Preface to Developmental Psychopathology, Third Edition

A decade has passed since the second edition of *Developmental Psychopathology* was published. The two prior editions (Cicchetti & Cohen, 1995, 2006) have been very influential in the growth of the field of developmental psychopathology. The volumes have been highly cited in the literature and have served as an important resource for developmental scientists and prevention and intervention researchers alike. In the present third edition, we have expanded from the three volumes contained in the second edition to four volumes. The increased number of volumes in this current edition reflects the continued knowledge gains that have occurred in the field over the past decade.

A not insignificant contributor to this growth can be found in the very principles of the discipline (Cicchetti, 1984, 1990, 1993; Cicchetti & Sroufe, 2000; Cicchetti & Toth, 1991, 2009; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). Theorists, researchers, and prevention scientists in the field of developmental psychopathology adhere to a life span framework to elucidate the numerous processes and mechanisms that can contribute to the development of mental disorders in high-risk individuals as well as those operative in individuals who already have manifested psychological disturbances or who have averted such disorders despite their high-risk status (Cicchetti, 1993; Masten, 2014; Rutter, 1986, 1987, 2012). Not only is knowledge of normal genetic, neurobiological, physiological, hormonal, psychological, and social processes very helpful for understanding, preventing, and treating psychopathology, but also deviations from and distortions of normal development that are seen in pathological processes indicate in innovative ways how normal development may be better investigated and understood. Similarly, information obtained from investigations of experiments of nature, high-risk conditions, and psychopathology can augment the comprehension of normal development (Cicchetti, 1984, 1990, 1993; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe, 1990; Weiss, 1969).

Another factor that has expedited growth within the field of developmental psychopathology has been its ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary and translational research (Cicchetti & Gunnar, 2009; Cicchetti & Toth, 2006). In keeping with its integrative focus, contributions to developmental psychopathology have come from many disciplines of the biological and social sciences. A wide array of content areas, scientific disciplines, and methodologies has been germane. Risk and protective factors and processes have been identified and validated at multiple levels of analysis and in multiple domains.

The increased emphasis on a multilevel, dynamic systems approach to psychopathology and resilience, the increased attention paid to gene–environment interplay in the development of psychopathology and resilience, and the application of a multiple levels of analysis developmental perspective to mental illnesses that have traditionally been examined nondevelopmentally (e.g., bipolar disorder, schizophrenia, and the personality disorders) not only have contributed to a deeper understanding of the dysfunctions but also have educated the public about the causes and consequences of mental disorder (see Cicchetti & Cannon, 1999; Cicchetti & Crick, 2009a, 2009b; Miklowitz & Cicchetti, 2006, 2010; Tackett & Sharp, 2014).

Advances in genomics, GxE interactions, and epigenetics; growth in our understanding of neurobiology, neural plasticity, and resilience; and progress in the development of methodological and technological tools, including brain imaging, neural circuitry, hormone assays, immunology, social and environmental influences on brain development, and statistical analysis of developmental change, pave the way for interdisciplinary and for multiple levels of analysis research programs that will significantly increase the knowledge base of the development and course of maladaptation, psychopathology, and resilience. Moreover, randomized control prevention and intervention trials are being conducted based on theoretical models and efforts to elucidate the mechanisms and processes contributing to developmental change at both the biological and psychological levels (Belsky & van IJzendoorn, 2015; Cicchetti & Gunnar, 2008).

Despite the significant advances that have occurred in the field of developmental psychopathology, much important work lies ahead. Undoubtedly these future developments will build on the venerable contributions of the past; however, as work in the field becomes increasingly interdisciplinary, multilevel, and technologically sophisticated, it is essential that even more emphasis be directed toward the process of development (Harter, 2006; Sroufe, 2007, 2013). It is not only genes and environments but also the cumulative developmental history of the individual that influences how future development will unfold (Sroufe, 2007, 2013).

Developmental psychopathologists have incorporated concepts and methods derived from other disciplinary endeavors that are too often isolated from each other, thereby generating advances in knowledge that might have been missed in the absence of cross-disciplinary dialogue. The continuation and elaboration of the mutually enriching interchanges that have occurred within and across disciplines interested in normal and abnormal development not only will enhance the science of developmental psychopathology but also will increase the benefits to be derived for individuals with high-risk conditions or mental disorders, families, and society as a whole.

INTRODUCTION

The past 20 years have witnessed a sea change for *young children*'s mental health. It is now recognized that early childhood (0–5 years) is a crucial period for the development of self-regulation, a critical set of competencies that have implications for adaptive functioning in school and through the life span. Early childhood is also recognized as a time when psychopathology may begin to emerge and disrupt young children's developmental progress. In addition, enormous progress has been made in demonstrating that, when psychiatric disorders are defined in a manner that is developmentally meaningful, even very young children suffer from psychiatric disorders that are valid, impairing, and clinically very similar to those experienced by older children (Egger & Angold, 2006; Egger et al., 2006). Indeed, recent research has indicated that psychiatric disorders are just as prevalent in early childhood as they are in school-age children (Egger & Angold, 2006). Moreover, when young children manifest psychopathology that is impairing, it is often persistent and predicts later difficulties once they become of school age. Equally important, there is increasing awareness that these problems can interfere with learning within early childhood and may set in motion a developmental cascade that likely predicts challenges to lifespan functioning in multiple domains. Research focused on specific disorders has driven discovery of neurobiologic substrates, which has further validated the relevance and reality of early life psychopathology (Luby, Belden, Pautsch, Si, & Spitznagel, 2009; Luby, Si, Belden, Tandon, & Spitznagel, 2009; Stalets & Luby, 2006). These advances in our understanding of young child psychopathology are paralleled by, and one might argue largely driven by, an explosion in reliable, valid, developmentally sensitive measures for assessing a full range of self-regulation, social-emotional development in young

[1]Color versions of Figure 1.1 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

children. Specifically, over the past 15-plus years, a number of instruments have been developed to assess parent and other caregiver appraisals of social-emotional functioning utilizing both questionnaire and interview methods. There have also been advances in observational tools to assess clinically significant emotional and behavior problems. With greater acceptance and building on advances in measurement, we are poised to evaluate the benefits of a broad range of prevention and intervention efforts and see increasing discovery of biological and environmental influences on young children's mental health.

As the field presses forward to address the mental health needs of young children both efficiently and effectively, success will be optimized by a well-informed approach to assessment that (1) acknowledges *contextual factors,* including the caregiving environments at home and in other settings, such as child care and early education environments, caregiver influences on social-emotional functioning and assessment, recent changes in family structure or contextual stressors, and sociocultural factors; (2) is framed within the context of a child's *functioning in other developmental domains,* such as language, cognition, adaptive functioning, health, and sensory; (3) is tailored to the *goals and purposes of the assessment and evaluation setting* (e.g., pediatric clinic, day care center, mental health clinic, or private practice); (4) utilizes *reliable, valid, developmentally sensitive tools*; and (5) employs an approach to *interpretation* that views the whole child in relation to contextual and developmental factors and evaluates his or her capacities and participation in developmentally appropriate activities and settings (i.e., impairment).

A primary goal of this chapter is to help clinicians and researchers determine the most suitable measures to use from a wide array of parent and other caregiver report, observational, and direct assessment measures that are now available. Rather than trying to offer an exhaustive list of all existing measures of social-emotional functioning and psychopathology appropriate for young children, we highlight some of the most widely employed and promising tools and approaches, including those that reflect advances in *screening*, comprehensive *dimensional* parent- and other caregiver-report instruments, and diagnostic approaches to young child evaluation. These assessment tools can be categorized as follows: (1) parent and other caregiver report instruments that focus on general problem behaviors; (2) parent and other caregiver report instruments that focus on specific problem areas or disorders (e.g., anxiety, disruptive behavior); (3) parent and other caregiver report instruments designed to assess both problem behaviors and competencies; (4) comprehensive diagnostic interviews for parents of young children; and (5) observational tools and methods. Within the first three categories, measures can be further divided according to whether they are brief tools appropriate for *screening* or longer *checklist* tools or *diagnostic interviews* that provide more detailed information. Finally, we will close the chapter with a discussion of ongoing challenges, future directions, and opportunities in research on and clinical applications with assessment of young child psychopathology. Although many researchers and clinicians continue to express discomfort about pathologizing, or labeling, young children, our focus is on assessment tools that enhance the recognition and detection of early emerging psychopathology to address mental health needs in an effort to minimize adverse developmental cascades. Moreover, we argue optimistically that by labeling systematic behavioral patterns observed within young children (rather than labeling individual children) we create the potential to develop and disseminate guidance regarding appropriate contextual supports and specific behavioral interventions that are tailored to the needs of children with different behavioral profiles; these early prevention and targeted interventions can be designed to support family beliefs, values, and goals and children's developmental progress while minimizing child and family distress.

