mathbf{X}_i$ (chi) is a known $n_i \times R$ design matrix linking $\boldsymbol{\alpha}$, an $R \times 1$ of unknown fixed effects estimates, to $\mathbf{Y}_i$, $\mathbf{Z}_i$ (zeta) is a known $n_i \times K$ design matrix linking $\mathbf{d}_i$, a $K \times 1$ vector of unknown individual effects, to $\mathbf{Y}_i$, and $\mathbf{e}_i$ is an $n_i \times 1$ vector of residuals. The individual effects, $\mathbf{d}_i$, are assumed to be multivariate normal with means equal to 0 and covariance matrix $\boldsymbol{\psi}$ (i.e., $\mathbf{d}_i \sim MVN(0, \boldsymbol{\psi})$). The residuals are assumed to be normally distributed with mean 0 and covariance matrix $\boldsymbol{\Theta}_i$ (i.e., $\mathbf{e}_i \sim N(0, \boldsymbol{\Theta}_i)$). We note that the dimensions of $\boldsymbol{\Theta}_i$ are dependent on i, but the unknown parameters do not depend on i and $\boldsymbol{\Theta}_i = \theta\mathbf{I}$, where $\mathbf{I}$ is an identity matrix, and θ is a common residual variance. This model yields a mean vector of $\mathbf{Y}_i$ equal to $\mathbf{X}_i\boldsymbol{\alpha}$ and covariance matrix $\mathbf{Z}_i\boldsymbol{\psi}\mathbf{Z}_i' + \boldsymbol{\Theta}_i$.

The matrix specification of the multilevel growth model (equation 22.11) follows closely the specification within the SEM framework (equation 22.1). Of note, in the growth model without covariates and traditionally specified, the two design matrices, $\mathbf{X}_i$ and $\mathbf{Z}_i$, are equivalent and are individual functions of time. With these matrices being equivalent, the model more closely mimics the structural equation modeling specification with a separation of the mean vector for the latent variables (i.e., $\boldsymbol{\alpha}$) from the individual deviations (i.e., $\mathbf{d}_i$).

Noting these similarities, we now highlight the main differences. The first difference is the dimension of several matrices. In the multilevel modeling framework, the dimensions of several matrices vary over individuals. The vector of observed scores, the design matrices, and the residual vector have dimensions that vary at the individual level, whereas the comparable matrices within the structural equation modeling framework have dimensions that do not vary over the individual level and have dimensions based on the number of occasions from the chosen time metric.

The next major difference is that the design matrices within the multilevel modeling framework ($\mathbf{X}_i$ and $\mathbf{Z}_i$) vary at the individual level (subscripted by i), whereas the factor loading matrix from the structural equation modeling framework (Λ) does not vary at the individual level. Thus, the multilevel model is able to accommodate individually varying measurement schedules, whereas the structural equation modeling framework is for a fixed measurement schedule that all individuals follow. However, we note two things. First, although the measurement schedule is fixed, all participants do not need to be measured at each of the fixed measurement occasions. Second, recent advances within the SEM framework have allowed for the factor loading matrix to be individually specified

(essentially turning the structural equation model into a multilevel model).

The third major difference between the frameworks is the ways in which the latent variables or random coefficients combine within the model. The structural equation modeling framework is a linear modeling framework, which means that the latent variables can only combine in a linear or additive fashion (i.e., latent variables multiply the factor loading matrix and are then added together to yield predicted values). In the multilevel modeling framework, the random coefficients can also combine in a nonlinear or multiplicative fashion. Therefore, there are models that can be fit within the multilevel, or more specifically the nonlinear multilevel, modeling framework that cannot be fit within the structural equation modeling framework.

Alternative Specification

An alternative way to present the multilevel model is

$$Y_{it} = f(time_{it}, \mathbf{h}_i) + e_{it} \tag{22.12}$$

where Y_{it} is the observed response for the i-th individual at time t, $f(time_{it}, \mathbf{b}_i)$ is a linear or nonlinear function of time with random coefficients, $\mathbf{h}_i' = (h_{i1}, h_{i2}, \ldots, h_{iR})$, that combine linearly or nonlinearly, and e_{it} is the residual for individual i at time t, which is assumed to follow a normal distribution with constant variance (i.e., $e_{it} \sim N(0, \theta)$). The random coefficients are often assumed to follow a multivariate normal distribution, such that $\mathbf{h}_i \sim MVN(\boldsymbol{\alpha}, \boldsymbol{\psi})$, where $\boldsymbol{\alpha}$ is an $R \times 1$ vector of fixed-effects parameters and $\boldsymbol{\psi}$ is a $R \times R$ covariance matrix of random-effects parameters.

Specific Growth Models

Linear Growth

The linear growth model is written as

$$Y_{it} = h_{i1} + h_{i2} \cdot \left(\frac{time_{it} - k_1}{k_2} \right) + e_{it} \tag{22.13}$$

where Y_{it} are the repeated measures for individual i at time t, h_{i1} is the intercept or predicted score when $time_{it} = k_1$ for individual i, k_1 is a constant used to center the intercept, h_{i2} is the linear slope or the predicted amount of change in Y_{it} for a one unit change in $\frac{time_{it}}{k_2}$ for individual i , k_2 is a scaling coefficient used to adjust the metric of $time_{it}$ and the interpretation of h_{i2}, and e_{it} is a time-specific residual score for individual i at $time_{it}$.

The constants, k_1 and k_2, can be set to any value; however, the values for these constants impact interpretation and should be carefully considered. For example, to center the intercept at the zero point of the original time metric, $k_1 = 0$. Thus, the intercept, h_{i1}, would reflect an individual's true level at the attribute when $time_{it} = 0$. This may be reasonable for many time scales, but is inappropriate for other time scales and constructs. For example, when examining individual changes in depression as a function of age during adolescence, it might be reasonable to center the chosen time metric, *age*, around the age when measurements were first taken (e.g., $k_1 = 13$ years). In a similar vein, the choice of k_2 should be carefully considered to scale the time metric in an appropriate way. We note that k_2 is often set equal to 1 to scale the slope, h_{2i}, in terms of the original time metric, $time_{it}$; however, for certain constructs that change more rapidly or more slowly, it is reasonable to choose a different value of k_2.

Quadratic Growth

The quadratic model can be specified as

$$Y_{it} = h_{i1} + h_{i2} \cdot \left(\frac{time_{it} - k_1}{k_2} \right) + h_{i3} \cdot \left(\frac{time_{it} - k_1}{2k_2} \right)^2 + e_{it} \tag{22.14}$$

where h_{i1} is the intercept for individual i, h_{i2} is the linear slope for individual i, h_{i3} is the quadratic slope for individual i, and e_{it} is the time-specific residual score for individual i at $time_{it}$. Similar to the linear growth curve, the intercept remains the predicted score when $time_{it} = k_1$. The linear slope represents the rate of change when $time_{it} = k_1$ and the quadratic slope represents acceleration or curvature.

Inherently Nonlinear Models

One of the benefits of the multilevel modeling framework is the straightforward extension to the *nonlinear* multilevel modeling framework. That is, the multilevel model can be used to fit any type of nonlinear change model. This flexibility is important because development is often highly nonlinear and linearity often serves as an approximation for a truly nonlinear process. In this section, we present two nonlinear models, both of which follow an exponential trajectory, that vary in complexity.

The first exponential model can be written as

$$Y_{it} = h_{i1} + h_{i2} \cdot (1 - \exp(-\beta \cdot time_{it})) + e_{it} \tag{22.15}$$

where h_{i1} is the predicted score when $time_{it} = 0$ for individual i, h_{i2} is the total amount of change from h_{i1} to the asymptotic level for individual i, β is the rate of approach to the asymptotic level, and e_{it} is the time-dependent residual. In this model, β is an estimated (fixed effect) parameter and does not vary across participants, whereas h_{i1} and h_{i2} are random coefficients that vary over participants. This form of the exponential is *additive* because the random coefficients enter the model in a linear/additive fashion because β is an estimated parameter. We note that this model can be fit within the SEM framework (see equation 22.9) as long as nonlinear constraints are available, and the majority of structural equation modeling programs do allow for such constraints.

The second exponential model is written as

$$Y_{it} = h_{i1} + h_{i2} \cdot (1 - \exp(-h_{i3} \cdot time_{it})) + e_{it} \qquad (22.16)$$

where h_{i1} is the predicted score when $time_{it} = 0$ for individual i, h_{i2} is the total amount of change from h_{i1} to the asymptotic level for individual i, h_{i3} is the rate of approach to the asymptotic level for individual i, and e_{it} is the time-dependent residual. Now, the rate of approach varies over individuals. This simple change makes the model multiplicative because h_{i2} is a multiplier of h_{i3} and therefore, these random coefficients enter the model in a nonlinear fashion. Thus, the structural equation modeling framework is unable to estimate this model (see Browne, 1993); however, the multilevel model can estimate the model directly—a big advantage of the multilevel modeling framework.

Direct Expansions of the Latent Growth Modeling Framework

The specifications described are focused on the study of intraindividual change and interindividual variability in intraindividual change. A common next step involves the evaluation of determinants of interindividual variability in intraindividual change. As noted already, this is often accomplished with the inclusion of time-invariant covariates as predictors of the latent growth variables. Moving back to the linear growth model for simplicity, this model can be specified as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{pmatrix} \left[\begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} + \begin{pmatrix} \gamma_1 \\ \gamma_2 \end{pmatrix} \cdot (X) + \begin{pmatrix} d_1 \\ d_2 \end{pmatrix} \right] + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \qquad (22.17)$$

where α_1 and α_2 is the predicted value of h_1 and h_2 when the covariate X is 0, γ_1 and γ_2 are regression coefficients of the impact of X on h_1 and h_2, and d_1 and d_2 are latent variable disturbances representing unmodeled variability in h_1 and h_2.

Additionally, time-varying covariates are modeled as having an instantaneous impact on the observed score. Such a model can be expressed as

$$\begin{pmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} + \begin{pmatrix} \gamma_1 & 0 & 0 & 0 \\ 0 & \gamma_2 & 0 & 0 \\ 0 & 0 & \gamma_3 & 0 \\ 0 & 0 & 0 & \gamma_4 \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{pmatrix} + \begin{pmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{pmatrix} \qquad (22.18)$$

where X_1 through X_4 is a time-varying covariate—a single variable that varies across time—and γ_1 through γ_4 are the regression coefficients for the time-varying covariate describing the impact the time-varying covariate has on the outcome variable. Often these effects are constrained to be equal across time (e.g., $\gamma_1 = \gamma_2 = \gamma_3 = \gamma_4$) to mimic the way the model is typically fit within the multilevel modeling framework; however this constraint is not required.

Multiple Group Growth Model

The latent growth model of equation 22.1 can be extended to accommodate multiple observed groups of individuals. In this approach, the data are split based upon the grouping variable and separate growth models are specified for each group. Typically, a series of models are evaluated, which test the invariance of specific collections of parameters, such as the latent variable means, the latent variable covariances, and the structure of change. Extending equation 22.1, we can write the multiple group growth model as

$$\mathbf{Y}_i^{(g)} = \Lambda^{(g)} \mathbf{h}_i^{(g)} + \mathbf{u}_i^{(g)} \qquad (22.19)$$

where $\mathbf{Y}_i^{(g)}$ is a $T \times 1$ vector of the repeatedly measured observed scores for individual i in group g, $\Lambda^{(g)}$ is a $T \times R$ factor loading matrix for group g, $\mathbf{h}_i^{(g)}$ is an $R \times 1$ vector of latent factor scores for individual i in group g, and $\mathbf{u}_i^{(g)}$ is a $T \times 1$ vector of unique scores for individual i in group g.

The individual factor scores are written as deviations from the *group-level* means, expressed as

$$\mathbf{h}_i^{(g)} = \boldsymbol{\alpha}^{(g)} + \mathbf{d}_i^{(g)} \qquad (22.20)$$

where $\boldsymbol{\alpha}^{(g)}$ is an $R \times 1$ vector of latent variable means for group g, and $\mathbf{d}_i^{(g)}$ is an R x 1 vector of mean deviations

for individual i in group g. In the multiple group growth model, the covariance matrix of mean deviations is $\boldsymbol{\psi}^{(g)}$, a group-specific R x R covariance matrix indicates the magnitude of between-person differences in the latent growth factors within each group as well as the degree of linear association among the latent growth factors within each group. Finally, the covariance matrix for unique scores, $\boldsymbol{\Theta}^{(g)}$, is also group specific.

This specification of the multiple group model is equivalent to separately specifying a growth model for each of the $g = 1$ to G groups. In practice, a series of models are fit to evaluate where group differences manifest. There are a variety of approaches to systematically test for group differences, and here we follow the approach advanced by Ram and Grimm (2009). In this approach, the first model is the *invariant model* where all parameter estimates are constrained to be equal over group (i.e., $\Lambda^{(g)} = \Lambda$, $\boldsymbol{\alpha}^{(g)} = \boldsymbol{\alpha}$, $\boldsymbol{\psi}^{(g)} = \boldsymbol{\psi}$, and $\boldsymbol{\Theta}^{(g)} = \boldsymbol{\Theta}$). This model is equivalent to the latent growth model without accounting for any grouping variable. The second model is the *Means Model* where the latent variable means are the only parameter estimates allowed to vary over group (i.e., $\Lambda^{(g)} = \Lambda$, $\boldsymbol{\alpha}^{(g)}$, $\boldsymbol{\psi}^{(g)} = \boldsymbol{\psi}$, and $\boldsymbol{\Theta}^{(g)} = \boldsymbol{\Theta}$). Next, is the *Means+Variances Model* where the latent variable means, the latent variable variances, and the residual variances are allowed to vary over group (i.e., $\Lambda^{(g)} = \Lambda$, $\boldsymbol{\alpha}^{(g)}$, $\boldsymbol{\psi}^{(g)}$ and $\boldsymbol{\Theta}^{(g)}$). The fourth and final model is the *configural invariance model* (i.e., *curves model*), where the factor loading matrix is also allowed to vary over group (i.e., $\Lambda^{(g)}$, $\boldsymbol{\alpha}^{(g)}$, $\boldsymbol{\psi}^{(g)}$ and $\boldsymbol{\Theta}^{(g)}$). In this model, all parameter estimates are separately estimated for each group. Nested chi-square difference tests can be used to compare each model with the more restricted models to determine whether and where the groups differ in estimated parameters.

Latent Growth Modeling Studies for Understanding Developmental Pathways in Terms of Continuity–Discontinuity and Equifinality–Multifinality

Understanding Developmental Pathways Using Latent Growth Modeling

In this section, we illustrate several studies that demonstrate how growth curve models can be used to inform substantive questions in developmental psychopathology research focusing on the core principles of developmental psychopathology. A latent growth modeling study by Kim and Cicchetti (2006) demonstrates how growth curve models can be used to describe differential pathways to psychopathology. This study used latent growth modeling to investigate longitudinal relationships between self-system processes and depressive symptoms among maltreated and nonmaltreated children. One of the main goals was to describe developmental trajectories in self-system processes and depressive symptoms during the elementary school years among maltreated and nonmaltreated children. From a methodological viewpoint, an important advance of this study was to implement a latent growth curve model using SEM to examine interindividual differences in intraindividual variability (McArdle & Bell, 2000) in both initial levels and rates of change in children's self-system processes and depressive symptoms. The participants included 251 children (142 maltreated and 109 nonmaltreated) who attended a summer day camp research program. Children ranged in age from 6 to 11 years ($M = 8.46$, $SD = 1.11$) at Wave 1 and 64% of the children were boys. The four-wave longitudinal data involved 7- to 12-year-olds.

To investigate developmental trajectories of self-system processes and depressive symptoms, we conducted growth curve analyses with a maximum likelihood estimation method, which allows for inclusion of respondents with missing data by using full information maximum likelihood (FIML) estimation (Arbuckle, 1996). In evaluating the overall goodness-of-fit of each model, the root mean square error of approximation (RMSEA; Browne & Cudeck, 1993) index assesses the degree of lack of fit for a model and values less than .05 and .08 are taken to reflect a close fit and a reasonable fit, respectively. The comparative fit index (CFI; Bentler, 1990) varies along a 0–1 continuum in which values greater than .90 and .95 are considered to reflect acceptable and excellent fits to the data, respectively.

We first fit a two-factor growth model over the four time points. The first latent factor was the intercept (or level) representing the initial starting point of the growth function, and the four factor loadings for the latent intercept factor were fixed to one. The second latent factor was the slope of the growth function, representing the rate of change in the growth trajectory over time. The latent intercept and slope factors were freely correlated. To determine the shape of trajectories of study variables for the entire sample, three alternative models were fitted separately for depressive symptoms (measured by the Children's Depression Inventory, CDI; Kovacs, 1985) and self-esteem (measured by the Self Esteem Inventory, SEI; Coopersmith, 1981). The first model was a *no-growth* model that assumed no slope component (i.e., thus assumed no growth or change). The second model was a *linear growth* model that assumed a linear pattern of change over time and fixed values of slope parameters as

[$B(T1) = 0,\ B(T2) = 1,\ B(T3) = 2,\ B(T4) = 3$]. The third model was a *latent basis growth* model that estimated slope parameters from the data to yield an overall group shape. The slope parameter for the first occasion was fixed to zero [$B(T1) = 0$] to allow a separation of the intercept and slope components, and the slope parameter for the last occasion was fixed to one [$B(T4) = 1$] to provide a scale of measurement for the slopes. The slope parameters for the second and the third occasions were freely estimated from the data. Model comparison was facilitated by positing a nested ordering of models in which the parameter estimates for a more restrictive model were a proper subset of those in a more general model.

As can be seen in Table 22.1, the chi-square difference test indicated that a linear growth model provided the best fit to the data for the SEI. For the SEI, significant variance of both intercept ($\sigma^2 = .01,\ SE = .002,\ p < .05$) and slope ($\sigma^2 = .001,\ SE = .000,\ p < .05$) indicated the presence of significant individual differences in initial levels and change in children's self-esteem. Both intercept mean ($M = .68,\ SE = .01,\ p < .05$) and slope mean ($M = .03,\ SE = .004,\ p < .05$) were significantly different from zero, showing that children's self-esteem increased over time. In contrast, a latent basis growth model was the best-fitting model for the CDI. The coefficients of the slope factor loadings represented the percentage of growth relative to the total change occurring over all time points. The pattern of CDI slope factor loadings (i.e., .00, .59, .89, 1.00) reflected a nonlinear change in the CDI scores.

Significant variance existed in both intercept ($\sigma^2 = 38.45,\ SE = 9.42,\ p < .05$) and slope ($\sigma^2 = 25.55,\ SE = 10.93,\ p < .05$), reflecting meaningful individual variability in average level and change in depressive symptoms over time. The intercept mean was significantly different from zero ($M = 9.47,\ SE = .48,\ p < .05$), and the slope mean was negative and significantly different from zero ($M = -3.55,\ SE = .51,\ p < .05$), suggesting that children's depressive symptoms decreased over time. The intercept and the slope factors were negatively correlated ($r = -.74,\ p < .05$), suggesting that children who reported higher initial levels of depressive symptoms tended to show a more rapid decrease in depressive symptoms over time compared to children who reported lower initial levels of depressive symptoms. Therefore, the data indicated a significant decrease in depressive symptoms and linear increases in self-esteem over the four time points. There are no particular theories to delineate particular developmental trajectory patterns of depressive symptoms and self-systems among maltreated and nonmaltreated school-age children. However, this finding was consistent with some previous research that reported decreases in self-reported internalizing problems and increases in perceptions of internal control in similar samples (e.g., Bolger & Patterson, 2001).

In estimating developmental trajectories using latent growth modeling, the main goal is to estimate unobserved or latent trajectory as a function of the set of repeated measures that were observed to describe how the developmental process unfolds within each person—that is, intraindividual change. As shown in this example, the growth curve model can further inform the interindividual changes (the means and variances of the individual trajectory parameters *across* individuals) based on intraindividual trajectories. Within latent growth modeling, each individual is characterized by his or her own unique trajectory that best represents their observed data over multiple time points. The advantage of latent growth modeling is clear especially when we compare latent growth modeling to more traditional models (such as autoregressive regression models) in which a single parameter estimate represents the relation between two repeated measures pooled over all subjects over time (Curran & Willoughby, 2003).

[1]Sample size is 251 for CDI and SEI data. *p*(exact) = probability of an exact fit to the data; CFI = comparative fit index; RMSEA = root mean square error of approximation; *p*(close) = probability of a close fit to the data.
[2]$\Delta\chi^2$ = difference in likelihood ratio tests; Δdf = difference in *df;* *p*(*d*) = probability of the difference tests.

Studying Turning Points in Developmental Pathways Using Latent Growth Modeling

Hussong and her colleagues (2008) demonstrated a great example of using latent growth modeling for testing turning points that mark the life course of young adults as they moved from risk to resilience or maladjustment. They focused on the concept of snares that defined a turning point away from an expected course of adaptation. Within the context of youth antisocial behavior, the snares referred to the mechanisms responsible for prolonging what might otherwise be a developmentally normative pattern of desisting antisocial behavior. They tested two alternative hypotheses. The snares hypothesis proposed that substance abuse (i.e., the ensnaring factor) would act through a series of proximal influences on crime desistance, consequently making short-term alterations in the trajectory of antisocial behavior. In contrast, the launch hypothesis proposed that substance abuse early in young adulthood may not only identify young men who are on a long-term trajectory of elevated antisocial behavior but also set them on such a trajectory. These two alternative hypotheses were compared to a general deviance hypothesis, in which both substance abuse and antisocial behavior were viewed as multiple indicators of a single latent construct of problem behavior. Specifically, for the snares hypothesis, substance abuse was tested as a time-varying predictor of elevated antisocial behavior against an expected pattern of desistance over time. For the launch hypothesis, substance abuse was tested as a time-invariant predictor of intraindividual differences in the intercepts and slopes that defined trajectories of antisocial behavior over time.

The data were taken from the Dunedin Multidisciplinary Health and Development Study, a longitudinal investigation of a complete birth cohort born in Dunedin, New Zealand (Silva & Stanton, 1996). This study used self-reported substance (alcohol and marijuana) abuse and antisocial behaviors data gathered from men at ages 18, 21, and 26 (N = 461 at age 18 and 438 had complete data). They first estimated an unconditional linear growth curve model to examine whether the individual trajectories of antisocial behaviors varied across men. The unconditional growth curve model had a good fit [$Ø^2(1) = 9.31$, $p = .002$, $CFI = .98$] with a significantly decreasing slope over time ($t = -5.84$, $p < .001$). The variance estimates were both significant for the intercept ($t = 8.96$, $p < .001$) and the slope ($t = 2.69$, $p < .01$), indicating substantial interindividual variability in intraindividual trajectories of antisocial behavior.

Next, they tested the snares hypothesis by fitting a time-varying covariate growth curve model in which the repeated measures of substance abuse were included as time-varying covariates. In this time-varying covariate growth curve model, time-specific influences of alcohol abuse and marijuana abuse on antisocial behavior were estimated above and beyond the influence of each individual's underlying trajectory of antisocial behavior. The time-varying covariate growth curve model fit the data well [$\chi^2(1) = 10.59$, $p = .001$, CFI = .99]. Results indicated that, at age 18 and age 21, men with higher levels of alcohol and marijuana abuse reported significantly elevated levels of antisocial behavior than would be expected based on their individual trajectories alone. At age 26, the effect of alcohol abuse was marginally significant ($p = .07$) and the effect of marijuana was not significant ($p > .10$). This finding was interpreted that substance abuse appeared to ensnare those young men within elevated patterns of antisocial behavior and such an effect became weaker as those men aged through this period of crime desistance.

They further tested the launch hypothesis using a conditional growth curve model in which alcohol abuse and marijuana abuse at age 18 were included as two exogenous predictors of changes in antisocial behaviors. The conditional growth curve model fit the data well [$\chi^2(3) = 11.33$, $p = .01$, $CFI = .99$]. Higher levels of alcohol and marijuana abuse at age 18 predicted higher intercepts of the antisocial behavior trajectories ($t = 9.63$, $p < .001$ for alcohol and $t = 8.81$, $p < .001$ for marijuana). Both alcohol ($t = -2.86$, $p < .001$) and marijuana ($t = -2.86$, $p < .001$) abuse were also negatively related to the slope of the antisocial behavior trajectories. This finding suggested that men with higher substance abuse at age 18 showed steeper decreases in antisocial behavior over time, yet they were significantly elevated in antisocial behavior across all periods of assessment.

Finally, a general deviance hypothesis was tested using a second-order growth curve model in which the two second-order intercept and slope factors for deviance proneness were constructed based on three latent constructs representing deviance proneness at ages 18, 21, and 26. For each first-order latent factor, alcohol abuse, marijuana abuse, and antisocial behavior served as multiple indicators (e.g., the age 18 deviance proneness latent factor was constructed based on alcohol abuse, marijuana abuse, and antisocial behavior at age 18). In examining whether there were significant individual differences in the developmental trajectories of deviance proneness over time, factor loadings within the same construct needed to be constrained to be equal over time. The results revealed

a relatively poor fit, especially based on the chi-square test [$\chi^2(2) = 98.06$, $p < .001$, CFI = .95]. In particular, the source of the poor fit was the equality constraints on the factor loadings within the same construct over time. This finding indicates that the manifestations of the general deviance factor were variable over time. This problem reflects, in part, the challenge of determining continuity in the quality of adaptation across developmental time despite changing behavioral presentations of the developing individual (Sroufe, 1997).

Overall, this study illustrates how the growth curve model can offer a sophisticated approach to study changes over time and examine turning points in intraindividual development. Specifically, the analyses supported both the launch and the snares hypotheses, providing significant insights into the direction of causality in which substance abuse contributed to maintenance of antisocial behavior.

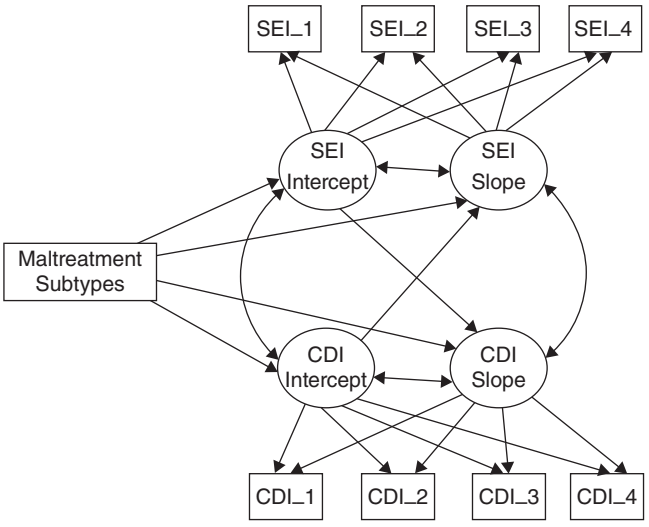

Figure 22.3 Multivariate growth model of self-esteem and depressive symptoms with maltreatment subtypes as predictors.

Understanding Risk and Protective Factors Using Latent Growth Modeling

In the following section, an empirical example is given of a study using latent growth modeling to investigate the effects of risk or protective factors on developmental trajectories leading to maladjustment. In the latent growth modeling study by Kim and Cicchetti (2006) that was reviewed earlier, the impact of different maltreatment subtypes on children's self-esteem and depressive symptoms was examined. As shown in Figure 22.3, both the intercept and slope factors of self-esteem and depressive symptoms were regressed on age (a demographic covariate) and the dichotomous maltreatment variables (presence or absence of emotional maltreatment, physical neglect, physical abuse, and sexual abuse). Different subtypes of maltreatment were assessed using the Maltreatment Classification System (MCS; Barnett, Manly, & Cicchetti, 1993). Of key interest was whether the strength of maltreatment's impact on self-esteem and depressive symptoms, and the relationships between self-esteem growth factors and depression growth factors would vary as a function of gender. Therefore, we used a two-group growth curve model with gender as the grouping variable: boys ($n = 159$) and girls ($n = 92$). For Model 2 in Table 22.2, we first fit a configural invariance model in which all parameters were freely estimated across the two groups, and then imposed equality constraints hierarchically to test the adequacy of the constraints using nested chi-square difference tests (Bollen, 1989).

We tested the equal maltreatment effects model by imposing equality constraints on all regression paths for the effects of four maltreatment subtypes and age on growth factors of self-esteem and depressive symptoms. These equality constraints did not degrade the model fit, suggesting that the effects of maltreatment and age on the self-esteem and depression growth factors were comparable between boys and girls. Examination of parameter estimates in the Equal Maltreatment Effects model indicated that for both boys and girls, physical

[1]Sample size is 251 for CDI and SEI data. *p*(exact) = probability of an exact fit to the data; CFI = comparative fit index; RMSEA = root mean square error of approximation; *p*(close) = probability of a close fit to the data.
[2]$\Delta\chi^2$ = difference in likelihood ratio tests; Δdf = difference in *df*; *p*(*d*) = probability of the difference tests.
Note: Based in part on "Longitudinal trajectories of self-system processes and depressive symptoms among maltreated and nonmaltreated children" by J. Kim and D. Cicchetti, 2006, *Child Development*, *77*, pp. 624–639.

abuse was related to lower initial levels of self-esteem ($B = -.06$, $SE = .02$, $p < .05$) and higher initial levels of depressive symptoms ($B = 3.63$, $SE = 1.23$, $p < .05$). Physical neglect was associated with higher initial levels of depressive symptoms ($B = 2.62$, $SE = 1.03$, $p < .05$). Regardless of gender, emotional maltreatment was positively related to the initial levels of self-esteem ($B = .05$, $SE = .02$, $p < .05$) and negatively related to change in self-esteem ($B = -.03$, $SE = .01$, $p < .05$). Emotional maltreatment was also significantly predictive of initial levels of depression ($B = -3.12$, $SE = 1.11$, $p < .05$) as well as change in depression ($B = 2.69$, $SE = 1.13$, $p < .05$). Additionally, age was positively related to the initial levels of self-esteem ($B = .04$, $SE = .01$, $p < .05$) and negatively related to the initial levels of depressive symptoms ($B = -1.55$, $SE = .39$, $p < .05$), suggesting that older children reported higher self-esteem and lower depressive symptoms compared to younger children.

Thus, the results of multivariate latent growth modeling analysis with covariates indicated that, regardless of gender, physical abuse was negatively related to initial levels of self-esteem, and physical abuse and physical neglect were positively associated with initial levels of depressive symptoms. The findings regarding the impact of emotion maltreatment suggested complexity. For depressive symptoms, emotional maltreatment was negatively related to initial levels but predicted slower decreases. For self-esteem, emotional maltreatment was positively related to initial levels but predicted slower increases over time. Taken together, these findings illustrate how latent growth modeling can contribute to enhancing our understanding of the developmental processes whereby early risk factors are linked to changes in adaptation and maladjustment in later life.

Understanding Mediating Processes Using Latent Growth Modeling

Using a longitudinal sample of 381 children (who were followed between ages 9 and 11 years), Troop-Gordon and Ladd (2005) studied whether social perceptions (self- and peer beliefs) acted as mediating mechanisms through which peer victimization was related to psychological maladjustment. Data were collected at five time points, including spring fourth grade, fall fifth grade, spring fifth grade, fall sixth grade, and spring sixth grade. Peer victimization was assessed using peer nominations, social self-acceptance was measured using the Harter's Self-Perception Profile for Children (1985), and children's perceptions of the social dispositions of their schoolmates were measured using the Peer Belief Inventory (Rabiner, Keane, & MacKinnon-Lewis, 1993). Children's maladjustment outcomes were measured using self, teacher, and parent reports of internalizing problems and peer, teacher, and parent reports of externalizing problems through various measures including the Child Behavior Checklist (CBCL, Achenbach, 1991) and the Teacher Report Form (TRF; Achenbach, 1991).

The multivariate growth curve model was tested separately for internalizing and externalizing problems. In each model, regression paths from the intercept factor of peer victimization to the intercept factors of both self-acceptance and peer beliefs as well as regression paths from the slope factor of peer victimization to the slope factors of both self-acceptance and peer beliefs were estimated. Within each construct, a regression path from the intercept factor to slope factor was estimated (e.g., the effect of peer victimization intercept on peer victimization slope was estimated). The latent constructs representing developmental changes in internalizing and externalizing problems were constructed based on multiple informants data of residualized scores that were computed by regressing spring sixth grade scores on spring fourth grade scores (e.g., the latent factor for changes in internalizing problems were constructed based on self-, parent-, and teacher-reported residualized scores).

For internalizing problems, the hypothesized model yielded an acceptable fit [$\chi^2(301) = 451.45$, $p < .001$, CFI = .95, RMSEA = .05]. Higher initial levels of peer victimization were predictive of more negative initial levels of self-acceptance ($\beta = -.55$ for boys and –.44 for girls) and peer beliefs ($\beta = -.32$ for boys and –.24 for girls). Moreover, an increasing peer victimization slope was related to declining self-acceptance ($\beta = -.25$ for boys and –.21 for girls). An increasing peer victimization slope was also related to decreasing prosocial presentation of peers for boys ($\beta = -.21$), whereas it was not associated with changes in peer beliefs among girls ($\beta = .04$). In turn, more derogatory initial self-acceptance ($\beta = -.70$ for boys and –.67 for girls) and peer beliefs ($\beta = -.25$ for boys and –.25 for girls) were predictive of increases in internalizing problems. Similarly, more negative growth in self-acceptance ($\beta = -.45$ for boys and –.45 for girls) and peer beliefs ($\beta = -.30$ for boys and –.30 for girls) was predictive of increases in internalizing problems. The indirect effects of initial peer victimization on subsequent change in internalizing problems through initial self-acceptance ($Z = 5.54$, $p < .001$) and through initial peer belief ($Z = 2.06$, $p < .05$) were statistically significant. The indirect effects of changes in peer victimization (i.e., peer victimization slope) through changes in self-acceptance

were significant ($Z = 2.57$, $p < .01$), whereas the indirect effects of changes in peer victimization through changes in peer beliefs were not significant.

Next, for externalizing problems, the final model that provided an acceptable fit [$\chi^2(301) = 467.31$, $p < .001$, CFI = .96, RMSEA = .05] revealed that the paths from intercept and slope factors of self-acceptance were not significantly different from zero. As expected, more derogatory initial peer beliefs ($\beta = -.23$ for boys and –.22 for girls) were predictive of increases in externalizing problems and more negative growth in peer beliefs ($\beta = -.23$ for boys and –.22 for girls) was predictive of increases in externalizing problems. The indirect effects of initial peer victimization on subsequent change in externalizing problems through initial peer belief were significant ($Z = 2.55$, $p < .01$), whereas the indirect effects of changes in peer victimization through changes in peer beliefs were not significant.

The findings of this study suggest that social perceptions construed in middle childhood played as mediating processes through which interpersonal risks, such as peer victimization established in the early elementary school years, are associated with increasingly deteriorating adjustment trajectories. This study illustrates how latent growth modeling can be used to specify developmental processes that are involved in the emergence and maintenance of psychopathology as earlier levels and developing trajectories of risk factors exert negative influences on more proximal psychosocial factors for the psychopathology outcomes.

Understanding Moderating Processes Using Latent Growth Modeling

Latent growth modeling can be used to examine not only additive but also interactive contributions of risk and protective factors to variance in the developmental trajectories of psychopathology outcomes. An *additive effect* model postulates that the risk or protective factor increases or decreases the probability of a maladaptive outcome independently of any probabilistic predictive effect of other risk or protective factors. An *interactive effect* model supposes that the link between the risk or protective factor and probability of maladaptive outcome differs (or is moderated) by the level of another risk or protective factor. For example, using a sample of 1,668 adolescents, Wills and his colleagues examined prediction about relationships of coping dimensions to substance use over the period from 12 to 15 years of age (Wills, Sandy, Yaeger, Cleary, & Shinar, 2001). They used a multivariate growth curve model to investigate whether engagement and disengagement coping variables measured at study outset may predict initial levels and growth in peer and adolescent substance use over time. Behavioral coping (i.e., do something to solve the problem) was used as the index of engagement and anger coping (i.e., get mad at people), helpless coping (i.e., give up on the problem), and hangout coping (i.e., hang out with other kids) were used as indices of disengagement. Peer and adolescent substance use were measured with items that asked about the typical frequency of cigarette, alcohol, and marijuana use. Additionally, life stress was assessed using a 20-item checklist of negative life events (Newcomb & Harlow, 1986).

They estimated latent growth factors (i.e., intercept and slope) of peer and adolescent substance use based on observed data measured in seventh, eighth, and ninth grades. In the latent growth modeling, covariances were estimated between the intercepts for peer and adolescent substance use, between the slopes for peer and adolescent substance use, and between the intercept and the slope factor for both peer and adolescent substance use. A regression path from peer substance use intercept to adolescence substance use slope was estimated, but a nonsignificant regression path from adolescence substance use intercept to peer substance use slope was not included. The final model yielded an acceptable fit [$\chi^2(48) = 132.04$, $p < .001$, RMSEA = .03], and revealed that engagement and disengagement coping operated through somewhat different pathways. Specifically, behavioral coping was related to lower intercepts of adolescent substance use and decreasing slopes of peer substance use over time. Disengagement was associated with higher intercepts for both peer and adolescent substance use and increasing slopes of adolescent substance use over time.

To determine whether effects of coping were contingent on the level of life stress, they performed multiple-group latent growth modeling analysis with two subgroups defined by a median split on life events. Chi-square difference tests indicated that the regression paths from coping to intercepts were significantly greater in the high-stress group [$\Delta\chi^2(3) = 10.07$, $p < .025$] than in the low-stress group. The regression paths from coping to slopes were also significantly greater in the high-stress group [$\Delta\chi^2(2) = 5.50$, $p = .05$]. In fact, the effect of behavioral coping on the slope of peer substance use and the effect of disengagement coping on the slope of adolescent substance use were significant in the high-stress group, but they were not significant in the low-stress group. However, the path from peer substance use intercept to adolescent substance use slope did not differ between the two groups [$\Delta\chi^2(1) = 0.21$, *ns*]. Therefore, the findings highlighted that behavioral coping had greater protective

effects on the development of peer substance use and disengagement coping had greater risk-promoting effects on the development of adolescent substance use at a higher level of life stress compared to a lower level of life stress. Finally, an interaction between risk and protective factors was tested in a multiple group growth curve model using subgroups of high vs. low behavior coping groups. The results revealed the buffering effects of behavioral coping indicated by significantly weaker effects of disengagement coping on the growth factors of substance use in the high behavioral coping group compared to the low behavioral coping group [$\Delta\chi^2(3) = 10.87,\ p < .025$].

This study illustrates testing of moderating effects of risk or protective factors using latent growth modeling. As we presented the conceptual reviews earlier, it appears that behavioral coping operated as a protective-enhancing process because it allowed adolescents to interact with stress in such a way that their behavioral engagement was more beneficial to reduce associating with substance using peers. There also was evidence of the risk factors of disengagement coping operating as the vulnerable and reactive processes where the overall disadvantage linked with the risk factors (i.e., disengagement coping) was heightened with increasing levels of stress. The findings regarding the moderation effect of behavioral coping reducing the potential adverse effects of disengagement types of coping further illuminate that the impact of stress on maladjustment depends on the interaction between protective and risk factors.

With the longitudinal design, the potential moderators of interest can vary over time thus creating the need for quantifying the time-varying moderator variables. Two approaches have been suggested by Flora, Khoo, and Chassin (2006). In the first approach, a potential moderator grouping variable can be estimated as a discrete latent class variable from a univariate growth mixture model (Muthén & Muthén, 2000). For example, suppose that we want to test whether changes in parental warmth over time moderate the links between changes in temperament-based behaviors and maladaptive outcomes. Using growth mixture modeling, we might find three classes for trajectories of parental warmth (stable, increasing, decreasing), and this categorical variable, based on the estimated probabilities, would then serve as a grouping/moderator variable when examining the predictive paths between temperament-based behaviors and the maladaptive outcome of interest. In the second approach, a variable representing each interaction term between the moderator variable and the predictor variable at each time point can be added to the existing growth curve model. Using the same hypothetical study, the interaction term between parental warmth and temperament-based behavior at each time point would be added to the growth curve model in the prediction of the maladaptive outcome. These two approaches to examining time-varying moderation effects may converge or may lead to distinct conclusions about whether and how the moderator in question is operating. However, we think that both approaches are appropriate depending on the specific developmental questions in hand. Time-varying moderation (or interaction) effects are complex, and a variety of statistical models are required to understand how they seem to be operating.

Latent Growth Modeling Studies for Understanding Contextual Influences

Latent Growth Modeling for Cross-Domain Relations in Risk and Psychopathology

Grimm (2007) provided illustrations of studying multivariate longitudinal relations between children's academic achievement and depression using a latent growth modeling framework. The data were drawn from a subsample from the National Longitudinal Survey of Youth (NLSY) (Baker, Keck, Mott, & Quinlan, 1993), a nationally representative study initiated in 1979 by the U.S. Department of Labor to study labor market behavior and experiences. The children of female respondents were assessed biennially from 1986 to 2000. The subsample contained $N = 7,078$ children who were measured at least once between the ages of 8 and 14 ($n = 3,602$ boys) with diverse ethnic backgrounds. Longitudinal data involved four repeated measurements assessed at ages 8, 10, 12, and 14. Academic achievement was measured using the Peabody Picture Vocabulary Test (PPVT)-Revised Form L (Dunn & Dunn, 1981). Raw PPVT-R scores were transformed to age 8 *t*-scores based on the mean and the standard deviation at age 8. Depression was assessed using the Behavior Problems Index (BPI; Zill & Peterson, 1986). The five anxious/depressed scores were summed and used to indicate the child's level of depression and these anxious/depressed scores were transformed into age 8 *t* scores in the same manner as the PPVT-R scores.