EARLY PROBLEMS MATTER

There is now a consensus among child clinicians that children as young as 2 years of age can suffer from significant social-emotional and behavior problems, or psychopathology. Prevalence estimates of clinically significant problems in nonreferred samples have ranged considerably, from as low as 7% to as high as 26%, depending on whether problems are defined in terms of meeting criteria for psychiatric diagnosis or by exceeding a clinical cutoff on a checklist measure (Briggs-Gowan, Carter, Skuban, & Horwitz, 2001; Egger & Angold, 2006; Gleason et al., 2011; Karabekiroglu et al., 2013; Keenan et al., 1997; Lavigne, Lebailly, Hopkins, Gouze, & Binns, 2009; Wichstrom et al., 2012). Rates also tend to be higher among young children exposed to poverty and other psychosocial risk factors (McCue Horwitz et al., 2012; Qi & Kaiser, 2003; Weitzman, Edmonds, Davagnino, & Briggs-Gowan, 2014). Early social-emotional and behavioral problems are linked with impairment in child and family functioning as well as increased parenting stress and worry (Briggs-Gowan & Carter, 2008a; Briggs-Gowan, Carter, Bosson-Heenan, Guyer, & Horwitz, 2006; Briggs-Gowan et al., 2001; Egger & Angold, 2006; Fuchs, Klein, Otto, & von Klitzing, 2013; Keenan et al., 2007; Lavigne et al., 1996; Luby, Belden, Pautsch, et al., 2009). Moreover, social-emotional/behavior

problems in young children have been associated with concomitant delays in child social-emotional competence (Briggs-Gowan & Carter, 2008a; Briggs-Gowan et al., 2001) and shown to predict poorer social competence in elementary school (Briggs-Gowan, Carter, & Ford, 2011). Intervening in preschool to address both social emotional problems and competencies is associated with greater improvements in both areas, including on experimental tasks of emotion knowledge and social problem-solving strategies (Ştefan & Miclea, 2013). Furthermore, contrasting with the historical belief that young children's difficult behavior is just a phase (Keenan & Wakschlag, 2000), there is consistent evidence that for some children these early emergent social-emotional and behavioral problems are persistent and predict poorer functioning at later ages (Briggs-Gowan & Carter, 2008b; Briggs-Gowan et al., 2006; Kim-Cohen et al., 2005; Lavigne et al., 1998; Mathiesen & Sanson, 2000; O'Neill, Schneiderman, Rajendran, Marks, & Halperin, 2014; Shaw, Lacourse, & Nagin, 2005; Speltz, McClellan, DeKlyen, & Jones, 1999; Spence, Najman, Bor, O'Callaghan, & Williams, 2002; Stalets & Luby, 2006; Wakschlag, Briggs-Gowan, et al., 2008). Notably, persistence has been documented for a wide range of problems, including anxiety, depression, attention-deficit hyperactivity, and disruptive behaviors. Thus, consistent and convincing evidence indicates that young children can and do suffer from a wide spectrum of social-emotional and behavioral problems that are often persistent—the presence of impairment further underscores the importance of early identification and prevention in this developmental period.

Progress in Psychiatric Diagnosis in Young Children

Empirical and conceptual work in the areas of posttraumatic stress disorder (PTSD), depression, and disruptive behavior disorders illustrates the role that developmental factors can play in how psychopathology manifests and how several groups have endeavored to establish the relevance of these psychopathologies in young children.

PTSD

Considerable work by Michael Scheeringa and colleagues documents that children as young as 9 months of age can and do suffer from PTSD (Scheeringa, 2007, 2008; Scheeringa, Myers, Putnam, & Zeanah, 2012; Scheeringa, Peebles, Cook, & Zeanah, 2001). This work highlights the importance of considering the developmental capacities of young children when determining the appropriateness of criteria employed for older children and illustrates the utility of adopting a multi-informant, multimethod approach to assessment (Hunsley & Mash, 2007). Scheeringa et al.'s work in this area has driven important recognition of developmental factors that affect how PTSD presents in young children. For example, many avoidance and numbing symptoms are either developmentally implausible (e.g., sense of a foreshortened future) or internal in quality (e.g., avoidance of internal thoughts, feelings, or reminders of the event), making them very difficult to identify in young children who have limited verbal skills (Scheeringa, 2008). Scheeringa also noted that these types of symptoms may manifest differently in young children. For example, "markedly diminished interest in significant activities" is often observed as constriction of play, and "feeling of detachment or estrangement from others" is often observed as social withdrawal.

Scheeringa and colleagues further documented the central role that parental reactions play in the emergence, promotion, and maintenance of symptoms in young children (Scheeringa & Zeanah, 2001), highlighting the importance of assessing young children's possible PTSD symptoms in the context of parent– or caregiver–child relationships.

Depression

Luby and colleagues' work has established the presence of early manifestations of clinically significant signs and symptoms of depressive disorders in young children (Luby, Belden, Pausch, et al., 2009; Luby & Navsaria, 2010; Luby, Si, et al., 2009; Stalets & Luby, 2006). Their research addresses the complicated developmental question of whether young children's emotional repertoire is itself sufficiently differentiated to encompass true depressive or elated affect and how to differentiate atypical from normative developmental manifestations. They have further noted that greater variability in young children's mood states calls into question the relevance of duration criteria employed by diagnostic systems developed for older children (Gaffrey, Belden, & Luby, 2011). Luby and colleagues utilized a multimethod, multi-informant approach that included (1) parent reports on both dimensional ratings scales and in an age-appropriate *diagnostic interview*; (2) comprehensive observation of the young child's affective range via a laboratory based temperament assessment, thematic play, and parent–child interaction across structured and unstructured conditions; (3) a developmentally sensitive direct interview for preschoolers; (4) cognitive assessment of the child; and (5) neurocognitive assessment of the child. By employing these techniques, they were able to identify a group of young preschool-age children who met modified depression criteria developed for young children.

Further, Luby and colleagues' empirical data have provided crucial insights into how depression manifests in young children (Luby, Belden, Sullivan, et al., 2009;

Luby, Belden, Pausch, et al., 2009; Luby, Si, et al., 2009). For example, their work has shown that withdrawal and vegetative symptoms are less consistently evident in young children with Major Depressive Disorder relative to older children. They have also shown that sadness, irritability, and thoughts of death, while evident in young children with depression, also are often present in children with anxiety disorders and attention-deficit/hyperactivity disorder (ADHD). In contrast, anhedonia, feelings of guilt, and psychomotor agitation appear to be fairly characteristic of young children with depression. Changes in activity, appetite, and sleep also have been noted. Anhedonia appears to be a very specific marker of depression in young children: it is commonly present in young children with depression and rarely seen in other psychiatric groups or typically developing children (Luby et al., 2002). A subtype of preschool depression characterized by anhedonia also appears to be particularly severe (Luby, Belden, Pausch, et al., 2009). The work of Luby and her colleagues is notable for inclusion of biological correlates, such as cortisol reactivity and addressing family genetic risk to document the *validity* of the revised young child criteria (Luby, Belden, Pausch, et al., 2009; Luby, Si, et al., 2009; Stalets & Luby, 2006).

Disruptive Behavior Disorders

The study of disruptive behavior disorders highlights the complexity of distinguishing normative from clinically problematic behavior during early childhood when some "problem" behaviors are normative (Wakschlag et al., 2007; Wakschlag, Tolan, & Leventhal, 2010). Historically, concern was raised about whether disruptive behavior problems could be reliably assessed during this period (Campbell, 1990) and whether it may be premature to diagnose children whose challenging behaviors might be transient and diminish over time. At the same time, disruptive behavior is the most common reason for referral of young children to mental health clinics (Keenan & Wakschlag, 2000; Thomas & Guskin, 2001). Wakschlag and her colleagues have pressed for the refinement of diagnostic approaches in a manner that describes early manifestations of disruptive behavior in a developmentally appropriate and meaningful fashion and distinguishes between clinically significant disruptive behaviors and expectable variation in children's capacity to regulate emotions and behavior as they consolidate their self-regulatory skills (Gray & Wakschlag, in press; Wakschlag et al., 2007). This work and the work of others has demonstrated that disruptive behavior disorders can be reliably and validly diagnosed and are associated with marked impairment in preschool children (Egger & Angold, 2006; Egger et al., 2006; Keenan & Wakschlag, 2000, 2002; Keenan et al., 2007; Wakschlag et al., 2007). Through a longitudinal study, this group further demonstrated persistence over time in early disruptive behavior disorders. In one study, 55% of those with disorders at baseline continued to meet criteria for disorder one year later (Wakschlag, Briggs-Gowan, et al., 2008). These rates are strikingly similar to levels of persistence observed in school-age children (Briggs-Gowan et al., 2003).

Summary

As our understanding of specific early emerging disorders evolves, it is quite likely that additional diagnosis-specific instruments will be developed, allowing clinicians and researchers to elicit information about behaviors that assist in making differential diagnoses (i.e., are specific to diagnostic conditions). Clearly, multimethod, multi-informant assessment is integral to understanding young children's development. Moreover, observations of the parent–child or caregiver–child interactions across several contexts must be considered a critical component of any young child assessment of social-emotional problems or psychopathology.

IMPORTANT CONSIDERATIONS IN YOUNG CHILD ASSESSMENT

Though challenges exist when conducting any mental health assessment, several are unique to or require greater consideration when assessing young children, including the following: (1) young children's *limited communication skills*, which results in greater reliance on caregivers for information about the child's functioning; (2) young children's *sensitivity to contextual influences* on their functioning and the resulting importance of assessing context when working with this population; and (3) the influence of *sociocultural factors*, which affect the meaning of the child's behaviors to caregivers and other family members, the way that caregivers report on the child's behavior, caregivers' level of worry about the child overall and in relation to specific behaviors, caregivers' decisions to seek or not seek services, and the assessor's interpretation of findings. Understanding these challenges can enhance the evaluation process.

Reliance on Caregivers for Information

The fact that infants and young children have no or limited verbal abilities and metacognitive capacities makes it

difficult or impossible to directly collect information from them about their thoughts and feelings about presenting complaints, historical experiences and behaviors, and contextual events. Thus, in contrast to older children, youth, and adults, caregivers play a central role in providing information about the young child's behaviors across multiple settings and contexts, including crucial insight into when behaviors may have emerged and changed over time and contextual factors that may have exacerbated or attenuated symptoms. Collecting information from caregivers brings unique considerations to the assessment process when evaluating questionnaire and interview assessment tools.

First, it is important to establish the best informant in the child's life to best speak for him or her about a given topic. This is usually determined by asking who has a parental or caregiving role for the child in relation to the area or domain of inquiry, that is, the person who assumes responsibility for meeting his or her physical and emotional needs. In this chapter, the term *parent* refers to biological, adoptive, or foster parents or guardians or extended family members who care for the child on a regular basis. The term *caregiver* encompasses parents as well as individuals who routinely spend enough time with the child to be knowledgeable about multiple aspects of the child's social-emotional functioning and day-to-day behavior. Thus, caregiver may refer to extended family members and child-care or day-care providers who have cared for the child for at least one month and who care for the child on a regular basis. (Note, however, that some measures may list different criteria for classifying someone as a suitable informant on the child's functioning.) Typically, the person who brings a child to his or her evaluation appointment and who consents to the evaluation is a parental figure and should be included in the evaluation process; however, it is also important to assess others who may function as caregivers—particularly when a child experiences care in multiple contexts. These additional individuals should also be included as informants. Moreover, it is important to invite relevant caregivers to participate in any child evaluation, as young children's behavior is more variable across contexts (Clark, Tluczek, & Gallagher, 2004; Tronick, 1989).

An evaluation of the child's larger family context facilitates the process of identifying caregivers. It also provides important cues regarding factors such as recent stressors or strained dyadic and triadic family relationships that are currently influencing the child's functioning or that may have had a role in shaping the child's functioning over time (Carlson, 1990; Hayden et al., 1998). Information about the larger family context also enhances the assessor's understanding of a given caregiver's perspective on the child (e.g., how long the caregiver has known the child, who else is present in typical interactions between the caregiver and the child, who supports or influences the caregiver's beliefs about the child), potentially illuminating sources of bias and avenues for intervention. For example, if in the process of assessing the family context it comes to light that a young mother has received criticism about her child's behavior and her own parenting from her own mother, who cares for the child on a regular basis, this information would point to the need for further assessment of the mother–grandmother relationship. This evaluation could focus on the potential utility of intervention to improve communication between and address inconsistencies in the disciplinary styles, beliefs and expectations of the two caregivers. It is important to note that in using the word *family* we refer to any person, whether biologically related to the child or not, who is considered by the child or other adults close to the child to be a family member. The assessor should consider the total makeup of the family group (e.g., how many members), who is considered a family member, how family members define relationships with one another, where family members live in relation to one another, and what roles family members hold from the perspective of the target child (Carlson, 1990). In addition to evaluating the current family context, a history of the family makeup should be obtained, including ruptures in family relationships, new additions to the family, and changes in the way family members are distributed across households.

In the process of assessing the family and caregiving context and history, assessors must be alert to their own biases about what constitutes a family and how families function. Accurate assessment of family functioning will be facilitated by knowledge of cultural norms regarding family relationships in the groups to which a child belongs. In contrast to the popular notion of the two-parent household and caregiving system, many children are cared for in part or whole by relatives such as aunts, uncles, and grandparents (Dressler, 1985; Wilson & Tolson, 1990). In fact, as of 2012, 10% of all American children reside with a grandparent (with or without a parent also in the home); this number is even greater for Black (14%), Latino (12%), and Asian (14%) children (Ellis & Simmons, 2014). Twenty-six percent of children under the age of 5 whose mothers are employed have a grandparent or other relative as their primary child-care provider (Laughlin, 2013). Many more children may have close but informal caregiving relationships with relatives other than their parents.

Thus, many children have nonparental caregivers who should be included in the evaluation process to elicit an accurate assessment of the child's functioning. The utility of including multiple caregivers' reports in the evaluation process is further discussed in the next section.

Sensitivity to Contextual Influences, Including Caregiving Contexts

Young children's behavior is highly sensitive to contextual and relational influences (Clark et al., 2004; Dirks, De Los Reyes, Briggs-Gowan, Cella, & Wakschlag, 2012; Gray et al., 2012; Tronick, 1989), and it is therefore critical to include an assessment of relevant contextual factors in any evaluation involving a young child. When working with young children, social-emotional and cognitive functioning and impairment should always be assessed within the context of caregiving relationships and settings, with assessors incorporating what they are able to observe and measure about the various aspects of caregiver functioning and setting characteristics into their interpretation of findings from assessment instruments designed to measure an individual's functioning. In many cases, the family history will reveal recent or chronic stressors to which the child may be responding. Where major events have occurred in the child's history—whether these are identified as stressors by the reporter or not—it may be useful to explicitly inquire about the child's functioning before and after the event as well as changes since the event. As an example, moving houses is a stressful—and common—transition for young children (Stoneman, Brody, Churchill, & Winn, 1999). In some cases, the family history may reveal a recent change in the child's caregiving relationships, as in the case of a child who has recently transitioned to the care of a new foster parent, or in the case of a child whose parents have recently moved the family into their own apartment after having lived with the child's grandparents for the majority of her life. In cases such as these, repeat assessment after one or two months may be warranted to assess the child's functioning after a period of adjustment to the new caregiving environment.

Understanding the makeup of a particular child's family is an essential assessment task because young children's development, behavior, and functioning are embedded within their caregiving relationships. While it is also true that older children are influenced by their caregiving contexts, young children may be especially sensitive to contextual influences due to their dependence on others for their basic needs, often limited exposure to outside institutions such as schools, limited relationships with peers, and their unlikelihood of having developed independent emotion-regulation or coping strategies that they can utilize in the face of environmental stressors (Compas, 1987).

Caregivers provide structure to the physical, emotional, and behavioral aspects of the child's environment; for example, infants learn to regulate their own affect through exchanges with their caregivers and practice with sensitive, engaged caregivers to repair dysynchronous interactions, to reengage after a rupture, to recover behaviorally and physiologically after exposure to a stressor, and to convey information through affective expression (Bridgett, Burt, Laake, & Oddi, 2013; Haley & Stansbury, 2003; Kogan & Carter, 1996; Martinez-Torteya et al., 2014; Tronick, 1989). As another example, in the behavioral domain, children whose caregivers provide encouragement for independent efforts to achieve goals or learn new tasks may develop a sense of competence and intrinsic motivation that facilitates effortful engagement in challenging tasks in settings outside the home (Ryan & Deci, 2000). Relatedly, consistent with Vygotsky's (1978) theory of proximal development, children whose parents engage in scaffolding behavior (including teaching, praise, encouragement, and positive affective engagement) to enable them to perform within their zone of proximal development—the space between what they have already mastered developmentally and what they are capable of doing with parental support—show superior academic and social self-regulation abilities compared with children whose parents' style of instruction is less contingent on their current level of achievement (Clarke, Kelleher, Clancy, & Cannon, 2012; Neitzel & Stright, 2003).

Caregivers' structuring of the physical environment also may be influential; as an example, low-income children on average have less access to cognitively stimulating books and games (Evans, 2004), which may both impact their actual academic attainment and deflate their scores on assessments due to a lack of familiarity with the types of tasks commonly used in intellectual and academic assessment of young children. A striking percentage of low-income children are in child-care settings that provide inadequate (24%) or minimally adequate (36%) support for their development; in turn, these children show higher levels of internalizing and externalizing behavior problems and demonstrate lower levels of positive behavior compared with their peers in higher quality child-care settings (Votruba-Drzal, Coley, & Chase-Lansdale, 2004). Within all of the areas in which caregivers provide structure for their children, the impact of a given factor is dependent on the match or mismatch between the two; children's temperamental and developmental characteristics may strongly

influence how they respond to a situation. Similarly, caregivers' individual characteristics, including expectations regarding child development and availability of personal psychological resources with which to meet the children's needs for whom they care, will influence whether a set of behaviors is viewed as problematic (Seifer, 2000).

Characteristics of the setting (home, day care, school, and any other place the child spends substantial amounts of time), including both the overall quality of the setting and the match between the child and the setting, may also impact the child's functioning. As noted already, young children's behavior is highly sensitive to contextual and relational influences (Clark et al., 2004; Tronick, 1989), and it may therefore be more variable across settings than older children's behavior. It is common for parents and teachers, for example, to provide very different perspectives, with often very low correlations between their reports (Achenbach, McConaughy, & Howell, 1987). Though this may be due to differences in caregiver behavior or attitudes, it may also, in many cases, be due to differences in the setting, including the physical structure of the setting, the way time and activity is structured in the setting, adult-to-child ratio, number of children, behavior of other children in the setting, level of sensory stimulation, and adequacy of sleep support. Inconsistency in rules between home and school or day care (e.g., requirements for where eating and sleeping take place) may also be a source of differences between caregivers' reports. Given children's sensitivity to contextual influences such as these, the evaluation process would ideally include information gathering not only from multiple caregivers but also across multiple settings and within multiple types of interactions (e.g., unstructured play, challenging goal-directed tasks, shared reading). However, as this goal is often impractical, a compromise is to ensure that data are collected from multiple informants who are familiar with the child's behavior in different settings and in different types of interactions. When gathering information as part of an evaluation, reports from multiple caregivers are likely to yield a more complete picture of the child's functioning than reports from the child's parents alone (Dirks et al., 2012).