First, a bivariate growth curve model was used to examine the following questions regarding longitudinal relations between academic achievement and depression from age 8 to 14: (1) Is the level of academic achievement related to the level of depression? (2) Is the amount of change in academic achievement related to the amount of change in depression? (3) Is the level of academic achievement related to the

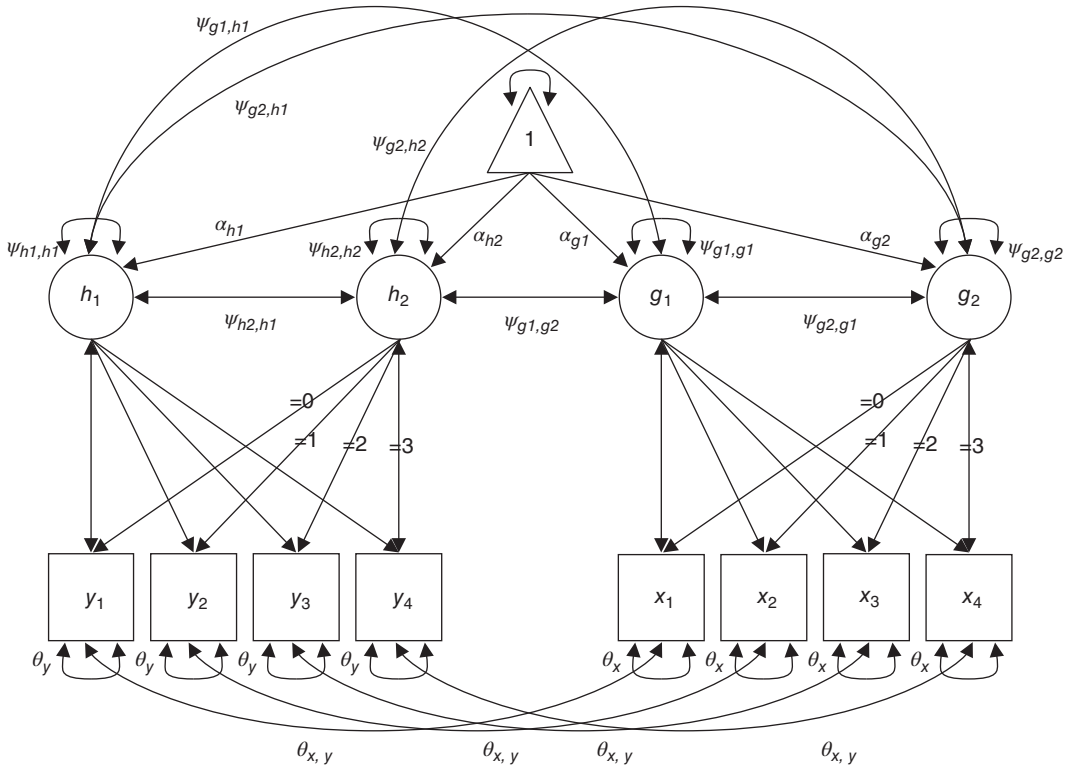

Figure 22.4 A bivariate growth curve model.

amount of change in depression? (4) Is the level of depression related to the amount of change in academic achievement? In the bivariate growth curve model (Figure 22.4), it is assumed that the two constructs are each governed by a separate developmental process and that the two processes are interrelated at the level of the latent growth factors (but not at the level of manifest variables).

Univariate growth curve models were estimated to determine the shape of developmental trajectories of academic achievement and depression. The latent basis model (in which the coefficients were estimated with the exception of two that were fixed for identification) yielded the best fits for both academic achievement and depression, compared to the intercept only and the linear growth models. Depression did not show significant systematic change, whereas academic achievement showed systematic and rapid increases from age 8 to age 14. The bivariate growth curve model fit the data well [$\chi^2(91) = 220$, RMSEA = .01]. In this bivariate growth curve model, there were two significant factor correlations ($p < .05$). First, the correlation between the intercept and the slope of depression was –.18 indicating that students with a lower level of depression at age 8 were likely to have a more positive change in depression from age 8 to 14. Second, the correlation between the intercept of depression and the intercept of academic achievement was –.14, indicating that students with an overall lower level of depression at age 8 were likely to have higher level of academic achievement at age 8.

Grimm (2007) further investigated an alternative growth curve model using a time-varying covariate. In the time-varying covariate growth curve model, the developmental processes of academic achievement were considered primary, whereas the developmental processes of depression were seen as control variables. As shown in Figure 22.5, the latent growth factors of academic achievement were estimated and the repeated measurements of academic achievement were regressed on the repeated measurements of depression. The latent growth factors of academic achievement were allowed to covary with the repeated measurements of depression. The following set of questions was asked: (1) How are the time-varying scores of depression related to the time-varying scores of achievement while controlling for interindividual differences in intraindividual change in academic achievement? (2) How are the time-dependent scores of depression related to the level and slope of the growth curve for academic achievement? (3) How does academic achievement change over time when controlling for depression over time?

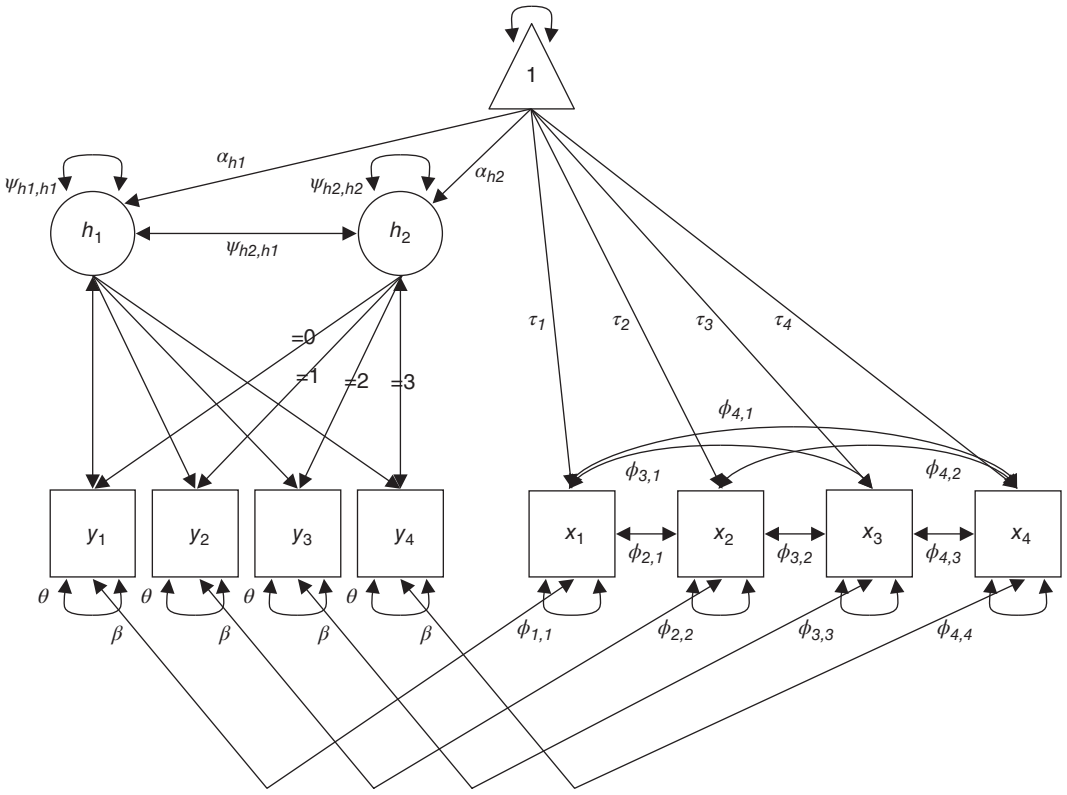

Figure 22.5 A time-varying covariate growth curve model.

The time-varying covariate growth curve model fit the data well [$\chi^2(57) = 109.04$, RMSEA = .01]. The growth factors of academic achievement were negatively correlated with the repeated depression scores ($r = -.02$ to $-.17$). More importantly, however, depression was not significantly related to academic achievement after controlling for changes in academic achievement from age 8 to 14 ($-.01$, $t = .82$, $p = ns$). Similar to the bivariate growth curve model, the average trajectory of academic achievement indicated a positive growth with a decelerating rate of change.

Taken together, the results from the bivariate growth curve model and the time-varying covariate growth curve model appear to offer somewhat different descriptions regarding the developmental relations between academic achievement and depression. The conclusions based on those results provide accurate answers to different developmental questions. These examples of using different types of latent growth modeling for examining longitudinal relations between developmental processes suggest that developmental psychopathologists should use the appropriate quantitative modeling approaches to accurately capture the dynamic nature of development in multiple levels or domains.

Latent Curve Modeling for Multiple Levels of Analysis

Over the past several decades, there has been a growing acknowledgment for the necessity of multidisciplinary and interdisciplinary investigations within the field of developmental psychopathology. Investigations of developmental pathways require researchers to consider biological, psychological, and environmental-contextual processes that result in diverse outcomes of psychopathology (i.e., multifinality) as well as those processes from which varied pathways to resilience might eventuate (i.e., equifinality). Research using multiple levels of analysis suggests that the influence of levels on one another is often bidirectional. That is, biological factors can influence psychological processes to produce psychopathology outcomes and psychosocial experiences can also modify the structure, function, and organization of biological mechanisms including the brain and gene expression (Cicchetti, 2010, 2015).

The following study illustrates how latent growth modeling can be used in the study of developmental psychopathology using multiple levels of analysis. In a recent longitudinal study of African American emerging adults ($N = 399$), Brody and his colleagues investigated

how life stress and genetic status were prospectively related with increases in drug use (Brody et al., 2012). The participants provided three waves of data at ages 17, 19, and 20 years regarding life stress using a checklist of 12 negative life events, peer and romantic partner drug use, vulnerability cognitions (a combination of willingness and intention to use drugs) and their drug use rates (0 = no use and 1 = any use). In addition, a saliva sample from the dopamine receptor D4 (DRD4) gene was genotyped.

It was hypothesized that emerging adults who carry the 7 + R allele would display higher rates of drug use over time when they experienced greater life stress (i.e., first-generation gene × environment or G×E interaction). It was also hypothesized that the first-generation G×E interaction would evince increases in affiliation with drug-using companions (peer and romantic partner drug use) and vulnerability cognitions for drug use, which both serve as two proximal mediators for drug use escalation. Latent growth modeling embedded in a multilevel modeling framework was used.

First, unconditional latent growth modeling analyses were estimated. The results indicated a significant and positive growth of youths' drug use ($\beta = 5.94$, $p < .001$) and companions' drug use ($\beta = 5.47$, $p < .001$) from age 17 to 20 years. There was no significant change in the slope of vulnerability cognitions ($\beta = .19$, $p = .64$). Next, DRD4, life stress, DRD4 × life stress interaction as well as two covariates (intervention status and youth gender) were regressed on the rate of change of drug use, companions' drug use, and vulnerability cognitions. Multilevel logistic regression was used and coefficients were calculated in log odds metric. There were significant interaction effects between DRD4 and life stress on the slopes of youths' drug use ($b = 1.82$, $SE = .92$, $p < .05$), companions' drug use ($b = 2.41$, $SE = .91$, $p < .01$), and vulnerability cognitions ($b = 1.28$, $SE = .58$, $p < .05$).

In the final step, time-varying effects of the two hypothesized mediators (companions' drug use, and vulnerability cognitions) on youths' drug use. Within-person variability in companions' drug use ($\beta = .13$, $p < .01$) and vulnerability cognitions ($\beta = .59$, $p < .001$) significantly predicted the probability of youths' drug use. More specifically, one unit change in companions' drug use over time increased the odds of past month drug use by the youth by 14%, and one unit change in vulnerability cognitions over time increased the odds of youths' drug use by 80%. After the time-varying effects of the two mediators were accounted for in the model, the DRD4 × life stress interaction effects on the slope of youths' drug use was no longer significant.

The findings of this study can be interpreted from the perspective of resilience. That is, the results suggest that genetic status can contribute to resilience by showing that carrying the 6-R allele (as opposed to the 7 + R allele) buffered emerging adults from escalating drug use when they experienced high levels of life stress. Furthermore, tests of the mediated moderation hypothesis revealed two pathways through which the interaction effects between DRD4 and life stress exerted: increases in affiliations with drug-using companions and increases in vulnerability cognitions. As the authors suggested, information regarding such mediating processes is critical for identifying targets for genetically informed prevention programs. This study exemplifies benefits of obtaining a process-level understanding of psychopathology through simultaneous assessment of multiple domains of variables both within and outside of the developing person.

Latent Growth Modeling for Cross-Population Comparisons in Risk and Psychopathology

As mentioned earlier in this chapter, a developmental psychopathology perspective emphasizes the mutual interplay between the study of normality and psychopathology (Cicchetti, 2010). The following investigation illustrates using latent growth modeling for studying interface between normal and abnormal development. Lansford and her colleagues (2006) examined how protective and risk factors alter trajectories of externalizing and internalizing behaviors from kindergarten through Grade 8. The participants included 585 children who were drawn from a multisite community sample and 11.8% of these children had been physically abused during the first 5 years of life. A set of protective and vulnerability factors was selected either because they had been found in previous research to be significantly related to children's externalizing and internalizing behaviors or because of a strong conceptual rationale for their moderating effects of physical abuse on externalizing and internalizing behavior trajectories. Two variables were used as indicators of child characteristics: early social competence and early hostile attribution. Several variables were used as indicators of the factors external to child including early socioeconomic status (SES), adolescent SES, early stress, adolescent stress, neighborhood danger, early proactive parenting, adolescent harsh discipline, unilateral parental decision making (i.e., the degree to which the parent made decisions for the adolescent concerning daily activities), parent-reported parental monitoring, and child-reported parental knowledge (i.e., knowing about various aspects of their children's life including activities and friends). Children's externalizing and internalizing

behaviors were measured based on teachers' reports on the Teacher Report Form of the Child Behavior Checklist (Achenbach, 1991) from kindergarten through Grade 8.

First, conditional latent growth modeling analyses were performed using the nonabused sample where each vulnerability or protective factor was included as a predictor of the latent growth factors of internalizing behavior or externalizing behavior after covarying out ethnicity and gender. These analyses focused on examining the normative main effects of the protective and vulnerability factors on behavior problem trajectories for children who were not physically abused. Three growth factors were specified including an intercept (the level at kindergarten), a linear slope, and a quadratic growth (the square of the slope term).

Next, two-group latent growth modeling analyses were conducted in which the effects of a particular predictor were estimated separately in the abused and nonabused groups. These analyses focused on examining how the protective and vulnerability factors moderate the association between early physical abuse and trajectories of externalizing and internalizing behaviors. Specifically, resilience was operationalized as a form of interaction between physical abuse and the predictor such that abuse had weaker impact at certain values of the predictor. In the two-group latent growth modeling, they imposed equality constraint on the effect of predictor on the developmental trajectory of externalizing or internalizing behavior.

For externalizing behavior, there was a significant interaction between abuse and unilateral parental decision making [$\Delta\chi^2(3) = 9.49,\ p < .03$]. A closer examination of the model-implied trajectories in each group at the high (+1 SD) and the low (−1 SD) levels of unilateral parental decision making (i.e., nonabused low unilateral parental decision making, nonabused high unilateral parental decision making, abused low unilateral parental decision making, and abused high unilateral parental decision making) revealed that abused children with parents low on unilateral parental decision making showed similar levels of externalizing behaviors to those of nonabused children by Grade 8. For internalizing behavior, there were significant interactions between abuse and early hostile attributions [$\Delta\chi^2(3) = 8.96,\ p < .03$], between abuse and early stress [$\Delta\chi^2(3) = 9.39,\ p < .03$], and between abuse and adolescent stress [$\Delta\chi^2(3) = 14.27,\ p < .01$]. A closer examination of the model-implied trajectories of abused and nonabused groups with high vs. low levels of early hostile attributions showed the highest levels of internalizing behaviors among abused children with low early hostile attributions followed by abused children with high early hostile attributions. Thus, this finding suggested that early hostile attributions had beneficial effects on the development of internalizing behaviors among abused children.

The model-implied trajectories in each group at the high and the low levels of early and adolescent stress suggested that family stress was a vulnerability process in the development of internalizing behaviors. Specifically, abused children with elevated early family stress showed the highest levels of internalizing behaviors from kindergarten to Grade 7 when the trajectories between low- and high-stress abused groups crossed. As expected, adolescent stress did not predict internalizing behaviors at kindergarten. Similar to early family stress results, abused children with elevated adolescent family stress showed the highest levels of internalizing behaviors until Grade 7.

The findings for externalizing behaviors, unilateral parental decision making showed a protective-stabilizing effect (Luthar et al., 2000) for abused children. For internalizing behaviors, there was evidence of protective effects of early hostile attributions, but unexpectedly it was higher levels of early hostile attributions that made abused children less vulnerable to developing internalizing behaviors. For the nonabused children, early hostile attributions did not have significant effects on their internalizing behaviors. As the authors suggested, these findings may indicate that making hostile attributions might be an adaptive strategy for abused children to avoid internalizing problems resulting from self-blame in their circumstances. A vulnerability process was suggested in relation to early and adolescent stress, as abused children were significantly more vulnerable to developing internalizing problems when experiencing high levels of family stress. Overall, this study's findings highlight the usefulness of latent growth modeling for examining effects of protective and vulnerability processes on developmental trajectories (rather than developmental outcomes at a single time point) and further illustrate how multiple group latent growth modeling can be used to evaluate trajectories delineating both normal development as well as the development in high-risk conditions.

Implications of Latent Growth Modeling for Prevention and Intervention Science

Studies using latent growth modeling to test the efficacy of prevention and intervention programs are relatively rare. The frequent statistical approach for evaluating prevention and intervention programs has been heavily reliant upon the analysis of covariance (ANCOVA). Yet an ANCOVA approach does not allow researchers to examine the pattern of intraindividual variability over time (including

before and after the introduction of the programs) of the determinants of the changes in intraindividual trajectories. Latent growth modeling has several advantages over an ANCOVA approach (Taylor, Graham, Cumsille, & Hansen, 2000). First, researchers can test the effect of programs (or treatments) on trajectories of change. Second, researchers can estimate the relationship between initial status and rate of change. Third, latent growth modeling allows simultaneous consideration of variables from multiple time points (i.e., multivariate approach) thus increasing statistical power for testing overall program effects that are consistent over time instead of detecting program effects that may be significant only at one time point out of many repeated measurements.

Specifically, the following example illustrates how latent growth modeling can be used to evaluate the efficacy of prevention and intervention programs by investigating effects of programs on the average level of outcomes, rate of change of outcomes, and acceleration or deceleration in the rate of change of outcomes. In their longitudinal study of the efficacy of a randomized drug prevention program, the Adolescent Alcohol Prevention Trial, Taylor and colleagues (2000) compared four groups: (1) an information only group (ICU), which was a control group, and it received lessons about the social and health consequences of using alcohol and other drugs; (2) a resistance training plus information group (RU) that received instruction regarding how to resist pressure to use alcohol and other drugs, in addition to the information lessons; (3) a normative education plus information group (Norm) that received lessons that corrected misperceptions concerning the prevalence and acceptability of alcohol and other drug use among peers and established conservative norms regarding substance use, in addition to the information lessons; and (4) a combined resistance training and normative education plus information group (COMB) that received lessons from each of the other three components. They collected data regarding cigarette and alcohol use among 3,027 adolescents over a 5-year period, beginning in Grade 7 prior to intervention and again in Grades 8, 9, 10, and 11 following the intervention.

In the growth curve model, they constrained the intercept loading to [1 1 1 1 1] and the slope loadings to [−2 –1 0 1 2]. As such, the zero point was perfectly centered over all time points thus the intercept represented the average level over the repeated measurements. In addition to the slope latent factor that represents a linear growth, a quadratic latent factor was introduced to estimate the average degree of curvature, with a positive mean suggesting acceleration and a negative mean suggesting deceleration. Because the Time 1 data were collected prior to introducing the prevention program, two different (but not nested) models were tested with one involving Time 1 measure as a pretest measure and the other involving Time 1 measure as part of the growth.

In the first model where the pretest (Time 1) measure was modeled as a separate covariate, the Norm group showed significantly lower average levels of drug use compared to the ICU group (the reference group). No significant effects were detected regarding the program effect on the slope factor. Furthermore, the Norm group had a positive effect on the quadratic term indicating that the acceleration was slower (or less steep) for the Norm group compared to the ICU group. The pretest covariate (Grade 7) was positively related to the level, whereas it was negatively related to the slope. This means that higher levels of pretest drug use were related to higher average levels of drug use over the time spanning from Grade 8 to Grade 11, yet higher levels of pretest drug use were also related to slower growth rates over the time.

In the second model where the pretest (Time 1) measure was modeled as part of the growth curve, the Norm group, compared to the ICU group, suggested beneficial effects of the prevention program on the slope factor. In addition, similar to the first model, the Norm group had a positive effect on the quadratic term indicating that the acceleration was slower for the Norm group. The intercept factor (Grade 7) was negatively related to the slope factor. Taking the two models together, it seems that the first model worked better for interpreting of program effects on the intercept or level, whereas the second model worked better for interpreting of program effects on the slope.

Overall, the results suggested that the Normative Education program had a beneficial effect on the level of drug use as well as the rate of growth in drug use. Specifically, students in the Norm group, compared to those in the ICU group, showed lower average levels of drug use as well as slower increases in drug use over time. The program effect on the slope factor is particularly useful because excessive rate of growth in drug use during adolescence may indicate atypical development of drug use behaviors (as opposed to typical development) indicating that those adolescents with a steeper trajectory may be at greater risk for subsequent drug use problems and consequently addiction. Furthermore, students in the Norm group maintained a lower, more stable rate of change for alcohol use over the 5 years, particularly the first 2 years. Such slower rates of growth in the early years mean later onset for the adolescents. Given the significant association between early onset of alcohol and drug use and later problem behavior (Hawkins et al.,

1997), it was speculated that interventions that can slow down drug use rates in early adolescence may be effective in reducing problem behaviors in later adolescence or early adulthood (Taylor et al., 2000).

Comparing the two models from a modeling perspective, it seems that including pretest measure as a covariate is useful for interpreting of program effects on the intercept or level, whereas modeling pretest measure as part of a growth curve is useful for interpreting of program effects on the slope. The lesson is that researchers should consider using different latent growth modeling approaches depending on their research questions. The study by Taylor and colleagues clearly demonstrate that latent growth modeling provides a powerful multivariate approach to testing overall program effects on changes in developmental trajectories.

LATENT CHANGE (DIFFERENCE) SCORE MODELING

Latent change score models, previously referred to as latent difference score models (McArdle, 2001; McArdle & Hamagami, 2001), place an emphasis of time-sequential intraindividual change across multiple constructs. These models recognize that intraindividual growth is not constant and may be dependent upon a variety of factors—potentially its prior status as well as the status of another variable at a specific point in time. These ideas and models map on to dynamical systems notions of change. Such models highlight the time-sequential *process* of change recognizing that there are shocks to the development that can and should be modeled.

Univariate Latent Change Score Models

We begin the discussion of latent change score models with commonly considered univariate models. We note that the models presented in this section are limited, but the latent change score framework can accommodate the variety of models discussed in the latent growth modeling section (see Grimm, Zhang, Hamagami, & Mazzocco, 2013).

Latent change score models are built upon *latent change scores* as opposed to latent true scores. The latent change scores are created by fixed structural relations as opposed to calculating observed change scores. To begin the description of such models, we fall back on classical test theory where each observed score is composed of a latent true score and an error or unique score. This can be written as

$$Y_{it} = y_{it} + u_{it} \tag{22.21}$$

where Y_{it} is the observed score for individual i at time t, y_{it} is the true score for individual i at time t, and u_{it} is the unique score for individual i at time t. The unique scores are assumed to be independent, whereas the latent true scores have a fixed autoregressive association, such that the latent true score at time t is set equal to the latent true score at time $t-1$ plus the amount of change that occurred between the two measurement occasions—the latent change score, Δy_{it}, which can be written as

$$y_{it} = y_{it-1} + \Delta y_{it}. \tag{22.22}$$

The latent change score is, in essence, the residual of this regression equation; however, because the regression weight for y_{it-1} is set equal to 1, the residual is the individual difference between the scores – the intraindividual change. This can also be shown by rearranging the terms and solving for the latent change score, such as

$$\Delta y_{it} = y_{it} - y_{it-1} \tag{22.23}$$

Thus, the latent change score is the simple difference between the latent true score at time t and the latent true score at time *t-1*.

Now that the latent change scores are defined, we can write a trajectory equation based upon the latent change scores. The overall trajectory for the latent true scores is written as

$$y_{it} = h_{i1} + \left(\sum_{r=2}^{t} \Delta y_{ir} \right) \tag{22.24}$$

where y_{it} is the latent true score for individual i at time t, h_{i1} is the latent intercept or the value of y_{i1} – the true score at the first measurement occasion, and $\sum_{r=2}^{t} \Delta y_{ir}$ is the summation of the latent change scores from Time 2 through time t. Thus, the trajectory equation for a latent change score model is an initial true level of the attribute, h_{i1}, plus an accumulation of changes that have taken place up to time t $\left(\sum_{r=2}^{t} \Delta y_{ir} \right)$.

The final piece of the latent change score model is a mathematical model for the latent change scores. This mathematical model controls the type of change model (e.g., linear, quadratic). We note that the majority of models that can be fit within the traditional latent growth modeling framework can also be specified within the latent change score modeling framework (see Grimm,

Zhang, et al., 2013). Additionally, some new models have emerged within this framework (as in McArdle, 2001, 2009; McArdle & Hamagami, 2001; McArdle & Nesselroade, 1994).

We begin with reiterating commonly fit latent growth models within the latent change score framework before presenting some models that can only be specified within the latent change score modeling framework. We can start with the linear growth model by writing the following change equation:

$$\Delta y_{it} = h_{i2} \tag{22.25}$$

where h_{i2} is the constant change factor. This model is often referred to as the *constant change model* because the change equation states that the latent change score at time t is simply equal to a latent factor, h_{i2}, that varies over individuals. Thus, changes taking place between consecutive measurement occasions are constant within an individual. Since changes are constant, the overall growth trajectory is linear. This can be seen by writing the predicted true scores for the first four measurement occasions based on the trajectory model for latent change score models (equation 22.24) and this change equation (equation 22.25). The following are equations for the first four measurement occasions (assuming constant spacing between measurement occasions)

$$\begin{aligned} y_{i1} &= h_{i1}, \\ y_{i2} &= h_{i1} + h_{i2}, \\ y_{i3} &= h_{i1} + h_{i2} + h_{i2}, \text{and} \\ y_{i4} &= h_{i1} + h_{i2} + h_{i2} + h_{i2}. \end{aligned} \tag{22.26}$$

Thus, the trajectory is linear over time, $y_{it} = h_{i1} + h_{i2}(t-1)$

The change equation for the quadratic model is

$$\Delta y_{it} = h_{i2} + h_{i3} \cdot (t-1) \tag{22.27}$$

where h_{i2} is the constant change factor, and h_{i3} is the linear change factor. Writing out the trajectory equations for the first four measurements yields

$$\begin{aligned} y_{i1} &= h_{i1} \\ y_{i2} &= h_{i1} + h_{i2} + h_{i3} \\ y_{i3} &= h_{i1} + (h_{i2} + h_{i3}) + (h_{i2} + 2h_{i3}) \\ y_{i4} &= h_{i1} + (h_{i2} + h_{i3}) + (h_{i2} + 2h_{i3}) + (h_{i2} + 3h_{i3}) \end{aligned} \tag{22.28}$$

Rearranging terms of the last equation yields $y_{i4} = h_{i1} + (h_{i2} + h_{i2} + h_{i2}) + (1h_{i3} + 2h_{i3} + 3h_{i3})$ and continuing this progression yields $y_{it} = h_{i1} + h_{i2}(t-1) + h_{i3}\left(\frac{(t-1)^2}{2} + \frac{t}{2}\right)$, which is equivalent to the quadratic model.

As seen in these progressions for the linear and quadratic models, commonly fit latent growth models can be specified within the latent change score modeling framework by specifying an equation for the latent change scores that is the first derivative of the trajectory equation specified within the traditional latent growth modeling framework. Generally, this holds with the exception of models for which the first derivative is undefined for certain values of t (see Grimm, Zhang, et al., 2013).

As we noted, the latent change score framework also opens up opportunities for new models that could not previously be considered within the latent growth modeling framework. These models allow for time-sequential associations between latent true scores and latent change scores as well as time-sequential association between latent change scores over time. For example, changes can be proportional to the latent true score at the previous occasion. Such as model can be written as

$$\Delta y_{it} = \beta \cdot y_{i(t-1)} \tag{22.29}$$

In this *proportional change* model, the coefficient β is the proportional change coefficient or the auto-proportion coefficient and is an estimated parameter. This model yields exponential-like trajectories depending on the magnitude and sign of the initial true score and the proportional change coefficient. For example, with a positive initial true score and a positive proportional change coefficient, the model yields an exponential growth type of change pattern whereby changes accelerate over time.

Another model that is commonly fit combines aspects of the *constant change* model and the *proportional change* model. Thus, the change equation contains both the constant change factor (h_{i2}) and the proportional change () effects. This model is referred to as the *dual change score* model and is written as

$$\Delta y_{it} = h_{i2} + \beta \cdot y_{i(t-1)} \tag{22.30}$$

The combination of the constant change and proportional change within the dual change score model leads to a complex nonlinear growth trajectory that follows an increasing or decreasing, accelerating or decelerating exponential trajectory depending on the magnitude and

sign of the constant change factor, the proportional change coefficient, and the initial value.

The use of latent change scores is a general approach to studying time-sequential change, which has been extended in a variety of ways. For example, McArdle (2001) examined the proportional change model with independent residuals on the latent change scores, which leads to a type of an autoregressive model, and fit latent change score models with common factor scores. Furthermore, Hamagami and McArdle (2007) proposed second-order change models where acceleration as opposed to the rate of change is the key outcome of interest. Grimm et al. (2012) highlighted how prior latent change scores can be included as predictors of current latent change scores and Grimm et al. (2013) showed how such models can be used to fit a variety of nonlinear change models to emphasize the intraindividual rate of change. Thus, it is easy to say that the models presented here are simply the beginning of univariate models that can be considered within the latent change score modeling framework and that the latent change score framework opens the door to a collection of interesting models focused on time-sequential change.

Bivariate Latent Change Score Models

The latent change score framework lends itself to the study of bivariate or multivariate processes because intraindividual change at a given point in time is the outcome of interest and time-sequential effects can be included (e.g., proportional change coefficient). Prior to the introduction of the latent change score framework, multivariable time-sequential associations were often studied with the autoregressive cross-lagged model (Cook & Campbell, 1977; Jöreskog, 1974; Rogosa, 1980). In this model there are autoregressive effects where the prior state of the variable at time $t - 1$ (i.e., $y_{i(t-1)}$) is a predictor of the current state of the variable (i.e., y_{it}) as well as cross-lagged effects where the prior state of a second variable at time $t - 1$ (i.e., $x_{i(t-1)}$) is also a predictor of the current state of the variable (i.e., y_{it}) and vice versa. In terms of understanding intraindividual growth, the autoregressive cross-lagged model only captures relative deviations from a sample-level mean and does not capture systematic intraindividual change.

For this reason, researchers have turned to multivariate growth curves, also referred to as parallel process growth models (i.e., cross-domain growth models; MacCallum, Kim, Malarkey, & Kiecolt-Glaser, 1997; McArdle, 1988). This popular alternative examines whether change in one variable is associated with change in the second variable. Although, this model captures intraindividual changes and associations among intraindividual changes, the model is unable to capture time-sequential associations and all associations involving intraindividual change are between-persons as opposed to within-person changes, which are often of interest.

As noted, the latent change score framework lends itself to the analysis of multiple variables over time. Specifically, a series of change equations are written as opposed to a single univariate change equation. Building on equation 22.30, we can write change equations for and Δx_{it}, based on constant change and proportional change, such as

$$\begin{aligned} \Delta y_{it} &= h_{i2} + \beta_y \cdot y_{i(t-1)} \\ \Delta x_{it} &= g_{i2} + \beta_x \cdot x_{i(t-1)} \end{aligned} \tag{22.31}$$

where h_{i2} and g_{i2} are the constant change factors and β_y and β_x are the proportional change effects for Δy_{it} and Δx_{it}, respectively. From here coupling effects, akin to cross-lagged effects from the autoregressive cross-lagged model, can be added to evaluate how the prior status of x impacts changes in y and how the prior status of y impacts changes in x. Thus, we write

$$\begin{aligned} \Delta y_{it} &= h_{i2} + \beta_y \cdot y_{i(t-1)} + \gamma_y \cdot x_{i(t-1)} \\ \Delta x_{it} &= g_{i2} + \beta_x \cdot x_{i(t-1)} + \gamma_x \cdot y_{i(t-1)} \end{aligned} \tag{22.32}$$

where γ_y and γ_x are the coupling coefficients describing across variable time-sequential associations. We note that the proportional and coupling coefficients are often held to be invariant over time; however, in many cases this constraint is unneeded and relaxing this constraint may theoretically reasonable (see Dogan, Stockdale, Widaman, & Conger, 2010).

Interpretation of bivariate latent change score models is often centered on the *dynamic parameters*—the proportional change and coupling coefficients. If a coupling coefficient is significantly different from zero, it can be said that there is a lead-lag relationship, such that the prior status of one variable provides an indication of the subsequent changes in the second variable. For example, if γ_y is significantly different from zero and γ_x is not, then it can be said that x is a leading indicator of y. We emphasize that this type of association is simply an association, and is not causal in any way. Additionally, it is important to note that this association is observed in the potential absence of other potential leading indicators.

Latent Change Score Modeling Studies for Understanding Risk and Protective Mechanisms as Predictors, Mediators, and Moderators

We used a latent change score modeling approach to study how the effects of negative affect—a risk factor of children's behavioral and emotional problems—may be moderated by attentional regulation in the development of internalizing and externalizing problems (Kim & Deater-Deckard, 2011). Extant literature suggests that a good attention span is critical to healthy social emotional development, especially in the sense that attention control reflects effective cognitive self-regulation of negative emotions such as anger. Using the national sample of children ($N = 1{,}079$) from the Study of Early Child Care and Youth Development (SECCYD), who were assessed four times from 4.5 to 11 years of age, we examined attention span as a moderator of reciprocal links between changes in anger and changes in externalizing and internalizing problems. Composite scores for anger and attention (i.e., poor attention span or distractibility) were computed using indicators from multiple informants including mothers, fathers, and teachers. Every indicator was standardized, averaged, and standardized again to yield composite z scores within each of the four time points for anger and inattention. Externalizing and internalizing problems were reported by mothers using the total raw scores of the Child Behavior Checklist (CBCL; Achenbach, 1991).

The latent change score modeling was used to predict dynamic changes in externalizing/internalizing problems from repeatedly measured anger from age 4.5 to 11. As shown in Figure 22.6, the hypothesized latent change score model included the time-varying predictor of anger to examine the prospective effects of anger on developmental changes in behavioral/emotional problems. Because anger scores were standardized z scores compositing different scales reported by multiple informants, its time series data were constructed as a Markov simplex model based on manifest variables instead of a latent change score model. Furthermore, the hypothesized model estimated bidirectional cross-lagged effects between anger and behavioral/emotional problems as well as the concurrent correlations between the two constructs within each time point. Therefore, this model tested whether anger predicts changes in behavioral/emotional problems or vice versa, after accounting for the autoregressive effects of the prior anger or behavioral/emotional problems.

Two-group structural equation models were used to test the moderating effects of attention in the link between anger and behavioral/emotional problems. The sample was divided into the poor (above median, $n = 540$) versus good attention (below median, $n = 539$) groups based on each individual's grand mean of the inattention composites from 4.5 to eleven years. We first fit a model in which all parameters were freely estimated across the two groups. In subsequent models, equality constraints were added to test numeric invariance between poor and good attention groups with respect to the effects of anger on behavioral/emotional problems (the Equal Anger Effect model) and the effects of behavioral/emotional problems on anger (the Equal Behavior Problem Effect model).

The chi-square difference tests comparing nested model fits revealed that the model in which parameters were separately estimated provided the best fit for externalizing problems. Thus, the results indicated that the poor and good attention groups showed significantly different patterns and magnitude for the effects of anger on externalizing problems as well as for the effects of externalizing problems on anger. Specifically, as shown in Figure 22.6, the poor attention group showed more persistent effects of anger on externalizing problems over time compared to the good attention group. In the poor attention group, anger at 4.5, 7, and 9 years consistently predicted smaller decreases (or in some cases larger increases) in externalizing problems from 4.5 to 7 years ($t = 6.93$, $p < .05$), from 7 to 9 years ($t = 2.64$, $p < .05$), and from 9 to 11 years ($t = 5.12$, $p < .05$), respectively. In terms of the reciprocal effects of externalizing problems on anger, higher initial levels of externalizing problems at 4.5 years predicted increases in anger between 4.5 and 7 years ($t = 4.40$, $p < .05$). Larger increases in externalizing problems between 4.5 and 7 years were related to smaller increases in anger between 7 and 9 years ($t = 3.95$, $p < .05$), whereas larger increases in externalizing problems between 7 and 9 years were related to larger increases in anger between 9 and 11 years ($t = 2.69$, $p < .05$). The model-estimated mean levels of externalizing problems decreased from 12.25 to 7.56 over the four assessments, indicating significant decreases between 4.5 and 7 years and between 9 and 11 years.

For the good attention group, the effects of anger on externalizing problems decreased over time. Anger at 4.5 and 7 years predicted smaller decreases (or in some cases larger increases) in externalizing problems from 4.5 to 7 years ($t = 12.20$, $p < .05$) and from 7 to 9 years ($t = 5.54$, $p < .05$), respectively. However, the prospective effect of anger at 9 years on changes in externalizing problems from 9 to 11 years was not significant ($t = 1.42$, *ns*). Significant reciprocal effects of externalizing problems on anger indicated that higher levels of externalizing

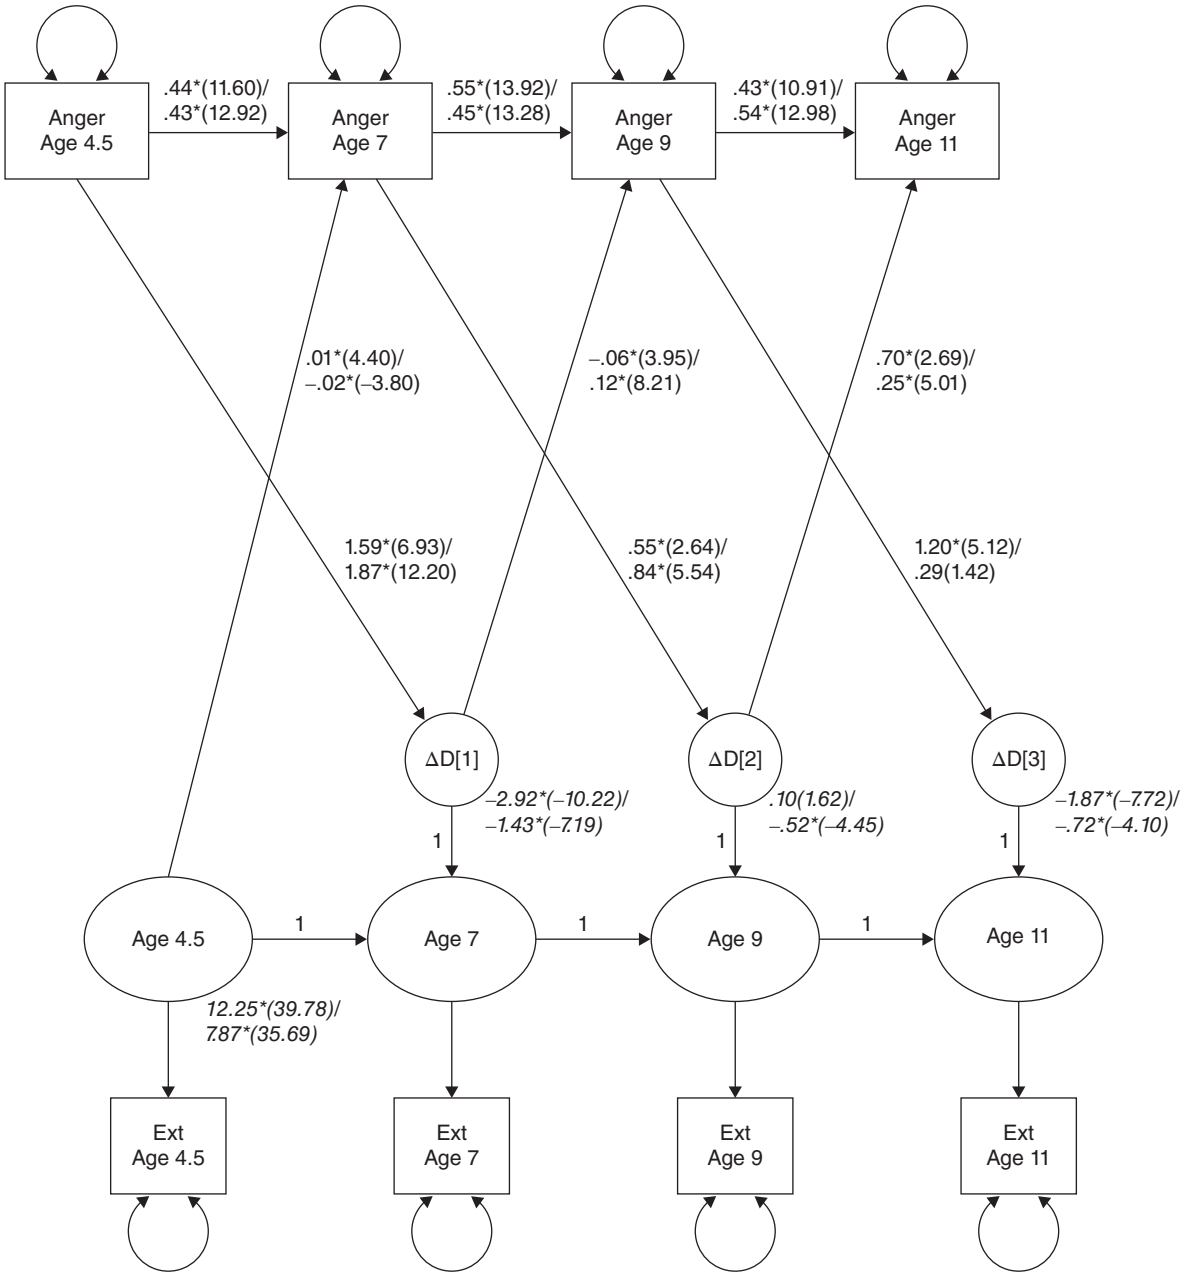

Figure 22.6 Latent change score model of the moderation of inattention between anger and externalizing problems. Values given are unstandardized coefficients with critical ratio (CR) in parentheses. For each path, the coefficients (CR) are listed for poor attention/good attention groups. * $p < .05$. *Source*: Adapted from "Dynamic changes in anger, externalizing and internalizing problems: attention and regulation" by J. Kim and K. Deater-Deckard, 2011, *Journal of Child Psychology and Psychiatry*, *52*, pp. 156–166.

problems at 4.5 years were related to smaller increases in anger between 4.5 and 7 years ($t = –3.80$, $p < .05$). However, increases in externalizing problems between 4.5 and 7 years and between 7 and 9 years predicted increases in anger between 7 and 9 years ($t = 8.21$, $p < .05$) and between 9 and 11 years ($t = 5.01$, $p < .05$), respectively. Children in the good attention group showed significantly lower initial levels of externalizing problems compared with those in the poor attention group, and their estimated means of externalizing problems decreased from 7.87 to 5.20 over the four assessments indicating consistently significant decreases between consecutive time points.