It is especially important to gather information from multiple caregivers in cases where a child regularly spends time in different contexts, with different primary caregivers in each (e.g., a child who is in full-time day care with a neighbor, is cared for by his mother at home during the week, and spends weekends in the care of his father). As discussed, where the reports of different caregivers diverge—for example, where a child's father reports problematic levels of disruptive behavior and her teacher reports no issues with disruptive behavior—the discrepancy should typically be viewed not as evidence of error on the part of one reporter but rather as evidence that contextual, cultural, interpersonal, or other influences may be contributing to the perceived problem. The review of assessment data should then include an analysis of the contexts in which a child is reported to have difficulties, with an eye toward identifying clues for intervention strategies to recommend for the child (e.g., creating consistency between home and day care with respect to the child's nap schedule). In the case in which the child's difficulties occur across multiple caregiving relationships or contexts, they may be more severe than the case in which the difficulties are limited to one relationship or one caregiving context.

Lastly, and briefly, it is also important to consider aspects of the child's context outside of his or her caregiving environment, such as neighborhood and community relationships and functioning. As an example, acts of violence occur considerably more frequently in high-poverty areas compared with more advantaged areas (Briggs-Gowan, Ford, Fraleigh, McCarthy, & Carter, 2010; Friday, 1995; Sampson, Raudenbush, & Earls, 1997), and some studies have reported extremely high rates of community violence exposure among children in high-risk urban areas, with estimates ranging from 42 to 78% (Schechter & Willheim, 2009). Based on these figures, the possibility that a child's behavioral, academic, or emotional difficulties are trauma related should become particularly salient when a child is known to live in a high-poverty/high-risk urban neighborhood; assessors will be even better served by more specific and nuanced knowledge of neighborhood characteristics in the communities in which they work. Even without identifying specific trauma exposure, living in underresourced neighborhoods is associated with elevated disruptive behavior in toddlers (Heberle, Thomas, Wagmiller, Briggs-Gowan, & Carter, 2014).

Sociocultural Factors

In addition to identifying the child's caregiving relationships, mapping out the larger web of family relationships in which the child is developing, and considering the ways the child's presentation may be influenced by the caregiving context and the setting in which the child is cared for, assessors must also consider the ways sociocultural factors may affect caregiver reports, children's performance on assessment instruments, the meaning of a child's behaviors to the caregiver and other family members, whether family members are worried or concerned about the child, family members' service seeking behavior and openness to referrals, and the assessor's own interpretation of the child

TABLE 1.1 Illustrative Examples of Sociocultural Factors that Impact Assessment Findings[1]

	Example of norm	Explanation of relevance in the assessment context
Communication style	Expectations for appropriate eye contact vary across cultural groups; for example, Asian American children may avoid eye contact with authority figures as a symbol of respect and deference (Thaler, Allen, & Scott, 2014).	Avoidance of eye contact may be interpreted as symptomatic if an assessor from a group in which sustained eye contact is normative (e.g., European Americans) is unaware of the variability in cultural norms for these behaviors.
Caregiving norms	Middle-class Puerto Rican mothers have been found to engage primarily in mother-led feeding practices (in which the mother feeds her infant with a spoon or bottle, in contrast to the infant using a spoon or bottle on his or her own) with their 12-month-old infants and to expect that their infants will not yet be able to self-feed at this age (Schulze, Harwood, & Schoelmerich, 2001).	Instruments designed to measure adaptive behavior through the lens of middle-class Euro American culture, in which early attainment of self-feeding skills is emphasized, may falsely identify delays in children whose caregivers have simply not yet organized their interactions with their children to require the development of these skills.
Priorities for child behavior	Endorsement of conformity as a child-rearing goal among mothers is negatively correlated with income, educational attainment, and occupational prestige; thus, overall, as socioeconomic status increases, mothers are less likely to see conformity to externally imposed norms as a model for their children's ideal behavior (Luster, Rhoades, & Haas, 1989).	An assessor primed to assess a given caregiver's attitude regarding conformity versus self-direction is likely to have greater success communicating with the caregiver about his or her child's strengths and weaknesses than an assessor who assumes that the caregiver shares his or her own values regarding conformity versus self-direction.
Beliefs about mental health services	Latinos, Asian Americans, and African Americans have been found to report high levels of perceived stigma regarding mental health problems in their communities (Alvidrez, 1999; Brown, Marshall, Bower, Woodham, & Waheed, 2014).	An assessor who is familiar with how perceived stigma might function as a barrier to service engagement is likely to be more effective than one who is not at addressing caregivers' concerns about confidentiality and encouraging the family's continued engagement in services (if needed).

[1] Endorsement of cultural norms may vary depending on ethnicity, race, socioeconomic status, immigration status, level of acculturation (for immigrant families), geographic location, and other aspects of identity, both separately and in intersection with one another.

and family's presentation (Table 1.1). Early childhood social-emotional and behavioral problems are identified when a set of behaviors appears with heightened or reduced frequency and intensity or when a child shows developmental deviance through the presence of unusual behaviors or the quality of typical behaviors. While diagnostic guidelines sometimes specify the frequency with which a behavior must occur to be consistent with a clinical diagnosis, it is often the case that caregivers are asked to determine whether a behavior occurs frequently or not, a determination that will necessarily be influenced by the caregivers' expectations for child behavior. Such expectations will vary across cultures and communities. In addition, the determination of whether a behavior (e.g., arguing with adults) has occurred at all is culturally mediated. Thus, the identification of social-emotional and behavioral problems is far from culturally neutral. In addition to problems related to the frequency, intensity, or quality of behavior, children may also show delays in the acquisition of social-emotional competencies (Briggs-Gowan & Carter, 1998). The identification of delays in competencies, like the identification of problem behaviors, is dependent on the caregivers' expectations for the child as well as the child's access to opportunities to develop and demonstrate competencies.

For these reasons, sociocultural considerations must inform the entire assessment process, from instrument selection through interpretation of findings. In selecting instruments for assessment, assessors should consider the following (note that this is not an exhaustive list): (1) Are the items on the instrument culturally relevant for this parent–child dyad? (2) Does the sample on which this instrument was normed represent this parent–child dyad? (3) Is the language in which this instrument is written the optimal language in which to assess this parent–child dyad? (4) If an instrument is designed to use familiar tasks as part of the assessment process (e.g., asking a child to complete visual puzzles), are these tasks actually familiar for this parent–child dyad?

Unfortunately, in many cases socioculturally and linguistically appropriate instruments may not be available. The use of culturally inappropriate instruments may have striking effects and is therefore no small problem; one example comes from a study of Australian Aboriginal children, in which all 124 children who participated in the study screened below the cutoff for detecting developmental disabilities or academic delays on a normed and validated screening tool (the Brigance screen) (D'Aprano, Carapetis, & Andrews, 2011). Such results highlight the damage that may occur when culturally invalid instruments are used

with young children—though, unfortunately, the failure of the instrument to work as intended will likely be far less obvious in the context of one-on-one assessment with a child (as opposed to a large research study or a large-scale universal screening effort). In work with young children and their families, several strategies may be used to enhance the overall cultural appropriateness of an assessment, even if culturally appropriate standardized instruments are not available. For example, it may be helpful to review items with a caregiver, discussing the caregiver's understanding of the meaning of both symptoms that have been endorsed and those that have not. Caregivers can be asked to give examples of a time when they observed a behavior that they have endorsed on a symptom checklist. (Note that this strategy is likely to yield valuable information from parents belonging to a cultural group on which an instrument was normed as well as from parents for whom an instrument may not be culturally valid.) In addition, it is important to ascertain whether the behaviors assessed by a given instrument—whether observed, assessed in an interview, or reported on a questionnaire—are culturally relevant for the target child. For example, if a child is from a cultural group in which nonverbal expression is valued, the examiner should be careful to look for signs that a child is responding nonverbally to a prompt meant to elicit a verbal response in the dominant culture but designed to fit a different cultural group (McLaughlin, Gesi Blanchard, & Osanai, 1995). (A nonverbal response in this case may indicate not a deficit in the skills needed to respond verbally but rather an incongruence between the forms of communication expected by the test designer and the forms of communication familiar to the child.) In addition to attempting to compensate for inaccuracies in a given standardized instrument (or set of instruments) that are not culturally valid for a given client, assessors should also consider whether there is important information about the child's development that is missed entirely by standard measures. For example, standard psychological assessment batteries typically do not include measures of ethnic and racial identity development, although these are essential aspects of the overall development of racial and ethnic minority children (Yasui & Dishion, 2007). Thus, overall, in cases in which the set of available instruments contains no culturally valid tools, assessors must be resourceful in identifying means for gathering supplemental information and extremely cautious about interpreting any standardized results obtained by calibrating a child's functioning against a normative group that does not represent their experience.