Nested model comparisons indicated that the equal anger effect model provided the best fit for internalizing

problems. Results of the best-fitting model further revealed that the reciprocal effects of internalizing problems on anger were stronger and more persistent in the poor attention group, but the two groups did not differ regarding the effects of anger on internalizing problems. As shown in Figure 22.7, regardless of inattention level, higher anger at 4.5 and 7 years predicted greater increases in internalizing problems from 4.5 to 7 years ($t = 7.12$, $p < .05$) and from 7 to 9 years ($t = 3.93$, $p < .05$), respectively. Differential reciprocal effects between the two attention groups suggested that the patterns of reciprocal effects were more consistent and stronger for the poor attention group. For children in the poor attention group, higher initial levels of internalizing problems at 4.5 years predicted

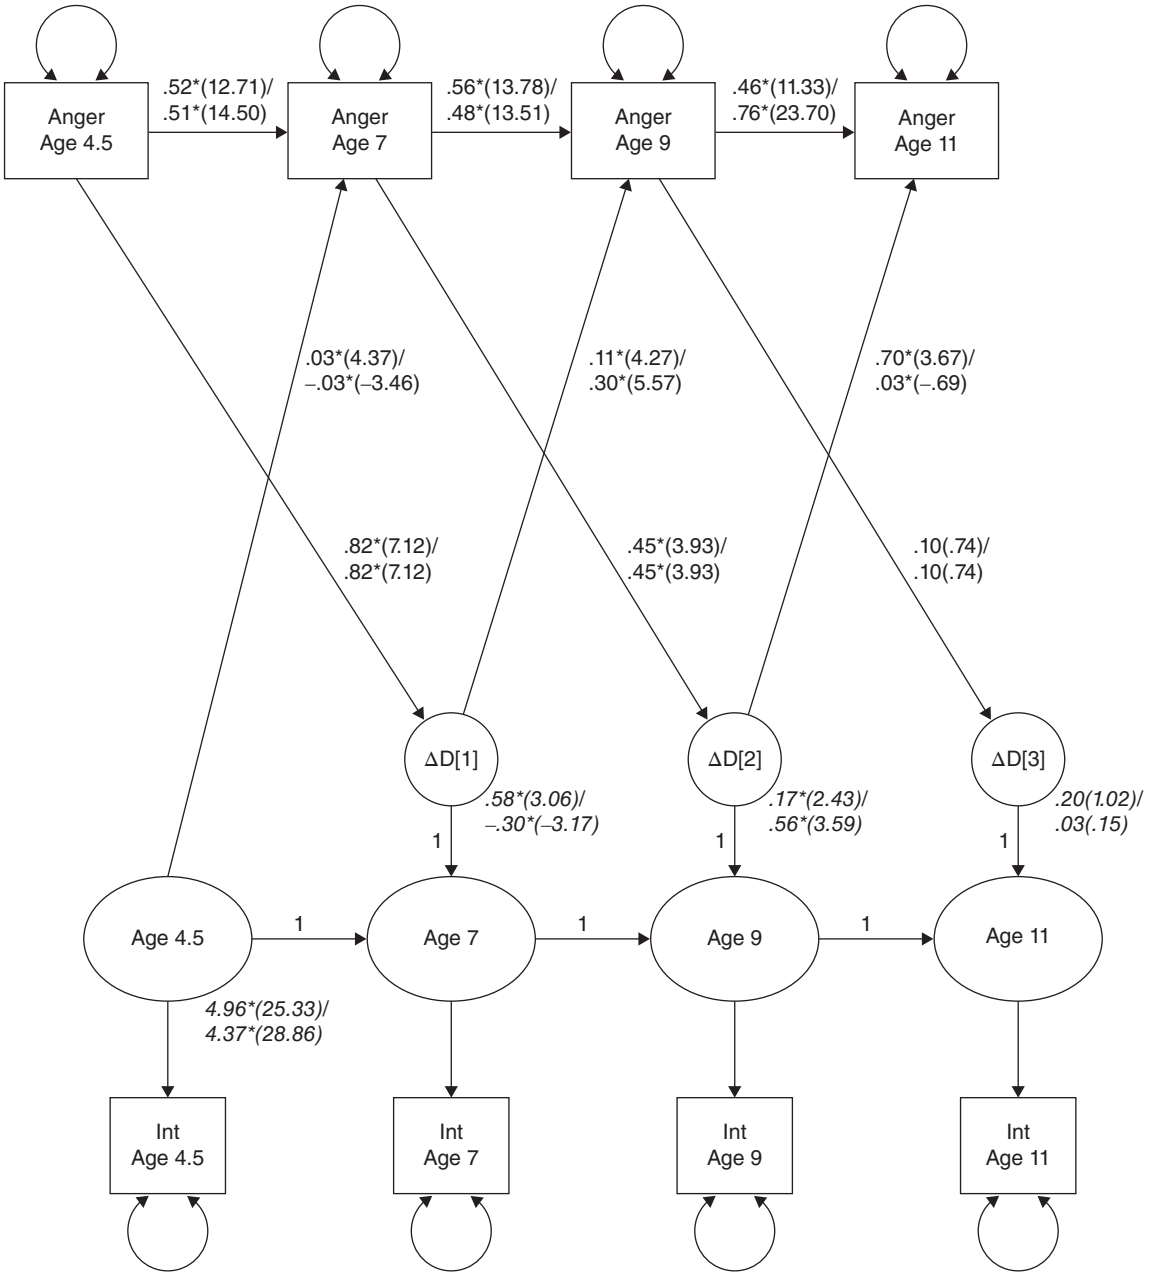

Figure 22.7 Latent change score model of the moderation or inattention between anger and internalizing problems. Values are given unstandardized coefficients with critical ratio (CR) in parentheses. For each path, the coefficients (CR) are listed for poor attention/good attention groups. * $p < .05$. *Source*: Adapted from "Dynamic changes in anger, externalizing and internalizing problems: attention and regulation" by J. Kim and K. Deater-Deckard, 2011, *Journal of Child Psychology and Psychiatry*, *52*, pp. 156–166.

increased anger between 4.5 and 7 years ($t = 4.37,\ p < .05$). Increases in internalizing problems between 4.5 and 7 years and between 7 and 9 years consistently predicted increased anger between 7 and 9 years ($t = 4.27,\ p < .05$) and between 9 and 11 years ($t = 3.67,\ p < .05$), respectively. The model-estimated mean levels of internalizing problems increased from 4.96 to 5.91 over the four repeated assessments, indicating significant increases between 4.5 and 7 years, and between 7 and 9 years.

In contrast, for the good attention group, higher levels of internalizing problems at 4.5 years were associated with smaller increases in anger between 4.5 and 7 years ($t = -3.46,\ p < .05$). Increases in internalizing problems between 4.5 and 7 years predicted increased anger between 7 and 9 years ($t = 5.57,\ p < .05$). Changes in internalizing problems between 7 and 9 years did not predict changes in anger between 9 and 11 years ($t = -.69$, *ns*). Children in the good attention group showed consistently lower levels of internalizing problems compared to those in the poor attention group, with some fluctuations. Their estimated means of internalizing problems showed significant decreases between 4.5 and 7 years (from 4.37 to 4.07), significant increases between 7 and 9 years (from 4.07 to 4.63), and then no significant changes between 9 and 11 years (from 4.63 to 4.66).

To summarize, the findings showed significant moderating effects of attention indicating more persistent effects of anger on externalizing problems in the poor attention group. For both good and poor attention groups, high anger was associated with increases in internalizing problems, but the reciprocal effects of internalizing problems on anger were stronger and more persistent in the poor attention group. Thus, it appears that strong attention regulation may serve to protect children with higher levels of dispositional anger from developing behavioral and emotional problems in middle childhood. This study illustrates how latent change score models can be used to test reciprocal lagged effects between changes in risk factors (e.g., negative affect) and changes in psychopathology and to test moderating (or interactive) effects of protective factors (e.g., attention regulation) in the link between risk factors and psychopathology.

Latent Change Score Modeling Studies for Understanding Contextual Influences

Latent Change Score Modeling for Cross-Domain Relations in Risk and Psychopathology

In the study we reviewed earlier, Grimm (2007) used bivariate latent change score growth models to investigate the developmental relationships between depression and academic achievement in childhood. The latent change score modeling carries all the advantages of the latent growth modeling and offers additional advantages of directly testing time-dependent change. As shown in Figure 22.8, in a latent change score model, the outcome of interest is represented by latent change scores that can be predicted by previous scores. Specifically, four bivariate latent change score growth models were fit to the repeated measurements of achievement and depression. Different restrictions were introduced to determine whether academic achievement or depression were leading or lagging indicators.

The first model was a baseline model where the coupling parameters were fixed to zero. This no-coupling model fit the data well [$\chi^2(99) = 242,\ \text{RMSEA} = .01$]. In the second model, the previous level of depression was predictive of the changes in academic achievement and the model fit was nearly identical to the model with no-coupling effects [$\chi^2(98) = 241,\ \text{RMSEA} = .01;\ \Delta\chi^2 = 1,\ \Delta df = 1$]. However, when the coupling parameter from academic achievement to changes in depression was estimated, the model fit improved significantly [$\chi^2(98) = 233,\ \text{RMSEA} = .01;\ \Delta\chi^2 = 9,\ \Delta df = 1$]. In the final model, bidirectional coupling parameters were estimated and the fit was similar to the third model in which only the coupling parameter from academic achievement to changes in depression was estimated [$\chi^2(97) = 231,\ \text{RMSEA} = .01;\ \Delta\chi^2 = 2,\ \Delta df = 1$].

Thus, the results indicated that academic achievement was the leading indicator in the development of academic achievement and depression in childhood, suggesting that knowing the levels of the prior academic achievement score helped predict the subsequent changes in depression. Specifically, the coupling parameter from academic achievement to changes in depression was significant and negative ($\gamma = -.03,\ p < .05$), indicating that children who had a higher previous level of academic achievement showed larger decreases or smaller increases in depression. The findings further imply that academic achievement may be considered a protective factor against increasing trajectories of depression between ages 8 and 14. As shown in this study, findings from multivariate latent change score models can provide information about which risk or protective factors lead the psychopathological outcomes and which lag in such longitudinal relationships, whereas findings from multivariate LGM reveal only general associations among developmental changes across different variables. One caveat is that, although bivariate latent change score models allow us to examine time-dependent

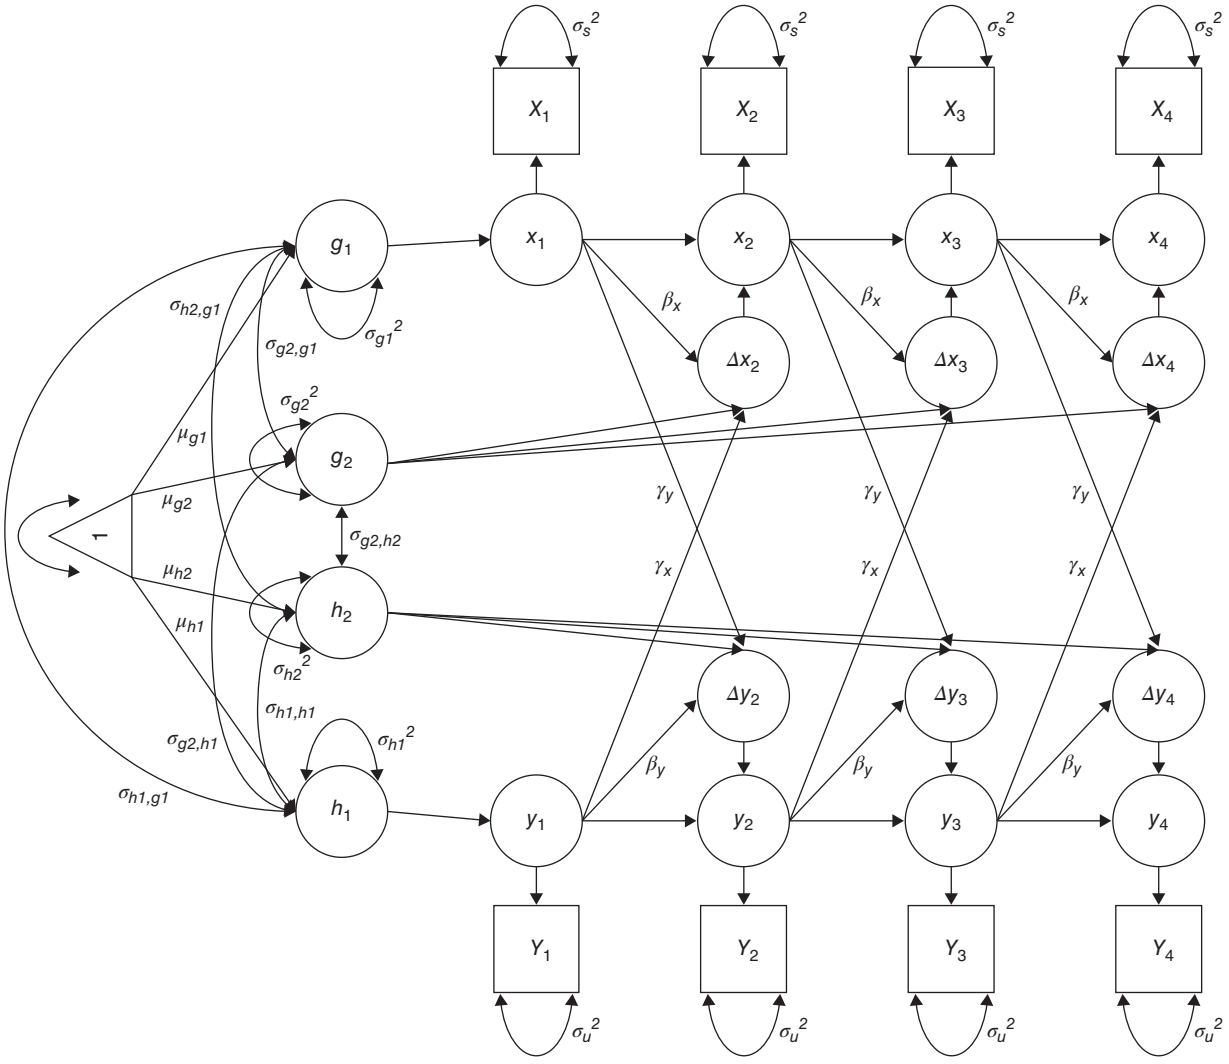

Figure 22.8 A bivariate dual change score model.

relationships (i.e., leading and lagging indicators), they are not causal models.

Latent Change Score Modeling for Multiple Levels of Analysis

Externalizing psychopathology encompasses a broad range of psychiatric disorders, including substance use disorders and conduct disorders, and a characteristic common to different types of externalizing psychopathology is high levels of behavioral disinhibition (Bogg & Finn, 2010). Research also suggests that reduced working memory capacity seems to play a crucial role in disinhibited patterns of behavior associated with externalizing psychopathology (Endres, Rickert, Bogg, Lucas, & Finn, 2011). McArdle and his colleagues used latent change score models to examine dynamic interrelationships between longitudinal changes in memory performance and longitudinal changes in brain structure (McArdle et al., 2004). Participants included 225 healthy adults with no evidence of major clinical disease ($n = 109$ men). These participants were 30–80 years of age at baseline (with an average of 40 individuals per decade), and they were followed up about seven years after the initial assessment ($n = 197$ reevaluated). The brain structure was assessed using the computerized axial tomography (CT) information focusing on the lateral ventricular size (LVS; the mean of the measurements from the left and right hemisphere). Memory was assessed by the Wechsler Memory Scores (WMS; Wechsler, 1945).

They fit four alternative age-based latent change score models to the data by using the observed ages (i.e., developmental trajectories of memory and LVS from age 30 to age 90). The first model was a no-change

model that estimated three parameters including an initial mean, an initial variance, and a constant error variance but no slope parameters ($\chi^2 = 0$, $df = 0$). The second model was the constant change score model in which three additional time-dependent slope parameters were estimated. For LVS, there were small but positive systematic increases in slope means ($\mu = .006$, $p < .05$), slope variances ($\sigma = .004$, $p < .05$), and covariances between intercept and slope ($\rho = -.66$, $p < .05$) over every 5 years of age. This model showed a statistical improvement over the no-change model ($\chi^2 = 114$, $df = 13$). For memory, there were small but negative systematic changes over age ($\mu = -.01$, $p < .05$; $\sigma = .002$, $p < .05$; $\rho = -.28$, *ns*), with a small statistical improvement in fit over the no-change model ($\chi^2 = 13$, $df = 3$).

In the third model, only the proportional changes (β) were estimated while the additive changes (α), slope means, slope variances, and covariances between intercept and slope were fixed to zero. The results showed positive proportional changes for LVS ($\beta = .02$, $p < .05$), and negative proportional changes for memory ($\beta = -.01$, $p < .05$). This proportional change model yielded substantial improvement in fit for LVS ($\chi^2 = 109$, $df = 1$) and minor improvement for memory ($\chi^2 = 5$, $df = 1$). Finally, they fit a dual change model in which the mean of the slopes were allowed to be free and additive changes (α) were fixed to one (for identification purposes). The results indicated positive proportional changes for both LVS ($\beta = .03$, $p < .05$) and memory ($\beta = .05$, $p < .05$) as well significant slope variances for both LVS ($\sigma = .004$, $p < .05$) and memory ($\sigma = .003$, $p < .05$). The linear slope means were significant for memory ($\mu = -.05$, $p < .05$), but not for LVS ($\mu = -.001$, *ns*). Dual change models showed significant improvement over the no-change model ($\chi^2 = 124$, $df =$ 4 for LVS and $\chi^2 = 24$, $df = 4$ for memory) and yielded the best fits compared with the previous models.

Next, four alternative bivariate latent change score models were tested. The first model was a full bivariate latent change score model where all coupling parameters were estimated ($\chi^2 = 0$, $df = 0$). In the second model, the parameter representing the effect of LVS on the latent change scores of memory was fixed to zero and this model yielded a significantly degraded fit compared to the full bivariate latent change score model ($\chi^2 = 20$, $df = 1$). The third model had the parameter representing the effect of memory on the latent change scores of LVS fixed to zero and there was a much smaller loss of fit ($\chi^2 = 3$, $df = 1$). Finally, in the last model, no coupling was allowed and this model showed a notable loss of fit ($\chi^2 = 23$, $df = 2$).

Thus, the results of the best fitting model, no memory to LVS coupling effect model, showed notable and systematic coupling across the LVS and memory variables. A closer examination of the coupling effects indicated a significant negative coupling effect from LVS to changes in memory ($\gamma = -.18$, $p < .05$), but a nonsignificant trivial coupling effect from memory to changes in LVS ($\gamma = 0$, *ns*). Consistent with prior research on neurophysiological influences on neuropsychological and behavioral changes, these findings suggest that an increase in the relative size of the lateral ventricle is a leading indicator of decreases in memory, and the reverse is not apparent.

This study was the first report demonstrating the cross-lagged longitudinal relationship between in vivo brain measurements and cognitive function across adulthood. The latent change score models used in this study highlight the recent advancement in longitudinal modeling techniques that can be utilized as a quantitative test of cross-domain temporal relations within a person over time. It should be noted, however, that as with most longitudinal multivariate data in developmental psychopathology research, the data were not collected in a randomized controlled pre- and posttest design, thus causal influences were confounded and were difficult to isolate.

Latent Change Score Modeling for Cross-Population Comparisons in Risk and Psychopathology

A recent study by Kim-Spoon, Cicchetti, and Rogosch (2013) using a sample of maltreated and nonmaltreated children illustrates how latent change score models can be used to interface between normal and abnormal development. We examined longitudinal contributions of emotion regulation and emotion lability/negativity to internalizing symptomatology in a low-income sample of 171 maltreated and 151 nonmaltreated children. These children attended a week-long day camp program for inner city children and they were annually assessed from age 7 to 10 years. Four subtypes of maltreatment, emotional maltreatment, physical neglect, physical abuse, and sexual abuse, were assessed using the Maltreatment Classification System (MCS; Barnett, Manly, & Cicchetti, 1993). Counselors' ratings on the Emotion Regulation subscale and the Lability/Negativity subscale of the Emotion Regulation Checklist (ERC; Shields & Cicchetti, 1998) were used to capture processes central to emotion regulation and emotion lability/negativity. The emotion regulation subscale consisted of items assessing adaptive regulation, including socially appropriate emotional displays, empathy, equanimity, and emotional understanding. The emotion

lability/negativity subscale was composed of items assessing arousal, reactivity, emotional intensity, expression of negative emotions, and mood lability.

Preliminary latent change score analyses indicated that the means and variances of latent change score factors were not significantly different from zero for emotion regulation and emotion lability/negativity. Therefore, the time series data of predictors (emotion regulation and emotion lability/negativity) were constructed as a Markov simplex model based on manifest variables instead of a latent change score model. The baseline latent change score model for internalizing symptomatology showed significant and negative path estimates for proportional change for internalizing symptomatology, indicating annual decreases in internalizing symptomatology from age 7 to 10 ($b = -1.08$, $SE = .17$, $p < .05$). The model-estimated mean levels of internalizing symptomatology decreased from 6.89 at age 7 to 3.69 at age 10.

We were primarily interested in developmental processes by which emotion regulation and emotion lability/negativity conjointly contributed to change in internalizing symptomatology. We tested time-lagged mediation models estimating whether the prospective prediction of emotion lability/negativity was mediated by emotion regulation or vice versa. These models were tested using two-group structural equation modeling approaches to explore any significant differences between maltreated and nonmaltreated groups. We first tested the Direct Effect models in which the time series data of emotion regulation or emotion lability/negativity predicted the latent change scores of internalizing symptomatology. We compared the configural invariance model in which all parameters were freed to be estimated [$\chi^2(28) = 39.78$, $CFI = .97$, RMSEA = .04 for emotion regulation direct effects and $\chi^2(28) = 50.14$, $CFI = .94$, RMSEA = .05 for lability/negativity direct effects] and the equal direct effect model in which direct effects were fixed to be equal between the two groups [$\chi^2(31) = 40.85$, CFI = .97, RMSEA = .03 for emotion regulation direct effects, and $\chi^2(31) = 51.13$, CFI = .95, RMSEA = .05 for lability/negativity direct effects]. The nonsignificant difference between the configural invariance model and the equal direct effect model indicated that there was no difference in the direct effects of emotion regulation and emotion lability/negativity between maltreated and nonmaltreated children [$\Delta\chi^2 = 1.07$, $\Delta df = 3$, $p = .79$ for emotion regulation and $\Delta\chi^2 = .99$, $\Delta df = 3$, $p = .80$ for lability/negativity]. Specific findings indicated that higher emotion regulation predicted decreases in internalizing symptomatology at all ages ($p < .05$). In contrast, higher emotion lability/negativity predicted increases in internalizing symptomatology from age 7 to 8 and from age 8 to 9 ($p < .05$), but its effect became weaker between ages 9 and 10 ($p = .08$).

Next, we tested two sets of longitudinal mediation models, first, with emotion regulation as a mediating variable in the prospective relations between emotion lability/negativity and change in internalizing symptomatology, and second, with emotion lability/negativity as a mediating variable in the prospective relations between emotion regulation and change in internalizing symptomatology. As shown in Figure 22.9, we examined time-lagged mediation effects (e.g., age 7 emotion lability/negativity → age 8 emotion regulation → change in internalizing symptomatology between ages 8 and 9). Within each set, we performed two-group SEM analyses and compared two nested models to evaluate any differences between maltreated and nonmaltreated children. In the first model, the Configural Invariance Model, all the parameters were freed to be estimated for maltreated and nonmaltreated children. In the second model, equal direct and mediated effect model, both direct and indirect effects were fixed to be equal between maltreated and nonmaltreated groups.

In the first set of models in which emotion regulation was tested as a mediator, the model fit of the equal direct and mediated effect model [$\chi^2(58) = 92.10$, CFI = .96, RMSEA = .04] was not significantly worse than that of the configural invariance model [$\chi^2(31) = 89.22$, CFI = .95, RMSEA = .05], indicating no difference in direct and indirect effects of emotion lability/negativity between maltreated and nonmaltreated groups [$\Delta\chi^2 = 2.88$, $\Delta df = 8$, $p = .94$]. As shown in Figure 22.9, the results of the equal direct and mediated effect model indicated that higher levels of emotion lability/negativity at age 7 and at age 8 predicted lower levels of emotion regulation at age 8 and at age 9, respectively, which in turn predicted a subsequent increase in internalizing symptomatology from age 8 to 9 and from age 9 to 10 respectively. These influences were above and beyond, or controlling for, autoregressive effects and natural change (i.e., decreasing slope) in internalizing symptomatology. However, previously significant direct effects of emotion lability/negativity on internalizing symptomatology became nonsignificant. Sobel's approximate significance tests (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002) for the significance levels of the indirect effects revealed that both of the paths involved in the mediation (emotion lability/negativity → emotion regulation → diff2/3) were significant: $z = 2.21$, $p < .05$ for prediction of diff2; and $z = 2.15$, $p < .05$ for diff3. The significance

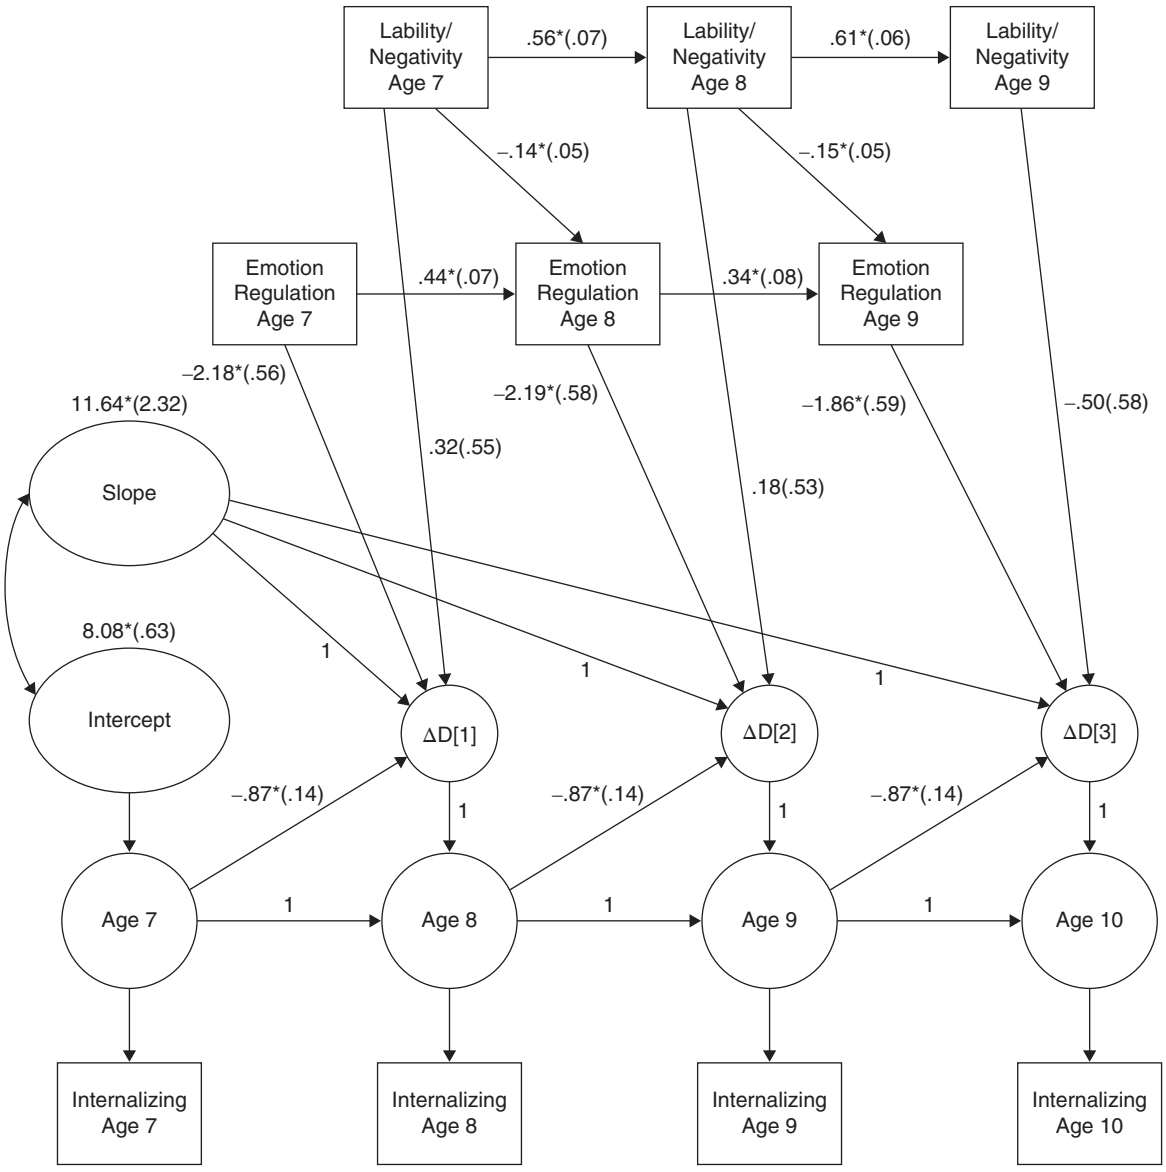

Figure 22.9 Latent change score model of emotion lability/negativity predicting internalizing symptomatology, mediated by emotion regulation. Unstandardized parameter estimates (SE) are presented. *Source*: Adapted from "A longitudinal study of emotion regulation, negative emotionality, and internalizing symptomatology in maltreated and nonmaltreated children" by J. Kim-Spoon, D. Cicchetti, and F. A. Rogosch, 2013, *Child Development*, *84*, pp. 512–527.

test for the equality of the two mediated effects indicated consistent (of similar magnitude) mediated effects of emotion regulation for the link between emotion lability/negativity and internalizing symptomatology across ages ($z = 0.03$, $p = .98$).

In the second set of models in which emotion lability/negativity was tested as a mediator of the link between emotion regulation and change in internalizing symptomatology, the equal direct and mediated effect model [$\chi^2(58) = 105.88$, CFI = .94, RMSEA = .05] was selected as the better-fitting model compared to the Configural Invariance Model [$\chi^2(50) = 101.54$, CFI = .94, RMSEA = .06]. Thus, the results indicated no significant difference in direct and indirect effects of emotion regulation between maltreated and nonmaltreated groups. Specifically, higher levels of emotion regulation directly predicted a subsequent decrease in internalizing symptomatology at all ages ($b = -2.52$, $SE = .56$, $p < .05$ for age 7 emotion regulation → ΔD[1]; $b = -2.62$, $SE = .58$, $p < .05$ for age 8 emotion regulation → ΔD[2]; $b = -2.43$,

$SE = .58$, $p < .05$ for age 9 emotion regulation → ΔD[3]). However, neither the cross-lagged effects of emotion regulation on emotion lability/negativity ($p = .38$˜.50) nor the direct effects of emotion lability/negativity on internalizing symptomatology difference scores ($p = .18$ ˜.49) were significant. Therefore, the results of our mediation models indicated that emotion regulation is a mediating process for the longitudinal association between emotion lability/negativity and internalizing symptomatology, whereas emotion lability/negativity is not a mediating process for the longitudinal association between emotion regulation and internalizing symptomatology.

Overall, the results of testing mediation models using the latent change score modeling suggest that emotion regulation may be a proximal process through which emotion lability/negativity may influence developmental changes in internalizing symptomatology for both maltreated and nonmaltreated children. This study exemplifies how latent change score models can be used to enhance the knowledge base of developmental psychopathology by allowing the examination of cross-lagged associations among multiple levels of processes (such as emotion lability/negativity, emotion regulation) and psychopathological outcomes (such as child internalizing symptomatology) to determine directionality in the prediction of risk and protective factors for change in psychopathology outcomes.

Implications of Latent Change Score Modeling for Prevention and Intervention Science

The following example illustrates how latent change score model can be used to illuminate processes that occur following treatment or intervention. Hawley, Ho, Zuroff, and Blatt (2006) considered how an individual's specific vulnerability as shown in personality and interpersonal context of therapy may influence underlying symptom change during therapeutic processes. Specifically, they examined the longitudinal dynamics between depression and perfectionism (a personality vulnerability factor) as related to the quality of therapeutic alliance during treatment for depression. The latent change score approach was the most suitable choice to understand the multidimensional nature of therapeutic change because it provides a statistical framework to evaluate dynamic longitudinal growth within time series data while considering interrelationships between multivariate change processes.

Participants included 162 patients with major depressive disorder who were identified as treatment completers (those who attended at least 12 treatment sessions over a 15-week period). The perfectionism subscale of the Dysfunctional Attitudes Scale (Weissman & Beck, 1978) was used to assess patients' tendency to view the self in punitive terms (e.g., regarding failure in meeting self-imposed standards). Depression was assessed using the Hamilton Rating Scale for Depression (Hamilton, 1960). Both perfectionism and depression were assessed at intake (i.e., Week 0) and Weeks 4, 8, 12, and 16. To measure the strength of the therapeutic alliance, therapy sessions were rated using an observation-based measure of the Vanderbilt Therapeutic Alliance Scale (Hartley & Strupp, 1983) that distinguishes between patient and therapist contributions to the alliance.

They set out to evaluate the temporal course of growth and change in perfectionism and depression and further determine the longitudinal interrelationship of these variables as related to the therapeutic alliance. They first conducted latent change score univariate analyses of the repeated-measures time series separately for perfectionism and depression to understand the temporal nature of change in therapy. They compared four statistical alternative models to identify a model that best represents longitudinal changes in perfectionism and depression. A dual change score latent change score model was compared to (1) a no change model, (2) a constant change model (estimating changes only in latent slope coefficients), and (3) a proportional change model (estimating changes only that are proportional to the previous latent scores). For both perfectionism and depression, the dual latent change score model was the best fitting model [$\chi^2(7) = 11.19$, CFI = .98, RMSEA = .06 for depression and $\chi^2(8) = 17.87$, CFI = .98, RMSEA = .09 for perfectionism].

Next, the authors conducted bivariate analyses to evaluate dynamic coupling between depression and perfectionism. Based on several theoretical models, they tested four alternative bivariate latent change score models. First, the personality vulnerability model proposed that personality plays an essential role in the etiology, maintenance, and treatment of depression. Second, the scar model proposed that personality change occurs as a consequence of depression. Third, the reciprocal causality model proposed that the relationship between personality and depression is interactive. They also tested a no-coupling model in which no dynamic coupling was allowed between the repeated measures of perfectionism and depression. The no coupling and scar models yielded poor goodness-of-fit indices and thus were not considered further. The personality vulnerability model and the reciprocal causality model provided acceptable model fit estimates [$\chi^2(35) = 56.67$, CFI = .97, RMSEA = .07 for the personality vulnerability model and $\chi^2(31) = 60.33$, CFI = .96, RMSEA = .09 for the reciprocal causality model]. In the reciprocal causality

model, the cross-lag coefficients in which depression leads to personality change were nonsignificant.

Based on model fit indices and parameter significance, the personality vulnerability model was determined to be the best-fitting model. The personality vulnerability model indicated a significant unidirectional coupling from perfectionism to depression change throughout therapy (γ = .10 to .17, $p < .05$). A close examination of the meaning of this significant coupling revealed that patients with higher levels of initial perfectionism would experience less reduction in their depression scores throughout treatment, compared to patients with lower levels of initial perfectionism.

Finally, they examined the role of the therapeutic alliance as related to the bivariate coupled system between depression and perfectionism. The findings supported their hypothesis suggesting that the strength of the therapeutic alliance significantly predicted the rate of change in perfectionism and, in turn, perfectionism predicted the rate of change in depression throughout treatment. In this model, therapeutic alliance was included as a covariate that predicts the rate of change in perfectionism throughout the therapy process. The model yielded a good fit [$\chi^2(64) = 83.01$, CFI = .98, RMSEA = .04] and the effect of therapeutic alliance on latent change scores of perfectionism were significant ($b = -.90$, $p < .05$). Probing the effects of therapeutic alliance suggested that patients with higher therapeutic alliance showed greater decreases in perfectionism throughout treatment compared to patients with lower therapeutic alliance.

Therefore, the findings of this study supported the personality vulnerability model showing significant dynamic coupling between perfectionism and depression in which the level of perfectionism predicted the subsequent rate of change in depression throughout therapy. Furthermore, the results indicated that patient contribution to the therapeutic alliance had a significant indirect effect on depression symptom alleviation, in that a strong alliance was related to improvement in perfectionism vulnerability, which in turn, predicted the rate of change in depression symptoms throughout therapy. These findings demonstrate how latent change score analysis can contribute to obtaining a comprehensive understanding of the therapy process by evaluating indicators that capture the multidimensional nature of the therapeutic process.

GROWTH MIXTURE MODELING

The growth mixture model (Muthén & Shedden, 1999), a combination of the latent growth model and the finite mixture model, continues to be a favorite analytic technique for understanding intraindividual change and interindividual variability in intraindividual change. The growth mixture model adds to the types of interindividual variability in intraindividual change by allowing for multiple classes of individuals. That is, individuals can manifest different change trajectories because they belong to different classes or clusters of individuals and because of variability in change within a given class.

Another perspective on the growth mixture model is that the sample is drawn from multiple populations. That is, the traditional latent growth model assumes that the sample is drawn from a single population characterized by a single set of parameters (i.e., means, variances, and covariances) and if the sample was, in fact, drawn from multiple populations the latent growth model is inappropriate because sets of parameters are needed for each population. In many cases, researchers have a measured variable that may be able to characterize multiple populations. For example, a sample is often composed of males and females, which can be thought of as different populations. If a researcher were interested in testing whether there were differences between males and females in terms of their change trajectories, then the researcher could fit a multiple group growth model and statistically test whether or not the parameter estimates for males and females were invariant. Building upon this example, there may be multiple groups with different sets of parameter estimates, and the groups may not be well defined by a single measured variable. In these situations, it may be reasonable to rely on the observed change trajectories (the data) and, in essence, search for groups of individuals with different sets of parameter estimates.

Growth Mixture Model

The growth mixture model can be conceived as a multiple group growth model in which the grouping variable is latent or unobserved. In a similar vein to the goals of the multiple group growth models—describing differences in longitudinal change for defined subsets of individuals, researchers utilize the growth mixture model to describe differences in longitudinal change for subsamples of individuals who are not well defined in terms of observed or measured variables. In growth mixture modeling the grouping variable is, essentially, unobserved. Thus, the goal is to estimate or create a variable that maximally distinguishes individuals based upon their change trajectories.

The growth mixture model is one approach to estimate a categorical latent variable (latent class variable) in an

attempt to classify individuals into groups based upon their observed change trajectories along with user-defined constraints. Following latent class analysis, this classification is probabilistic because the grouping variable is unobserved, and following the multiple group growth model, the user specifies a series of equality constraints (e.g., on the factor loading matrix) to examine where differences between the latent classes are evident. The growth mixture model can be written as

$$\mathbf{Y}_i^{(c)} = \sum_{c=1}^{C} (\pi_i^{(c)} (\Lambda^{(c)} \mathbf{h}_i^{(c)} + \mathbf{u}_i^{(c)}))$$

$$\text{given } 0 \leq \pi_i^{(c)} \leq 1 \text{ and } \sum_{c=1}^{C} \pi_i^{(c)} = 1. \qquad (22.33)$$

where $\pi_i^{(c)}$ is the individual probability of being a member of class c, which is constrained to range between 0 and 1 and which the all of the class probabilities for individual n sum to 1. The matrices defining the growth model are superscripted by c to indicate the elements of those matrices can vary over latent classes as in the multiple group model. As in the multiple group growth model, we recommend a series of progressive models to evaluate where class differences emerge. Thus, a logical starting point is an invariance model, which is equivalent to the one-class model. In subsequent models, the latent variables means, latent variable covariances and residual variances, and pattern of change can be relaxed. Furthermore, within each of these types of models, multiple models are fit with a different number of classes. This combination of types of models with varying number of classes seeks to determine not only whether class differences emerge, but also where they emerge and how many classes are appropriate.