In addition to instrument selection, assessors must also consider cultural factors throughout the process of interviewing parents and children and interpreting the overall findings of the assessment (Kleinman, Eisenberg, & Good, 1978). We suggest that assessors consider the following questions as a starting point for framing a culturally informed evaluation: (1) What does the caregiver see as the problem? (2) What are the caregiver's expectations with regard to treatment? (3) How does the problem affect the child, caregivers, and other family members? (4) What does the caregiver see as optimal behavior for this child? (5) What are the caregiver's beliefs about child development? What does the caregiver see as the key tasks of development at this stage in the child's life? (6) How have community members responded to the child and caregiver? (7) What is the predominant attitude regarding help seeking in the caregiver's community? If known, how do community members see the organization with which the assessor is affiliated? Does the caregiver share these beliefs?

Culturally competent assessment requires that these and related questions be addressed for each family individually; however, familiarity with the cultural groups with which a family identifies is likely to enhance the assessment process by informing the questions asked by the assessor, the way questions are asked, and the way the caregiver's responses to questions are understood. To this end, consultation with colleagues who share an identity status with the caregiver may be invaluable.

In many cases, assessors may have only limited access to information about a child's caregiving context, family relationships, and cultural affiliations. For example, screening instruments may collect only minimal demographic information about a family and are often administered in contexts in which an assessor has little or no direct contact with caregivers. In these cases, the selection of instruments that are appropriate for the target population is particularly important, as is additional, culturally competent assessment of any problems identified by a screening instrument. Care should be taken to ensure that screening results are delivered in a culturally competent manner, with consideration given to the linguistic needs of the family receiving feedback as well as to beliefs known to be widely held in the community that may impact caregivers' understanding of screening results and their actions following the delivery of these results.

DOMAINS OF DEVELOPMENT

One of the myths about early emerging psychopathology that has been debunked in the past two decades of research on young children's mental health is that early emerging

psychopathology is undifferentiated. Indeed, whether validating the presence of differentiation across broad band domains of psychopathology, such as distinctions between disruptive or externalizing problems (which typically include problems in aggression, hyperactivity, inattention, and defiance), mood or internalizing problems (which typically include problems in social withdrawal, depression, and anxiety), and regulatory problems (which typically include sleep, eating, negative emotionality, and sensory symptoms) (Achenbach, 1966; Achenbach, Edelbrock, & Howell, 1987; Carter, Briggs-Gowan, Jones, & Little, 2003) or validating distinctions between different types of symptoms within a dimension of psychopathology, such as anxiety (Mian, Carter, Pine, Wakschlag, & Briggs-Gowan, in press; Mian, Godoy, Briggs-Gowan, & Carter, 2012; Spence, Rapee, McDonald, & Ingram, 2001) or disruptive behavior (Wakschlag et al., 2014; Wakschlag, Henry, et al., 2012; Wakschlag, Briggs-Gowan, et al., 2008; Wakschlag, Hill, et al., 2008), both parent reports and observations support differentiation of psychopathological symptoms in the toddler/preschool period. Based on this relatively new recognition of differentiation in the early emergence of psychopathology (and as reviewed later in this chapter), screening and assessment tools that focus on differentiated aspects of psychopathology have been developed.

Whether used in clinical or research settings, tools that assess social-emotional behaviors and psychopathology need to be interpreted in relation to knowledge about children's relational, family, and cultural contexts and in relation to the children's developmental context, or developmental functioning. We consider the child's developmental context quite broadly, as multiple developmental domains transact with normative social-emotional development and psychopathological trajectories. Risks for or the occurrence of psychopathology intersect with delays, deficits, or atypical functioning across many other developmental domains.

Indeed, intersections in developmental risk across psychopathology and other developmental domains is almost always observed; children with intellectual and developmental disabilities (Einfeld et al., 2006; Emerson, 2003), language delays and specific language disorders (Henrichs et al., 2013; Ross & Weinberg, 2006), learning disabilities (Morgan, Farkas, Tufis, & Sperling, 2008; Yu, Buka, McCormick, Fitzmaurice, & Indurkhya, 2006), or sensory processing disorders (Ben-Sasson, Carter, & Briggs-Gowan, 2009; Ben-Sasson, Soto, Heberle, Carter, & Briggs-Gowan, 2014) show increased rates of psychopathology. Importantly, the nature of these intersections varies from one condition to another, so knowledge of neurocognitive and linguistic profiles or identified intellectual and developmental disabilities can inform which aspects of psychopathology are assessed in greater depth. Thus, if a child has a known neurodevelopmental condition, such as autism or fragile X syndrome, a literature review should help to identify common areas of difficulty in the social-emotional domain (e.g., anxiety) that should be given additional attention in the assessment process. Conversely, if a social-emotional problem such as ADHD is under consideration, problems in executive functioning should be assessed as these two often co-occur.

Direct assessment of multiple developmental domains is often essential to understanding the *whole child*. Further, given that many young children will not be in environments in which informants will have the knowledge to report on the child's functioning across all of the relevant developmental domains, we strongly encourage including direct, norm-referenced assessment of cognitive and linguistic functioning prior to interpreting the results of social-emotional assessments, particularly since some assessments of social-emotional and behavioral functioning assume normative competencies in other developmental domains. single-informant screeners are not adequate for this purpose. For example, within assessments of attention, questions may include ratings of the child's ability to follow multistep instructions, which may be better explained by a receptive language deficit than inattention. Similarly, a young child with an intellectual disability may not be engaging in pretend play, but this may reflect a general cognitive delay or deficit rather than a specific delay or deficit in the social-emotional domain. In general, we do not expect gains in social-emotional development to exceed those observed in language or cognitive domains. Therefore, these two developmental lines are particularly crucial for contextualizing interpretation of findings in the social-emotional domain.

In clinical settings, assessment of other developmental domains may aid in motivating parents to participate in preventive and targeted interventions designed to reduce psychopathology. In early childhood parents are often more concerned about and more attuned to delays in language development than to atypical emotional, social, or behavioral development (Godoy, Carter, Silver, Dickstein, & Seifer, 2014). Presenting to parents the ways symptoms may be interfering with language (or other) cognitive learning can aid in building a shared view of the child that will motivate parents to participate in interventions focused on reducing symptoms.

Explaining the intersections of developmental lines in relation to establishing risk for psychopathology may also aid in freeing parents from the unfair burden of responsibility or feeling blamed for causing their child's social-emotional or behavioral problems. For example, explaining the ways challenges in processes such as inhibitory control, executive functioning, language processing, and emotional reactivity can intersect with and heighten risk for psychopathology—particularly given that the explanation can emphasize temperamental and neurocognitive vulnerabilities or adverse environmental exposures—can often facilitate greater empathy for a child who has been engaging in problem behaviors that cause burden to the family system. Therefore, knowledge of multiple developmental domains and their intersections, many of which are well documented in the literature, is extremely important in assessment domain and measurement selection. Moreover, knowledge of children's functioning in multiple developmental domains is often essential to appropriate interpretation of findings in research and clinical settings, and can be used to promote a stronger alliance between clinicians and parents when giving feedback and offering recommendations about intervention to parents whose children evidence elevated symptoms and disorders in clinical settings.

SELECTING AN ASSESSMENT APPROACH AND TOOL

When selecting tools to assess social-emotional problems in young children, a number of factors should be considered: (1) making sure the tool will best suit the needs and goals and purposes of the assessment and will fit within any setting constraints; (2) reviewing psychometric properties, such as *reliability* and validity; (3) evaluating the appropriateness of the tool; and (4) reviewing the *appropriateness of the tool for* children of a particular age or cultural background.

Types of Tools

When selecting a tool, it is important to determine what *type* of tool will provide the level of information required given the goals of the assessment. We discuss three types of tools for collecting information from parents and other caregivers: brief screeners, more comprehensive in-depth checklists, and psychiatric interviews (Table 1.2). These different types of tools vary tremendously in their format, the level of information that they provide, and the purposes for which they are most appropriate. Screeners typically yield scores that indicate whether a child *may* have

TABLE 1.2 General Characteristics of Different Types of Parent and Other Caregiver Report Tools

Type	General format	Type of information obtained
Screeners	5–10 minutes to complete Completed by parents or other caregivers Minimal training to administer or interpret Many assess a wide array of problems, such as behavior problems and emotional problems Some focus on a specific problem area, such as behavior problems only	Screeners usually provide one or two scores that indicate whether a child falls into a risk category suggesting that the child may have problems without providing detail into the specific nature of the problem. Results often trigger a more in-depth assessment to determine specific areas that are problematic, to identify treatment needs, and to inform planning.
Comprehensive checklists	15–30 minutes to complete Completed by parents or other caregivers Minimal training required to administer Interpretation typically requires training in psychological assessment Provide 2+ broad domain level scores (e.g., externalizing, internalizing) May provide narrowband scores about specific areas (e.g., anxiety)	Comprehensive checklists provide in-depth information about a child's functioning. Most cover multiple areas, but some focus on specific types of difficulties, such as executive functioning problems. Scoring typically provides a profile of functioning, showing strengths and weaknesses in different areas. These results can be used to establish eligibility for services, generating treatment plans, and documenting change over time.
Diagnostic interviews	1–2 hours to complete at a minimum Parent or other caregiver is interviewed by a trained individual All interviewers must be trained in administration Some may be administered by nonclinicians; others require clinical interviewers Interviews probe for information about whether symptoms are present, duration and onset of symptoms, and impairment	The detailed information obtained from these interviews allows determination of whether a child meets psychiatric criteria for a range of disorders. Scoring also can yield symptom counts within disorders, such as how many depressive symptoms were reported.

social-emotional problems but do not provide in-depth information about specific areas that are problematic. Longer, comprehensive checklists provide more in-depth assessment of problems within a specific area or areas. Many of these checklists provide detailed profiles that illustrate a child's strengths and weaknesses relative to children of a similar age in multiple areas, such as depression, anxiety, impulsivity, aggression, and social competencies. Such profiles and score details can be especially helpful for treatment planning, and documenting change over time or with treatment. However, checklist tools are *not* appropriate for establishing whether a child meets criteria for a psychiatric disorder. Instead, psychiatric interviews collect very detailed information necessary to establish whether a child meets diagnostic criteria for a range of psychiatric disorders (e.g., symptom presence, onset, duration, and impairment), and can be important for treatment planning. Observational methods also can supplement more traditional informant report methods. In the next section of this chapter, we will review each type of measure in detail and provide a review of selected measures available for assessing social-emotional functioning in young children.

Understanding Psychometric Properties

The first step in reviewing an instrument should be to examine its psychometric properties. Unfortunately, in both clinical and research settings, practical considerations such as a tool's ease of use; the time required for training administration, scoring, and interpretation; costs associated with use; the level of professional training required to administer, score, and interpret the instrument; and the influence of common regional practices often outweigh consideration of psychometric properties. The following section outlines psychometric issues most relevant to parent–caregiver reports in young child assessment: reliability, validity, sensitivity/specificity, positive and negative *predictive value*, and *normatization*. Other factors such as cultural considerations, developmental appropriateness, and response formats that may influence instrument adoption also are discussed.

Reliability

Reliability refers broadly to the consistency or stability of a measure. For measures that have scale scores, the consistency of a measure is typically evaluated by examining two or three aspects of reliability: internal consistency, test–retest reliability, and interrater reliability. Table 1.3 provides an overview of these types of reliability and the types of tools to which they generally apply. Rules of thumb for interpreting whether a tool has good enough reliability for different types of measures and related statistics are presented in Table 1.4.

Internal consistency is the extent to which individual items on the scale hang together and reflect the same construct. Usually, this is assessed with Cronbach's alpha (Cronbach, 1951). Scales with Cronbach's alpha of .70 or greater are usually considered to have adequate internal consistency, whereas those with alphas between .60 and .69 are considered marginal and those falling below .60 are considered unacceptable (Cicchetti & Sparrow, 1981; Nunnally, 1978). However, some clinically informative young child measures may not have acceptable internal consistency. This can occur if a measure includes behaviors that rarely occur in the population (e.g., atypical behaviors related to autism spectrum disorder; ASD) or sets of behaviors that are clinically concerning but not likely to co-occur (Achenbach, Edelbrock & Howell, 1987; Briggs-Gowan & Carter, 1998). For example, the ITSEA Atypical Behaviors Index and Maladaptive Index each concern a set of behaviors that are rare but clinically important (e.g., rocking, spinning, PICA, head banging). These indices are expected to have low internal consistency in a normative population (Carter & Briggs-Gowan, 2006),

TABLE 1.3 Types of Reliability

Type	Definition	Measures to which this is most relevant	Statistic used
Internal consistency	How well do the items in a scale hang together?	Measures with scale scores, such as screeners or checklists	Cronbach's alpha (α)
Test–retest reliability	How consistently does the tool provide the same results over time?	All measures	Correlation coefficients (r) or intraclass correlation coefficient (ICC) (Bartko, 1976)
Interrater reliability	How consistently does the tool provide the same results when different individuals rate it?	All measures, especially those where judgment is involved, such as semistructured interviews or observational systems	Intraclass correlations, kappa

TABLE 1.4 Reliability Statistics and Rules of Thumb for Interpreting Reliability

Measure type		Score types	Statistic	Criteria[1]
Dimensional	Dimensional scores Test–retest (about the same person at different times) Interrater (about the same sample of information about the same person by different raters)	Symptom counts Coding composite scores Scale scores	Intraclass correlation (ICC)	<.40 Poor .40 to .59 Fair .60 to .74 Good .75 to 1.0 Excellent
	Dimensional scores Internal consistency (how well the items hang together)	Items that comprise scale scores Codes the comprise composite scores	Cronbach's alpha	<.60 inadequate .60 to .69 poor/marginal .70 Fair .80 Good .90+ Excellent
Categorical	Categorical variables Interrater reliability Test–retest reliability	Disorder vs. not Below cut score vs. above cut score Ordinal coding scale	Kappa statistic (*K*)	<.40 Poor .40 to .59 Fair .60 to .74 Good .75 to 1.0 Excellent

[1]Cicchetti, 1994; Landis & Koch, 1977.

despite measuring behaviors that may be red flags for a need for further evaluation and be clinically and diagnostically important in and of themselves. Thus, while internal consistency is one important indicator of reliability, low internal consistency may be tolerated if a score is based on rare behaviors that when present may be clinically informative. Therefore, understanding the items that go into a scale is important to interpreting internal consistency (Cicchetti & Sparrow, 1981).

Test–retest reliability reflects the stability of a measure when it is completed twice over a relatively short time frame. High test-retest reliability suggests that respondents tend to understand items in a similar way over time and that the underlying construct that is measured does not change substantially over a brief period of time. When test–retest reliability is assessed in older children and adults a two- to four-week period is often used. However, a shorter time period is desirable for infants, toddlers, and preschoolers because the rapid pace of development in this period can reduce test–retest reliability. Contextual variation also could contribute to lower reliability between two *assessments*. For example, peer aggression scores may be quite different if a parent answers questions during a time period when the child has not had much interaction with peers (e.g., during summer break) versus when the child routinely attends a child care program. Thus, contextual and developmental variation may contribute to lower reliability over time in young children.

For interview assessments or observational measures, *interrater reliability,* or the consistency of the measure across raters, should also be evaluated. Interrater reliability indicates whether different people who have the same information about a child tend to rate that information in the same way. In the case of a checklist measure, this might refer to agreement between parents and teachers or between mother and father. In the case of a psychiatric interview, this would mean that after reviewing the parent response, two different people rate the symptom as similarly present or absent. For psychiatric interviews the unit of reliability analysis may be symptom counts or diagnosis. In general, the more structured the assessment format and the lower the inference level required to make ratings, the greater the probability that adequate test–retest and interrater reliability can be obtained in interviews. The availability of detailed administration manuals or training further enhances interrater reliability. A problem often encountered when using clinical interviews is that even the best-trained individuals may drift over time, gradually changing how they administer or rate an interview. This can be minimized by having periodic reviews by an expert who independently reviews and rates the same interview and provides feedback to the interviewer.

Validity

Validity refers to a measure's ability to measure the problem, skill, or trait that it is intended to measure. Using a measure that does not have adequate validity for measuring a particular problem may lead to mistaken conclusions about the nature of a child's problems and affect clinical decisions and care. For example, use of a measure with poor validity for assessing anxiety may mean that clinically impairing anxiety does not receive adequate clinical attention, potentially affecting not only anxiety outcomes but also other areas of functioning affected by anxiety, such as participation in age-expected social activities in

which social skills are honed. More accurate, valid characterization of a child's strengths and weaknesses can drive more targeted, tailored treatment planning and optimize outcomes. For research purposes, validity is essential to ensure that constructs of interest are well characterized and optimize capacity to truly test the hypotheses of interest. Several types of validity that are commonly studied in the course of developing social-emotional/behavioral assessment tools are briefly introduced in this section.

Content validity or *face validity* refers to whether the individual items, questions, and scales actually measure the underlying construct they are intended to measure. One aspect of this that is particularly important for young children is whether the items are developmentally appropriate for the target age range. This is often established during a measure's development phase by an independent expert review process. *Construct validity* refers to how well a measure assesses the specific construct it is intended to measure. This can be assessed by comparing scores on one measure with scores on another validated measure of the same problem. Another way to evaluate construct validity is to examine how well a tool classifies children with a particular kind of clinically significant problem or disorder from both other children with other types of clinically significant problems or disorders and from those without clinically significant problems and disorders. This type of validity is evaluated in terms of the measure's sensitivity and specificity, which is discussed in detail later in this section.

Factor structure provides another indicator of validity, by empirically testing whether the structure of the data fits together statistically in a manner that fits with expectations, based on theory or prior evidence in the area. An evaluation of factor structure can test, for example, whether different types of anxious behaviors cluster together into multiple discrete clusters (e.g., with separation anxiety items on one factor and phobic/fearful items on another) that load onto a higher order structure, as has been demonstrated in young children (Mian et al., 2012; Spence et al., 2001). *Convergent validity* refers to whether a measure is positively associated with other measures of related, but different, constructs. For example, given that anxiety and depression symptoms are often correlated, one would expect that a measure of early anxiety would correlate positively with a measure of early depression.

Discriminant validity or *between groups validity* refers to whether a measure differentiates children who are identified as having a particular problem it is intended to measure from children who do not have that problem. For example, one might examine whether children who have been diagnosed with anxiety disorders have higher scores on a measure of anxiety than healthy children who do not have anxiety disorders.

Predictive validity refers to a measure's ability to predict the same problem over time. For example, evidence that higher anxiety scores on a measure predict higher anxiety later in childhood would support predictive validity. Predictive validity often is not formally evaluated when a tool is being developed, but it can be an important form of validity for young child measures. Demonstrating that a tool predicts later functioning is essential to showing that it captures a clinically meaningful aspect of early functioning that is not simply a transient perturbation in functioning that wanes with development.