Determining an appropriate number of latent classes is not a straightforward process and multiple criteria have been recommended. This is because in growth mixture modeling and mixture models generally, there is not a deterministic set of rules to follow (see Ram & Grimm, 2009). The goal here is not necessarily to determine an optimal model for the data based on model fit, but to yield results that will replicate in a new sample. Mixture models specifically search to maximize differences and are therefore extremely data dependent, which can lead to results that are not generalizable. In the model fit comparison approach outlined below, our goal is to yield results that are defensible, viable, and replicable. We also note that statistical programs vary in the amount of fit indices reported. Mplus provides the most amount of fit information and we utilize this available information. To reiterate, the goal is to build a defensible judgment regarding the optimal number of latent classes using a combination of model results, substantive theory, and statistical fit information.

A first consideration when evaluating a given model is to carefully examine the model output to determine whether parameter estimates are all in bounds. Mixture models have a tendency to yield out of bounds parameter estimates, such as negative variances and correlations greater than 1, especially when models are fit with too many classes. Furthermore, the interpretability of the parameters for each latent class is critical for model selection. For example, multiple classes may exhibit nearly identical change trajectories or a class may show a highly unusual change pattern indicating a general lack of replicability. In such cases, these models should be set aside while models with fewer classes are considered carefully. This first consideration is sure to exclude several models.

The remaining models are then compared using comparative fit criteria, such as the Bayesian information criterion (BIC), Akaike information criterion (AIC), and sample size adjusted BIC. All of these fit criteria are calculated from the –2 log-likelihood and a penalty for the number of estimated parameters. The penalty for the AIC is twice the number of parameters and the penalty for the BIC is the natural log of the sample size multiplied by the number of parameters. The sample size adjusted BIC uses ad adjusted sample size in an attempt to reduce the impact of sample size when examining model fit. For all fit criteria, lower values indicate better model fit. Thus, models with lower information criteria more closely represent the data; however, it is important to recognize that these criteria are sensitive to sample size and often favor more parameterized models. The principle that we forward is simply that models that do not fit better than the one-class (latent growth) model can be dismissed and that plotting these criteria against the number of classes (akin to a scree plot) can be useful in making relative comparisons regarding improvement in fit.

The next consideration when comparing models is classification quality, which is based on the confidence with which individuals have been classified in to their respective class. *Entropy*, a statistic that ranges from 0.00 to 1.00 (as implemented in Mplus), is a commonly used global statistic for classification quality. Entropy is based on the conditional probabilities of individuals' class membership (Jedidi, Ramaswamy, & Desarbo, 1993). Higher entropy values indicate a greater confidence in the classifications and that there is adequate separation between the latent classes. Often, a lower bound on entropy is imposed (e.g., 0.80) and models with entropy values below the cut-off

are viewed with skepticism or outright discarded. Overall, we note that models with higher entropy are favored when selecting from models with similar levels of model fit, based on the available information criteria. Additionally, we recommend a thorough examination of the average latent class probabilities, specifically for individuals who are likely to be in the same class. Again, a lower bound is often considered, such as 0.80, which would indicate that for individuals who are likely to be in a given class, there is a 0.80 average probability of being in the class.

The final piece of model fit and model comparison information comes from an array of *likelihood ratio tests* (LRT), which can be used to specifically compare two models that only differ in the number of latent classes. Specifically, these approximate test statistics can be used to compare a given model of interest to a model with one fewer class. The LRTs available in Mplus include the Vuong-Lo-Mendell-Rubin likelihood ratio test (VLMR-LRT), the adjusted Lo-Mendell-Rubin likelihood ratio test (adjusted LRT), and the bootstrap likelihood ratio test. The VLMR-LRT and adjusted LRT apply a corrected likelihood-ratio distribution to compare the model with C classes to the model with $C - 1$ classes (see Lo, Mendell, & Rubin, 2001; Muthén, 2004; Nylund, Asparouhov, & Muthén, 2007; Vuong, 1989). The bootstrap LRT examines the change in likelihood values for the model with C classes and the model with $C - 1$ classes compared to bootstrapped distribution where the model with $C - 1$ classes is the true model. All LRTs provide a p-value for the significance test. A low p-value ($p < .05$) indicates the model with $C - 1$ classes should be rejected in favor of the model with C classes. Again, we note that these LRTs are only to compare models that differ only in the number of classes and cannot be used for comparing models with between-class constraint.

Generally, researchers should pay attention to and report all of the available fit indices, relevant theory, and past research findings when selecting the growth mixture model that provides the most reasonable representation of the data (see also Masyn, 2009). These recommendations provide a practical guide to make sense of all of the available information when deciding on the number of latent classes.

Cautions

Growth mixture models have been used extensively over the past decade and have been able to highlight multiple subpopulations in the development of several constructs, including achievement, behavior problems, and substance use. However, growth mixture models have not been without their limitations and naysayers. Here, we overview some of these potential issues.

First, we note that growth mixture models are exploratory and data driven and with any exploratory model, the true value is replicability. Thus, any single set of results based upon a single data set must be taken cautiously. Second, as highlighted by Bauer and Curran (2003), growth mixture models, and mixture models more generally, can accommodate and represent nonnormality in observed data. That is, if data are nonnormal, then it is likely that a multiple class mixture model will provide a better fit than a single class model. The issue is that nonnormality may indicate a true mixture distribution, but it may simply be caused by measurement anomalies, such as artificial floor and ceiling effects, making inappropriate distributional assumptions (e.g., data come from a Poisson distribution but are treated as being normally distributed), and poor measurement instruments or the misuse of a measurement instrument. Given these possibilities, results from a mixture model can be misinterpreted and there is a real danger in identifying false groups (see Bauer & Curran, 2003, 2004).

Growth Mixture Modeling Studies for Understanding Risk and Protective Mechanisms as Predictors, Mediators, and Moderators

Growth Mixture Modeling Studies for Understanding the Influences of Risk and Protective Mechanisms Using Cross-Population Comparisons

The following study illustrates how growth mixture modeling can be used to examine continuity and discontinuity in developmental trajectories of maladjustment and further investigate risk and protective mechanisms that predict different patterns of developmental trajectories based on cross-population comparisons. Kim, Cicchetti, Rogosch, and Manly (2009) investigated the longitudinal impact of maltreatment parameters on personality processes and maladjustment and prospective relationships between personality trajectory classes and subsequent maladjustment outcomes. The main goal was to study developmental processes contributing to dysfunction and resilience (i.e., multifinality) to better understand pathways to adaptive and maladaptive development of personality and related psychopathology. Therefore, in this study we investigated different psychopathological outcomes (internalizing and externalizing symptomatology) as well as multiple processes eventuating in psychopathological outcomes (ego control and ego resiliency). Given the extreme failure

of the average expectable environment that is associated with child maltreatment, it was expected that maltreated children would manifest maladaptive types of personality processes that include low ego resiliency and tendencies toward ego undercontrol.

Participants included 449 children (249 maltreated and 200 nonmaltreated) who attended a summer day camp research program in a Northeastern city. Children ranged in age from 6 to 9 years ($M = 6.76$, $SD = 1.03$) when they first participated in the camp and they were followed longitudinally between ages 6 and 10. Sixty-three percent of the children were boys, and children were from diverse ethnic backgrounds: 61.2% African American, 23.2% European American, 12.7% Latino, and 2.9% other ethnic groups. The narrative reports of the maltreatment incidents from the Department of Social Services (DSS) records were coded according to the MCS (Barnett et al., 1993). Children's externalizing and internalizing behavior was assessed through completion of the TRF (Achenbach, 1991). Camp counselors' ratings of children's ego resiliency and ego control were obtained using the California Child Q-Set (CCQ; Block & Block, 1980). Ego resiliency was defined as the relative flexibility of impulse control that enables effective regulation of affect and behavior. Ego control was defined as the ability to monitor and modulate impulses, with ego over-control being characterized by excessive inhibition of affect and impulses, whereas ego under-control being characterized by insufficient modulation, including poor frustration tolerance and poor attention seeking (Block & Block, 1980).

Consistent with a person-centered approach to data analysis that emphasizes individual differences in development, we used growth mixture modeling. Three criteria were used to determine the optimal numbers of classes. First, we used a sample-size adjusted Bayesian information criterion (SABIC; Sclove, 1987) that is a parsimony goodness-of-fit index based on the log-likelihood adjusted for the number of parameters. Lower SABIC values reflect a better model fit. Second, we used the adjusted Lo-Mendell-Rubin test (ALMR; Lo, Mendell, & Rubin, 2001) that is a nested model likelihood ratio test and provides a significant test of whether C trajectory classes provided a better fit to the data than did the $C - 1$ class model. Thus, a small probability value (i.e., $p < .05$) indicates that the $C - 1$ class model should be rejected in favor of the model with at least C classes. Finally, we also checked the usefulness of the classes based on the subjective interpretation of the developmental trajectories and the number of children in each class. As shown in Table 22.3, we obtained fit indices for one-, two-, three-, and four-class models of developmental trajectories. In these models, the latent variables means, latent variable covariances and residual variances, and pattern of change were relaxed. In identifying the growth mixture model that best delineates the data, we chose C class model over $C - 1$ model when both the SABIC (i.e. decreased) and the ALMR (i.e., $p < .05$) indicated a better fit for the C class model compared to the $C - 1$ class model.

TABLE 22.3 Fit Indices for Univariate Growth Mixture Modeling of Personality Processes and Behavioral Problems in Maltreated and Nonmaltreated Children[1]

	Maltreated		Nonmaltreated	
Number of classes	SABIC	ALMR	SABIC	ALMR
Ego-resiliency				
1 class	279.68		**127.82**	
2 classes	**261.64**	15.68[2]	107.93	27.13
3 classes	258.58	11.66	103.10	12.75
4 classes	261.87	5.63	88.73	21.86
Ego-control				
1 class	**−330.70**		−279.15	
2 classes	−330.43	8.73	−290.78	19.24[1]
3 classes	−335.67	13.990	**−296.52**	13.62[1]0
4 classes	−338.08	11.280	−294.02	5.740
Externalizing symptomatology				
1 class	**6469.65**		**4732.05**	
2 classes	6469.57	99.060	4704.46	34.49
3 classes	6472.24	6.43	4696.19	016.030
4 classes	6475.33	6.03	4689.63	14.40
Internalizing symptomatology				
1 class	**6383.36**		**4718.05**	
2 classes	6382.25	10.04[1]	4715.69	10.38
3 classes	6381.21	07.78[1]	4712.44	10.75
4 classes	6385.12	05.240	4709.28	011.160

[2] $p < .05$.

A two-class model yielded the best fit to the ego resiliency data for maltreated children. As shown in Figure 22.10, the two trajectories started at similar levels, but 59% of children (Class 2, the increasing class) were characterized by a U shape trajectory with decreasing up to age 7 and then continuously increasing afterwards, whereas 41% of children (Class 1, the "declining" class) showed significant decreases in slopes. Turning to ego control, the best-fitting model of the one-class growth mixture model indicated stable and somewhat elevated levels of ego undercontrol for the entire sample of maltreated children, as indicated by the significant intercept mean and the nonsignificant means of the linear and quadratic slopes. Meanwhile, growth mixture modeling analyses revealed three distinct growth trajectories for nonmaltreated children. As shown in Figure 22.11, about half of the nonmaltreated children (53%, Class 2, the low-stable

class) showed consistently low levels of ego undercontrol (with nonsignificant means for linear and quadratic slopes) and about 40% of children (Class 1, the increasing class) showed a U shaped slope with significant increases. A small number of nonmaltreated children (7%, Class 3, the declining class) showed a higher initial level than the other two classes, and they displayed a decreasing linear trend that was marginally significant ($p = .06$).

After determining the most appropriate number of trajectory classes, we then tested whether latent class differences could be described by maltreatment parameters and gender using a multinomial logistic regression approach for the variables with more than one class and conditional growth curve models for the variables with one class. The main interest was to examine whether different features of the maltreatment experience—such as type, multiplicity (i.e., experiencing multiple subtypes), onset, and chronicity—may have significant independent effects on child outcomes. For these analyses, two models were estimated separately for testing effects of physical or sexual abuse (PA/SA) and for testing the effects of other maltreatment risk factors including multiple subtypes, chronicity, and onset so that we could prevent potential multicollinearity problems. Gender was included in the model as a covariate.

For ego resiliency among maltreated children, the logistic regression coefficient (or logit) predicting membership in the declining class indicated that children with early onset, regardless of the maltreatment subtypes, were more likely to be in the decreasing class with a marginal significance ($b = .69$, $SE = .37$, $p = .07$, *odd ratio* = 2.00). The growth curve model analyses with maltreatment subtypes and gender for ego control produced reasonable fits [$\chi^2\,(15) = 18.69$ and RMSEA = .03 for the model involving the PA/SA predictor, and $\chi^2\,(19) = 23.49$ and RMSEA = .03 for the model involving multiple subtypes, chronicity, and onset]. Experiencing multiple maltreatment subtypes and physical/sexual abuse were related to higher levels of ego undercontrol.

The final step of data analysis validated the distinctiveness of the trajectory classes by testing whether the personality trajectory classes predicted later behavioral adjustment. Our growth mixture modeling results indicated two trajectory classes of ego resiliency among maltreated children and three trajectory classes of ego control among nonmaltreated children. We examined whether those trajectory classes based on personality scores during ages

6–10 years would predict adjustment outcomes observed during ages 10–12 years using ANOVA.

We compared the prospective adjustment outcomes among the five classes that were identified in the current sample, including the declining ego resiliency and the increasing ego resiliency classes among maltreated children, and the increasing ego (under)control, the low-stable ego (under)control, and the declining ego (under)control classes among nonmaltreated children. Significant group differences in externalizing symptomatology were identified by Tukey range tests and linear contrasts, indicating that (1) the maltreated declining ego resiliency class showed the highest levels of externalizing symptomatology, and the nonmaltreated increasing ego (under)control class had significantly higher levels of externalizing symptomatology compared to the maltreated increasing ego resiliency class and the nonmaltreated low-stable ego (under)control class, and (2) the nonmaltreated declining ego (under)control class and the maltreated increasing ego resiliency class showed higher levels of externalizing symptomatology than the nonmaltreated low-stable ego (under)control class, which showed the lowest levels of externalizing symptomatology [Tukey range tests, $F\,(4,\ 333) = 26.64$, $p < .05$; $p < .05$ for all comparisons, except the linear contrast for the nonmaltreated declining ego (under)control class vs. the nonmaltreated low-stable ego (under)control class, $t = -1.71$, $p = .09$]. Turning to internalizing symptomatology, Tukey range tests and linear contrasts revealed that the maltreated declining ego resiliency class and the nonmaltreated declining ego (under)control class showed significantly higher levels of internalizing symptomatology compared to the other three classes [Tuckey range tests, $F\,(4,\ 333) = 10.31$, $p < .05$; and linear contrasts, $t = -2.01$ ˜ $t = -2.24$, $p < .05$].

Thus, our examination of subsequent adjustment outcomes among the five subgroups (consisting of the two ego resiliency classes for maltreated children and the three ego control classes for nonmaltreated children) provided a clearer picture regarding joint contribution of ego resiliency and ego control to internalizing and externalizing symptomatology. Maltreated children in the declining ego resiliency group showed the worst outcomes with distinctively higher levels of both externalizing and internalizing symptomatology. In contrast, maltreated children in the increasing ego resiliency group exhibited better adjustment functioning as indicated by their relatively low levels of externalizing and internalizing symptomatology. Overall, the findings suggest that ego resiliency and ego control—personality processes related to self-regulation—may be important factors in identifying distinct pathways to later personality disorders as well as pathways to resilient functioning.

Traditionally, research on developmental psychopathology has taken predominantly variable-centered approaches to examine how variables differ on average between groups. In contrast, person-centered approaches to developmental psychopathology emphasize the importance of the person as the major unit of analysis and the structure of person profiles across variables. The integrated variable- and person-centered approach provides increased insights about the relationships between risk and protective factors and developmental trajectories of psychopathology. The findings of this study illustrate the potential utility of a growth mixture modeling approach to examining the patterns of developmental trajectories and further highlight that developmental psychopathology researchers should consider that possibility that there are heterogeneous trajectory classes even when class membership is not observed.

Growth Mixture Modeling Studies for Understanding Contextual Influences

Growth Mixture Modeling for Cross-Domain Relations in Risk and Psychopathology

The following longitudinal study illustrates how growth mixture modeling can be used to study cross-domain relations in psychopathology. In a longitudinal study, Reinke, Eddy, Dishion, and Reid (2012) utilized growth mixture modeling to identify patterns of developmental changes of disruptive behaviors and depression and further examine the joint, longitudinal trajectories of symptoms of disruptive behaviors and depression. Participants included 361 adolescents (49% male, 15% non-White) who were recruited from at-risk neighborhoods based on high rates of police contact regarding youth delinquency. Adolescent depressive symptoms and disruptive behavior problems were assessed six times from age 10 to 16 years. Depressive symptoms were assessed using adolescents' reports on the Child Depression Inventory (CDI; Kovacs, 1992) and disruptive behavior problems were assessed using mothers' reports on the Child Behavior Checklist (CBCL; Achenbach, 1991). Distal outcomes during emerging adulthood (age 18 to 23 years) included youth reports of disruptive behavior problems using the Youth Self-Report (YSR: Achenbach, 1991), depressive symptoms using the Brief Symptom Inventory (BSI: Derogatis, 1975), substance use using the Michigan Alcoholism Screening Test (MAST; Selzer, 1971) and the Drug Abuse Screening Test (DAST; Skinner 1982), diagnosis of antisocial personality disorder (ASPD) and major depressive disorder (MDD)

using Diagnostic Interview Schedule (DIS-IV, American Psychological Association, 1994), and police arrests (juvenile and adult arrests) using court data.

Univariate growth mixture modeling analyses were performed to identify distinct subgroups based on patterns of growth in depressive symptoms and disruptive behavior problems. Four indicators were used to determine the best-fitting growth mixture model including the Akaike information criterion (AIC; Akaike, 1987), the Bayesian information criterion (BIC; Schwartz, 1978), and the sample-size adjusted (SABIC; Sclove, 1987), as well as the entropy. For depression, comparing between the four-class and five-class solutions, the addition of a fifth class did not provide unique information (AIC = 10998.25, BIC = 11113.99, SABIC = 11018.82, Entropy = .93 for the four-class solution; and *AIC* = 10957.13, BIC = 11088.30, SABIC = 10980.44, entropy = .92 for the five-class solution). Thus, the four-class model was chosen as the best-fitting model. The four classes included a group showing increases in depression ($n = 18$, 5.1%), a group showing high levels of depression ($n = 18$, 5.2%), a group showing decreases in depression ($n = 31$, 8.9%), and a group showing low levels of depression ($n = 283$, 80.9%). Latent class regression analysis further indicated that adolescents in the increasing and decreasing depression classes were significantly more likely to report depression as young adults (odds ratio = 18.70 and 4.27, respectively) compared to the adolescents in the low depression class. Furthermore, compared to the low depression class, adolescents in the increasing depression class were significantly more likely to report disruptive behavior as young adults (odds ratio = 18.70). Adolescents in the high depression class were significantly more likely to report problems with alcohol (odds ratio = 16.39) and drugs (odds ratio = 4.06).

For disruptive behavior problems, comparing between the three-class and four-class solutions, the addition of a fourth class did not provide unique information (AIC = 10547.22, BIC = 10627.13, SABIC = 10560.52, Entropy = .96 for the three-class solution; and AIC = 10510.69, BIC = 10602.01, SABIC = 10525.89, Entropy = .96 for the four-class solution). Thus, the three-class model was chosen as the best-fitting model. The three classes included a group showing increases in disruptive behavior problems ($n = 19$, 5.9%), a group showing high levels of disruptive behavior problems ($n = 11$, 3.2%), and a group showing consistently low levels of disruptive behavior problems ($n = 302$, 90.9%). Latent class regression analysis further indicated that adolescents in the increasing and high disruptive behavior problems classes were significantly more likely to report disruptive behavior problems as young adults (odds ratio = 2.85 and 3.28, respectively). In addition, adolescents in the increasing disruptive behavior class, when compared to the low disruptive behavior class, were significantly more likely to report depression as young adults (odds ratio = 6.59), to be arrested as juveniles (odds ratio = 7.85), and to report problems with alcohol as young adults (odds ratio = 2.89). Adolescents in the high disruptive behavior class, compared to the low disruptive behavior class, were significantly more likely to report problems with alcohol (odds ratio = 2.19) and drugs (odds ratio = 5.04), and to be arrested (odds ratio = 10.32) as young adults.

Furthermore, parallel process growth mixture modeling was used to integrate the trajectories of disruptive behavior and depressive symptoms into one model and investigate the co-occurrence of disruptive behavior problems and depression. Specifically, parallel process growth mixture models evaluated the joint probability of individuals simultaneously being in a class for each of the two growth classes as well as the conditional probability of membership in each disruptive behavior class conditional on each depression class, and vice versa. Among adolescents in the high depression class, 11% were in the high disruptive behavior class and 22% were in the increasing disruptive behavior class. In contrast, among adolescents in the low depression class, only 5% were in the high disruptive behavior class and 3 % were in the increasing disruptive behavior class. Among adolescents in the high disruptive behavior class, 5% were in the high depression class and 16% were in the decreasing depression class. Among adolescents in the increasing disruptive behavior class, 15% were in the high depression class and 8% were in the decreasing depression class. In comparison, among adolescents in the low disruptive behavior class, 2% were in the high depression class and 5% were in the decreasing depression class. Thus, these findings indicate that adolescents with high depression may be at greater risk for co-occurring disruptive behavior problems and also that adolescents with high or increasing disruptive behavior problems may be at greater risk for co-occurring depression.

Findings from this study highlight the utility of person-centered approaches for the study of developmental courses across different dimensions of psychopathology. Using the growth mixture modeling can be particularly beneficial in providing crucial information regarding comorbidity—that was identified based on developmental trajectories—as a source of heterogeneity. These subtypes may represent distinct subgroups that should be

differentially targeted in terms of preventive intervention efforts.

Growth Mixture Modeling for Multiple Levels of Analysis

The following study illustrates how growth mixture modeling procedure can be utilized to examine the developmental significance of early individual risk factors on subsequent risk for maladjustment outcomes. Using longitudinal data across several domains and multiple developmental time points, Lynne-Landsman, Bradshaw, and Ialongo (2010) evaluated a dynamic cascade model of substance use by examining the indirect effects of early risk factors on substance use during adolescence and adjustment in adulthood. Specifically, they examined the process by which early-onset aggressive behavior problems and academic readiness influence risk for substance use during adolescence and further adjustment problems during young adulthood.

Data were drawn from a sample of 678 urban, primarily African American youth (87% African American and 13% Caucasian; 53% male) followed from first grade through age 21. Early risk factors included parental discipline and parental rejection, oppositional defiant behavior, academic failure, peer rejection, and affiliation with substance-using peers. Parental discipline and parental rejection in first grade were assessed using The Structured Interview of Parent Management Skills and Practices, Parent Version (Capaldi & Patterson, 1989). Oppositional defiant behavior and peer rejection in first and third grades were assessed using the Teacher Observation of Classroom Adaptation—Revised (Werthamer-Larsson, Kellam, & Wheeler, 1991). Academic achievement in first, third, and eighth grades was measured using teachers' reports on the child's overall grade performance. Substance-using friend affiliation in seventh grade was assessed using adolescents' reports on the friends drug use subscale from the Monitoring the Future National Survey (Johnston, O'Malley, & Bachman, 1995). Teachers provided data on adolescent conduct problems via the Classroom Behavior Checklist. Frequency of substance use in the last year (cigarettes, alcohol, and marijuana) was measured using adolescents' reports on the questions from the Monitoring the Future National Survey (Johnston et al., 1995). Adjustment in young adulthood was indicated using five variables measured at age 21 including educational attainment (e.g., graduating high school on time), mental health problems (life-time major depressive disorder and antisocial personality disorder), drug abuse and dependence, risky sexual behaviors (unsafe sexual behaviors and pregnancy), and criminal behavior (court records of involvement in the juvenile and adult criminal justice systems).

They first conducted a series of growth mixture modeling analyses to model developmental trajectories of cigarette, alcohol, and marijuana use in high school (from ninth to twelfth grades). For cigarette, a two-class model provided the best fit to the data suggesting a group of abstainers ($n = 437$, 82%) and a group of adolescents with "ncreasing cigarette use ($n = 96$, 18%). For alcohol use, a three-class model was the best-fitting model suggesting three distinct trajectories of none/low alcohol use ($n = 583$, 83%), "moderate" alcohol use ($n = 88$, 13%), and heavy alcohol use ($n = 28$, 4%). Similarly, for marijuana use, a three-class model was the best-fitting model. The three classes represented distinct groups of abstainers ($n = 437$, 82%), increasing marijuana users ($n = 58$, 11%), and heavy marijuana users ($n = 36$, 7%).

Next, predictors and distal outcomes that were associated with the high school substance use trajectories were examined. For adolescent cigarette use, parental education ($b = .20$, $SE = .08$, $p = .02$) and female gender ($b = .48$, $SE = .24$, $p = .04$) were associated with significant increases in the odds of being in the abstainers group. In terms of the distal outcomes of adjustment in young adulthood, those who belonged to the increasing class, compared to abstainers, were less likely to graduate on time ($\chi^2 = 26$, $p < .001$), and were more likely to report poor mental health ($\chi^2 = 8.66$, $p < .01$), alcohol abuse ($\chi^2 = 7.20$, $p < .01$), marijuana dependence ($\chi^2 = 16.38$, $p < .001$), unsafe sexual activities ($\chi^2 = 26$, $p < .001$), and involvement in criminal justice system ($\chi^2 = 19.61$, $p < .001$).

For adolescent alcohol use, parental education and gender were not significant predictors of trajectory classes. In terms of the distal outcomes of adjustment in young adulthood, the only adult outcome that was differentiated by the trajectory classes was antisocial personality disorder. Those who belonged to the moderate use class, compared to the no/low use class, were more likely to have antisocial personality disorder ($\chi^2 = 6.42$, $p < .01$). Turning to adolescent marijuana use, parental education differentiated the heavy use class from the increasing class ($b = .32$, $SE = .14$, $p = .02$) and the abstaining class ($b = .31$, $SE = .11$, $p = .003$). Female gender ($b = .77$, $SE = .31$, $p = .01$) were associated with significant increases in the odds of being in the abstaining class compared to the increasing class. With respect to the distal outcomes of adjustment in young adulthood, compared to abstainers, those who belonged to the increasing class and heavy use class were less likely to graduate high school

on time ($\chi^2 = 17.87$, $p < .001$), and were more likely to show antisocial personality disorder ($\chi^2 = 15.54$, $p < .01$), alcohol abuse ($\chi^2 = 18.12$, $p < .001$), marijuana abuse and dependence ($\chi^2 = 14.79$, $p < .001$ and $\chi^2 = 21.63$, $p < .001$, respectively), unsafe sexual activities ($\chi^2 = 7.06$, $p < .05$), and involvement in the criminal justice system ($\chi^2 = 16.21$, $p < .001$).

Finally, the developmental cascade model was tested to determine if the effect of each childhood/adolescent predictor on substance use class membership was mediated by the subsequent predictors along the cascade. The indirect effects were calculated by the product of the two pathways: of the pathway from each predictor at time t to a subsequent predictor at time $t + 1$ (α) and the pathway from each predictor to substance use class membership (β). For cigarette use, the indirect effect of oppositional defiant behavior in first grade on high school cigarette use class membership was mediated by peer rejection in third grade ($\alpha\beta = .04$, $SE = .02$, $p = .05$). Both peer rejection and academic achievement in third grade had indirect effects on high school cigarette use class membership via affiliation with substance-using peers ($\alpha\beta = .05$, $SE = .02$, $p = .04$ and $\alpha\beta = .05$, $SE = .03$, $p = .04$, respectively). In turn, substance-use peer affiliation was indirectly associated with high school cigarette use class membership through conduct problems in eighth grade ($\alpha\beta = .11$, $SE = .04$, $p = .002$).

For alcohol use, both peer rejection and academic achievement in third grade had indirect effects on high school alcohol use class membership via affiliation with substance-using peers ($\alpha\beta = .06$, $SE = .03$, $p = .02$ and $\alpha\beta = .06$, $SE = .03$, $p = .02$, respectively). In addition, substance-use peer affiliation was associated with high school cigarette use class membership mediated through conduct problems in eighth grade ($\alpha\beta = .11$, $SE = .04$, $p = .001$). Turning to marijuana use, the indirect effect of oppositional defiant behavior in first grade on high school marijuana use class membership through peer rejection in third grade was marginally significant ($\alpha\beta = .05$, $SE = .03$, $p = .06$). Both peer rejection and academic achievement in third grade had indirect effects on high school marijuana use class membership via affiliation with substance-using peers ($\alpha\beta = .07$, $SE = .03$, $p = .04$ and $\alpha\beta = .07$, $SE = .03$, $p = .03$, respectively). Substance-use peer affiliation was associated with high school marijuana use class membership indirectly through conduct problems in eighth grade ($\alpha\beta = .13$, $SE = .04$, $p = .002$).

Thus, the results of testing a developmental cascade model highlight how growth mixture modeling analyses can be used not only to examine heterogeneity in developmental trajectories of psychopathology but also to identify multiple levels of pathways to psychopathology trajectories. The main finding indicated distinct developmental trajectories of high school cigarette and marijuana use that were explained by the peer rejection pathway (rather than the academic achievement pathway). That is, early childhood peer rejection was related to subsequent affiliation with deviant substance-using peers, which resulted in higher odds of following trajectories of using cigarette and marijuana. This study also underscores testing the validity of the groupings by examining difference in long-term outcomes across trajectory groups. However, future research will be beneficial to replicate results for further validation of the groups.

Implications of Growth Mixture Modeling for Prevention and Intervention Science

Studies using growth mixture modeling to assess prevention and intervention effects are extremely rare despite that Muthén and colleagues (2002) have published a nice example of applying growth mixture modeling for evaluating effects of a randomized preventive intervention program. Basically, using growth mixture modeling allows researchers to examine effects of prevention and intervention programs on subgroups that are characterized by different types of growth trajectories. Muthén and colleagues (2002) examined the effect of a randomized intervention, the Good Behavior Game, aimed at intervening during first and second grades to reduce aggressive behaviors that were assessed through middle school and beyond. Participants included 119 boys in the intervention group and 80 boys in the control group. The main question was to examine if subgroups of children benefit differently from the intervention. In growth mixture modeling, intervention effects were expected to be captured by the average slopes of each class.

First, separate analyses were performed for the control and the intervention group to study the normative development of aggressive behavior in the absence of an intervention shown in the control group compared to the intervention group. Model comparison for different numbers of classes was guided by a BIC. For the control group, the four-class solution was deemed to best describe the data and those four classes included high (8%), medium (38%), low (41%), and late-starters (13%). For the intervention group, the three- and four-class models revealed that the High class showed a decline earlier than the control group, suggesting a beneficial effect of the preventive intervention program especially for boys who were at the greatest risk.

Next, the joint analysis of the control and the intervention group, and both the three- and four-class models were compared. For the three-class model, beneficial effects of the intervention were shown with the lowered aggression trajectory for the high class of the intervention group, compared with the high class of the control group. It should be noted that, although the difference in the means was sizable ($\gamma = -.45$; with γ indicating a change in average growth rate that can be different for different classes), it was not significantly different from zero (95% CI : $-.92$, 0.02). There was no indication of intervention effects for the Medium and Low classes, suggesting that the intervention effects were more effective for children with the highest risk. Similar patterns for the intervention effects on the High group were observed in the 4-class model. Beneficial effects of the intervention were also suggested for the Late-starter group with late-starters who received intervention showing a flatter trajectory compared to late-starters in the control group. However, the likelihood-ratio test of any intervention effect over the four classes was very small ($\chi^2(8) = 1.40$, $p > .05$). The authors attributed the lack of significance to the low power given small class sizes (e.g., 18 boys in the intervention group and 12 boys in the control group) as well as large within-class variation.

This study illustrates how growth mixture modeling can be employed to examine different intervention effects in the different subgroups as well as to investigate when those effects are likely to appear. Furthermore, as Muthén and colleagues (2002) suggested, the results of this study imply future directions that researchers may select different types of interventions for individuals belonging to different trajectory subgroups using longitudinal screening procedures.

CONCLUSION AND FUTURE PERSPECTIVE

The main goal of this chapter was to demonstrate currently existing latent growth modeling approaches, examine implications of these approaches for testing developmental psychopathology theory, and illustrate examples of using these approaches to enhance our understanding of risk, disorder, and adaptation focusing on the developmental psychopathology principles. Investigators interested in developmental psychopathology will continue benefiting from the advancement of latent growth modeling methodology. This is especially because the understanding of individuals with high-risk conditions and psychopathological disorders will require careful examination of interindividual differences in intraindividual changes based multidomain and prospective assessments. Latent growth modeling provides a tool to delineate continuity/discontinuity and turning points in developmental pathways. Furthermore, the recent development of growth mixture modeling allows researchers to model multiplicity of processes and outcomes in the development of adaption, maladaptation, and psychopathology, and thus better appreciate equifinality and multifinality in the developmental pathways.

Growth curve models are the current standard approach to study within-person changes over time and have many benefits over classical approaches to repeated-measures data because of their emphasis on *individual* change and the ability to statistically quantify the magnitude of between-person differences in the magnitude of within-person change. At the same time, advances in the conceptualization of individual change to examine time-dependent effects on change, nonlinear change, and a greater emphasis on the individual have called into question the utility of the growth curve model. We expect such movements to continue, highlight these trends, and discuss potential avenues for the expansion of growth curve models.

With the work of McArdle and Hamagami (2001), the conceptualization of individual change as examined with growth curve models was transformed from a deterministic model (a smooth trend characterized by few parameters plus noise) to a stochastic one where dynamic noise (separate from residual variation or measurement noise) could be estimated and impact the predicted trajectories over time. Additionally, time-lagged associations between multiple on-going processes could be studied, such that change at a given time point was potentially impacted by prior states within and across developmental processes. Theoretically, this makes sense as it is unlikely that a smooth developmental trajectory would not be perturbed by events taking place at the individual level and changes are often dependent on the prior and/or current states and rates of change in multiple constructs. We expect continued movement in the direction of stochastic, rather than deterministic, models.

This movement is coinciding with changes taking place in the ways in which longitudinal data are being collected. Researchers are increadingly relying on cell phones to collect data as participants live their lives. The enormous amount of data streams provided by cell phones and the accessibility of participants to researcher invoked ongoing interventions has led to statistical challenges in the analysis of such data. Such data are often analyzed on an individual-by-individual basis where the aggregation

of results can be difficult because of the idiosyncracy of people's daily lives. However, the data streams can be analyzed and interventions can be timed based on the data streams. Such individually timed interventions can reduce between-person differences in change and status prior to intervention, and the impacts of the intervention can be realized with growth curve type models since the aggregation of information across individuals is more easily justified.

In closing, we identify future research directions for developmental psychopathology research that will benefit from employing latent growth modeling approaches. First, with respect to the emergence of psychopathology, all periods of life are consequential in the sense that the developmental process can take a pernicious turn toward psychopathology at any phase (Cicchetti & Rogosch, 1999). More investigations are needed that elucidates developmental trajectories across the life course (e.g., infancy through senescence). Second, our examination of published illustrations suggests that prior research using latent growth modeling predominantly focused on the psychopathology outcomes of internalizing and externalizing symptomatology. It is recommended that latent growth modeling approaches are applied to broader high-risk conditions and mental disorders that have traditionally been investigated in a nondevelopmental fashion, including Down syndrome, fragile X, autism, schizophrenic disorder, bipolar disorder, and borderline personality disorder. In particular, studying developmental trajectories across different populations will help us learn about what is specific to a given risk condition as well as what characterizes a number of conditions (i.e., similarities vs. differences). Such cross-population studies should engage not only processes linked to pathological outcomes but also pathways to resilience and the effects of intervention and prevention.

Third, using latent growth modeling for future research that involves multiple domains of psychopathology will be particularly fruitful to better understand the concept of comorbidity from the perspective of developmental psychopathology. Such studies will better inform us regarding how we think about comorbidity, how we analyze comorbidity, how much is due to differentiation or truly unique disorders, and if differential pathways exist for comorbid symptoms. Fourth, to better capture the nature of transactional developmental processes, future investigations using latent growth modeling must strive to apply a multilevel developmental psychopathology perspective (Cicchetti, 2010) to attain genetic–neurobiology–psychology trajectories within individuals as well as culture, community, family, and individual trajectories. It has been a decade since Curtis and Cicchetti (2003) emphasized the need for research that applies a multiple-levels-of-analysis perspective to evaluate the efficacy of preventive interventions. As efficacious interventions are expected to change both behavior and biology through alterations in gene expression as well as changes in the brain (Kandel, 1999), deeper understanding for the mechanism of change will be obtained through investigating the change processes in multiple levels of functioning.

Finally, from an analytic point of view, continuous time models (Oud & Jansen, 2000) and the use of differential equation models will become more common, partially brought on by the increase in the number of assessments. Such models more easily account for unequally spaced measurement occasions and allow for the comparison of parameter estimates across studies that are based on different time lags by relating typically utilized discrete time models to their underlying models in continuous time. We expect continued improvements in the estimation of complex nonlinear and growth mixture models as well as approaches to research synthesis in longitudinal studies of change to accumulate information over studies and datasets.

CHAPTER OVERVIEW

The importance of research synthesis from a body of evidence using more rigorous, systematic, and quantitative approaches has been echoed in the field over years; yet most of the literature reviews are narrative or qualitative in nature. It is possible to conduct two different narrative literature reviews and to have contrasting sets of hypotheses if the reviews were not sufficiently extensive or done selectively. Even in extensive and systematic reviews, determining which studies are more important and relevant than others to report or discuss in detail may very well be within the realm of subjective judgments. Iain Chalmers

(2003) poignantly pointed out missed opportunities of the past citing that, for example, cases of sudden infant death syndrome (SIDS), for babies sleeping on their fronts (tummy), could have been prevented much earlier, had there been a rigorous, systematic and quantitative review of available evidence. He also cited exemplary cases of the past that saved numerous lives (e.g., low doses of aspirin reducing the risk of cardiovascular morbidity and mortality; see O'Rourke, 2007, for a historical account of this report that appeared in the *Lancet* editorial in 1980). Furthermore, as the number of relevant studies increases, it becomes much more difficult to summarize findings from multiple studies in a narrative review.

Quantitative research synthesis can help us to draw inferences that are not afflicted with chance findings and optimism bias, when conducted routinely and vigorously with the most up-to-date compiled evidence. Quantitative research synthesis is aimed at quantifying the overall effect of interest across studies and providing the uncertainty surrounding the point estimate. The resulting summary estimate can be helpful for deciding the benefits of the effect in question if, for example, a new treatment were brought to market. In the field of preventions and interventions, one can examine the average effect size of existing interventions, and subsequently channel efforts into more effective interventions, thus saving limited resources available in the current, tight funding environment. The Cochrane Collaborative Network (Higgins & Green, 2011) and the Human Genome Epidemiology Network (Ioannidis et al., 2006) represent such efforts to promote systematic reviews and to obtain efficient and reliable findings, respectively, by utilizing large-scale evidence in the medical and epidemiological genetic research fields.

In addition, recent high profile reports and discussions have fueled the need for quantitative research synthesis. These reports pointed out that findings from single studies are often not replicable, and are subject to publication bias and afflicted by low power and high false discovery rates (e.g., Begley & Ellis, 2012; Ioannidis, 2005). Thus, findings from single studies that are conducted independently, regardless of how important they may sound, may be best interpreted with some caution and scrutiny. At the same time, data from individual studies may be utilized more often for a large-scale research synthesis to obtain more robust evidence in the future.

Synthesizing data across studies in a meta-analysis allows one to obtain more credible estimates of effects than are possible from individual studies and to achieve better generalization of how causal relationships may change over variations in study features (Shadish, Cook, & Campbell, 2002). From a more discovery-oriented or exploratory perspective, individual single studies are not well equipped for novel discoveries due to lack of power. By combining data from multiple sources, we can overcome several important, inherent limitations of single studies. In the future, single studies may serve two distinct goals: a preliminary investigation for novel discoveries, and a component data set as part of a bigger, pooled data set, for more robust and generalized inference.

The momentum toward more robust research synthesis via quantitative approaches has been building in recent psychological research. Quantitative research synthesis from available data—either published aggregated data (AD) in terms of effect size estimates or raw individual participant-level data (IPD)—has prominently been discussed as one of the central strategies for building a cumulative knowledge base. The journal *Prevention Science* recently published a special issue focusing on subgroup analysis by pooling data from multiple trials or by utilizing more advanced analytic approaches in prevention and intervention research (Supplee, Kelly, MacKinnon, & Barofsky, 2013). In addition, *Psychological Methods* published a special issue focusing on integrative data analysis (IDA) in 2009 (Curran, 2009), discussing advantages and disadvantages of pooling and combining raw data from multiple studies, compared with either single studies (Curran & Hussong, 2009) or meta-analysis using AD (Cooper & Patell, 2009). Similarly, *Perspectives on Psychological Science* recently published a special section on replicability (Pashler & Wagenmakers, 2012). In this special section, the Open Science Collaboration (2012) and other contributors have called for sharing of data and/or publishing raw data for IPD meta-analysis to achieve better transparency and higher standards for research (e.g., Ioannidis, 2012).