Validity Within a Longitudinal Developmental Context

Developmental processes also may affect construct validity. One of the steps in psychometric development is to test and establish the factor structure of a measure, or how items load on scales (e.g., aggression), how scales correlate with one another (e.g., aggression, hyperactivity, oppositional behaviors), and how multiple scales load onto higher order factors (e.g., an externalizing factor that includes aggression, hyperactivity, and oppositionality). However, when following children over time or using a measure that is the same across a broad range of ages, it is also important to evaluate a measure's factor structure over time or between more narrow age groups (Carter et al., 2003). This is rarely reported and it can be difficult or impossible to find information about the consistency of a measure's structure over time. Without knowledge that a measure demonstrates a consistent factor structure across development it is impossible to interpret whether longitudinal patterns represent heterotypic or homotypic stability or instead change.

Validity of Classification

Another important consideration is how well a measure classifies a child has *having a problem* or *not having a problem*. Although a test or measure may be a reliable and valid measure of an underlying construct or behavior, there is still an issue of how useful it might be for a given diagnostic or classification purpose (e.g., meets criteria for oppositional defiant disorder). This is important for tools that yield categorical scores that indicate whether a child's problems are above or below a clinical threshold indicative of problems. In psychological testing, this most commonly applies to screening tools or longer checklist measures that are used to identify children who may have problems and to trigger an action to be taken, such as further evaluation

or referral. The problem of misclassification and its impact on the person being classified is of particular concern.

Sensitivity, specificity, positive predictive value, and negative predictive value are statistics that pertain to classification. *Sensitivity* refers to the proportion of children who fall within a given problem group (e.g., those known to have a disorder according to another criterion) who are successfully classified by the tool in question. If a measure classifies 85 of 100 children with established anxiety disorders as having high anxiety, it has 85% sensitivity. As sensitivity goes up, false negatives go down. *Specificity* refers to the proportion of children who do *not* have a particular problem who are correctly classified by the tool in question. Therefore, a measure that classifies 90 of 100 children who do not have an anxiety disorder as not high in anxiety has 90% specificity. As specificity goes up, false positives go down.

Positive predictive value (PPV) is the proportion of children flagged as positive by a screening tool who truly have that problem according to another criterion. Thus, if 50 of 100 children who are positive according to the tool indeed have problems, PPV is 50%. PPV is correlated with prevalence rates; that is, as prevalence goes up or down, so does PPV, assuming sensitivity and specificity are constant. *Negative predictive value* (NPV) refers to the percentage of children who screen negative that are truly negative according to another criterion.

A general guideline is that assessment tools used for early identification should have minimum sensitivity and specificity of 70% and false positive rates of no greater than 30% of all screened (Cicchetti, Volkmar, Klin, & Showalter, 1995; Disabilities, 2001). Though no minimum PPV exists (to our knowledge) for social-emotional assessment tools, tools should successfully identify a subpopulation in which the prevalence of the problem is more common than in the original population (Milgrom, Mendelsohn, & Gemmill, 2011). Low PPV is usually tolerated when failure to detect a problem is associated with a very poor outcome, such as death. For example, a minimum PPV of 10% has been proposed for ovarian cancer screening because the likelihood of death when this form of cancer is not detected is high (Hensley & Spriggs, 2004; Milgrom et al., 2011) As these examples illustrate, different criteria may be appropriate depending on the purpose of the assessment and the risk of harm associated with failure to detect a problem. Generally, sensitivity should be high (and thus false negatives low) for assessment tools designed to aid in specific diagnoses or treatment recommendations (e.g., structured clinical interviews) because of the potential costs to the child and family of misclassifying a child who *actually has* a specific disorder as *not having* the disorder. However, when the goal is to screen large samples to identify at-risk individuals regardless of their diagnostic status, it can be challenging to find a balance whereby a sufficient proportion of children with problems are detected, while maintaining an acceptable rate of false positives. When scoring thresholds or cut scores are too high, screeners tend to have high specificity and a low rate of false positives, but low sensitivity, meaning that children are more likely to go unidentified. In contrast, when thresholds are too low, sensitivity will be high, but specificity will be low, leading to misclassification and potential flooding of the service system with false positives. False positives also bring some practical costs to the setting conducting the screening and potential emotional cost to families by raising concern or worry unnecessarily.

Finally, one should not assume that a given test will have stable sensitivity and specificity across developmental periods or over time. This is in part because the prevalence of the condition being assessed often varies across periods. A test that has excellent sensitivity, specificity, and positive predictive value with one age group could function poorly in a different age group, particularly if the prevalence of the problem changes. Thus, it is important to review a tool's classification statistics for your target developmental period.

Normatization

The purpose of norms is to provide a means of comparing individuals with their age-based peer group. In many ways, the concept of norms is central to a developmental perspective for assessment. Although traditionally a norm is considered to represent the average test performance of a standardization sample, norms also represent the average, median, or modal performance of a particular developmental level or stage. This is essential at all ages but is especially important in early childhood because children's social-emotional functioning will change with development within this domain and related domains. For example, as illustrated by our work with the ITSEA (Carter et al., 2003) there were age-related changes in some social-emotional problems, from 12 to 35 months, including increases in general anxiety and decreases in separation distress. We and others have also identified robust age differences in children's social-emotional competencies/skills (Carter et al., 2003). For example, on the ITSEA we observed linear increases in 6-month blocks from 12–17 months to 18–23 months to 24–29 months, followed by a social competence leveling from 24–29 and 30–35 months

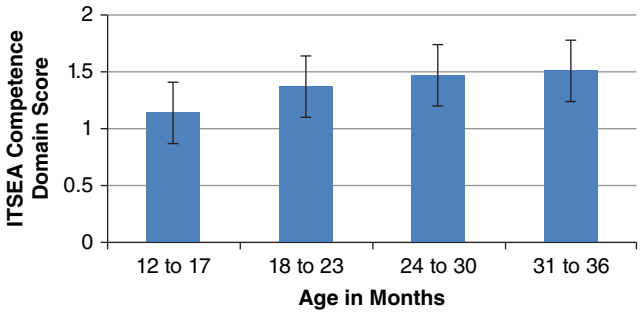

Figure 1.1 Illustration of age effects in social competence from 12 to 36 months of age. See footnote 1.

(Figure 1.1). We also identified sex differences, with greater competence in girls. Thus, a child's competence will be most accurately assessed in relation to children who are the same sex as the child and of similar age within the developmental period from 12 to 36 months.

In selecting a tool and interpreting its results, it is important to be familiar with the sample and conditions in which the normative data were collected—the more similar the normative sample is to your target population, the more relevant the norms (Carter, Marakovitz, & Sparrow, 2006). In a majority of the tests available, the most typical way to operationalize development has been based on chronological age. However, another consideration when comparing a particular child's scores with norms is the child's developmental functioning in other areas. Generally, social-emotional development does not exceed development in other areas. Thus, as noted already, if a child is substantially delayed in multiple areas, such as cognitive and language development, scores may need to be adjusted for developmental level. If a 4-year-old is functioning overall at a mental age of 36 months, then it may make sense to apply 36-month-old norms to determine whether social-emotional functioning is consistent with expectations for mental age. In an ideal world, special norm group data would be available for children with intellectual and developmental disabilities and with genetic and other conditions known to be associated with delays and deficits in social-emotional development and psychopathology.

Normative data also have to be considered within the historical and societal contexts in which they are established. Historical events such as natural disasters, war, or famine may impact the developmental progression of a cohort of children. Norms developed during these periods of relative variation may not be appropriate representations for children growing up in different periods, who are not exposed to these types of experiences. Thus, periodic restandardization of measures is very important.

Cultural Validity and Cultural Norms

Despite a dramatic increase in the diversity of the United States and around the world, issues of cultural validity and the establishment of cultural norms continues to be a challenge to the assessment of social-emotional and behavior problems and disorders in young children. Importantly, translation, even when forward- and back-translation methods are employed, is often inadequate to address issues of cultural appropriateness and validity (cf. van Widenfelt, Treffers, de Beurs, Siebelink, & Koudijs, 2005). Ideally, measures would be developed simultaneously in multiple languages for use in different parts of the world, and examinations of psychometric properties and item and construct equivalence would be established during development. However, there is still extremely limited information about the psychometric properties of measures that have been translated or about the samples or subsamples in which translations have been employed. For example, the ITSEA item "Runs away in public spaces," which is extremely rare in the U.S. context, was rated as normative in Finland until the addition of "for example, in train stations" was added to the item to increase the equivalence of item across these two countries. This is a good example of the limits of translation, as different caregiving patterns and expectations across cultures may lead to situations in which the same words do not have the same meaning in relation to young child psychopathology. Moreover, few measures that have been translated have gathered appropriate normative group data that would permit easy comparisons of the range of relevant psychometric properties across cultural groups. Even when normative data are available for a child and family's home country, these norms may not be appropriate in a new cultural context. For example, for families who have been living in a new country for some time, immigration stress and acculturation may also impact the appropriateness of the use of home country normative data among families. This is clearly an area that will require greater attention in the future.