The current chapter discusses quantitative methods for research synthesis. We discuss any quantitative methods aimed at synthesizing information from multiple, independent sources under the big IDA tent. The covered methods encompass meta-analysis using AD for different outcomes, such as odds ratio, mean difference, or other effect size estimates; meta-analysis using IPD; and other approaches to analyzing multiple, independent data sets. This chapter is intended to provide a more inclusive coverage of these various quantitative approaches under the umbrella of IDA (Figure 23.1). Curran and Hussong (2009) defined IDA more specifically as "the statistical analysis of a single data set that consists of two or more separate samples that have been pooled into one" (p. 82) to distinguish IDA from either AD meta-analysis or single studies and to highlight the unique advantages and

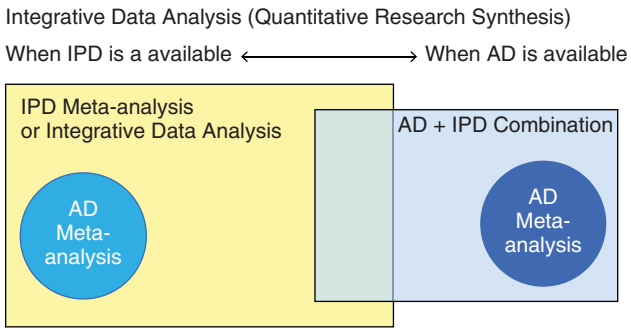

Figure 23.1 Integrative data analysis (IDA) and meta-analysis using individual participant-level data (IPD) and aggregated data (AD). AD meta-analysis can be conducted either as part of IDA when IPD is available (see the circle inside the rectangle on left) or based on reported AD in publications (the circle inside the right rectangle). See footnote 1.

challenges associated with analyzing raw IPD. In contrast, we include AD meta-analysis under the IDA framework because results from AD meta-analysis can be obtained by using raw IPD (Figures 23.1 and 23.2). For example, the overlap in the middle between the two rectangles in Figure 23.1 indicates situations where IPD is available for some of the studies and consequently AD meta-analysis is possible. The circles for AD meta-analysis within the two rectangles are shaded in different colors to reflect some differences in the procedures and possibly different results involved in AD meta-analysis depending on the source of data. The strict distinction between AD and IPD may not be useful for the purpose of research synthesis. Because IPD is not always available and IPD analysis can be quite challenging, analysis based on combinations of AD and partially available IPD may provide an alternative in some situations (see Yamaguchi et al., 2014, for a proposed method that combines these two data structures) while taking advantage of all available data. Figure 23.1 shows the relationships between IDA, IPD meta-analysis, and AD meta-analysis. Note that in the current chapter, we use the term IDA in two different ways. On one hand, we broadly use IDA as a general evidence-based framework for research synthesis that includes all quantitative methods. At the concrete level of analysis, on the other hand, we use IDA interchangeably with IPD meta-analysis and contrast it against AD meta-analysis. Table 23.1 provides a list of several important approaches and summarizes notable characteristics and challenges of each approach.

Despite some differences across various methods, these quantitative approaches under the broad umbrella of IDA share many benefits identified by Curran and Hussong (2009): built-in replication, increased statistical power, increased sample heterogeneity, increased frequencies of low base-rate behaviors, broader psychometric assessment of constructs, extended period of study, and increased efficiency in time and money. Analysis utilizing IPD may provide an especially good framework for facilitating new discoveries, as well as strengthening research practices, by improving the sample analyzed and by adopting advanced, better analytical approaches that may not have been available before. From the perspective of single studies, this approach may also propel desirable changes in the way individual single studies are conducted in the future. For example, in the field of brief motivational interventions to reduce excessive drinking and related harm among college students, Mun and her colleagues (2015) recommended that single studies be designed and implemented to increase overlap in measures and follow-up assessments across trials, to reduce heterogeneity in intervention groups across trials, and to improve transparency and documentation overall.

Figure 23.2 depicts various analytic approaches to research synthesis in a snapshot. First, at the broadest level, we distinguish methods based on whether IPD is available. In the absence of IPD, one has to rely on AD for quantitative synthesis. For the analysis of AD, one can combine AD across studies using fixed-effects or random-effects meta-analysis models (see the Model-Based Approaches section). One can further analyze between-study variation by using meta-regression, which can reveal study-level moderators of the effect under investigation. Meta-analysis using AD tends to be larger in scale in terms of the number of studies and sample size because collecting and analyzing AD is relatively straightforward and also because there is no need to establish commensurate measures. Effect size estimates provide readily available standardized measures in AD meta-analysis.

Meta-analysis has been on the rise in clinical research. It has had an exponential rise in the number of publications as a publication type in PubMed and also as a method covered in an influential journal, *Statistics in Medicine*, between 1990 and 2006 (Sutton & Higgins, 2008). Similarly, between 1997 and 2012, the papers published in a flagship journal in the field of developmental psychopathology, *Development and Psychopathology*, increasingly either reported findings from a meta-analysis or utilized evidence from a meta-analysis reported elsewhere when generating hypotheses or discussing findings (Figure 23.3).

When IPD is available, meta-analysis using IPD can be conducted. One can closely check and correct data, if necessary, and reanalyze data by using more suitable analytical models for robust inference. IPD meta-analysis has long been championed and discussed as a promising method in the field of medical research synthesis (e.g., Steinberg et al.,

TABLE 23.1 Research Synthesis Methods

Approaches	Notable characteristics	Weaknesses or challenges
Nonempirical research synthesis		
Narrative review of single studies	• Can quickly be conducted • Can draw information from a wide range of studies (e.g., animal models, cross sectional studies, experimental studies) • Vote counting, the process of counting the number of significant and nonsignificant studies, is often used	• May be subject to publication bias and reviewer subjectivity • Variations across studies can become too complex as the number of studies increases • Limitations of single studies cannot be overcome • The results from single studies cannot be quantified using a precise metric • Vote counting is not a valid approach
Empirical research synthesis		
Classical meta-analysis approaches	• Relatively easy to conduct • Essentially fixed-effects model	• Groups or conditions to be compared should be similar across studies • Publication bias remains a threat, which can be countered by conducting an extensive search of the published and unpublished literature
Model-based meta-analysis: Fixed-effects model (using either AD or IPD)	• One common true effect for all studies is assumed • Within-study variability, not between-study variability, is assumed • Between-study heterogeneity may be accommodated by grouping similar studies together and stratifying them or by including covariates • Covariates can be included	• Between-study heterogeneity is not part of the model, which may be an unreasonable assumption • Study-level missing data (i.e., did not assess) can cause difficulty estimating a common model across studies • Inference cannot be generalized beyond the sample of studies analyzed (in terms of sample characteristics and study designs/effects)
Model-based meta-analysis: Random-effects model (using either AD or IPD)	• A distribution of true study-specific effects is assumed • Between-study heterogeneity (i.e., different intervention effects and design/sample characteristics) can be taken into account • Population-based inference can be made • Compared to a fixed-effects model, relatively greater weights are assigned to smaller studies • Compared to a fixed-effects model, this will result in wider confidence intervals around pooled effect estimates • Covariates can be included	• Study-level missing data (i.e., did not assess) can cause difficulty estimating a common model across studies • Relatively a large number of studies are needed. With a few studies, estimates may not be reliable • Can be difficult to characterize the population to which inference is made
Complex research synthesis—multivariate meta-analysis, network meta-analysis, IDA*		
Network meta-analysis (using either AD or IPD but much more promising for IPD)	• When IPD analysis is used, it is widely considered the "gold standard"—efficient, unbiased, and powerful • With IPD, both study-level and participant-level covariates can be included • Particularly useful for research synthesis of randomized controlled trials (RCTs) • Multiple intervention comparisons are possible via direct, indirect, and mixed evidence of intervention effects	• Randomization of groups within studies is needed to derive relative intervention effects • Within-study covariance matrix can be hard to obtain in analysis using AD • Without IPD, ecological inference bias may occur when using study-level covariates • Can be computationally intensive with IPD
Multivariate meta-analysis (using either AD or IPD but much more promising for IPD)	• When IPD analysis is used, it is widely considered the "gold standard"—efficient, unbiased, and powerful • With IPD, both study-level and participant-level covariates can be included • With IPD, analytic models are not limited to those used in single studies; many different statistical models are feasible • Correlated parameters for multiple outcomes, time points, or intervention groups can be estimated	• Randomization of groups within studies is needed to derive relative intervention effects • IPD may not be available for clinical trial data due to privacy concerns • With IPD, data cleaning and checking take considerable time and resources • With IPD, common metrics across studies need to be established to minimize missing data and to interpret individual-level findings • Key study design characteristics may vary, causing study-level missing data • Can be computationally intensive with IPD
Other etiological (longitudinal) IDA**	• Take advantage of existing data sets that are expensive to collect (e.g., fMRI, DNA, or longitudinal data) • Create a pooled data set that has more desirable characteristics than possible from single studies • More advanced and appropriate analysis can be conducted • Used for validation and to quantify an average effect size • Have greater power to detect small effects	• Data dimensions can be exceedingly large • Compiled data can be very sparse due to study-level missing data (e.g., candidate genes not available in some studies) • Common metrics across studies need to be established to minimize missing data and to interpret individual-level findings • Can be computationally intensive • Typically a few studies are analyzed together as a single data set

*AD = Aggregated data; IPD = Individual participant-level data (or individual patient-level data in medical research).

**In principle, IDA investigations of etiological and/or long-term longitudinal studies can use the same analytical methods as those listed under the complex synthesis methods. It is listed separately to highlight the challenges of harmonizing and analyzing extremely high dimensional data.

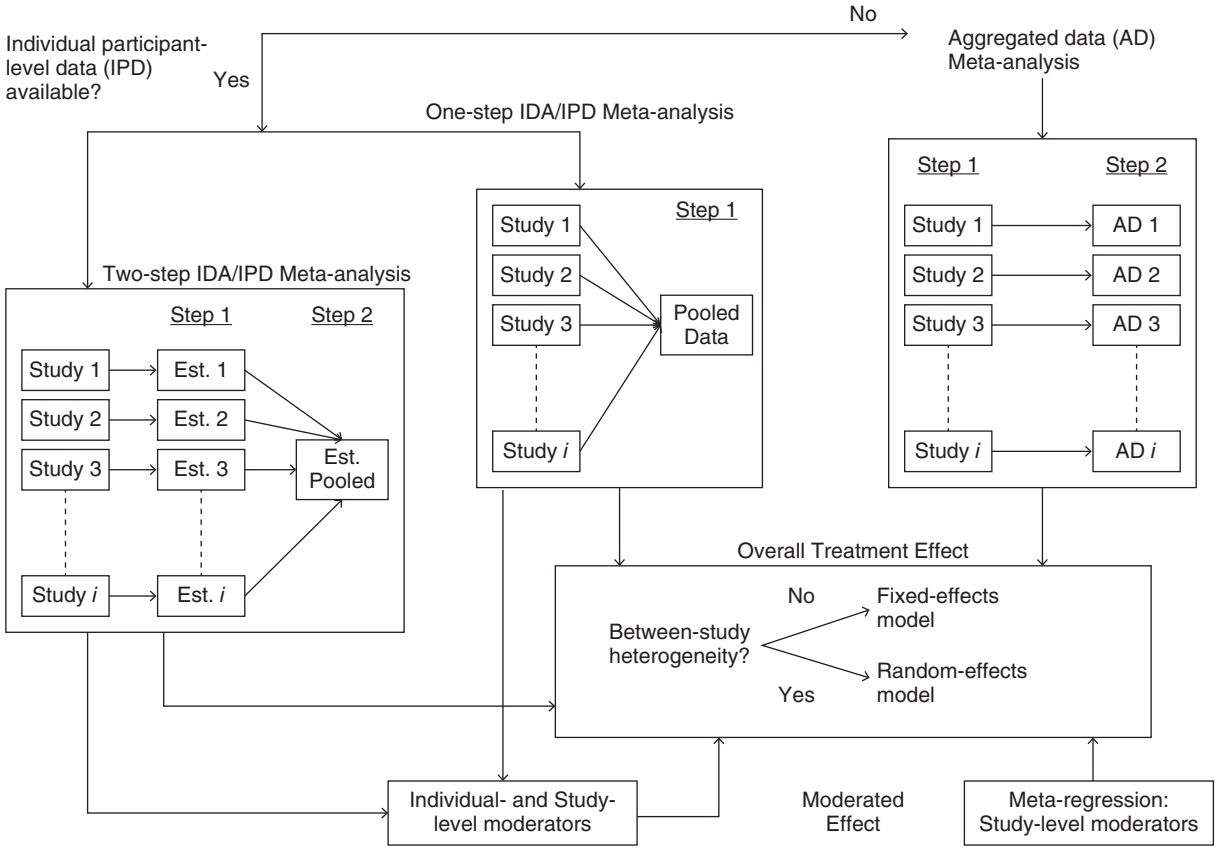

Figure 23.2 Analytical approaches under IDA.

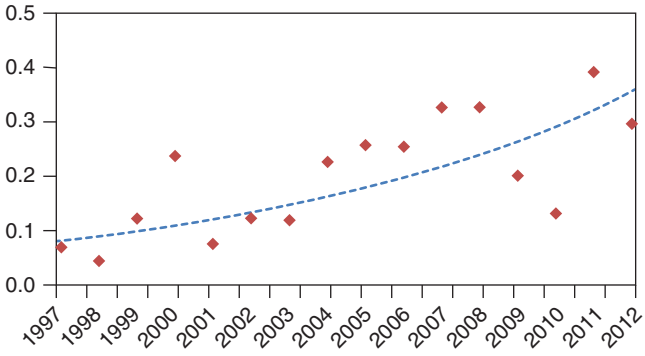

Figure 23.3 Proportion of the articles citing meta-analysis studies published in *Development and Psychopathology* from 1997 to 2012. See footnote 1.

1997; Stewart, 1995) but is a newly emerging approach for psychological research. IPD meta-analysis studies in psychological research have been rare primarily because of the challenge to establish measurement invariance across studies for valid inference. This can be a formidable challenge particularly for psychological measures (Hussong, Curran, & Bauer, 2013). Establishing measurement invariance can be challenging enough even when the same measure is used across key target groups (e.g., different developmental periods or different countries; Steenkamp & Baumgartner, 1998). It can be quite another challenge when different items or measures are used across studies and any overlap in items and measures is tenuous. Once measurement invariance across groups or studies is established, individuals can be placed on common metrics across different groups or studies.

Integrated analysis can then be conducted under various advanced analytical model frameworks (Figure 23.2). IPD meta-analysis can be very attractive in the sense that it can achieve two important goals: (1) strengthening our inference on prespecified (or confirmatory) hypotheses; and (2) giving an opportunity for serendipity, namely exploring new insights from IPD. In relation to the second goal, subgroups or moderated relationships can be examined via analyzing IPD (Borenstein & Higgins, 2013; Brown et al., 2013; Sutton & Higgins, 2008). Moderated effects require large samples to detect when they truly exist. The availability of both individual-level and study-level covariates makes it feasible to formally test these moderated relationships.

Within the IDA framework, one-step analysis is probably more typical, but places a greater burden on IDA researchers to resolve any discrepancies between studies and to deal with missing data as pooled IPD is analyzed in a single analytical model. Alternatively, two-step integrative analysis can proceed as follows: IDA researchers, after harmonizing data across studies (see the Selection of Variables and Harmonization of Groups and Measures section), develop a common analytical model and conduct separate analysis for each study included in the pooled data set. Estimates resulting from separate analyses from the first step can then be pooled across studies in the second integrative step (see the Outcome Analysis section for examples). Relative to the one-step approach, this may more flexibly address design differences across studies when analyzing the combined data. Alternatively, the two-step IDA can be conducted by original investigators under the same analytic strategy instead of sharing original data sets with IDA researchers (Brown et al., 2013). Brown and colleagues called this a *parallel analysis* strategy. Choosing an appropriate method for IPD meta-analysis may depend on several factors, including how easily data can be shared among researchers; how similar and dissimilar studies are in relation to research questions; the number of studies and, more generally, the dimension of the combined data; and how resources and research credits can be shared between research teams. IDA or IPD meta-analysis is a relatively new approach, but its applications are expected to increase in the coming years.

The current chapter will present methods of research synthesis for the field of developmental psychopathology, present classical and emerging meta-analysis approaches, provide data examples, and discuss future directions.

UTILITIES FOR RESEARCH IN DEVELOPMENTAL PSYCHOPATHOLOGY

In a review of the past achievements of developmental psychopathology and its future directions, Cicchetti and Toth (2009) stated that developmental psychopathology as a discipline has long sought to transcend many existing dualisms to better understand the developmental processes involved in maladaptive, as well as competent, trajectories across the life course. In addition to breaking down the schism between normative and nonnormative development, developmental psychopathology as a field has advocated a systems perspective (Ford & Lerner, 1992) and a holistic approach to development (Magnusson, 2000) to better understand complex developmental processes. The dynamic systems perspective and its nonlinear analytic tools, when combined with better known concepts and tools for linear statistical modeling approaches, may help to break the existing knowledge barriers in the literature.

Researchers in the field of developmental psychopathology have been early adopters of advanced analytical methods and led debates about their utilities (e.g., Bergman & Magnusson, 1997; Sterba & Bauer, 2010). Furthermore, researchers have championed the importance of maintaining feedforward and feedback loops between etiological discovery-oriented research and prevention and intervention research, while emphasizing that cultural vistas may affect the developmental processes of those living in them (Cicchetti & Toth, 2009). In essence, developmental psychopathology is a discipline that synthesizes data either directly or indirectly in single studies or multiple studies across multiple systems, across scales, and across time. By doing so, developmental psychopathology transcends the typical boundaries of disciplines in search of new insights and ideas.

We discuss ways in which methods for research synthesis can help shed new light for the field of developmental psychopathology. Some of the application examples in the literature are discussed to highlight the benefits of IDA, as well as the areas for improvement in the future.

Etiology

One of the critical challenges for research in developmental psychopathology is to understand developmental continuity and discontinuity of an underlying problem despite changing or different norms across age, gender, race and ethnicity, and other contexts. Focusing on age-related patterns, specific behaviors can repeatedly be assessed using the same set of questions across age. However, the same behavior observed at different ages may signal different levels or forms of risk. Likewise, different behaviors observed at different ages may indicate the same underlying trait. There are many excellent examples across different research fields. In the field of alcohol research, for example, there is a clear age-related trend in the prevalence of alcohol use prior to, during, and after college years (Substance Abuse and Mental Health Services Administration, 2012), and its associated risks and consequences vary across these distinctive developmental phases (e.g., White, Lee, Mun, & Loeber, 2012). Similarly, the legal drinking age differs across countries (Kuntsche et al., 2013), which affects the meaning of early onset drinking and its associations with other risky behaviors across nations.

The basic understanding of the underlying continuity and discontinuity across developmental phases is needed for screening individuals for intervention and for a better understanding of the etiology of alcohol problems. This issue of the continuity and discontinuity across time has been widely noted as an important research goal in developmental psychopathology (Sroufe & Rutter, 1984). In reality, however, this goal is difficult to achieve in individual studies. The complexity related to age is exacerbated when we consider race and ethnicity, as well as other situational and contextual influences. Single studies are typically limited in terms of demographic, contextual, and other situational influences. When data from multiple studies are combined, however, one can examine age-related continuity and discontinuity across different contexts and evaluate its generalizability.

In one of the early research studies that utilized meta-analysis in developmental psychopathology, Weiss and Garber (2003) examined developmental differences in the manifestation of depressive symptoms by meta-analyzing core, as well as associated, symptoms from 20 studies that varied in age, gender, and source of samples (clinical, diagnosed, normative). A total of 29 symptoms were examined in relation to age by using Cohen's effect size estimate *d* (Cohen, 1988). They found that for the vast majority of symptoms, significant study-to-study (i.e., between-study) heterogeneity in estimates existed, indicating that age-related patterns in symptoms substantially differed across studies. Of the 10 symptoms that were not significantly heterogeneous, the following five symptoms—anhedonia, hopelessness, hypersomnia, weight gain, and social withdrawal—showed higher levels among older individuals, which supported the notion that the specific manifestations of depressive symptoms may vary with development. Due in part to the high percentage of study-level heterogeneity, however, Weiss and Garber concluded the evidence inconclusive to call depression developmentally isomorphic. However, the implicit assumption involved in the meta-analysis under which this question was examined (i.e., a common true effect across studies under fixed-effects models) may have been unnecessarily too strict.

Recent meta-analytic studies tend to focus on explaining between-study variation in effect sizes (between-study heterogeneity) rather than assuming that effect sizes are the same across all studies. In general, it is more plausible to assume that study-specific effect sizes exist across studies, due to observed and unobserved differences in study contexts, designs, outcome measures, interventions, and subjects (Borenstein, Hedges, Higgins, & Rothstein, 2009). When the results from various studies differ, one can use this as an opportunity to investigate factors that may account for the observed heterogeneity across studies by allowing study-level covariates to be included in meta-regression (see the Model-Based Approaches section). When IPD is available, the search for explanations can be done at both the individual- and study-level.

Some studies may combine data from just a few studies. AD meta-analysis starts with an extensive search of all eligible and available evidence. However, three-quarters of meta-analyses indexed in the *Cochrane Database of Systematic Reviews* include five or fewer studies (Davey, Turner, Clarke, & Higgins, 2011). Nonetheless, evidence from two studies is better than evidence from one study, if all else is equal. By pooling original data from multiple sources, even if limited in number, one can extend the period under observation and test hypotheses in a more heterogeneous, diverse sample, which can strengthen our confidence in the derived conclusions. These benefits may be particularly salient for IDA studies that combine data from long-term, longitudinal studies because these studies are virtually impossible to replicate and also because they tend to feature homogeneous samples.

For example, Hussong et al. (2007) obtained original IPD from two longitudinal studies of children of alcoholics (COAs) and combined them to examine externalizing behavior problems in COAs. The two longitudinal studies combined and harmonized were the Michigan Longitudinal Study (MLS; Zucker et al., 2000), a community-based study of alcoholic parents and their young biological children and comparison families within the same neighborhoods, and the Adolescent/Adult Family Development Project (AFDP; Chassin et al., 1991) that followed adolescent COAs and their matched controls as well as their parents. Most cohorts for the MLS were originally between the ages of 3 and 5 and followed up every 3 years thereafter, with yearly assessments between the ages of 11 and 17. The AFDP project interviewed the adolescents when they were between the ages of 11 and 15. They were followed up twice when they were between the ages of 12 and 16 and again between the ages of 13 and 17. The MLS had observations covering mostly from ages 3 to 14, whereas the AFDP had observations spanning from ages 10 to 17. When these two samples were combined, the overlap that existed for ages 10 to 14 provided an important chain in measurement models and the basis to test subsequent, substantive hypotheses. With the two distinctive but similar samples combined, an observational period was stretched from ages 2 to 17 for the entire combined sample. This pooled sample had some of the core characteristics (i.e., COAs and non-COAs) in common, but differed in other aspects (e.g., race/ethnicity, and geographical and socioeconomic backgrounds).

With the combined data described above, Hussong and her colleagues (2007) examined whether (1) the number of alcoholic parents in families; (2) comorbid parental diagnoses (i.e., depression and antisocial personality disorder); and (3) subtypes of parental alcoholism (i.e., controls, depressed alcoholic type, and antisocial alcoholic type) were linked to the development of externalizing behavior problems. They found that children in multi-alcoholic families were at greater risk for externalizing symptoms that emerged by mid-adolescence. Children in comorbid alcoholic families had a stable early risk for greater externalizing symptoms, compared to those in noncormobid alcoholic families. These observations were internally replicated—meaning that the effect was observed in two samples—within the same analytic model. Thus, in addition to lengthening an observational window and increasing sample heterogeneity, IDA can be used to provide opportunities for built-in, internal replications and for better-powered studies compared with single individual studies (Curran & Hussong, 2009; Hussong et al., 2013).

Infrequently or Rarely Observed Behaviors

Compiling and analyzing data from multiple, similarly designed studies can be particularly beneficial for research in developmental psychopathology when rare behaviors are of particular interest. In typical single studies, a low base rate behavior or atypical behavior is often ignored—neither researched nor reported. However, when isolated or infrequent behaviors of interest are aggregated across multiple studies, this combined information can provide a valuable insight for developmental psychopathology. For clinical trials, it is now required to report adverse effects as one of the basic data for the ClinicalTrials.gov site (Tse, Williams, & Zarin, 2009). Adverse effects can then be compiled across studies and used to assess the overall safety risk of clinical interventions, as well as the efficacy.

In the field of pharmaceutical clinical trials, there has been a high profile case in recent years, demonstrating the importance of infrequently observed behaviors and its treatment in analysis. It involves Avandia (rosiglitazone), marketed by GlaxoSmithKline (GSK), which was intended to improve blood sugar levels in diabetics. Nissen and Wolski (2007) compiled adverse event data from 42 studies and concluded that the drug significantly increased the risk for myocardial infarction (heart attacks). According to Finkelstein and Levin (2012), GSK's stock price dropped 7.8% on the day of the publication of the study by Nissen and Wolski. Thousands of lawsuits were filed against GSK, and in 2010 alone GSK had charges totaling $6.76 billion against earnings to deal with the Avandia cases (Finkelstein & Levin, 2012). Several other subsequent meta-analysis publications ensued that used different approaches (e.g., Liu, Liu, & Xie 2014; Tian et al., 2009) from the one taken by Nissen and Wolski. One of the most contentious issues surrounding this controversy involved the treatment of zero adverse observations in studies. Because the rate of adverse outcomes was low (i.e., approximately 0.5%), it was possible not to see any adverse outcomes in some of the small studies. In typical two-arm (i.e., treatment and control) clinical trials, if adverse outcomes are not observed in both arms, it is difficult to quantify the risk, because the risk is mathematically undefined using well-known risk measures, such as odds ratio. Nissen and Wolski chose to exclude data altogether from any studies with zero adverse observations and used Peto's method of combining odds ratios (Yusuf, Peto, Lewis, Collins, & Sleight, 1985; see the Peto's Odds Ratio section for Peto's method) only from studies with nonzero observations. Subsequent investigations tackled zero adverse observations in original studies by adding a constant, by imputing data, or by using alternative methods by which risk differences could be defined.

We can learn from this Avandia controversy that zero events can be important to report in original studies, and that they can and should be investigated by compiling data from multiple studies. Even if no reasonable statistical approach can be taken, zero events out of 100,000 cases certainly carry a different meaning than zero events out of 1,000 cases. Especially in the field of developmental psychopathology, many behaviors of interest that occur rarely have not been studied extensively. Although rare, these behaviors are nonetheless important to better understand because of their potentially huge impact. For example, using data from a longitudinal project on the development of delinquency and antisocial behavior among boys, Lee and White (2012) reported that those who experienced childhood maltreatment were more likely than those who did not experience it (defined as an officially substantiated record by age 13) to die before the ages 27–32 and ages 34–38, respectively, for two different birth cohorts. More specifically, 7.4% of 202 maltreated men died, whereas 2.5% of 711 nonmaltreated men died. Overall, 35 deaths were observed during the 913 person-year observation period, yielding an average mortality rate of 3,834 deaths per 100,000 person-years (7,426 for maltreated vs. 2,813 for nonmaltreated men). Many individuals followed-up by this project were exposed to violence in childhood and adolescence, and died from, or committed, homicide (see also Loeber et al., 2005). Childhood maltreatment, for this high-risk sample, further increased their risk of early death.

As the example described above shows, rare behavioral data have the potential to provide an important new insight in the field, yet many such behaviors have been understudied. From the analyst's perspective, it also makes sense to combine data from individual studies because low base-rate, binary behaviors (such as death or maltreatment) and their associated binomial confidence intervals can be quite erratic (Brown, Cai, & DasGupta, 2001). When data from multiple studies are combined, the number of cases increases, although average prevalence rate remains the same, which improves the stability of model estimation and reduces the influence of extreme observations, thus achieving better precision.

Even when behaviors of interest may not be as rare as what was previously discussed, many clinical outcomes of interest have generally low base rates. Behaviors with prevalence rates of 10 to 20% are huge numbers at the population level, but can still be difficult to study in single studies. The median and mean total sample sizes for articles published in four major psychological journals (*Journal of Abnormal Psychology, Journal of Applied Psychology, Journal of Experimental Psychology: Human Perception and Performance,* and *Developmental Psychology*) in 2006 were 40 and 196, respectively (Marszalhk, Barber, Kohlhart, & Holmes, 2011). At this level of sample size, a behavior with the prevalence of 5% or less, despite highly prevalent at the population level, would be practically impossible to examine in single studies. Furthermore, some of the advanced analytic approaches for nonnormally distributed data, including Poisson or zero-inflated hurdle mixed models, tend to be more complex and challenging and require many parameters to be estimated (Atkins, Baldwin, Zheng, Gallop, & Neighbors, 2013). Thus, pooling data from multiple, similar studies and analyzing them together for research synthesis can be particularly attractive for many clinical behaviors of interest.

Screening and Diagnostic Tests

It is important to develop screening and diagnostic tests and to derive cut-off scores that are sensitive for detecting true cases (i.e., sensitivity) yet correctly differentiate those cases that, in truth, do not meet the criteria (i.e., specificity). Only a small proportion of individuals typically meet any clinical criteria by definition. Thus, one can achieve better sensitivity and specificity estimates of a screening tool by combining multiple data sets. Both estimates—sensitivity and specificity—are important to simultaneously consider when making informed decisions under which a particular screening tool should be used. This is because these estimates are typically considered in the context of the cost of administering diagnostic or screening tests, and the consequences of missing potential cases and of falsely diagnosing noncases. In addition, these two estimates are *negatively related within studies* because lowering a threshold may enhance sensitivity but increase the likelihood that noncases are falsely identified as meeting the cutoff. As a result, these estimates are also related across studies. Thus, one estimate (either sensitivity or specificity) needs to be considered in the context of the other in the same analysis when pooling data from multiple sources (Reitsma et al., 2005). Failing to do so can lead to misleading or inaccurate conclusions.

One of the recent advances made in the meta-analysis methodological literature involves analysis of multiple, related outcome variables (see Jackson, White, & Thompson, 2010; see the Complex Research Synthesis section). The capacity to examine multiple related outcomes in a meta-analysis framework is an important advance when examining comparative advantages of various tools for diagnostic accuracy. In the field of medical research, Reitsma et al. (2005) reanalyzed data previously reported in a univariate meta-analysis that examined a single combined measure of sensitivity and specificity—the log of the diagnostic odds ratio (DOR; Scheidler, Hricak, Yu, Subak, & Segal, 1997)—using a bivariate meta-analysis. Their reanalysis provided contextualized, richer conclusions than the previous univariate meta-analysis of DOR (Scheidler et al., 1997). More specifically, Scheidler et al. concluded that three screening tools—lymphangiography (LAG), computed tomography (CT), and magnetic resonance imaging (MRI)—performed similarly when diagnosing lymph node metastases in women with cervical cancer. They further suggested that given the invasive nature of the LAG procedure, CT and MRI may be preferable over LAG. When both sensitivity and specificity were jointly estimated as two related outcomes in a bivariate meta-analysis, however, CT and MRI were found to be comparable in terms of sensitivity but LAG was significantly more sensitive than CT (Reitsma et al., 2005). In addition, LAG was lower in specificity compared to either CT or MRI. Thus, even though the three screening tools could not be distinguished in terms of their overall accuracy based on a single combined measure of sensitivity and specificity in the previous univariate meta-analysis (Scheidler et al., 1997), this new bivariate meta-analysis approach provided useful information about the relative accuracy of three different screening tools. Based on the new results, one may suggest that for high-risk individuals, the invasive nature of the LAG procedure be weighed less, in favor

of its better sensitivity, when making a decision about which screening tool to use. In contrast, for non-high-risk individuals, the lower specificity of the LAG procedure, which could lead to unnecessary anxiety, combined with its invasive nature, suggest that other screening procedures may be more preferable.

As illustrated in the example of cervical cancer screening tools, there is a value in knowing the unique estimates of both sensitivity and specificity from a clinical perspective when deciding which tools to use for whom. Given the purpose of screening measures, pooling data from independent studies can provide a *needed scale and diversity* in terms of both sample and clinical tool when examining relative advantages and disadvantages. In a way, it can emulate a multisite planned study without the enormous resource required. Similarly for etiological research, pooled data from multiple sources can provide a better sense of how strict or lenient one should be when deriving cutoff scores for positively meeting the diagnostic criteria, as the recommendation based on the finding from a single homogeneous sample may not be ideal for general populations. Screening individuals and reaching accurate diagnoses are the critical initial steps for formulating strategies for prevention and intervention. Therefore, research synthesis through innovative methods holds important promise for the field of developmental psychopathology.

Prevention and Intervention

In the era of evidence-based, health decision-making, central questions become those of *what works* (on the whole), *what works for whom* (subgroups or treatment modifiers), and *how it works* (mechanisms of behavior change). Although individual studies have long attempted to address these questions, there are good reasons to believe that findings from single studies alone may not be sufficient in guiding these evidence-based treatment decisions. First, there is a growing concern about the dismal reproducibility (replicability) in the biomedical and psychological research fields (Begley & Ellis, 2012; see also Ioannidis, 2005; Nosek, Spies, & Motyl, 2012), prompting further high-profile publications illustrating ironies about the *p*-values (Nuzzo, 2014) and calling for better standards for clinical trials (Begley & Ellis, 2012). Second, the effect sizes reported in single, typically small studies may be overestimated (Cumming & Maillardet, 2006; Kraemer, Mintz, Noda, Tinklenberg, & Yesavage, 2006). The magnitude of any intervention effect is important to correctly estimate to determine its cost effectiveness and to develop strategies for dissemination. However, effect size estimates vary widely across studies that differ in designs, measures, and participants; thus, research on the true magnitude of the intervention effect may be necessary via large, controlled multisite studies or meta-analysis studies.

The danger of overly relying on evidence from individual studies can be seen in the case of the efficacy of antidepressants in recent literature. Turner, Matthews, Linardatos, Tell, and Rosenthal (2008) meta-analyzed the data submitted to the Food and Drug Administration (FDA) between 1987 and 2004 (i.e., 74 individual trials for a total of 12 drugs and 12,564 patients), and compared their own findings with the published findings from the same trials. Their reanalyses indicated that effect sizes had been substantially overestimated in published studies (i.e., publication bias; see the Publication Bias and Selection Bias section). On average, Turner and colleagues found a 32% difference in effect size estimates between the FDA data and the published data. Thus, supporting evidence for intervention efficacy in single studies may be best viewed cautiously. Subsequent analysis found that this positive outcome bias was associated with deviations from study protocol, such as switching from an intent-to-treat analysis to a per-protocol analysis (Moreno et al., 2009). Similarly, a recent reanalysis of randomized clinical trial data reported that 35% of the reanalyzed studies required a different interpretation from that of the original article, including changed direction, magnitude, and statistical significance of findings (Ebrahim et al., 2014).

There is another source of bias in our perception of evidence for intervention efficacy. Researchers investigating interventions are more likely to cite previous studies with positive outcomes than equally valid studies with disappointing outcomes; this is referred to as the *optimisim bias* (also referred to as the *citation bias*; Chalmers & Matthews, 2006). This bias, along with the publication bias, can have harmful consequences, such as spending limited resources on less promising trials instead of spending time and resources to develop better interventions.

In the next section, we provide a review of quantitative methodologies that are aimed at synthesizing information from multiple studies. We focus on methods for AD meta-analysis, IPD meta-analysis, and IDA.

RESEARCH SYNTHESIS

The first known use of a meta-analytic method was by Karl Pearson in 1904. Pearson examined the association between inoculation and mortality from typhoid among soldiers who had volunteered for inoculation against

typhoid for their deployment in various places across the British Empire (O'Rourke, 2007). It was not until 1976 that the term *meta-analysis* was introduced by Gene Glass as "the statistical analysis of a large collection of analysis results from individual studies for the purpose of integrating the findings" and the method took off (O'Rourke, 2007; p. 580). Meta-analysis has caught on in many substantive fields, especially in medicine. For the past two decades, the Cochrane Collaboration (2013, http://www.cochrane.org/about-us) has been a major influence in the field of medical research, conducting over 5,000 systematic reviews that can affect evidence-based health decisions. Recent methodological advances in the field of meta-analysis include methods utilizing IPD and complex meta-analysis methods, such as multivariate meta-analysis and meta-regression. Below we review some of the considerations needed for conducting meta-analysis. We then review classical and model-based approaches to meta-analysis as well as complex research synthesis methods involving IPD or multivariate meta-analysis.

Inclusion Criteria for Studies

One of the first decisions in research synthesis involves which studies should be screened and combined. In meta-analysis, inclusion and exclusion criteria for selecting studies need to be carefully specified to protect against selection bias. There are two stages of screening in a typical meta-analysis. The first stage determines eligibility criteria that are based on the goal of the meta-analysis to ensure that only relevant studies are included. The second stage involves more careful screening and coding of relevant information (Berman & Parker, 2002).

As in any empirical research, research synthesis starts with certain goals that it is intended to meet. Is the study intended to derive average effect sizes of the relationships between emotion regulation strategies and symptoms of psychopathology in observational studies? Or is it to validate findings from a new intervention to general populations? Depending on the answers to these questions, studies to be included or excluded can be decided. For the former objective, it may be reasonable to include both cross sectional and longitudinal studies that are observational or etiological in nature, as well as experimental studies. For the latter question of the efficacy of a new intervention, however, it would be reasonable to eliminate any single studies that are not randomized controlled trials.

As an illustration, there are several meta-analysis or systematic review studies in the field of brief alcohol interventions for college students (Carey, Scott-Sheldon, Carey, & DeMartini, 2007; Carey, Scott-Sheldon, Elliott, Garey, & Carey, 2012; Cronce & Larimer, 2011; Larimer & Cronce, 2007). The review by Cronce and Larimer (2011), which was not quantitative but systematic, was intended to provide a quick overview of recent findings in the field of alcohol interventions for college students. Cronce and Larimer used the following inclusion criteria: studies should (1) report alcohol-focused behavioral outcomes from individual-focused preventive interventions for college students; (2) be published or conducted between 2007 and 2010; and (3) utilize a randomized controlled trial (RCT) or quasi-experimental design (i.e., one active condition and one control or wait-listed, and randomization). Similarly, Carey et al. (2007) included any published studies in their meta-analysis if studies (1) examined any educational, behavioral, or psychological alcohol intervention; (2) sampled college or university students; (3) used an RCT design; (4) assessed drinking behaviors as outcome measures; and (5) provided sufficient information to calculate between-group effect size estimates. These inclusion criteria set the boundaries of the generalizability of subsequent inference. Based on these inclusion criteria, a list of search terms may be developed to cast a wide net during the search phase. A flowchart (e.g., the *P*referred *R*eporting *I*tems for *S*ystematic reviews and *M*eta-*A*nalysis [PRISMA]; Moher, Liberati, Tetzlaff, Altman, & The PRISMA group, 2009) is often provided to show the systematic search and selection process of eligible studies, which looks like a CONSORT flowchart (Schulz, Altman, & Moher, 2010) for an RCT.

The American Psychological Association (APA) Publications and Communications Board Working Group (2008) developed the meta-analysis reporting standards (MARS), which are different from the journal article reporting standards (JARS) for typical empirical articles. The MARS includes specific recommendations for all sections of a meta-analysis. Specifically, for describing search strategies, the MARS recommends that the following information be provided:

- Reference and citation databases searched
- Registries searched and keywords used
- Time period in which studies needed to be conducted
- Other efforts to retrieve all available studies, including listserv queries and personal contacts made
- Method of addressing reports in languages other than English
- Process for determining study eligibility, including aspects of studies examined, number and qualification of judges, and their agreement
- Treatment of unpublished studies

And for coding procedures:

- The number and qualification of coders
- Interrater agreement and how disagreements were resolved
- Assessment of study quality
- How missing data were handled

In the case of IDA investigations of etiological and longitudinal studies, the number of similar studies may be fairly limited. Some of the studies considered for IDA investigations may be ongoing and complex, and data may not be available publicly. In such situations, the availability of the original investigators throughout all phases of IDA may become one of the important considerations. Etiological longitudinal studies focusing on developmental pathways of children of alcoholic parents (e.g., Hussong, Huang, Curran, Chassin, & Zucker, 2010) or twin or genome-wide association studies (GWAS; Schumann et al., 2011) that are geared toward understanding genetic susceptibility in the regulation of alcohol consumption may be such examples.

When original studies are under way at the same time as IDA investigations, an additional set of considerations at the outset of IDA investigations may be especially helpful. Hussong et al. (2013) recommended the following steps when building the supportive team science environment needed for IDA research: (1) decide how the responsibility and resources for data preparation will be divided up between the original study teams and the IDA research team; (2) make clear what the IDA study aims to answer that is different from the aims of original research projects; (3) coordinate research teams across manuscripts within the IDA study and the original study teams; (4) reflect the contributions of researchers in a balanced way when deciding publication credit; and (5) communicate about study differences and reconcile any discrepancies between IDA study findings and original study publications.

An alternative model of collaborations between the original and IDA investigators may be a prospective one. In the field of genetic epidemiology, there is a movement toward establishing collaborative networks of consortia prospectively from the onset of studies with the possibility in mind that their data may be utilized as an input data set for a larger investigation down the road (Ioannidis et al., 2006). In prospective collaborations, some of the critical design elements, such as phenotypes, exposures, end points, and analyses, can be coordinated in advance to be sufficiently similar or the same across studies within consortia (i.e., *networks of single studies*; see also Figure 23.4). This type of prospective collaborations among researchers can lessen the burden of labor-intensive data unpacking (Hussong et al., 2013) needed for typical IDA investigations in the future.

Publication Bias and Selection Bias

When planning a meta-analysis, one needs to consider the potential threat of publication bias. *Publication bias* or *file drawer problem* refers to the selective publication of studies with statistically significant outcomes (e.g., beneficial

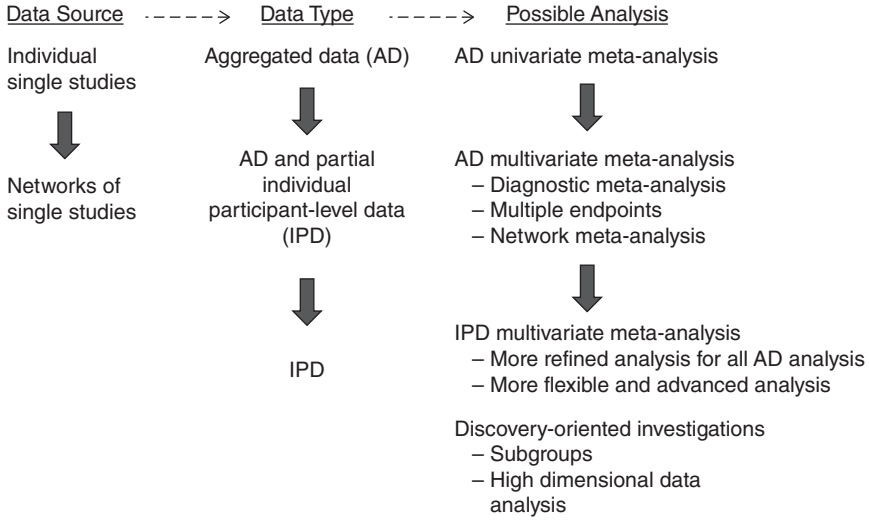

Figure 23.4 Current and future directions of research synthesis. Black arrows indicate the emerging directions and dotted arrows indicate the flow of research synthesis from data to analysis. Note that IPD approaches are computationally intensive and may not always be feasible.

intervention effects). The inclusion of unpublished data in meta-analysis may be helpful for avoiding or lessening publication bias. However, some authors have used the inclusion of only published studies to ensure some minimal research standards. As an alternative, individual studies can be scored on a number of items that indicate quality. Summed *quality scores* can then be used when deciding a minimum threshold score for studies to meet to be included or as study weights in a meta-analysis. However, it should be cautioned that quality scores can be calculated in many different ways, which can result in different conclusions (Herbison, Hay-Smith, & Gillespie, 2006), despite sharing common frameworks (Chalmers et al., 1981; Shadish et al., 2002) for assessing the validity of studies.

Publication bias can happen if oversampling of studies with significant findings occurs because they are more easily identifiable or accessible or because they are from colleagues in the same discipline (i.e., citation bias, availability/cost bias, familiarity bias; Borenstein et al., 2009). *Selection bias* can occur when studies are included or omitted for systematic reasons. For example, authors may include certain types of studies in meta-analysis while excluding or missing others selectively, which can result in a biased sample of studies. A recent review of meta-analysis studies published in the American Psychological Association and the Association for Psychological Science journals from 2004 to 2009 indicates that meta-analysis studies that include unpublished studies are just as likely to show evidence of publication bias as those that do not, due to selection bias (Ferguson & Brannick, 2012).

There are several ways to examine publication bias. A *funnel plot* is a graphical approach to examining publication bias. It displays the estimated effect sizes on the x axis and sample size or related measure (e.g., standard error) on the y axis for a sample of studies. It is based on the assumption that smaller studies will exhibit more variable effect sizes due to their lack of precision, and thus the scatter plot should look like a funnel. Figure 23.5 shows examples of a funnel plot. An asymmetrical funnel plot (bottom figure) suggests the presence of publication bias. Several other procedures also exist, such as the trim-and-fill method (Duval & Tweedie, 2000), Begg and Mazumdar's rank correlation test (Begg & Mazumdar, 1994), and Egger's regression asymmetry test (Egger, Smith, Schneider, & Minder, 1997). Nonetheless, the presence of this publication bias is not always examined or adjusted in a meta-analysis. Ferguson and Brannick (2012) found that 30% of the recent meta-analysis studies did not report checking publication bias in their sample of studies.

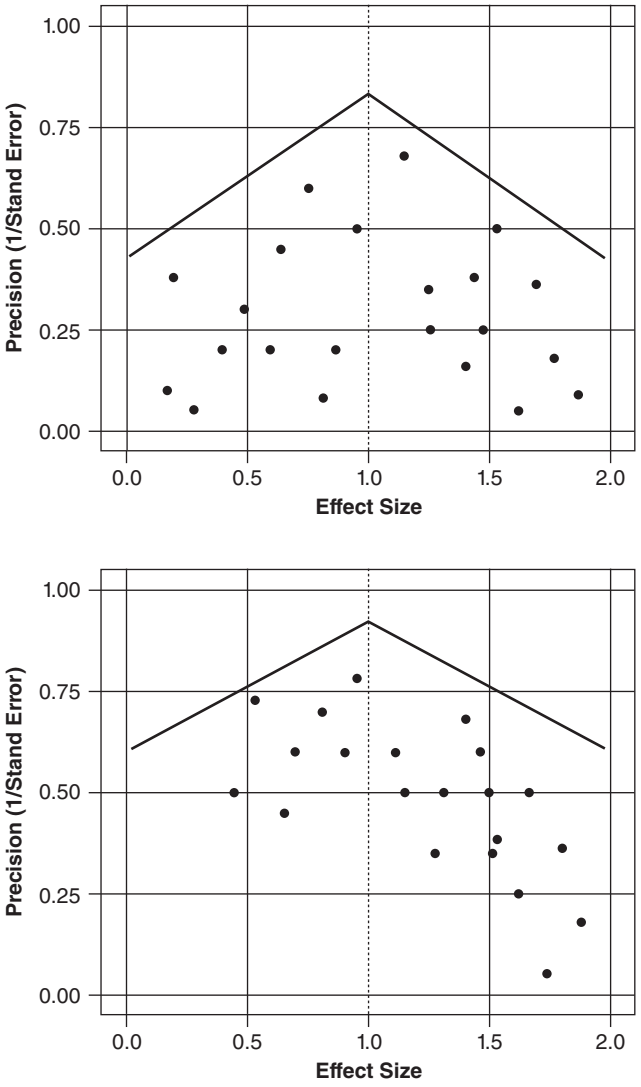

Figure 23.5 Symmetrical (top) and asymmetrical (bottom) funnel plots. The bottom figure shows evidence of publication bias.

Selection of Variables and Harmonization of Groups and Measures

Next, what are the outcomes of interest? For this question, outcome variables need to be operationally defined. In medical research, often an outcome is the occurrence of a certain binary event, such as morbidity (yes–no) and mortality (yes–no) as end points of a disease, and therefore can clearly be defined using a binary indicator. In other situations, a success may be operationally defined based on meeting cutoff scores on some indicator variables. For example, alcohol consumption can be quantified as the alcohol intake per day in grams of pure alcohol (e.g., Roerecke & Rehm, 2012) to examine the relationship

between alcohol use and ischemic heart disease (IHD). The average amount of alcohol consumed per day can then be categorized as less than 12 grams (one standard drink) or more than 24 grams (more than two standard drinks).

For psychological traits, however, it is more difficult to place individuals on common metrics (Curran & Hussong, 2009; Huo et al., 2014). Furthermore, the definition of a critical independent variable (e.g., intervention conditions) can be substantially different at the operational level across studies; thus, it must be made equivalent across studies before any synthesis can be conducted. In the IDA study of brief motivational interventions (BMIs) for college students (Mun et al., 2015), for example, we found that some of the intervention and control groups sharing the same labels were not equivalent across studies in terms of their intervention content, personalization, and other procedures. In the case of control groups, they differed, ranging from an assessment-only control group to a treatment-as-usual control group. In some studies, a treatment-as-usual group was closer to an educational group than to an assessment-only control group. We addressed this problem by carefully coding all intervention content materials and their delivery characteristics, which was carried out by two independent expert raters (Ray et al., 2014). Similarly, the operational definition of alcoholic parents can be slightly different across the three longitudinal studies of children of alcoholics included in the Cross Study Project (Hussong et al., 2013). Some of the between-study differences may be accounted for by adding covariates (e.g., COA and COA by study) in subsequent analytic models. When possible, however, it may be best to harmonize groups and derive equivalent measures across studies, prior to analysis, to reduce between-study heterogeneity. More important, any reported findings may be biased without the commensurate measures and groups established across component studies.

As for the selection of variables for outcome analysis, harmonization of measures is typically not required for meta-analysis using AD since the unit of analysis is already standardized. However, this is a serious challenge for IPD meta-analysis or IDA. The need for ensuring commensurate measures across studies is widely discussed as a notable barrier for IDA or meta-analysis using IPD, especially in psychological research (Cooper & Patall, 2009; Curran & Hussong, 2009). As indicated in the literature, the resources needed to establish commensurate measures for individuals within and across studies are quite extensive (Hussong et al., 2013; Mun et al., 2015, for detail). The task of establishing measurement equivalence starts from poring over codebooks and data to see if they are consistent across time within studies as well as across studies. If items are different in terms of the referent time frame, stem, or body of questions, or if response options are different across studies, they should be treated differently until these differences are resolved through harmonization processes. Some of the examples can be seen in Hussong et al. (2013) and Mun et al. (2015).

Once the demanding data preparatory work is completed, one can proceed to analyze measurement models specifically developed to meet the unique needs of each IDA study. In the field of psychological IDA research, item-level data have been analyzed via utilizing item response theory (IRT) based models or factor analysis (FA) based models. These models include a unidimensional, two-parameter logistic (2-PL) IRT analysis (Curran et al., 2008; Hussong et al., 2007), a multi-unidimensional 2-PL IRT analysis for multiple groups (Huo et al., 2014), a generalized partial credit model (Mun et al., 2015) for polytomous items, and longitudinal invariant Rasch test analysis (LIRT; McArdle, Grimm, Hamagami, Bowles, & Meredith, 2009). For other applications, moderated nonlinear factor analysis (MNLFA; Bauer & Hussong, 2009; Curran et al., 2014) has been utilized. Each analytical approach, although the goal of the task remains the same, has originated to address the unique demands of different IDA studies.

The entire process of establishing common metrics across studies, starting from checking data to estimating latent trait scores, can quickly become quite complex as the number of items in studies increases, as the number of studies increases, and as the number of observations or the observed duration increases. Liu, Liu, and Xie (2015) considered a new methodology to synthesize information from independent studies with heterogeneous designs, which may help to lessen the constraint that common design metrics exist across studies. But more research is still needed. Some of the challenging issues that arise from more complex situations include missing data, high dimensionality, and differential item functioning (DIF) (see Mun et al., 2015, for detailed discussion). Other measurement models, adaptations, and computing algorithms are expected to accommodate these challenges in the field of IDA research in the future.

Classical Meta-analysis Approaches

The earliest meta-analysis approaches combine *p*-values, which is particularly suitable for situations under which the only available data in original studies are *p*-values or *z* statistics. There are also a number of classical approaches

for synthesizing discrete and, in particular, binary data from independent studies. In this section, we review these approaches.

p-Value Combination

Assume that the p-values from original studies test the same null hypothesis. We can use Fisher's method (Fisher, 1948), which can be traced back to the 1930s, to combine the p-values and provide an overall inference. Consider the case with k studies. Fisher's method combines the p-values into a X^2 test statistic using the formula

$$X_{2k}^2 = -2\sum_{i=1}^{k} \ln(p_i) \sim \chi_{2k}^2$$

where p_i is the p-value of study i. Under the null hypothesis, the test statistic X^2 has a chi-squared distribution with $2k$ degrees of freedom. We often use this combined X^2 test statistic to obtain an overall p-value for combined inference. Another closely related approach is Stouffer's Z (Stouffer, Suchman, DeVinney, Star, & Williams, 1949). This approach converts p-values to Z scores first and then combines the resulting Z scores. More specifically, we first let

$$Z_i \sim \Phi^{-1}(1 - p_i)$$

where Φ is the standard normal cumulative distribution function. Then, the combined Z score

$$Z \sim \frac{\sum_{i=1}^{k} Z_i}{\sqrt{k}}$$

follows a standard normal distribution under the null hypothesis. Other p-value combination methods include Tippett's (Min) method, Max method, and Sum method, etc. (Marden, 1991).

Weights can also be applied in p-value combination methods to account for different sample sizes across studies and to improve the efficiency of the combination methods. For instance, in Stouffer's Z score method, if the Z score for study i is weighted by w_i, then the combined weighted Z score is

$$Z \sim \frac{\sum_{i=1}^{k} w_i Z_i}{\sqrt{\sum_{i=1}^{k} w_i^2}}.$$

Along with the unweighted Stouffer's Z score, the weighted Z score follows a standard normal distribution under the null hypothesis. Note that Stouffer's Z score method, as well as other p-value combination methods, can be used also for combining results from multiple independent tests within a single study (see Donovan, Wood, Frayjo, Black, & Surette, 2012, for an example of how this method can be used in applied research).

Combining 2 × 2 Tables

Mantel-Haenszel Method

Many outcomes of interest are binary, discrete event data. There can be many important, naturally binary outcomes, such as mortality or meeting the diagnostic criteria for disorders. Whether an adverse event occurred following a pharmaceutical trial is also one example. Even with continuous numerical data, dichotomizing may be preferable in some situations (Shentu & Xie, 2010) when there are errors in measurement or when obtained data can be naturally fluctuating due to their sensitivity to internal and external stimulation (e.g., blood pressure). Furthermore, dichotomized outcomes can be more straightforward to communicate to various stakeholders (Mun, Bates, & Vaschillo, 2010).

To explain some of the methods for binary data, Table 23.2 shows model setting for 2 × 2 tables for k independent studies, where X_i and Y_i follow a binomial distribution with fixed numbers n_i and m_i of binary observations, respectively. We denote $X_1, X_2, \ldots, X_k$ and $Y_1, Y_2, \ldots, Y_k$ as responses for k studies following binomial distributions with expectations expressed as p_1 and p_2, respectively; t_i stands for the total number of events for study i. For discrete binary data, odds ratio or log odds ratio is often used as an effect size estimate. Some studies also consider other measures, such as risk ratio, risk difference, etc. The goal of a meta-analysis for 2 × 2 tables is to synthesize the overall effect across k independent studies.

The Mantel-Haenszel (MH) method (Mantel & Haenszel, 1959) estimates common parameters from 2 × 2 tables under a fixed-effects model, which assumes a common odds

TABLE 23.2 Model Setting of 2 × 2 Tables for *k* Independent Studies

	Event	Nonevent	Total
Treatment	X_i	$n_i - X_i$	n_i
Control	Y_i	$m_i - Y_i$	m_i
Total	t_i	$N_i - t_i$	N_i

ratio across studies (see Table 23.2 for the model setting used). The MH method proceeds:

- Estimate odds ratio and its variance for each individual study:

$$\hat{\pi}_i = \frac{R_i}{S_i} = \frac{\frac{X_i(m_i - Y_i)}{N_i}}{\frac{Y_i(n_i - X_i)}{N_i}} \text{ and}$$

$$\widehat{Var}(\hat{\pi}_i) = \hat{\pi}_i^2 \left(\frac{P_i}{R_i} + \frac{Q_i}{S_i} \right)$$

$$= \hat{\pi}_i^2 \left(\frac{1}{X_i} + \frac{1}{n_i - X_i} + \frac{1}{Y_i} + \frac{1}{m_i - Y_i} \right) \text{ where}$$

$$R_i = \frac{X_i(m_i - Y_i)}{N_i}, \quad S_i = \frac{Y_i(n_i - X_i)}{N_i},$$

$$P_i = \frac{X_i + m_i - Y_i}{N_i}, \text{ and}$$

$$Q_i = \frac{Y_i + n_i - X_i}{N_i}$$

- Estimate the combined odds ratio from k studies:

$$\hat{\pi}_{MH} = \frac{\sum_{i=1}^{k} R_i}{\sum_{i=1}^{k} S_i} = \frac{\sum_{i=1}^{k} \frac{X_i(m_i - Y_i)}{N_i}}{\sum_{i=1}^{k} \frac{Y_i(n_i - X_i)}{N_i}}$$

and

$$\widehat{Var}(\hat{\pi}_{MH}) = \hat{\pi}_{MH}^2 \left[\frac{\sum_{i=1}^{k} P_i R_i}{2\left(\sum_{i=1}^{k} R_i \right)^2} + \frac{\sum_{i=1}^{k} \left(P_i S_i + Q_i R_i \right)}{2\left(\sum_{i=1}^{k} R_i \right)\left(\sum_{i=1}^{k} S_i \right)} + \frac{\sum_{i=1}^{k} Q_i S_i}{2\left(\sum_{i=1}^{k} S_i \right)^2} \right]$$

The MH method provides consistent and asymptotically efficient estimates when study sizes are large or when a large number of small studies are combined (Breslow, 1981). Standard error of estimate can be obtained by using the final previous equation (Robins, Breslow, & Greenland, 1986).

Peto's Odds Ratio

Peto's odds ratio method (Yusuf et al., 1985) is also commonly used for 2 × 2 table data in meta-analysis. Similar to the MH method, it yields a weighted log odds ratio estimate under the fixed-effects model framework (see the Model-Based Approaches section). However, this method is different from the MH method in the sense that, instead of using observed odds ratios, an approximated log odds ratio is calculated for each study and then combined. Hence, it is sometimes known as the Peto's one-step method or the "O–E" method since log odds ratio is estimated by using the observed number of events (O) and the expected number of events (E).

Peto's odds ratio method can be computed as follows:

- Estimate log odds ratio and its variance for study i:

$$\hat{\theta}_i = \frac{O_i - E_i}{V_i}$$

$$\widehat{Var}(\hat{\theta}_i) = \frac{1}{V_i}$$

where $O_i = \mathrm{X_i}$, $E_i = \frac{t_i n_i}{N_i}$, $V_i = \frac{t_i m_i n_i (N_i - t_i)}{N_i^2 (N_i - 1)}$

- Estimate the combined log odds ratio from all k studies:

$$\hat{\theta}_{Peto} = \frac{\sum_{i=1}^{k} O_i - \sum_{i=1}^{k} E_i}{\sum_{i=1}^{k} V_i}$$

and

$$\widehat{Var}(\hat{\theta}_{Peto}) = \frac{1}{\sum_{i=1}^{k} V_i}$$

For both the MH and Peto's methods, the confidence interval for the estimated log odds ratio can then be obtained by using the previous formula along with z critical value. The Peto's method, as well as the MH method, relies on the combined estimators approximating to a standard normal (z) distribution.

Both the MH and Peto's methods rely on large sample theory to justify the validity of the approaches. There is also an exact meta-analysis method for combining 2 × 2 tables based on Fisher's exact test and conditional likelihood inference (see, e.g., Gart, 1970). For the parameter of risk difference, Tian et al. (2009) proposed a simple

procedure to combine confidence intervals of risk difference for 2 × 2 tables without assigning any arbitrary numbers to empty cells in meta-analysis, and reanalyzed the controversial data reported in Nissen and Wolski (2007). For more recent discussions of exact meta-analysis of discrete data, see Liu et al. (2014).

Data Example

To illustrate combining discrete binary data across similar studies, we utilize the intervention data reported in Wilk, Jensen, and Havighurst (1997). Wilk and colleagues examined the effectiveness of brief alcohol interventions targeted for adult heavy drinkers. They searched for brief interventions that were (1) motivational in nature, (2) as short as 10–15 minutes, and (3) aimed to reduce drinking and related harm to treat nondependent heavy or problem drinkers. Two databases, MEDLINE and PsychLIT, were searched with the following, more specific inclusion criteria: (1) focus on alcohol abuse/dependence or heavy drinking; (2) focus on intervention and outcome; (3) human subjects between the ages of 19 and 65; (4) publication in English; and (4) a randomized control trial that includes a control group. The resulting sample consisted of 3,948 heavy drinkers across 12 clinical trials. The brief interventions common to all trials were short, and all sessions included feedback, education, and advice. The intervention outcome was measured by using a binary indicator of moderated alcohol use at 6–12 months post intervention. Of the 12 trials, eight reported outcome data. Table 23.3 shows 2 × 2 tables, observed odds ratios, and their associated confidence intervals (last column) for all eight studies as well as overall estimates from the Peto's one-step method and the MH method (the bottom two rows).

For the purpose of illustration, here we use the 2 × 2 table for the second study (Study 2 in Table 23.3). Moderation in use indicates that participants reduced their heavy drinking, whereas nonmoderation indicates no change in drinking at 6–12 months post intervention. Typically, odds ratio, as a measure of association, is highly skewed and asymmetrical. Thus, log odds ratio and its standard errors are often computed instead for inference. The log odds ratio for Study 2 can be calculated using

$$\text{Log OR}_2 = \log\left(\frac{14/66}{4/70}\right) = \log\left(\frac{14\times 70}{4\times 66}\right) = 1.31.$$

Next, we show how to compute the corresponding 95% confidence interval. First, the standard error of the log odds ratio 1.13 is

$$se_2 = \sqrt{\frac{1}{14}+\frac{1}{66}+\frac{1}{4}+\frac{1}{70}} = 0.59.$$

Assuming the log odds ratio is approximately normally distributed, its 95% confidence interval is

$$1.31 \pm 1.96 \times 0.59 = [0.15, 2.47].$$

TABLE 23.3 Pooling Data from 2 × 2 Tables Using the Peto's Odds Ratio and the Mantel-Haenszel Method

Article	Group	Moderation	Nonmoderation	Observed odds ratio	95% CI
			Individual study estimate		
1	Intervention	201	247	2.25	[1.70, 2.97]
	Control	122	337		
2	Intervention	14	66	3.71	[1.16, 11.85[a]]
	Control	4	70		
3	Intervention	9	24	1.09	[0.38, 3.11]
	Control	10	29		
4	Intervention	391	367	1.80	[1.40, 2.33]
	Control	134	227		
5	Intervention	9	50	1.74	[0.44, 6.95]
	Control	3	29

	Control	13	48		
			Pooled estimate		
Peto's odds ratio				1.95	[1.66, 2.30]
Mantel-Haenszel odds ratio				1.98	[1.67, 2.34]

Source: Wilk et al. (1997).
[a] = the upper limit of this *CI* is different from the text due to rounding.

This log odds ratio can then be converted back to odds ratio as follows:

$$\mathrm{OR}_2 = \exp(\mathrm{Log\ OR}_2) = \exp(1.31) = 3.71.$$

Similarly, the 95% confidence interval for the odds ratio can be obtained by exponentiation of lower and upper limits of the log odds ratio:

$$[\exp(0.15),\ \ \exp(2.47)] = [1.16, 11.82].$$

The MH estimate can be obtained by combining these odds ratios across studies via the combining equation shown previously. The MH odds ratio estimate was 1.98 with its 95% confidence interval ranging from 1.67 to 2.34.

Whereas the MH method combines observed odds ratios only, the Peto's method uses both observed and expected odds ratios (see the Peto's Odds Ratio section). Peto's log odds ratio for Study 2 can be calculated as

$$\mathrm{Log\ OR}_2^{\mathrm{P}} = \frac{14 - (14+4)\times(14+66)/(14+66+4+70)}{\mathrm{V}_2} = 1.16$$

and its associated standard error

$$\mathrm{V}_2 = \frac{(14+4)\times(4+70)\times(14+66)\times(66+70)}{(14+66+4+70)^2\times(14+66+4+70-1)} = 4$$

with

$$se_{\mathrm{Log\ OR}_2^{\mathrm{P}}} = \sqrt{\frac{1}{\mathrm{V}_2}} = 0.5.$$

If we convert the Peto's log odds ratio to odds ratio, it becomes 3.19, which is different from the previous observed odds ratio 3.71 obtained using the MH method.

The combined overall odds ratio across all eight studies using the Peto's method was 1.95 with its 95% confidence interval ranging from 1.66 to 2.30. The combined overall estimate is also different from that obtained by using the MH method. However, both estimates suggest we reject the null hypothesis. Based on the size of the overall odds ratio, our interpretation is that those who participated in the brief interventions were almost twice as likely to moderate their drinking compared to controls. The results from both methods are expected to be similar given that the rate (37%) of the outcome (i.e., moderation in drinking in the combined sample) was not too severely low, and also because the two randomized groups were similar in size. In other extreme data situations, the two methods can result in different conclusions. It has been shown that for meta-analysis of rare events (e.g., 1% or less), the Peto's method is the least biased and most powerful method, according to a simulation study that evaluated several methods, including the MH method (Bradburn, Deeks, Berlin, & Russell Localio, 2007). Bradburn et al. also observed that the Peto's method can yield biased results when sample sizes substantially differ between groups (e.g., treatment and control) in 2 × 2 tables, and that it yields worse results than the MH method (conducted without any corrections for zero cells) when the rate of event is not that extreme (5% or 10% as opposed to 1% or less).

Model-Based Approaches

There are at least two major sources of variation to consider when combining statistics (e.g., mean difference) across studies. First, *sampling variability* may vary across studies. Studies with larger samples have more information and hence better precision, which can be indicated in taller and narrower distributions. In contrast, studies with smaller samples have shorter and wider distributions and less precision surrounding their means (Figure 23.6). Second, the statistics of interest can be assumed to have a common value (Figure 23.6) or to have come from an underlying distribution of study-specific values (Figure 23.7). The first source of variation refers to *within-study variability* and the latter addresses *between-study variability*.

Fixed-Effects Model

A fixed-effects model assumes that each study summary statistic, Y_i, is a realization from a population of study

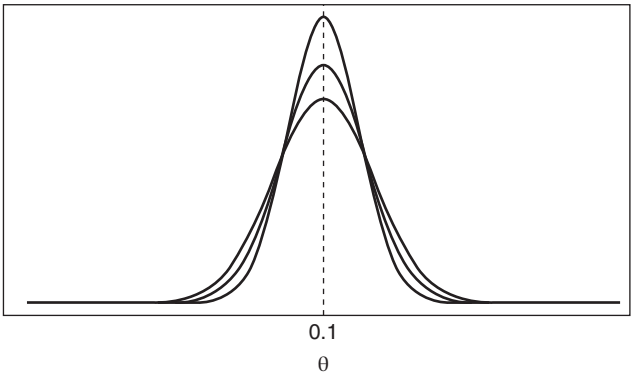

Figure 23.6 A fixed-effects model. It assumes a common underlying mean θ and different variances s_i^2 due to sampling variability for study i. This figure was drawn based on Figure 3 from Normand (1999).

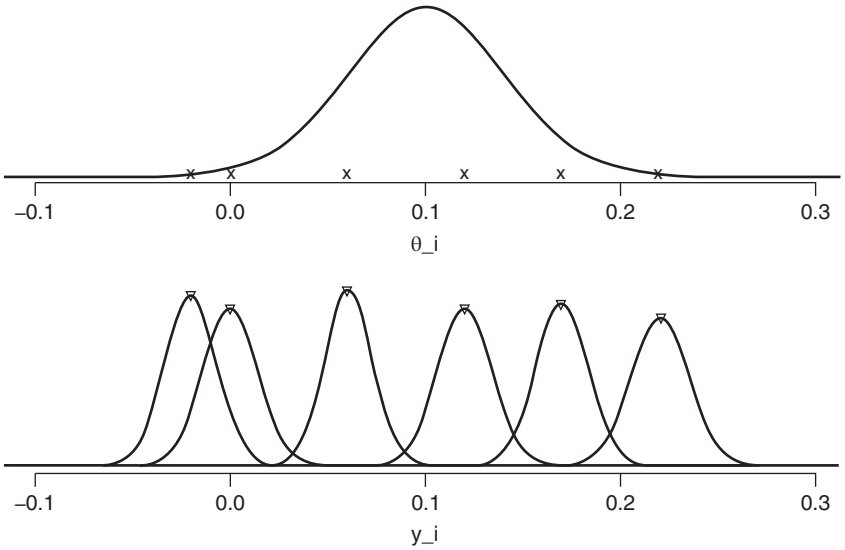

Figure 23.7 A random-effects model. It assumes a superpopulation with a mean θ and a variance τ^2 (top figure) from which distributions with different means θ_i and variances s_i^2 (bottom figure) are drawn. Figure 23.7 was drawn based on Figure 4 from Normand (1999).

estimates with a common true value θ. Let θ be the parameter of interest (e.g., mean intervention effect size) and there are $i = 1,\ 2, ..., k$ independent studies. Then, θ value quantifies the average effect size across k studies, which is assumed to be the same across studies (see Figure 23.6 for a graphic illustration) so that there is no subscript for θ. Variance of summary statistic, Y_i for study i is assumed to be known, which is denoted as s_i^2. This variance estimate can differ across studies and is indicated by subscript i. Within-study variability s_i^2 can be seen as tall and skinny (better precision) vs. short and wide (less precision) distributions in Figure 23.6.

A fixed-effects model usually takes the inverse variances (s_i^2) of the estimates as weights when pooling data. Between-study variability surrounding θ is assumed to be essentially zero or nothing more than what is expected from random errors. This can be more formally expressed as

$$Y_i \sim N(\theta,\ s_i^2) \text{ for } i = 1, 2, \ldots, k.$$

To see if this assumption holds, the test of homogeneity across studies is conducted by using the Q statistic (Cochran, 1950)

$$Q = \sum_i W_i (Y_i - \overline{Y}_w)^2$$

where W_i is the inverse of the sampling variance for study i and $\overline{Y}_W = \sum_i W_i Y_i / \sum_i W_i$ is the weighted estimator of the effect of interest (e.g., estimated mean intervention effect). Under the null hypothesis, Q follows a chi-squared distribution with $k - 1$ degrees of freedom. This test quantifies the extent of heterogeneity by examining the proportion of the total variation in point estimates that can be attributed to heterogeneity across studies. If the Q test is rejected, we can conclude that there exists significant variation across studies due to many reasons, including differences in study designs, procedures, measures, and samples. Note that this Q test suffers from low power (Sutton & Higgins, 2008), and I^2 test (Higgins & Thompson, 2002) may be an alternative. More important, it may be unrealistic and too strict to assume that there is one true common effect size across all studies and that no variability exists surrounding the true effect size (Jackson et al., 2010; Thompson & Pocock, 1991).

Random-Effects Model

A random-effects model assumes that each study summary statistic, Y_i, comes from a study-specific distribution, and that the expectations of these study-specific distributions follow a common distribution. Hence, in addition to within-study variability s_i^2, there is study-to-study variation surrounding the underlying common effect θ, which can be expressed as variance τ^2. The top figure in Figure 23.7 shows the underlying superpopulation with a mean θ and a variance τ^2, from which study-specific true effect size estimates are drawn.

These relationships can be expressed more formally as follows:

$$Y_i \,|\, \theta_i,\ s_i^2 \sim N(\theta_i,\ s_i^2) \text{ and } \theta_i \,|\, \theta,\ \tau^2 \sim N(\theta,\ \tau^2).$$

Hence, the distribution of each study summary measure, Y_i, after averaging over the study-specific effects, is normally distributed with mean θ and variance $s_i^2 + \tau^2$. The distribution of θ_i can be helpful for identifying subgroups of intervention procedures that are more effective. When between-study variability $\tau^2 = 0$, random-effects models reduce to fixed-effects models. Given that between-study variability τ^2 is typically greater than zero, fixed-effects models will almost always have narrower confidence intervals than random-effects models. Likewise, the larger the τ^2, the wider the confidence intervals for the effect of interest. This is because the underlying between-study variation of the effect is incorporated into weights in a random-effects model (DerSimonian & Laird, 1986).

Estimators of Variance

Most commonly used methods for estimating variance are the maximum likelihood estimator (MLE), restricted maximum likelihood (REML), DerSimonian and Laird (DL; DerSimonian & Laird, 1986), method of moments, and Bayesian (see Normand, 1999, for a review of estimators, including equations and detailed discussion). To obtain θ estimates in a model-based model, the MLE and Bayesian methods are used. The REML, DL, and method of moments are used to estimate between-study variance in a random-effects model. Note that both fixed-effects and random-effects models are typically based on the assumption of a normal distribution. Sensitivity to this distributional assumption or to any individual study may need to be examined (Normand, 1999). For example, leaving one study out of analysis in a series of analyses and examining the stability of the estimates across these analyses may be performed as part of sensitivity analysis. However, there may be limited options when a few studies are analyzed.

Fixed-Effects Versus Random-Effects Model

Synthesizing data from sufficiently similar studies that have some variation in measures, samples, and designs has an important benefit in that it provides new understanding about the boundaries of the effect being examined. When the evidence of a significant difference exists across studies based on the Q test of homogeneity, it is often used as the basis for choosing a random-effects model over a fixed-effects model. However, the significant Q test can also be used to imply that at least one study distinctively differs from others in the effect size estimates examined. In a meta-analysis of intervention studies, this may indicate the presence of an important subgroup in which the efficacy of intervention substantially differs from the rest. Thus, pooling these heterogeneous intervention studies into one model may not make sense when estimating the overall intervention effect size. For example, if there are outlier studies with strongly negative intervention effects, it may not be informative to include them with the rest of the studies that have clear positive intervention effects, only to yield no overall effect. Rather, it may be more useful to pool data only from *sufficiently similar* studies. Alternatively, the magnitude of heterogeneity across studies can be reduced by including informative covariates in the model. Covariates can be study-level variables for an AD meta-analysis and individual- and study-level variables for an IPD meta-analysis.

Otherwise, when heterogeneous studies are combined in a fixed-effects meta-analysis model, studies with larger samples can dominate the combined estimate in a meta-analysis, essentially throwing away studies with small samples (Al khalaf, Thalib, & Doi, 2011). Similarly, pooling data from heterogeneous studies in a random-effects model may yield findings that may shift an inverse variance weighted meta-analysis back toward an unweighted mean estimate (Al khalaf et al., 2011).

The decision of which model to use may depend on other practical considerations. When there is a sufficiently large number of similar studies with normally distributed outcome data (i.e., effect size estimates or IPD outcome variable), a random-effects model can be used, in which studies are viewed as a random sample drawn from a superpopulation of studies and, consequently, any resulting inference can be generalized back to this broad population. If there are a limited number of studies, however, one may need to be cautious about using a random-effects model, since in this case the between-study variability τ^2 may not be estimated accurately and the quality of the overall meta-analysis estimator may be affected. In such a situation, a fixed-effects model can be used not to draw broad inference but to obtain specific summary results about the pooled studies (see also Borenstein, Hedges, Higgins, & Rothstein, 2010).

Last, when the number of individual studies is finite, Claggett, Xie, and Tian (2014) proposed an alternative, resampling-based *nonparametric meta-analysis* approach that is more flexible than both random- and fixed-effects models. Note that, in the fixed-effects and random-effects models, we often assume that the underlying study-level parameters are either exactly the same across individual studies and that they are realizations of a random sample from a population (often normal), respectively. In the approach by Claggett et al., one needs to assume only that the study-level parameters are unknown fixed

parameters. This approach draws inferences about, for example, the quantiles of the set of parameters using study-specific summary statistics. This nonparametric approach proposed by Claggett et al. is more flexible than the fixed-effects model method, because it allows the underlying study-level parameters to be different across different studies. It is also more flexible than the random-effects model method because it does not need to limit the underlying study-level parameters to be from a normal distribution or any other assumed known distribution, and also because it accommodates any population of the underlying study-level parameters.

Unifying Approach to Synthesize Data from Multiple Studies

Xie, Singh, and Strawderman (2011) proposed a broad, unifying approach to combining data from multiple studies. This approach can encompass all of the procedures reviewed previously, including those from model-based approaches (i.e., fixed-effects and random-effects models using MLE or Bayesian estimator) under one inclusive theoretical umbrella. This approach by Xie et al. is more comprehensive than combining point estimates (e.g., means) or *p*-values like Stouffer's Z or confidence interval estimates from multiple studies. When combining data, it uses the so-called confidence distribution (CD). CD is a sample-dependent distribution function that can represent confidence intervals of all levels for a parameter of interest. It uses a distribution function, instead of a point (point estimator) or an interval (confidence interval), to estimate a parameter of interest. For example, in the simple normal example with sample $x_i \sim N(\mu, 1)$, for $i = 1, \ldots, n$, the CD approach invokes the distribution function $N(\overline{x},\ 1/n)$ to estimate, instead of estimating just a point estimate, sample mean $\overline{x}$ and 95% confidence interval $(\overline{x} - 1.96/\sqrt{n},\ \overline{x} + 1.96/\sqrt{n})$, for the parameter of interest, μ. Analogous to a Bayesian posterior distribution that contains a wealth of information for Bayesian inference, CD contains rich information for constructing frequentist inference (Xie & Singh, 2013). Unlike a few point estimators or confidence intervals, CD contains information about not only important point estimators—mean, median, and mode—but also confidence intervals of all levels and *p*-values for various tests. Depending on the set up, the CD approach to combining data can be used to make either *approximate* (i.e., justified based on large sample theory) or *exact inference* for the parameters of interest. The CD combining approach has also been generalized for *robust meta-analysis* that is resistant to errors in data, misspecified models, and outlying or bad studies (Xie et al., 2011). An R package *gmeta* has been developed to combine data using conventional as well as robust meta-analysis approaches (Yang & Xie, 2010).

Complex Research Synthesis

Complex research synthesis, although somewhat arbitrary to define, involves models that (1) incorporate evidence on multiple related parameters (e.g., multiple intervention comparisons or multiple end points—two or more related outcome variables), (2) specifically model data from different study designs (e.g., experimental studies and observational studies), or (3) involve raw IPD (Sutton & Higgins, 2008). In other words, complex research synthesis is a collection of emerging analytical approaches that are aimed at taking full advantage of existing data to respond to research questions not easily addressed in a single individual study or in a typical AD meta-analysis.

Multivariate Meta-analysis

Multivariate meta-analysis generally refers to the joint synthesis of multiple related parameters across studies, which can be found in terms of multiple intervention conditions, covariates, or outcomes, and repeatedly observed single measures. These variables are correlated within studies by their nature and are referred to as the *within-study correlation*. In contrast, the *between-study correlation* indicates how the true estimates are related among studies. A multivariate model takes into account within-study correlations, which allows one to *borrow strength* from other related data and obtain more desirable estimates. Riley (2009) demonstrated in a simulation study that ignoring within-study correlations results in increases in the standard errors of overall effect estimates (precision) and mean-square error (between-study variance), and results in bias when nonignorable missing data exist. The diagnostic application example we discussed in the Screening and Diagnostic Tests section (i.e., Reitsma et al., 2005) utilized a bivariate meta-analysis for the joint estimation of two related estimates (i.e., sensitivity and specificity). The utilities of multivariate meta-analysis, however, extend much beyond diagnostic meta-analysis. Multivariate meta-analysis methods can be utilized for synthesizing treatment effects on multiple related outcomes (also called *multiple end points*), multiple interventions, or exposure groups (also called *network meta-analysis*; see Jackson, Riley, & White, 2011, for a review).

More formally and generally, multivariate meta-analysis can be shown as below. When multiple outcomes are

synthesized using the framework of a random-effects model, we typically assume the following multivariate model:

$$\mathrm{Y}_i|\theta_i, \mathrm{S}_i \sim N(\theta_i, S_i)$$
$$\theta_i|\theta, \sum \sim N\left(\theta, \sum\right)$$

where Y_i denote the $p \times 1$ vector of outcomes of interest for study i; θ_i is the true underlying effect for study i; and S_i is the within-study covariance matrix, which is assumed to be known. N denotes the multivariate normal distribution with dimension p. We also assume that θ_i varies from study to study and follows a multivariate normal distribution with overall mean θ and between-study covariance matrix Σ. The estimate $\hat{\theta}$ can be expressed in terms of $\hat{\Sigma}$:

$$\hat{\theta} = \left(\sum_{i=1}^{n}\left(S_i + \hat{\Sigma}\right)^{-1}\right)^{-1}\left(\sum_{i=1}^{n}\left(S_i + \hat{\Sigma}\right)^{-1}\mathrm{Y}_i\right)$$

where $\hat{\Sigma}$ can be obtained by using the MLE, REML, method of moments, or Bayesian method. The estimated variance is

$$\mathrm{Var}(\hat{\theta}) = \left(\sum_{i=1}^{n}\left(S_i + \hat{\Sigma}\right)^{-1}\right)^{-1}.$$

If some studies have missing data for the vector of interest, one way of incorporating these studies with missing data in multivariate analysis may be to replace the missing data with estimates with a negligible weight and information. This can be achieved by setting very large within-study variances to the missing data points and by constraining within-study correlations with other end points to be zeros (Jackson et al., 2010). Thus, multivariate meta-analysis methods achieve better efficiency in using all available information than univariate methods.

The idea that multivariate meta-analysis should take into account the correlated nature of data when there are multiple end points is not new, although its utilization has been rare in applied research. Jackson and colleagues (2011) summarized the following five advantages of multivariate meta-analysis over univariate methods: First, we can obtain estimates for all effects in a single modeling framework. A single integrated multivariate meta-analysis is more elegant than multiple univariate ones. Conceptually, it is analogous to conducting a multivariate analysis of variance (MANOVA) as opposed to conducting a series of analysis of variance (ANOVA) when there is a need to analyze multiple related outcomes. Second, we can utilize the relationships among the multiple effects examined when making inferences. For example, in quadratic growth curve models, linear and quadratic growth parameters are often negatively associated and this information can be interpreted and used in a multivariate analysis. Similarly, sensitivity and specificity estimates are negatively associated and this information can be used when jointly estimating the region of significance.

Third, we can obtain parameter estimates with better statistical properties. When we utilize the correlations among related end points in a multivariate analysis, each end point can borrow strength from the other related end points, resulting in smaller standard errors for the overall estimates compared to those from separate univariate models. Moreover, it also results in smaller mean square error of the between-study variance. This gain in estimation is directly related to the within-study correlation. As the within-study correlation increases, we generally obtain better estimates. Fourth, we can make potentially different clinical conclusions, compared to those from multiple univariate meta-analyses. By providing all results in a single multivariate meta-analysis, it is easier to compare the results than it is from different analyses that make different assumptions. Fifth, the multivariate methods have the potential to reduce bias due to partial reporting of data. These advantages apply to both AD and IPD analysis. With IPD, however, the implications of the multivariate meta-analysis methods significantly change. Its promise is very appealing and clear. At the very least, within-study correlations can be directly estimated using IPD. More important, data can be newly and directly analyzed using IPD with advanced analytical models.

Multivariate meta-analysis is particularly well suited for use in prevention and intervention research. Many behavioral outcome measures are highly correlated and typically not fully reported in publications. When multiple related outcome data exist in studies and when they are examined one by one (and separately at each follow-up) or selectively, it raises the possibility of chance findings, especially in studies with small samples (Tversky & Kahneman, 1971). This research practice can lead to misleading conclusions with regard to whether the intervention is efficacious overall. In some situations, investigators may selectively report some outcomes and omit others when publishing, which is a questionable research practice that should be avoided (Bakker, van Dijk, & Wicherts, 2012). Given that the average behavioral intervention effect is generally small, the likely conclusion one can make under

this questionable research practice is that an intervention has an effect for some of the outcome variables but not for others.

When it comes to univariate meta-analysis using AD, multiple related outcomes are analyzed separately one by one, which can result in different samples for different analysis because not all studies report or have those outcome measures. As a consequence, each meta-analysis includes only those studies that have the measure being analyzed. Any different conclusions across different outcome measures from univariate meta-analysis methods can be attributed to different studies or samples being included, as well as to different intervention benefits for different outcomes. For a relatively understudied outcome variable, it is also possible to have just a few available studies, which seriously limits our ability to draw any firm conclusions in a typical univariate meta-analysis. Multivariate meta-analysis is a promising new approach, especially when the method is used with IPD. Below, we discuss how the multivariate meta-analysis methods can be used for comparing multiple intervention groups.

Network Meta-analysis

Network meta-analysis refers to synthesis of a network of trials connected by evidence (Jansen et al., 2011). When a multivariate meta-analysis is performed for comparing multiple intervention groups, it can be viewed as a network meta-analysis (Hoaglin et al., 2011; Jansen et al., 2011). This approach enables us to draw conclusions about relative intervention effects of different intervention approaches that have not been compared head-to-head in a trial using a network of direct and indirect evidence (Jansen et al., 2011). It takes advantage of a greater share of available evidence than a traditional meta-analysis of RCTs, which typically features comparing just two arms (i.e., intervention and control). Furthermore, when a new intervention surfaces, it is rarely compared against another, effective intervention approach. As a result, there is a dearth of evidence suggesting relative benefits when attempting to make evidence-based health decisions. Via network meta-analysis, the existing interventions can be contrasted with new ones through connected evidence, even when they were never directly compared.

To know the relative strengths of all available interventions, it may be best to include them in a large-scale study and compare them pairwise to derive estimates of relative intervention effects. However, with limited resources, this is practically impossible to carry out. In the absence of direct head-to-head comparisons of competing interventions, network meta-analysis utilizes networks of direct and indirect comparisons to derive relative intervention effect size estimates between competing interventions. Figure 23.8 illustrates the concepts of direct and indirect evidence. The solid lines between ovals indicate that direct head-to-head intervention comparisons are possible. The dotted lines indicate indirect comparisons are possible. As long as indirect pairwise comparisons can be anchored, indirect comparisons of multiple intervention conditions are possible. For example, head-to-head pairwise comparisons of intervention conditions A and B and A and C are anchored on the common condition A. With A serving as the anchor, relative effects of intervention conditions B versus C can be obtained indirectly (the figure on left). Intervention conditions B and C are connected indirectly through the condition A. This is the essence of an indirect comparison through using an anchor intervention in a network of evidence. The figure on the right shows that both direct and indirect comparisons are possible between intervention conditions B and C. Many more intervention conditions can be compared even though they are not directly compared in any trials. For example, intervention conditions B and D, B and E, C and D, C and E, and D and E are possible due to the anchor intervention A. As more intervention conditions are linked to the existing network, more interventions can be directly and indirectly compared.

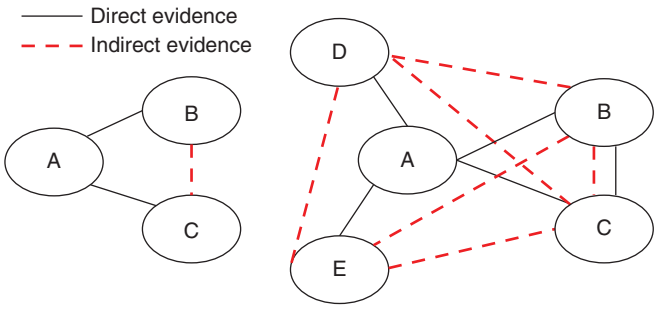

Figure 23.8 Network meta-analysis. The figure on the left shows an example of an indirect comparison between interventions B and C. The figure on the right shows mixed networks of evidence (both direct and indirect) for interventions B and C. Interventions B and C are connected via both solid and dotted lines. See footnote 1.

It is important to note that there are necessary assumptions for network meta-analysis to be valid—similarity and consistency (Jansen et al., 2011). The assumption of similarity necessitates that trials included in relative comparisons should be *sufficiently similar* in terms of participant characteristics, protocols, and measures and that any between-study variation in these characteristics should not systematically modify the intervention effect across studies. The assumption of *consistency* dictates that

when both direct and indirect comparisons are possible in a network of connected evidence (Figure 23.8, on the right side), the evidence from direct and indirect comparisons should be consistent. Jansen and colleagues (2011) recommended that network meta-analysis be used when the evidence base consists of more than two RCTs connecting more than two interventions.

IPD Meta-analysis and Integrative Data Analysis

As discussed thus far, IPD meta-analysis or IDA can be conducted to address whether the effect of interest exists across the board and how large the effect is at the population level. When utilized in the context of multivariate meta-analysis for multiple related parameters, IDA or IPD meta-analysis can be a particularly compelling approach because the advantages of multivariate methods can be fully exploited.

At the same time, some cautionary comments about IPD are needed. When IPD is analyzed in a large study, one can achieve much needed precision about point estimates and standard errors. In a small IDA project with a few studies, however, it is difficult to obtain such precision, especially when considerable between-study variability exists. For this reason, there should be a sufficiently large number of studies available for IPD meta-analysis and consequently greater resource, compared to AD meta-analysis (Mun et al., 2015; Steinberg et al., 1997). For any population-based inference, some researchers have suggested that 10–20 studies may be needed for its population representation and validity of parameter estimates (Hussong et al., 2013). In relation to this population based inference, it is also important to communicate how the set of studies included in IDA relates to the body of existing studies in the literature.

In this section, we focus on combining IPD for comparing multiple intervention groups across studies. Whenever there are multiple competing intervention conditions in some of the studies, data are typically combined and analyzed only from the studies that have the target intervention groups, and this analysis is repeated for all intervention pairs. However, the downside of this approach is that the studies being included in each set of analysis can be different, and any effect size estimate cannot be directly compared because uncertainty surrounding the estimates can be due to the different samples analyzed. Furthermore, it is unreasonable to assume that these interventions or multiple outcomes are independent within studies. Thus, comparing intervention conditions separately is an inefficient use of data, and can also lead to misleading and/or biased estimates.

In a multivariate meta-analysis, we can include all conditions across studies as long as they can be linked together by utilizing the correlational structure among these conditions. In the current chapter, we illustrate a new two-stage multivariate meta-analysis for IPD. We use the methodology proposed by Liu et al. (2015) but extend this method for IPD. This analysis proceeds in two stages. At the first stage, the analyst formulates a model to run for each data set based on a substantive conceptual model. This model can be flexibly designed by the analyst based on the research goals and data characteristics of the study. It can be a latent curve model with polynomials, piecewise model, or mixed-effects model. In addition, an intervention effect can be variously defined and derived. It can be derived from a model that includes baseline outcome levels. Alternatively, one can specify an intervention effect on the rate of growth of an outcome behavior. In addition, different distributions of outcome measures can also be accommodated by selecting a model of the appropriate form.

At the second stage, the vectors of estimated coefficients of the selected model across studies are analyzed to obtain the vector of overall estimates and its covariance matrix. For the second step, different estimators for the between-study covariance matrix, such as the MLE or method of moments, can be utilized. If estimates for some of the covariates are not available from the first stage analysis of individual data sets because the covariates were not assessed originally or because estimates were not identifiable (e.g., all participants were men), the coefficients for these covariates for some specific studies would be selectively omitted when estimates are combined at the second stage. For example, if there is a total of five coefficients in the formulated model, three may exist in one study but four in another. It is possible that none of the studies has all five coefficients. The design differences across studies are accommodated by applying appropriate mapping matrices (see Liu et al., 2015 for technical details). This multivariate meta-analysis approach is well suited for IPD because IPD can be analyzed separately for each study using an advanced or complex model and, consequently, resulting coefficients and their within-study covariance matrices can be directly obtained. For a multivariate meta-analysis with AD to be feasible, within-study covariance matrices should be reported in publications in the first place or made available subsequently. However, this IPD approach may not be feasible in some situations. Although there are no restrictions as to the number of coefficients that can be analyzed and combined, it can quickly become challenging as the number of coefficients or studies increases and as sparseness goes up.

To present the method more formally, we first assume that the model to be analyzed at the first stage is

$$y_{ijt} = \beta_i^T x_{ijt} + u_{ij} + \varepsilon_{ijt}$$

where y_{ijt} is the outcome score for participant j at time t in study i, x_{ijt} and β_i are the corresponding design and coefficient vectors, respectively. u_{ij} is the random intercept for participant j in study i, and ε_{ijt} is the residual error term. Each β_i is a subset of the vector β, and its estimate $\widehat{\beta}_i$ and the covariance matrix of $\widehat{\beta}_i$ denoted as $\widehat{\Sigma}_i$, are obtained separately for each study (first stage) and subsequently combined across studies (second stage).

At the second combining stage, we assume a hierarchical model with the form

$$\beta_i|\theta_i, S_i \sim N_{P_i}(\theta_i, S_i);$$
$$\theta_i|\theta, \Sigma \sim N_P(A_i\theta, A_i\Sigma A_i^T)$$

where β_i and θ_i are the observed and true parameter vectors for study i, respectively. S_i is the covariance matrix of θ_i, which is typically assumed to be known. θ and Σ are the population parameters and the corresponding covariance matrix Σ can be estimated by many estimation methods, such as the REML. A_i is the mapping matrix for study i that indicates missing data and maps θ to θ_i. The particular estimation approach utilizes the CD method (see the Unifying Approach to Synthesize Data from Multiple Studies section) and explicitly incorporates the overall structure of missing data into the model through a mapping matrix A_i. If there are no missing data points (i.e., covariates or coefficients), A_i becomes an identity matrix. The CD estimator consequently becomes equivalent to other estimation methods (see Jackson et al., 2011), which is extremely unlikely for any IPD analyses in behavioral and clinical research.

When applying the CD method, the combined estimates of θ and its covariance, denoted as $\widehat{\theta}_E^{(c)}$ and $S_{c,E}$, respectively, have the following forms:

$$\widehat{\theta}_E^{(c)} = \left(\sum_{i=1}^{n} A_i^T \left(S_i + A_i\widehat{\Sigma}_i A_i^T\right)^{-1} A_i\right)^{-1} \times \left(\sum_{i=1}^{n} A_i^T \left(S_i + A_i\widehat{\Sigma}_i A_i^T\right)^{-1} A_i A_i^T \beta_i\right)$$

and

$$S_{c,E} = Var(\widehat{\theta}_E^{(c)}) = \left(\sum_{i=1}^{n} A_i^T \left(S_i + A_i\widehat{\Sigma}_i A_i^T\right)^{-1} A_i\right)^{-1}.$$

These equations are used when combining estimates of θ and its covariance. This multivariate meta-analysis approach for comparing multiple intervention groups using IPD can be seen as a network meta-analysis application when multiple interventions are compared across studies. At the same time, this multivariate approach using IPD is more general and flexible than typical network meta-analysis methods using AD in the sense that the effects combined in the former reflect input from all available data. Furthermore, any data and model can be combined in principle. Thus, this new two-stage approach using IPD is not restricted to what has been reported by primary studies.

It is also important to note that IDA is not limited to a large number of studies. It can be conducted to pool just two or three non-RCT studies into one. When two or more non-RCT studies are pooled into one, the resulting pooled data can still enjoy many advantages of IDA. The pooled data set would be more heterogeneous in terms of samples and study characteristics, be larger in sample size, and have more follow-ups for a longer duration. Overall, combined data from two studies may be better than data from a single study, if the measurement equivalence can be established across the studies being pooled. IDA or IPD meta-analysis, regardless of the nature of its component studies, is highly innovative. Not only does it strengthen causal inference based on existing data, but more importantly it allows testing of a new set of hypotheses and mechanisms of change that may not be feasible to examine in single studies. One possibility for new analyses is to detect moderated effects and explore subgroups, which can be explored in the pooled data of RCTs or non-RCTs.

Subgroups, Moderated Effects, and New Discoveries

IPD meta-analysis or IDA can be useful for understanding subgroups because individual-level, as well as study-level, covariates can be explicitly studied in connection with different intervention effects. Subgroups in this context extend beyond subgroups of individuals to include any meaningful differences that may affect intervention outcomes, such as any differences in intervention protocols and follow-up periods. These investigations are of critical interest in intervention and prevention research, as they suggest clues for mechanisms of behavior change at the individual level. Through the use of IDA, one can conduct new analyses well suited to reveal subgroups for a large pooled sample. IPD analysis can overcome issues of *low power, publication bias,* and *ecological fallacy*.

The power advantage of IPD analysis over single studies or AD analysis is generally well known. Investigations

aimed at revealing subgroups require a considerably large sample in original single studies. In comparison with AD analysis, the power to detect these effects by using the summary-level data will often be prohibitively low, and IPD analysis is necessary to detect effects of covariates at the individual level (Sutton & Higgins, 2008). However, with careful considerations, an AD meta-analysis may gain back the power even under heterogeneous designs (Liu et al., 2015).

As for publication bias, single studies lack sufficient power to detect moderated effects. Thus, statistically nonsignificant moderated effects may go unreported in many publications. Furthermore, the analytic approaches chosen for subgroup analysis in single studies vary widely, which makes it even more difficult to combine effect sizes across individual studies in AD meta-analysis. More important, there is an issue of interpretation. This applies to the relative advantage of IPD over AD. When study-level covariates are used to explain any differences in the effects of interest, this can lead to invalid statistical conclusions.

Meta-regression (via using AD; Figure 23.2) requires careful interpretation, as it is more prone to ecological bias than analysis using IPD. *Ecological fallacy* or *ecological bias* occurs when conclusions are made about the mechanism at the lower-level data (e.g., individual participants) based on the higher-level data (e.g., study-level information). For example, in the field of college alcohol intervention research, some of the studies comprise all men or all women. If gender is included as a study-level moderator of the treatment effect in a meta-regression analysis, which is then confounded with study membership, the resulting conclusion may be subject to ecological bias. Thus, IPD meta-analysis is better suited than single studies and AD meta-analysis when examining subgroups (Brown et al., 2013; Simmonds & Higgins, 2007).

Of course, IPD analysis has other advantages, such as the capabilities to check the quality of data and reanalyze data using more appropriate approaches (Curran & Hussong, 2009; Sutton, Kendrick, & Coupland, 2008). For these reasons, IPD meta-analysis is widely considered as the "gold standard" in the statistical literature (Lin & Zeng, 2010; Sutton & Higgins, 2008). At the same time, it has been echoed by many that such analyses require much more time and efforts to carry out (Cooper & Patall, 2009; Mun et al., 2015; Steinberg et al., 1997; Sutton et al., 2008).

The advantages of IDA need to be understood in the context of challenges. IDA requires the availability of data and subsequent contacts with original investigators who have conducted relevant studies. Other challenges include the need for harmonizing groups and measures across studies. These challenges go up when the number of studies increases because the number of variations to be harmonized across studies goes up along with the number of studies (see Mun et al., 2015, for some examples). In addition, as the number of studies goes up, overall percentage of missing data at the study level (i.e., did not assess or could not be harmonized) may become prohibitively huge when individual data sets are combined for a single-step integrated analysis. When one of the goals of IDA is to fully utilize available data in analysis, missing data can cause great difficulties for IDA studies throughout all stages of analysis.

Table 23.1 provides an overview of various methods discussed in this chapter. Figures 23.1, 23.2, and 23.4 graphically summarize the relationships among the source of data, type of data being pooled, analytic methods, and approaches to the univariate and multivariate methods. Figure 23.4 shows emerging directions in the field of research synthesis. Namely, future innovations may be obtained by prospectively coordinating and designing single studies as part of research networks, then channeling IPD from these sources for innovative multivariate analysis, and maximally utilizing all available data for more robust inference and new discoveries. Next, we illustrate two data examples from an IDA research project that pooled data from multiple alcohol intervention studies for college students.

DATA EXAMPLES

In the field of college alcohol intervention research, brief motivational interventions (BMIs) have received empirical support for reducing excessive alcohol use and related problems among college students at least on a short-term basis (Carey et al., 2007; Cronce & Larimer, 2011). However, there are several outstanding questions, including inconsistent intervention effects within and between studies, as well as the small intervention effect sizes reported in the literature. Furthermore, the mechanisms of behavior change remain sketchy. Project INTEGRATE (Mun et al., 2015) was a response to address these outstanding questions. More specific goals were to examine (1) whether BMIs are efficacious for bringing about changes in theory-based behavior targets, such as normative perceptions about peer alcohol use and the use of protective behavioral strategies while drinking; (2) whether positive changes in behavior targets predict greater reductions in alcohol use and negative consequences; (3) whether subsets of interventions are more promising; and (4) whether subgroups of individuals exist for whom different interventions are more efficacious.

Pooled Data

To compile data from BMIs, we contacted individual investigators in spring 2009 who had published data on BMIs. All but one agreed to share their data. In the case of the single exception, there was an ongoing project within the research team that had similar research goals. There was also a snowballing recruitment of other investigators. The unpublished data by these investigators were also compiled. Unlike a typical meta-analysis project, we did not systematically search databases or launch an exhaustive search of all eligible studies. Thus, the sample of studies we have is a convenience sample that is nonetheless broadly representative of the existing intervention studies conducted between 1990 and 2009 (published between 1998 and 2010). The combined data set was diverse in terms of original investigators, college campuses from which participants were recruited, demographic characteristics, and intervention study designs (Table 23.4; see also Mun et al., 2015).

Sample

Data were pooled from 24 independent studies (Studies 1–7, Studies 8a, 8b, and 8c, and Studies 9–22; see Table 23.4), resulting in a combined data set consisting of 12,630 participants (42% men; 58% first-year or incoming students) who were assessed two or more times from baseline up to 12 months. The majority of the sample is White (74%), with 12% Asian, 7% Hispanic, 2% Black, and 5% belonging to other or mixed ethnic groups. Approximately 15% are college students mandated to complete a university program (e.g., a BMI or educational program) as a result of alcohol-related infractions; 27% are members (or pledged to be a member) of fraternities and sororities; and 13% are varsity athletes or members of club sports. The majority of the individual studies included in Project INTEGRATE have been previously described in the published literature (see Mun et al., 2015, for more information).

Intervention Groups and Procedures

All studies included one or more BMI conditions, with the majority (21 studies) including either a control condition or other comparison condition (i.e., alcohol education). Across studies, some groups with the same intervention label were different; and several other groups with different intervention labels were actually similar when examined at the operational level. To determine which groups are equivalent to and different from others, we developed a quite detailed coding procedure to go over all published and unpublished intervention materials and quantitatively code their content and characteristics. Two content experts coded independently and any discrepancies were discussed in detail, at first between them and, if necessary, with the rest of the research team (see Ray et al., 2014 for details). We consequently relabeled intervention groups based on their intervention characteristics and content.

Newly labeled five intervention groups for Project INTEGRATE were Motivational Interview plus Personalized Feedback (MI + PF), stand-alone Personalized Feedback (PF), Group Motivational Interview (GMI), Alcohol Education (AE), and Control. There were also several unique conditions that did not fit these categories, including an MI + PF condition combined with an alcohol expectancy challenge, an MI without PF, and an MI + PF condition combined with a parent-based intervention. Participant recruitment and selection also varied across studies, ranging from volunteer students recruited with flyers to students who were required to complete an alcohol program because they violated university rules about alcohol.

In a preplanned, large multisite RCT, intervention conditions or groups can be perfectly balanced as in a factorial design, which is practically not feasible for IDA studies. For Project INTEGRATE, five intervention conditions sparsely existed across 24 studies. Table 23.5 shows the unbalanced nature of the intervention conditions in terms of their number and type for a subset of studies that were utilized in the current chapter. Studies 9 and 13/14 had all four groups (GMI excluded), but all other studies had two or three groups. Some of the studies did not have a control group (Studies 1 and 3), and only three studies had an Alcohol Education group. If these groups were to be analyzed simultaneously in one-step IDA using typical analytic approaches, it is likely that missing conditions would create estimation difficulties in analysis.

Measures

We now describe how measures were harmonized and how latent traits were estimated across studies for two of the measures used in the outcome analysis. See also Huo et al. (2014) for technical detail and Mun et al. (2015) for an accessible overview of the measurement approach taken for Project INTEGRATE.

Measures: Protective Behavioral Strategies

Protective behavioral strategies refer to specific cognitive behavioral strategies that can be employed to reduce risky drinking and limit harm from drinking (Martens et al., 2004). We identified five major questionnaires used to assess protective behavioral strategies: the 10-item Protective Behavioral Strategies (PBS) measure taken from the

*N = 12,630. Studies are numbered arbitrarily. MI + PF = Motivational Interview plus Personalized Feedback; PF = Stand-alone Personalized Feedback; GMI = Group Motivational Interview; AE = Alcohol Education; PBI = Parent-based Intervention.

[a] = These groups are quite unique despite having the same label as others without the superscript;

[b] = GMI in Study 7 provided personalized feedback, whereas other GMIs did not;

[c] = These groups represent unique intervention conditions not found in any other studies included in Project INTEGRATE.

[1]The control group (n = 119) for Study 2 received feedback at 2 months post baseline and thus their follow-up data at 6 months post baseline were excluded;

[2]Mandated students who were in the control group (n = 24) in Study 7.1 received GMI at 1 month post baseline and their follow-up data at 6 month post baseline were excluded. "--" indicates that follow-up was not administered. Follow-up sample sizes were based on selective alcohol use measures and could differ from those reported in published articles.

National College Health Assessment survey (American College Health Association, 2001); the 15-item Protective Behavioral Strategies Scale (PBSS; Martens et al., 2005); the 37-item Self Control Strategies Questionnaire (SCSQ; Werch & Gorman, 1988); a seven-item Drinking Restraint Strategies (DRS) scale used in Wood, Capone, Laforge, Erickson, and Brand (2007); and a nine-item Drinking Strategies (DS) scale reported in Wood et al. (2010). The PBS was assessed by Studies 1, 2, 8a, 8b, 8c, and 9; the PBSS was assessed in Studies 4, 16, 18, and 21; the SCSQ by Study 3; the DRS by Studies 12 and 22; and the DS by Study 22. In these studies, items were assessed in Likert-type scales. Note that many items were similar in wording. Given that slightly differently worded items can be responded differently by responders, we initially treated them as different items. In addition, we limited item-level data only for those who reported recent drinking (i.e., past 1 to 3 months) due to the nature of the construct.

Of the compiled pool of items, items indicating abstinence from drinking (two items; *cut back on drinking* and *choose not to drink alcohol*) or manner of drinking (one item; *drink shots of liquor*) were dropped, as they do not conceptually fit the definition of protective behavioral strategies. Study 3 included an additional 16 items related to protective behavioral strategies, which were dropped from the pool because they were assessed only in Study 3 and could not be linked to any other items across studies. Study 7 assessed protective, as well as risky, behaviors (a total of 17 items) as a set of behaviors that one can engage during drinking, such as "leaving drinks unattended" or "drank lower alcohol content beverage." Participants were asked to provide the total number of times that they participated in such activities in the past month (possible values ranging from 0 to 99). Their response patterns were very different from those of other studies measured on a Likert-type scale and difficult to harmonize reasonably. We thus decided not to include these items in the pool.

A total of 58 protective behavioral strategy items assessed by 13 studies (Studies 1–4, 8a–8c, 9, 12, 16, 18, 21, and 22) were then analyzed using item response theory (IRT) analysis. Different questionnaires had different stem questions leading to specific items. Some of the major variations were as follows:

- The following set of questions asks about your drinking behavior. Please indicate how often you did the following . . . " (PBS)
- Please indicate the degree to which you engage in the following behaviors when using alcohol or "partying" . . . (PBSS)
- How often did you use each of these strategies to deliberately limit your drinking? (SCSQ)
- Do you deliberately try to . . . (DRS)
- How often do you . . . (DS)

We assumed that these stem questions did not make a difference. Of the remaining 58 items, 20 were combined into five individual items because they were very similarly worded. Examples of similarly worded questions were "avoid drinking games," "avoid or limit your participation in drinking games to drink less," and "avoid playing 'drinking games.'" Collapsing such similarly worded items may not be ideal, as participants can respond differently to slightly differently worded items or different leading (stem) questions. However, to be able to link items across studies, we made an assumption that these similarly worded items were essentially the same in eliciting responses. Many pooled items were similar, as they had been adopted or modified from other existing questionnaires included in the pool of items. If we were to take the strictest route and treat all items as different, one consequence would be to analyze only those few studies that administered exactly the same questionnaire for exactly the same time frame using exactly the same response options. For example, the PBS was administered in six studies and the PBSS was administered in four studies. If these data sets were analyzed separately, it would be difficult to draw any direct comparisons between the two sets of analyses.

In general, there is a trade-off between item coverage across studies and quality of information when

harmonizing measures. The coverage of items will be greater when we accept slightly imperfect items as commensurate across studies. However, the coverage will suffer if slight variations are not tolerated across studies. This decisional balance may have to be determined individually depending on the research questions, available data, and subsequent analytic methods (to see examples in which harmonization may not be reasonable, see Mun et al., 2015).

Our subsequent analysis did not involve comparing intervention cases and control cases across studies (called *breaking randomization* or *naïve comparison*). We compared intervention cases against their own controls within studies, before their relative differences were pooled across studies. Thus, we made an assumption that this item linkage we established would not yield biased results. In situations where naïve comparisons are made, however, one cannot assume that even the same item has the same item function across studies. In other words, when participants in one study are combined with participants in another study without the nested data structure taken into consideration, item functions may differ across studies, which may result in biased inference. In such situations, DIF tests across studies and appropriate follow-up actions may be needed to demonstrate measurement equivalence across studies.

Response options were harmonized and recoded to indicate 0 = never; 1 = rarely, seldom, occasionally, or sometimes; 2 = often or usually; and 3 = always. Response options rarely, seldom, occasionally, and sometimes were originally assessed as different categories but were combined into one because endorsement rates were relatively low for these categories. Also, for protective behavioral strategies, answers in either extreme (i.e., never or always) and adjacent steps from the extremes are more important than any difference that exists in the middle of the scale (e.g., rarely vs. seldom or occasionally vs. sometimes).

A total of 43 items (38 unique and five collapsed items) were then analyzed, specifying a single, underlying dimension of protective behavioral strategies. Because we deemed it important to distinguish *often* from *always*, we used a generalized partial credit model (GPCM; Muraki, 1992) to assign partial credit for polytomous items (for more detailed explanations of the GPCM parameters, see Mun et al., 2015). We developed Markov chain Monte Carlo (MCMC) algorithms to fit several IRT models, including the GPCM model, within a hierarchical Bayesian framework. Huo et al. (2014) provided the theoretical and technical details of the IRT models and MCMC algorithms, which were written in Ox (Doornik, 2009).

Measures: Alcohol-Related Problems–Neglecting Responsibilities

Alcohol-related problems is one of the critical outcome measures and our measurement approach for this construct is described in greater detail elsewhere (see Huo et al., 2014; Mun et al., 2015). Briefly, individual items and items from well-known questionnaires for alcohol-related problems were identified from each study and compiled in a separate data set. These items mostly came from the Rutgers Alcohol Problem Index (RAPI; White & Labouvie, 1989), the Young Adult Alcohol Problems Screening Test (YAAPST; Hurlbut & Sher, 1992), the Brief Young Adult Alcohol Consequences Questionnaire (BYAACQ; Kahler, Strong, & Read, 2005), the Alcohol Use Disorders Identification Test (AUDIT; Saunders, Aasland, Babor, De La Fuente, & Grant, 1993), the Positive and Negative Consequences Experienced questionnaire (PNCE; D'Amico & Fromme, 1997), and the Alcohol Dependence Scale (ADS; Skinner & Allen, 1982; Skinner & Horn, 1984). For each item, responses were dichotomized to indicate 1 = Yes; 0 = No, because this response format was the common denominator across studies. When someone did not drink during the time frame referenced, the score was recoded as zero.

We utilized both a unidimensional IRT model and a four-dimension IRT model for alcohol-related problems for Project INTEGRATE. In the former, a single overall, severity latent trait is assumed to give rise to item responses. In the latter, four distinct but related latent trait dimensions give rise to item responses within their dimensions, which were Neglecting responsibilities, Interpersonal difficulties, Dependence-like symptoms, and Acute heavy-drinking, respectively. Estimated correlations among the four dimensions exceeded 0.8, which indicates that these dimensions are highly correlated but still distinct. Both IRT models showed acceptable fit and parameter estimates were similar between the two models. In the current chapter, we focus on a single dimension of alcohol-related problems obtained from the four-dimensional IRT model–Neglecting responsibilities (NR) as an example in the Outcome Analysis section. Some of the example items for this dimension were "Got into trouble at work or school because of drinking" and "Missed a day (or part of a day) of school or work."

Outcome Analysis

For outcome analysis, we provide data examples for model-based meta-analysis and multivariate meta-analysis (network meta-analysis) using data for latent trait scores for protective behavioral strategies (henceforth referred

to as PBS) and neglecting responsibilities (henceforth referred to as NR), respectively. For the first data example, we utilized both fixed-effects and random-effects models to examine whether college students who were assigned to a brief alcohol intervention utilized protective behavioral strategies more often their counterpart controls at the first, immediate follow-up. Protective behavioral strategies are increasingly seen as an important behavioral target of alcohol intervention efforts for college students. For the second example, we demonstrated how multiple intervention arms could be combined across studies and analyzed in a single combined, multivariate analysis using the CD approach.

Model-Based Meta-analysis

For model-based meta-analysis, we used PBS data. Of the 13 studies (Studies 1–4, 8a–8c, 9, 12, 16, 18, 21, and 22) that assessed PBS, we excluded three studies due to the lack of an equivalent control group (Studies 1, 3, and 4). Studies 9 and 21 had multiple intervention arms and we combined them into one intervention group (i.e., MI + PF, PF, and Alcohol Education were combined for Study 9; MI + PF and PF were combined for Study 21). Thus, we had a two-arm design (one intervention and one control) for a total of 10 studies, and examined their PBS data at their first follow-up. The first follow-up assessment occurred within 1–3 months for Studies 2, 9, 12, 16, 18, and 21; 9 months for Study 22; and 12 months for Studies 8a, 8b, and 8c.

Results indicated that there was no significant between-study heterogeneity, Q (df = 9) = 12.03, p = 0.21. The statistical conclusion from either a fixed-effects or a random-effects model was the same. That is, there were no significant differences between the intervention and control groups in terms of their tendency to utilize PBS at the first follow-up. The overall mean difference in PBS latent traits between the two groups was 0.05 under the fixed-effect model. The 95% confidence interval [–0.002 to 0.102] included 0. The random-effects model estimated the overall mean difference to be 0.05 and had the slightly larger 95% confidence interval [–0.008 to 0.104] to account for between-study variability, although in the present case there was no statistically significant, between-study variability in the mean differences in PBS scores. Figure 23.9 shows the results from the fixed-effects model in a forest plot. At the individual study level, only Study 8a showed a statistically significant, favorable outcome for the intervention group, compared to control.

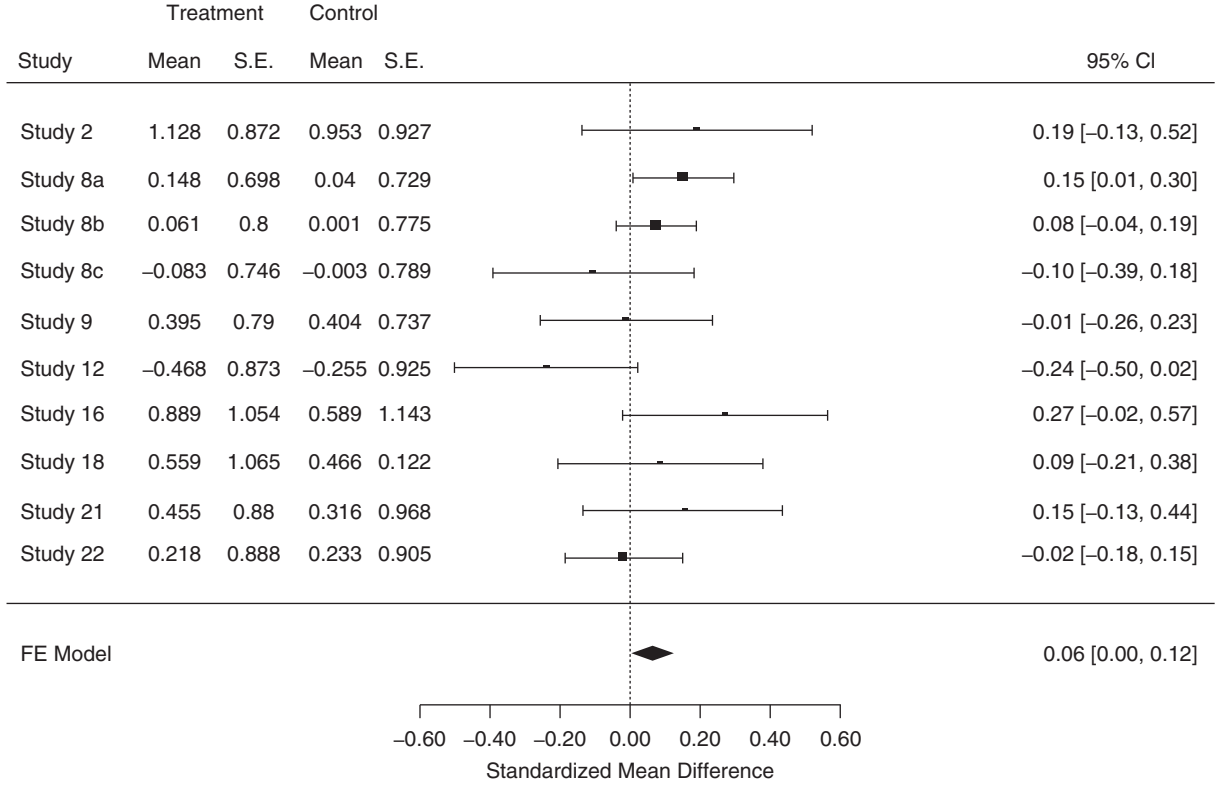

Figure 23.9 Protective behavioral strategies at the first follow-up under the fixed-effects model for 10 studies.

Although there was no statistically significant, between-study variability in estimates, the nonsignificant Q statistic should not literally be interpreted as evidence to indicate that the effect sizes are consistent across studies, since such nonsignificance can be due to lack of power. With a small number of studies or large within-study variances in individual studies, even substantial between-study dispersion might yield a nonsignificant Q statistic (Borenstein et al., 2009). In the forest plot shown in Figure 23.9, we had narrow confidence intervals (small within-study variances) in large studies, such as Studies 8a and 8b, but in many other studies with small samples (e.g., Studies 16 and 18), the within-study variances and associated confidence intervals were large. In addition to the highly discrepant sample sizes (Table 23.4), studies varied in terms of their follow-up periods and sample characteristics, and also the interventions implemented. For example, the eligibility criteria for participation in Study 12 (Wood et al., 2007) were geared toward enrolling high-risk heavy drinkers: (1) 14 or more drinks per week for men and 10 per week for women; (2) at least one episode of heavy drinking in the past 30 days; and (3) endorsement of at least two alcohol-related consequences in the past year. Although Wood et al. excluded and referred the students who reported more than 40 drinks per week or exhibited moderate to severe dependence to the university counseling center, this sample placed on the extreme end of risk for excessive and problematic drinking, relative to other study samples (see Huh et al., 2015, for alcohol use data across studies). Furthermore, this sample was estimated to have the lowest levels of PBS at baseline across all 10 studies (Figure 23.10). For these reasons, when we excluded data from Study 12, the results from the remaining nine studies indicated a favorable outcome for the intervention group at follow-up; overall mean difference = 0.08, with 95% confidence interval ranging from 0.01 to 0.15 (Figure 23.11).

The point about this subsequent analysis without Study 12 is not to draw a conclusion that the intervention was efficacious for increasing the utilization of PBS, which was not the case for the pooled sample of 10 studies, but to suggest that the intervention's role in the utilization of PBS may differ depending on the levels of alcohol use and their PBS utilization at baseline. To test this hypothesis, however, a further investigation is required that incorporates individual-level covariates in the model. Without examining the individual level data, drawing any conclusion based on study-level data (like the one that we tentatively discussed here) may be subject to ecological fallacy, and lead to inaccurate inference about how changes occur following an intervention.

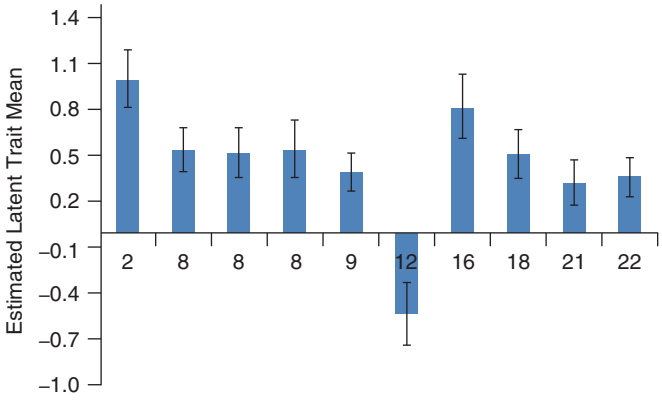

Figure 23.10 PBS latent trait means across studies estimated from the GPCM analysis. The second, third, and fourth bars indicate data from Studies 8a, 8b, and 8c, respectively. The error bars indicate two times standard errors in each direction. Participants in Studies 2 and 16 were estimated to utilize PBS more often than students in other studies. Study 12 was an outlying study—Participants in Study 12 were least likely to utilize PBS. See footnote 1.

Multivariate Meta-analysis

For multivariate meta-analysis, we used the new two-stage approach for IPD described previously. We had the following inclusion criteria for studies: at least two intervention arms existed and participants were randomly assigned to these groups (Studies 5, 6, and 17 excluded); and the intervention utilized should not be unique (Studies 4, 7, and 19 excluded). Studies 15 and 16 were further excluded because they were exclusively for first-year female students, which represented a missing data problem (due to no variability) for two covariates (first-year student and gender) and posed a difficulty at the second stage of combining estimates. In addition, the latter two studies were small in sample size, were conducted on the same college campus by the same investigators, and utilized the same intervention (i.e., GMI). Due to the elimination of other GMI studies, these two studies became unique in the pooled data set. Of the studies that met the inclusion criteria, we further removed some conditions (e.g., alcohol expectancy challenge, parent-based intervention, or MI without PF) because they were deemed sufficiently different from other intervention conditions and/or were unique to specific studies and could not be linked to other studies. Studies 13 and 14 were combined into one study for the purpose of analysis. Study 13 included an MI + PF intervention and a stand-alone PF intervention, and Study 14 included an MI + PF intervention and an assessment-only control group. In-person MIs combined with PF in both studies were, by and large, identical (i.e., high risk samples, same PF design,

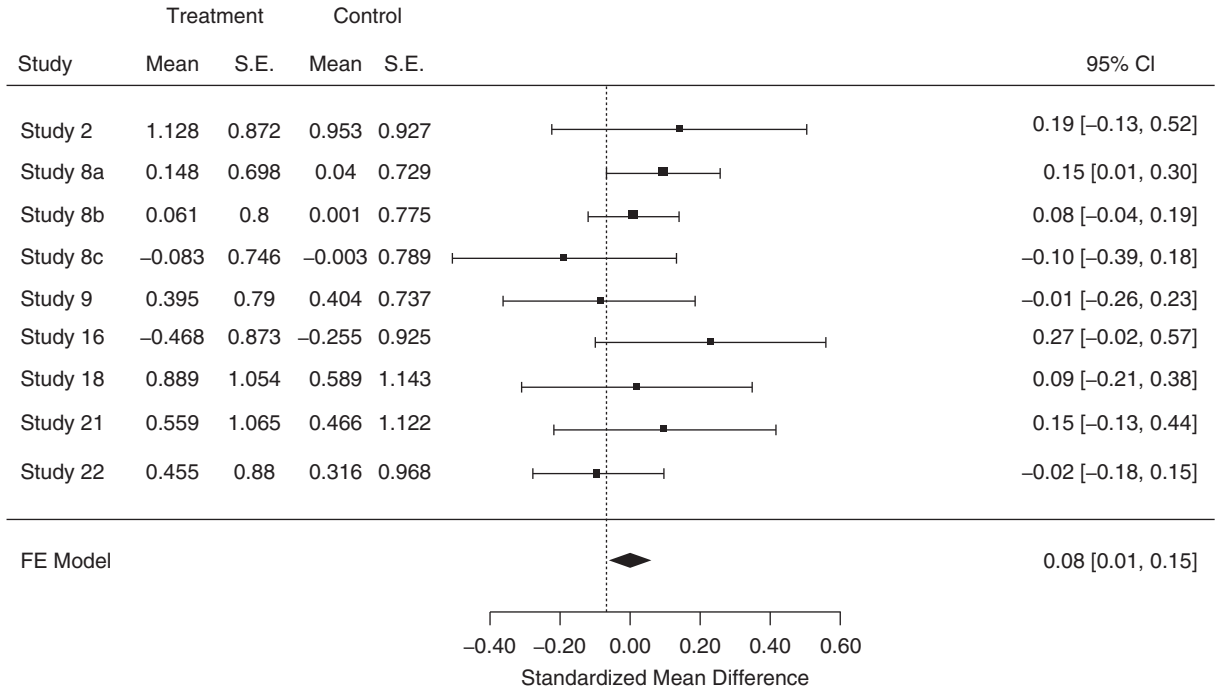

Figure 23.11 PBS at the first follow-up under the fixed-effects model for nine studies (Study 12 removed).

led by the same investigators, and on the same campus), and there were no baseline differences across these two groups. In addition, these two studies had very small samples. Thus, we collapsed these two studies into one combined study (i.e., Study 13/14), allowing an MI + PF group and a PF to be contrasted with a control condition.

Table 23.5 shows that only a subset of studies provides information for direct, head-to-head comparisons of intervention groups. For example, for a head-to-head, direct comparison between MI + PF and PF, data from Studies 1, 9, 13/14, and 21 can be analyzed. For a comparison between MI + PF and Alcohol Education, data from Studies 3, 9, and 13/14 can be utilized. For a comparison between MI + PF and control, Studies 9, 10, 12, 13/14, 20, 21, and 22 can be analyzed. However, for these potential subset analyses, eligible studies would be different, and the number of studies to be analyzed would be much smaller than the entire sample of eligible studies. This would be an inefficient use of available data and could also create inconsistent findings due to different data sets being analyzed for different comparisons. Furthermore, this subsetting strategy does not accommodate the fact that some of the intervention conditions are from the same studies and are hence related. Multivariate meta-analysis overcomes these data characteristics by taking advantage of all available information from all studies.

We first fit a random intercept growth model using NR latent trait scores as an outcome variable separately for each study. The regression model included a total of 15 covariate terms (Table 23.6). Alcohol outcomes following an intervention among college students typically show a pattern of an immediate decline followed by a rebound (e.g., Mun, White, & Morgan, 2009). Thus, we modeled the outcome over time by using a quadratic growth model (month post intervention as a time variable). We included three covariates to control for their differences in alcohol-related problems—being male, White, and first-year student. In addition, we included PBS scores at baseline as a covariate because it was related to dropout at follow-ups in some of the studies. To test intervention effects, we added interaction terms between each of the growth parameters (i.e., linear and quadratic growth slopes) and each of the three intervention groups (i.e., MI + PF, PF, and Alcohol Education). Naturally, three variables to contrast the three intervention groups against control were also included in the model. Note that the actual model for each study was different due to missing covariates at the study level. For example, if a study did not assess PBS, the model had a total of 14 covariates for that study (e.g., Study 13/14 in Table 23.6). Similarly, for studies that had just one follow-up, any coefficients involving a quadratic growth parameter could not be estimated. The

*"--" indicates missing by design. These include variables not assessed by study (PBS); the entire sample consisted of first-year students only (Studies 9, 10, and 11); particular intervention groups were not employed; and only one follow-up assessment available during the 12-month period, and thus their quadratic slope parameter in change could not be estimated.

**= in actual models, this group becomes a referent group for the three other intervention groups, and is not counted in the number of covariates included in the model.

overall pattern of covariates analyzed for each study is shown in Table 23.6.

The growth model was analyzed separately for each of the 15 studies (13/14 was analyzed as one study) in the first stage of the analysis using IPD. In the second stage, a vector of the estimates of regression coefficients and its covariance matrix were retrieved for each study and subsequently combined with the estimates from other studies using the formulas and the REML estimation approach shown in the IPD Meta-analysis and Integrative Data Analysis section.

The multivariate meta-analysis method utilized for this data example combines multiple estimates from multiple studies simultaneously and borrows information, when information is missing, from other studies by incorporating their correlations. This approach differs from existing multivariate meta-analysis approaches utilizing AD. This approach also differs from those combining single or bivariate estimates from multiple studies in the sense that what is integrated across studies is the entire model specified at the first stage of the multivariate meta-analysis. This IPD multivariate meta-analysis approach utilizes more data than any other existing approaches to meta-analysis. The combined model from the second stage can be interpreted and utilized for subsequent investigations.

Table 23.7 shows the IPD multivariate meta-analysis results from the combined model. With the effects of other covariates adjusted, Alcohol Education had higher levels of NR problems compared to control, reflecting their baseline difference (Figures 23.12–23.14) that was maintained throughout the follow-up period. In-person MI combined with PF (MI + PF) or PF did not differ from control. For the efficacy of these interventions, we focused on the interaction terms between growth parameters and intervention conditions. There was a statistically significant interaction effect on NR problems between the linear slope

of growth and MI + PF. The interaction term between the quadratic growth parameter and MI + PF was not statistically significant. These two terms are highlighted in bold in Table 23.7 because it is impossible to evaluate any growth trends or growth-related effects in a compartmentalized, piecewise manner. In a typical growth curve model, for those whose initial levels are high, their subsequent growth trends tend to be subdued. It would be misleading to focus on one growth parameter without considering the other as the first-order polynomial term (linear) is dominated by the second-order term (quadratic) in growth models.

Thus, to demonstrate this intervention effect as a whole, we estimated the NR trait levels at two important follow-up periods—6 months and 12 months post intervention—by plugging the meta-analyzed regression coefficients into the model and calculating the estimated scores for the intervention groups. For some studies, this resulted in extrapolated estimates and for others, these were actual estimates based on observed follow-up data (Figures 23.12–23.14). Note that confidence intervals (and error bars) in Figures 23.12–23.14 were calculated by using different formulas depending on the focus of the comparisons (within-group vs. between-group). In estimation, we used the following values for covariates: male = 1, first-year = 1, White = 1, and PBS = average value. Negative NR scores were due to anchoring (of a group in IRT analysis) and shorter bars indicate more severe problems for the present data in Figure 23.12.

Since first-year students tended to have more severe problems and those with greater PBS had lower levels of problems, depending on the covariates of interest, these bar graphs could be adjusted a little lower (or longer; i.e., less serious problems) for non-first-year students and

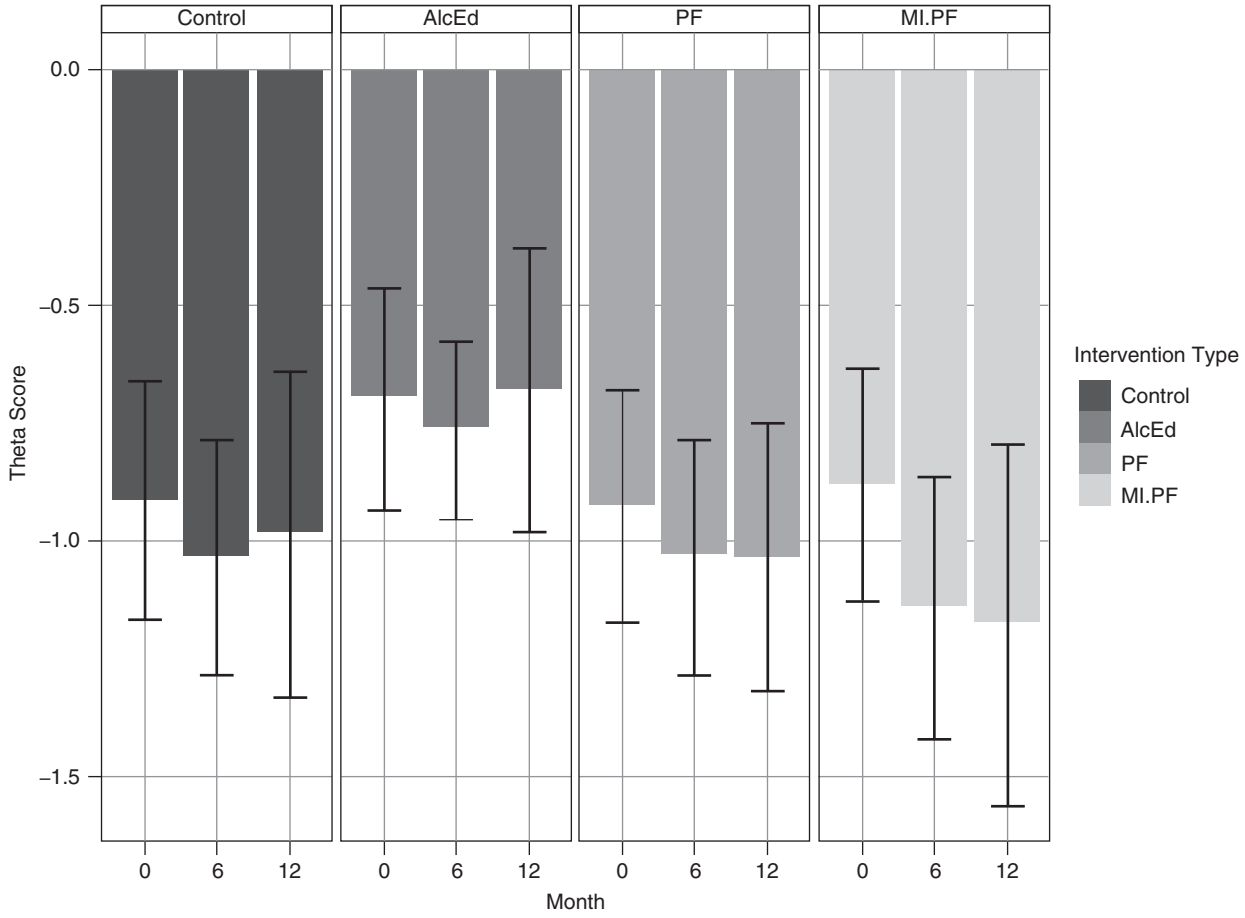

Figure 23.12 Model-based estimates of NR latent trait scores at baseline, 6 months and 12 months post intervention by group. NR = Neglecting responsibilities due to drinking; AlcEd = Alcohol Education; PF = Stand-alone Personalized Feedback; MI.PF = Motivational Interview plus Personalized Feedback (MI + PF); y-axis indicates NR scores. Higher scores (i.e., shorter bars in this figure) indicate greater severity. Error bars indicate 95% confidence intervals. Relatively speaking, there was a trend toward improving for those in the PF and MI + PF conditions.

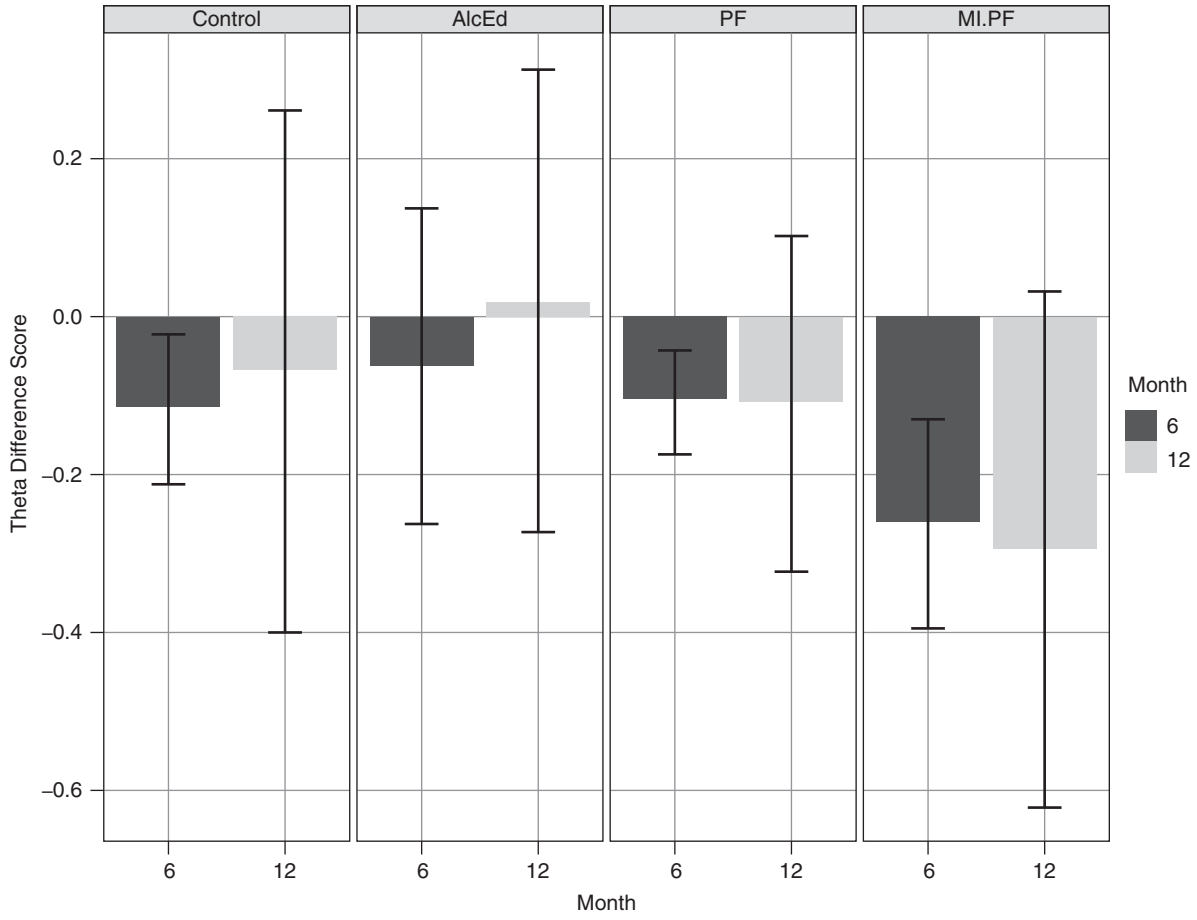

Figure 23.13 Model-based estimates of change at 6 months and 12 months post intervention by group. NR = Neglecting responsibilities due to drinking; AlcEd = Alcohol Education; PF = Stand-alone Personalized Feedback; MI.PF = Motivational Interview plus Personalized Feedback (MI + PF); y-axis indicates NR change scores. Error bars indicate 95% confidence intervals for these change scores. Confidence intervals that do not include zero indicate a statistically significant reduction at a given time point within groups. All groups with the exception of Alcohol Education showed a statistically significant reduction at 6 months. The significant reduction disappeared at 12 months for all three groups.

for those with higher levels of PBS at baseline. Relatively speaking, there was a trend toward improvement for PF and MI + PF. Figure 23.13 shows the statistically significant reductions from baseline at 6-month follow-up but not at 12-month follow-up for control, PF, and MI + PF. No evidence of change was found for Alcohol Education. Higher difference scores (positive scores on y axis) indicate higher levels of NR trait scores at follow-ups relative to their baseline levels (i.e., NR score went up; in other words, greater problems), whereas lower difference scores (negative scores on y axis) indicate reductions in NR scores at 6-month and 12-month follow-ups, compared with baseline. Given that control also significantly reduced NR at 6-month follow-up (zero not included in 95% confidence interval), the significant reductions shown by the PF and MI + PF groups could not be attributed to the interventions received. Thus, we then specifically compared the changes shown by three intervention groups against the change by control. Figure 23.14 shows the results. Compared to control, MI + PF showed significantly lower levels of NR at both 6-month and 12-month follow-ups. Those in the MI + PF condition were significantly better than those who received no intervention at both 6-month and 12-month follow-ups (zero not included in the 95% confidence intervals; Figure 23.14).

A few other things may be worth mentioning. Confidence intervals for 12-month outcome data were greater than those for 6-month data, which reflects greater uncertainty at 12-month follow-up, especially for PF, due to relative lack of data. Second, Alcohol Education exhibited greater problems at all three time points, reflecting their

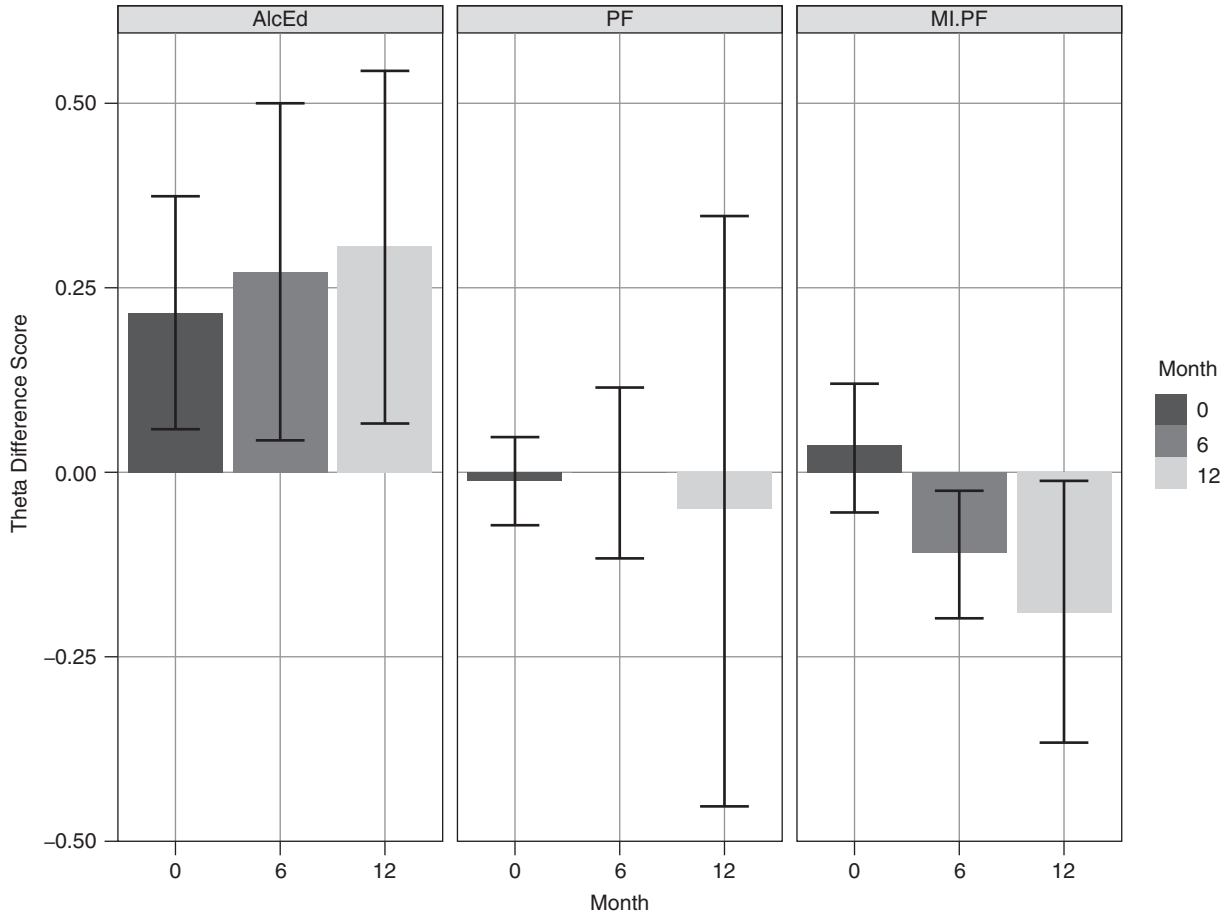

Figure 23.14 Multivariate meta-analysis of multiple intervention comparisons, showing a graphic demonstration of the significant MI + PF intervention effect compared with control. NR = Neglecting responsibilities due to drinking; AlcEd = Alcohol Education; PF = Stand-alone Personalized Feedback; MI.PF = Motivational Interview plus Personalized Feedback (MI + PF). Error bars indicate 95% confidence intervals. Confidence intervals that do not include zero indicate that the intervention condition at a given time point differed significantly in the estimated NR trait scores, compared with control. MI + PF, compared with control, showed significantly lower levels of NR trait scores at both 6 months and 12 months post intervention.

baseline differences. Combined with the data shown in Figure 23.13, we can say that Alcohol Education neither made it worse nor better for participants. The participants assigned to Alcohol Education more or less maintained their NR levels. This analysis was repeated for another dimension of alcohol-related problems and the results were largely similar (not reported). Thus, we can conclude that first, an in-person MI intervention with PF may make a difference in ameliorating alcohol-related problems among college students, at least up to 12 months; second, a stand-alone PF intervention may not be helpful for reducing alcohol-related problems, compared to control.

This finding is similar to the one reported in Huh et al. (2015) that utilized different analytic methodologies for a slightly different set of studies from Project INTEGRATE. In Huh et al., we used Bayesian multilevel overdispersed Poisson hurdle models in one-step IDA analysis to estimate intervention effects on drinks per week and peak drinking, and Gaussian models for alcohol problems in one-step IDA analysis. To overcome the unbalanced design, we utilized a three-level multilevel model, in which study-by-intervention condition was used as the highest, third level (repeated measures as the first level and individuals as the second level). To derive the overall intervention efficacy estimate (overall efficacy), as well as estimates for each of the intervention groups, we utilized posterior distributions from Bayesian analysis. The results indicated that there was no evidence of the overall intervention (BMI vs. control) effect on any of the outcomes examined but there was a small intervention effect by MI + PF on alcohol-related problems (Huh et al., 2015).

The substantive conclusion made in the current chapter is significant because the field of college alcohol interventions has embraced web-based normative feedback interventions, based on the previous findings from single studies that suggested that stand-alone PF interventions are just as efficacious as in-person MIs with PF at least for short term (e.g., see Walters & Neighbors, 2005 for a review). The current finding suggests that to reduce alcohol-related harm, an in-person MI may be needed. Although web-based interventions are easier to reach those who are in need and are attractive for their scalability, the findings from the IDA investigations reported in this chapter and in Huh et al. (2015) cautiously suggest a need to delve further into the mechanisms behind the in-person MI interventions with PF and to develop new interventions that may be more efficacious.

Note that the analytical examples shown in this chapter, as well as the one in Huh et al. (2015), are computationally demanding although the nature of the challenges is different. For the current IPD multivariate meta-analysis, the dimension of covariates was an important factor to consider. We added just four demographic covariates to the model, but the analysis required 15 × 15 covariance matrices (for 15 covariates) to be pooled across 15 separate analyses (for 15 studies with Studies 13 and 14 combined). The estimation of the between-study covariance matrix was quite challenging, especially with the embedded missing data in these matrices. Despite these challenges noted, the data examples shown in this section demonstrate new possibilities for the field of meta-analysis and IDA. Instead of focusing on qualitative or subjective interpretations of the relevant literature or counting the number of studies with a statistically significant intervention effect, IDA can be utilized using more advanced and flexible methodologies developed in recent years. It can overcome inherent limitations of single studies and AD meta-analysis. The value of fully utilizing existing data has been important and will most likely remain important in the coming years.

Software Programs and Packages

Univariate meta-analysis can be performed using commercially available software packages like Comprehensive Meta-analysis (CMA; Borenstein, Hedges, Higgins, & Rothstein, 2005) and MetAnalysis (Leandro, 2005) and other free DOS-based programs. Bax, Yu, Ikeda, and Moons (2007) reviewed their various features and different levels of usability in great detail. Table 23.8 lists available meta-analysis packages developed for R (R Core Team, 2014) and user-defined commands developed for Stata (StataCorp, 2013). For multivariate methods, *metafor* (Viechtbauer, 2010) can perform multivariate meta-analysis under fixed- and random-effects models, and the latter can be fitted through MLE or REML. In contrast, *mvtmeta* package (Chen, 2012) performs multivariate meta-analysis using the method of moments estimator for between-study covariance matrix when fitting random-effects model; *mvmeta* package (Gasparrini, Armstrong, & Kenward, 2012) uses the same method of moments estimation but allows missing data and handles meta-regression; and *metaSEM* package (Cheung, 2014) offers functions to perform fixed-effects and random-effects multivariate meta-analysis under the framework of structural equation modeling. All of these packages can handle both AD and IPD.

TABLE 23.8 Software Programs for Meta-analysis*.

	Univariate Meta-analysis	Multivariate Meta-analysis
R (packages)	epiR meta metafor rmeta gmeta	mvmeta mvtmeta metaSEM
Stata (User written commands)	metan metacum metareg	mvmeta mvmeta_make

*More information, including manuals and references, can be found at http://cran.r-project.org/web/views/MetaAnalysis.html and http://www.stata.com/support/faqs/statistics/meta-analysis.

For the multivariate meta-analysis illustrated in the present chapter, we developed our own functions to use in the R programming environment. The existing packages for multivariate meta-analysis discussed above could not be applied due to the complex data structure that we had. As indicated previously in the Multivariate Meta-analysis section, the dimension of the data estimated was high (15 × 15 covariance matrix) and this complexity was compounded with missing data. Thus, the second author wrote custom functions that were suited for the data. Essentially, the idea was to obtain the likelihood function while incorporating the missing data structure, which could not be accomplished using the existing packages. More specifically, we estimated the 15 × 15 between-study covariance matrix using REML by using the R package *optimx*. We also utilized different methods available in the *optimx* package (Nash & Varadhan, 2011) to confirm the final estimates reported in this chapter. We then calculated meta-analyzed individual coefficient estimates (reported in Table 23.7) by plugging the REML estimates into the last

two equations shown in the IPD Meta-analysis and Integrative Data Analysis section. Figures 23.12–23.14 were drawn using the combined individual estimates reported in Table 23.7.

TRANSLATIONAL IMPLICATIONS OF INTEGRATIVE DATA ANALYSIS

IDA is an emerging methodological approach that is well suited for translational research. Translational research, although variously understood by different people, is generally known as the bench-to-bedside translation of knowledge from basic sciences to produce new clinical or treatment options for patients (Woolf, 2008). Through this translation, a new clinical treatment can be brought to scale to treat hard-to-treat problems and to narrow health disparities. For the successful translation of knowledge for evidence-based, bedside clinical practice, however, the integrity and validity of evidence is critical: Evidence-based practice is only as good and valid as the evidence that it is based on.

IDA, especially meta-analysis using IPD, has many promising utilities over single studies and over traditional meta-analysis utilizing summary data from published reports. More broadly, with regard to translational research, IDA may have at least three unique advantages. First, IDA studies using IPD can scrutinize existing findings in the literature and generate more robust findings and conclusions than possible based on single studies or traditional meta-analysis. Second, via IDA, one can examine mechanisms of behavior change with data that are better suited to address them. Third, through the advanced, state-of-the-art multivariate models, one can overcome compartmentalized pieces of evidence at various levels of analysis to create a more comprehensive understanding based on integrated quantitative evidence.

In terms of scrutinizing existing findings and strengthening our statistical inference, meta-analysis is increasingly seen as an important tool to shore up our confidence in evidence. In the present chapter, we suggest that traditional meta-analysis using summary statistics may be viewed as part of IDA using IPD, a broader research synthesis approach involving original raw participant-level data. Both of these approaches are expected to be relied on in the coming years; yet more advances and applications may be in store for IDA using IPD. There have been public calls to raise research standards for single studies and, in response, several stakeholders, such as editors of major journals and the National Institutes of Health (NIH), have proposed a number of changes in research practice (Collins & Tabak, 2014). According to Collins and Tabak, one of the initiatives considered by NIH is to develop a searchable data index for locating and accessing primary data. Thus, IDA using IPD may be called upon to provide a self-correcting function of science, especially for preclinical research, at more rapid pace than before.

Even for clinical research, the examples of antidepressant medications (Turner et al., 2008) and reanalysis of RCTs (Ebrahim et al., 2014) reviewed earlier in the current chapter illustrate the dangers of overly relying on data from published single studies. Therefore, from this perspective, it is promising that researchers are calling for a need to build participatory, prospective collaborative projects to tackle hallmark clinical questions such as what works (on the whole), what works for whom (subgroups or treatment modifiers), and how it works (mechanisms of behavior change) through innovative analysis of pooled data from multiple RCTs (e.g., Collaborative Data Synthesis for Adolescent Depression Trials [CDSADT]; NIMH Collaborative Data Synthesis for Adolescent Depression Trials Study Team, 2013).

In addition, it is very attractive that, via IDA, one can transcend compartmentalized pieces of evidence at various levels of analysis. In its place, one can generate a new understanding that is based on integrated quantitative evidence, which has been largely unobtainable from single studies or review studies that exclusively rely on summary data from single studies. Using IDA, similar studies can be linked to provide comparative evidence of various treatment approaches; generate evidence for treatment efficacy from multiple related outcomes; and provide clues as to the duration of treatment efficacy. Instead of subjectively interpreting and evaluating multiple coefficients obtained from multiple analyses in a piecemeal fashion, we can better grasp, for example, which treatment may be best of all available approaches in the field through the use of advanced methods well suited for IDA, as demonstrated in the data example provided in this chapter.

FUTURE DIRECTIONS AND LIMITATIONS

The research environment for IDA is ripe in many disciplines, including that of psychology. There are several thrusts behind this momentum. First, there is a great movement away from the current research practices that heavily depend on null hypothesis significance testing (NHST), toward new statistical practices that emphasize estimation of effect sizes and confidence intervals, and meta-analysis

(Cumming, 2014). The journal *Psychological Science*, a flagship journal for the Association for Psychological Science, announced new changes in publication standards and practices to be implemented starting January 2014 (Eich, 2014). To shore up the foundations of scientific inquiries, the journal's editors have proposed five broad changes: (1) remove word limits for the methods and results sections; (2) challenge researchers to clarify the what, why, and how questions of the research; (3) adopt the four-item disclosure statement aimed at making visible what goes on behind publications (i.e., undisclosed flexibility in data collection and analysis; Simmons, Nelson, & Simonsohn, 2011); (4) promote open practices by creating incentives to share data and materials when publishing and to declare full research protocols in advance; and (5) emphasize effect sizes, confidence intervals, and meta-analysis. When these changes are fully implemented, metadata repository systems that are searchable and easily accessible by others will create opportunities to quickly validate existing findings.

Second, from the perspective of exploratory, discovery-oriented investigations, data sharing can yield unexpected, serendipitous exploratory findings, which may lead to a prespecified, confirmatory study. Indeed, there are many national survey datasets that can be downloaded for public use. Moreover, in recent years, NIH has launched large, multisite projects expecting that they can serve as seed projects for other investigations. Big initiatives, such as the Human Connectome Project (HCP) and the National Consortium on Alcohol and Neurodevelopment in Adolescence (NCANDA), take advantage of improved computing capability, easier access to the web for storing and searching information, and convenient use of biological indices to better understand a complex phenomenon across different time scales and across different domains.

A third important thrust is the development of innovative methods for research synthesis. As this chapter demonstrates, there has been an explosion of more flexible, efficient, and powerful research methods to accommodate various needs, and these developments will likely continue. With the improvement in computing capability, we can run computationally demanding models, such as Bayesian models that were unthinkable not long ago. Elucidating the complex developmental processes that we see in developmental psychopathology requires a transdisciplinary systems prospective that cuts across scale and time, which has also been the guiding vision at NIH to promote scientific breakthroughs (Mabry, Olster, Morgan, & Abrams, 2008). IDA is a promising new approach in the era of big data to build a knowledge base that is more robust and cumulative and to move us forward toward more integrated and innovative research.

Despite our enthusiasm for IDA, some cautionary caveats are in order. Controlled, multisite, large studies do not always yield the same results as those from meta-analysis studies. In addition, different meta-analysis approaches—IPD or AD and different models—can lead to different estimates or conclusions (e.g., Haines & Hill, 2011). Recall, in the case of Avandia illustrated previously, the FDA restricted marketing of the drug based on findings from several meta-analysis studies showing greater heart attack risk while simultaneously offering a disclaimer stating that large-scale RCTs did not show a statistically significant risk elevation (Finkelstein & Levin, 2012). Thus, this case demonstrates that there is a need to evaluate all available evidence as a whole, and to be cautious about overly relying on one approach.

In addition, the time and resources required for IDA are considerable and one needs to carefully weigh the benefits of IDA relative to the resources needed. Data processing for IDA can be as intensive as collecting original data (Hussong et al., 2013) because of the need to examine and scrutinize all aspects of the pooled data prior to harmonizing and conducting further analysis to establish measurement invariance across important groups. Missing data resulted from combining data from multiple studies also pose a huge challenge to overcome for studies utilizing IPD. However, as the overall research environment is moving toward preregistration of a trial, reporting of all outcome variables, and better disclosure of methods and results, the environment may become more favorable for IDA studies in the future. Even for nonexperimental studies, similar, more open research practices are likely to follow, which may make it easier to conduct IDA studies.

CONCLUSIONS

Systematic research synthesis, particularly IDA involving original IPD from multiple sources, provides exciting new capabilities. IDA is well suited to address unmet needs in the field of developmental psychopathology and critical challenges in the current research environment. At the same time, there is a need to further develop research methods intended for research synthesis and to bridge our knowledge gaps in implementing these methods for IDA. Despite its many challenges, IDA is expected to be utilized more often in the future as a means to strengthen our research practice and lead to new discoveries.

Three-form planned missing design, example, 785t
Three-generational families, 605
Time
meaning, 111–112
metrics, 991–993
transformation, 998–999
Time of measurement effects, sequential designs (usage), 790f
Time scales, interrelations, 720–721
Time-series analysis, 727–729
Time-series approach, examples, 141
Time-series designs, 140–142
Time-varying covariate, 732
growth curve model, 1011f
TLI, 778–779
Toddler Behavior Screening Inventory (TBSI), 20
Toddlers, emotion lexicon (development), 284
Total effect (TE), 974
Total natural direct effect (TNDE), 974
Total natural indirect effect (TNIE), 974
Total Problems scores, analysis, 77
TRacking Adolescents' Individual Lives Survey (TRAILS) study, 74
Traditional outcomes mediation analysis, potential outcome mediation analysis (comparison), 975–976
Traits, contrast, 812
Trajectories. *See* Conduct problems; Dynamic trajectories
alternatives. *See* Developmental trajectories.
atypical development, configural frequency analysis (CFA), 884–886
data example, 885–886
atypical trajectories, 877
autoregressive latent trajectory mediation models, 963
comparison, 908–912
individual trajectories, 706
mean growth trajectories, estimation, 1031f
prediction, 915–916
data example, 915–916
simulation, 685–686
two-group CFA, 881
typical development, configural frequency analysis (CFA), 884–886
data example, 885–886
typical trajectories, 877
Transactional family dynamics, Schermerhorn/Cummings's model, 612f
Transactions, construct, 588
Transference-focused psychotherapy (TFP), 367–368
Transformations, idea, 600
Translational efforts, 653
Translational epidemiology, 121
Translational research. *See* Family
configural frequency analysis, relationship, 917–919
Translational science, developmental epidemiology (contributions), 95f
Translation, concept, 174–175
Transmission gap, 336
Trauma therapies, 367
TRF. *See* Teacher's Report Form
Triangle. *See* Rigid triangles
idea, 582
Triangular capacity, 600
Triangulation, 614–617
dimensions, 616–617
T-tests, 718
Tukey range tests, 1032
Tumor necrosis factor-α (TNF-α), 539
Turning points (study), latent growth modeling (usage), 1005–1006
Tutor/child interaction (mathematics instruction), matches/mismatches/self-iterative utterances (changes), 690f
Twins
children of twins design, 135
co-twin, sex, 145
discordant twin pairs (natural experiments), 133–134
extended children of twins (ECoT) design (natural experiments), 135–136
longitudinal twins and parents (LTaP) design, 136

Twins *(Continued)*
multivariate twin designs (natural experiments), 133
Netherlands Twin Registry (NTR), 75
twin-singleton comparisons, 138–139
Twin-singleton comparisons, 129
Two-factor solution, positive/negative items, 859t
Two-group CFA, 880t
base model, estimation, 888
cross-classification, 911t
monotonic trend information, cross-classification, 888t
PRxVRxAR cross-classification, 900t
Two-group latent growth modeling analyses, 1013
Two-method planned missing data design, 789
candidate constructs, usage, 788t
Two-method planned missing data design, candidate constructs (usage), 788t
Two-method planned missing design, 787–789
Two-method planned missing model, variations, 788f
Two-parameter logistic (2-PL) IRT analysis, 1055
Two-state anxiety questionnaire parallel forms, means/linear trends (first-order CFA), 886t
Typical developmental patterns, 886
Typical trajectories, 877

UK Millennium Cohort study, 134
Unconditional model, 68
Undermining effect, 399
Unidirectional comorbidity, bidirectional comorbidity (contrast), 59–60
Unified individual, understanding, 813
Uniformity myths, 799
Univariate growth mixture modeling, fit indices, 1030t
Univariate latent change score models, 1015–1017
Universal mental health screening, importance, 19
Unmeasured confounders, regression discontinuity designs (usage), 146–147
Unstructured change, 999
U.S. Preventive Services Task Force (USPSTF), hypertension screening declaration, 172

Validity
cultural validity/norms, 16
diagnostic interviews, 34
longitudinal developmental context, 14
measurement ability, 13–14
types, 14
Values, 446
Vanderbilt Therapeutic Alliance Scale, 1026
VAR. *See* Vector autoregressive
Variability
impact, 724
self-organization, 704–707
Variable-oriented approach, 797, 800–803
description, 799–812
limitations, 801–803
Variable oriented, term (usage), 867
Variable x variable correlation matrix, 855
Variance, estimators, 1061
Vector autoregression model, 853–854
Vector autoregressive (VAR) process, 858
Verbal aggression against adults (VAAA), 820, 879, 899
path model, 821f
two-group model, 821f, 827f
Verbal communication, research, 279–280
Verbal emotional expressiveness, 277–278
emotional dysfunction risk, association, 278–280
Vertical-integrative neurobiological model, 290
Very early childhood (ages 2–4)
I-Self, impact, 475
Jamesian I-Self functions, 475
Victimization. *See* Peer victimization
assessment, 544
experiences, 546
forms, 544–545
study, 641
Vignettes, creation, 501
Vineland Adaptive Behavior Scales II, 36
Violence. *See* School system
frequency, cross-classification, 894t
Violent revenge, 498–503
negative self-processes, role, 473
Virginia Twin Study of Adolescent Behavioral Development (VTSABD), 120
Vuong-Lo-Mendell-Rubin likelihood ratio test (VLMR-LRT), 1029

Ward's method, 830, 834t, 835t
usage, 836t
Wave-missing designs, 789–790
Weak monotonicity, 887
Wechsler Memory Scores (WMS), 1022
Well-being, I-Self (impact), 473–474
Whole-family processes, 616
Willi-Prader syndrome, 275
WinBUGS, 996
Within-cohort predictive correlations (Dutch children), 63f
Within-family risk dynamics, 69
Within-grid analyses, 749
Within-individual changes, 960
Within-study correlation, 1062
Within-study variability, 1059
Woodcock-Johnson Applied Projects subtest, usage, 991
World Mental Health Survey, 116
Worthlessness, 417
Wouters, 393

Young Adult Alcohol Problems Screening Test (YAAPST), 1071
Young adults
antisocial peers/peer victimization, involvement, 649
anxiety symptoms/disorders, 635–637
attention-deficit/hyperactivity disorder (ADHD), 643–644
cognitive dispositions, 538
comorbidity, 644–645
depression/depressive symptoms, 633–635
eating disorders, 642–643
externalizing behaviors, development, 638
externalizing problems/disorders, 637–642
friendships, number/quality, 647–648
internalizing problems/disorders, 633–637
intimate partner violence (IPV), 640–641
mental health (promotion), I-Self (role), 639
methodological issues, 652–653
measurement issues, 652–653
mediating/moderating variables, 653
psychological outcomes/comorbidity issues, 653
public health implications/translational efforts, 653
sample issues/study populations, 652
study designs, 652
mixed-sex friendship groups, 639
Oregon Youth Study (OYS)/Oregon-Couples Study, 638–639
peer context, 647–650
peers/partners, online communication, 649–650
relationships, behavior/experiences, 634–635, 636–637
romantic involvement, 633–634, 636, 639–640
romantic relationships, 631–633
peer selection/socialization processes, 648–649
same-sex relationships, 646–647
theory development, issues, 651
translational implications, 653–655
Young children
assessment, parent-caregiver reports, 12
behavioral problems, checklist/questionnaire measures, 21t–22t, 25t
caregiver report tools, characteristics, 11t
caregiving contexts, 6–9
changes, 1
contextual influences, sensitivity, 6–9
depression, 3–4

development, domains, 9–17
disruptive behavior disorders, 4
early problems, importance, 2–4
emotional information, perception, 285
impairment, assessment, 35–36
information, caregivers (reliance), 4–6
Major Depressive Disorder, 4
negative emotion regulation, 292
observational assessment, 35
parent report tools, characteristics, 11t
post-traumatic stress disorder (PTSD), 3
problems, identification, 16–17
psychiatric diagnosis, progress, 3–4
psychometric properties, understanding, 12
psychopathology, assessment, 1
screening methods, 18–19
characteristics, 19–20
screening tools, 20, 23
self-initiated distraction, 292–293
social competence, age effects (illustration), 16f
social-emotional problems, checklist/questionnaire measures, 21t–22t, 25t
sociocultural factors, 7–9
Young children, assessment
approach/tool, selection, 11–17
checklist measures, coverage (breadth/depth), 26t–27t
classification, validity, 14–15
considerations, 4–9
diagnostic approaches, 29–30
Diagnostic Infant and Preschool Assessment (DIPA), 32
diagnostic interviews, 30–32
interrater reliability, 33–34
psychometric properties, 32–34
test-retest reliability, 32–33
types, 31t
validity, 34
findings, sociocultural factors (impact), 8t
multidomain checklists, 25, 27–28
normatization, 15–16
Preschool Age Psychiatric Assessment (PAPA), usage, 30–32
reliability, 12–13
interpretation rules, 13t
statistics, 13t
research, continuation, 37–38
response formats, 17
tools, types, 11–12
validity
cultural validity/norms, 16
longitudinal developmental context, 14
measurement ability, 13–14
Youth Risk Behavior Surveillance System (CDC), 119
Youth Self-Report (YSR), 65, 82, 1032
Yule's Q, representation, 610

Z test, 874
Zuid Holland Longitudinal Study, 73–74