Knowing What Problems Are Really Being Assessed

A name does not always adequately represent the content of a measure or the scales within it. Therefore, it very important to review the items that make up all of the scales within a measure to truly understand what is being captured and where. In such a review, you may find that a scale labeled "anxiety" includes items such as "cries easily" that could very well reflect other types of problems. Or, an "anxiety" scale might be composed largely or entirely

of items that describe fearful, shy, and socially anxious behaviors but may fail to assess separation anxiety. The term "withdrawal" is often part of a scale's name—item review is important to determine whether this refers behaviors that appear to reflect withdrawal related to (1) shy, slow-to-warm-up behaviors; (2) depressed, anhedonic behaviors; (3) behaviors that could be related to ASD problems such as lack of eye contact and unawareness of social context; or (4) some or all of these types of difficulties.

For clinical and research applications, another important consideration when goals involve following children over time is whether the tool (or tools) used are measuring the same construct over time. One might use the same tool over time or different tools because a single tool does not cover the whole intended age period. Whichever approach is used, we again recommend reviewing the items that make up the scale at different ages. The items within a scale may change in subtle or dramatic ways even within the same tool.

Response Formats

A final consideration when reviewing a checklist or interview is the type of response format that is used. Behaviors vary in terms of whether they are ever present, how frequently they occur when present, and how intensely they are displayed. Similarly, response formats vary in whether a problem is judged as present versus absent, ratings of frequency, or a judgment of how severely the behavior manifests (Achenbach & Rescorla, 2000; Carter & Briggs-Gowan, 2006). Many measures have a response option that crosses ratings of frequency with ratings of how typical the behavior is of the child. As most social-emotional and behavioral problems and competencies vary in frequency or intensity, a response format that captures variation in frequency and intensity makes some sense (Achenbach & Rescorla, 2000). For example, the response format for the ITSEA is 0 for "Not true/rarely," 1 for "somewhat true/sometimes," and 2 for "Very true/often." A contrasting approach, employed in the Behavior Checklist (BCL; Richman & Graham, 1971) is to ask the parent to rate the degree to which a particular behavior is perceived to be a problem. On the BCL parents are asked to rate a behavioral category as 0 for "No difficulties," 1 for "Moderate difficulties," and 2 for "Definitive difficulties." Although very different, each of these response scales is sufficient for identifying children at elevated risk for psychopathology when items are aggregated into meaningful clusters or scales (Achenbach & Rescorla, 2000; Campbell, 1995). For determining clinical diagnostic status, however, neither format is sufficient. Rather, information about onset, duration, and intensity of behaviors and impairment are required to determine diagnostic status. Given the complexity of the information that must be gathered to determine diagnostic status, it is usually preferable to gather this type of information in an interview format.

A final consideration is that some response formats can be overly complex, especially for informants with more limited educational backgrounds. Thus, a scale with a response format that changes from one question to the next or utilizes a wide response scale, but with far fewer anchors, can be confusing or off-putting to parents and introduce error variance into measurement. Items with double (or even single) negatives can also complicate a respondent's ability to use a particular response format (e.g., "Often/Very True" that this behavior is rarely present). Even a simple "Yes/No" format may introduce error, as the threshold for difficulty may not simply be the presence or absence of a behavior but the routine use of the behavior in appropriate contexts (e.g., eye contact). Finally, it is usually easier to rate one attribute or behavior at a time (e.g., child often has angry tantrums) rather than being forced to indicate whether the child is more like one pole of a continuum or another (e.g., whether being angry is more characteristic than being calm).

Summary

Many factors should be carefully reviewed and considered when embarking on a new type of assessment, including the psychometric properties and developmental appropriateness of the tool, how well its norm groups match with the target population (or child). Spending the time to understand the breadth and depth of the information the tool provides and the individual problems that go into different scales or domain scores is essential to a strong assessment foundation.

ASSESSMENT TOOLS

Several types of tools can be used to systematically gather information about social-emotional problems or competencies from parents and caregivers, including brief screening checklists, more comprehensive checklists designed to capture variation both in broad domains and within subareas within those domains, diagnostic interviews, and observational tools designed to capture clinically meaningful information that can supplement parent or teacher reports.

Screening Methods

Screening tools, designed as brief measures for detecting children who may be experiencing problems, are most appropriate when the goal is to quickly and efficiently identify such children from a larger population. Large-scale screening efforts can help to reduce the high rates of unmet mental health needs. Among school-age children, approximately 80% of children needing mental health services are not receiving them. Unmet mental health needs are even greater among young children, children of color, and uninsured children (Kataoka, Zhang, & Wells, 2002). The considerable unmet need for mental health services underscores the importance of enhancing early detection efforts through routine mental health screening.

Universal screening can help detect children at risk for developing mental health problems. Typically, screening yields information about which range a child's score falls within (e.g., normal, borderline, or abnormal). Screening should not be used for diagnosis but rather as a jumping-off point for discussions about mental health and further assessment. Once identified, at-risk children benefit from follow-up that can include more in-depth assessment (e.g., longer measure, clinical interview, clinical observations) to evaluate the extent and nature of the difficulties initially detected. This practice, referred to as multigated or multistage screening, can serve as a cost-effective and minimally burdensome means for screening large groups of children in a manner that permits characterization of risk status (stage 1) and a more detailed profile of problems and competencies when risk is elevated (stage 2). The decision to proceed to later stages of screening can be based on factors such as score profile, parent's indication of concern, and level of impairment. However, even if multigated screening is not being implemented, screening ideally involves attention to the child's behaviors, as well as contextual risk factors in the family and community, including exposure to violence, parental psychopathology, and neglectful parenting.

In addition to identifying the existence of concerns, screening can help to facilitate appropriate follow-up, such as referral for treatment, by identifying potential domains of concern (e.g., speech-language versus gross motor or anxiety versus disruptive behaviors) and severity of concerns. Agencies and providers employing multistage screening may wait until more comprehensive assessment is completed to make referrals, but in many cases second-stage screening does not occur and providers choose to use the results of screening to initiate a referral or begin addressing identified concerns. For example, within pediatric primary care settings, providers may refer a child to the local early intervention program following elevated developmental screening. However, in most cases, the places to which a provider is referring will do a more comprehensive assessment before beginning treatment. While screening tools can help in the treatment planning process and in the documentation of treatment gains, given the brevity of screeners and the limited information provided, it is not ideal to use screeners in this manner. Screening is ideally used at multiple points in time to ensure the continued monitoring of concerns among a large group of children.

Screening can occur universally or it can be targeted. In universal screening, all children in a particular setting or situation (e.g., all children seeing their physician for a well-child visit) would complete screening. Ideally, when universal screening is employed in pediatric practices, every parent (or adolescent child) completes a standardized screening tool at each well-child visit from infancy through adolescence, and identified risks or concerns are closely monitored and addressed as appropriate. In targeted screening, only those children identified via other means (e.g., developmental surveillance in which parents report their concerns about the child's behavior) would be screened.

Universal screening is ideal because it does not rely solely on provider judgment or parent expressions of concern, both of which can be flawed means of identifying issues particularly in early childhood. A review study of screening in pediatric primary care settings determined that sensitivity rates for pediatric providers ranged from 14 to 54%, and that specificity rates ranged from 69 to 100% (Sheldrick, Merchant, & Perrin, 2011). Furthermore, parents of children with mental health problems often do not report concerns or worries about their children's behavior (Godoy et al., 2014; Sheldrick, Neger, & Perrin, 2012). In particular, parents of younger children exhibiting social-emotional/behavioral problems report lower levels of worry or concern than parents of older children and often do not raise concerns with the pediatrician (Ellingson, Briggs-Gowan, Carter, & Horwitz, 2004; Godoy et al., 2014; Horwitz, Gary, Briggs-Gowan, & Carter, 2003; Sheldrick, Neger, et al., 2012). Thus, universal screening can help to identify at-risk children more accurately than when screening is not implemented. Moreover, universal screening can help to reduce disparities in health care because all children receive a similar assessment regardless of family characteristics and provider discretion.

Universal screening is growing increasingly popular, particularly within the pediatric primary care setting.

Pediatric primary care settings are well-suited to the task of detecting social-emotional and behavior problems ("Policy statement—The future of pediatrics: Mental health competencies for pediatric primary care," 2009) as pediatricians can act as the gatekeepers of mental health for a wide range of children. Pediatricians, who often have longitudinal, trusting relationships with families, regularly discuss social-emotional behavioral issues, and they are often the first professional with whom a parent discusses concerns. Thus, they are the people who can first identify problems and facilitate appropriate prevention and intervention services. Families with children who have social-emotional and behavioral problems tend to use pediatric services more than other families (Gadomski, Wissow, Slade, & Jenkins, 2010) and therefore have more opportunities for contact with pediatricians. Pediatric primary care may be particularly helpful in the identification and prevention and intervention of early childhood mental health problems given the more frequent visit schedule among children under 3 years. Additionally, prior to entering more formal child-care or school settings, pediatricians may be the only professional with whom some families have contact who can help to identify problems and facilitate referrals. Indeed, parents who discuss their children's social-emotional/behavioral problems with their pediatrician are more likely to obtain mental health services for their children than those who do not discuss these issues (Briggs-Gowan, Horwitz, Schwab-Stone, Leventhal, & Leaf, 2000).

Universal mental health screening is increasingly important given the growing list of topics pediatricians are expected to cover and shorter office visits. These factors make it more challenging for pediatricians to detect concerns on their own as they have less time to discuss behaviors and make clinical observations and as parents have less time to raise concerns. Additionally, implementing universal mental health screening, particularly in non–mental health settings, can help to destigmatize mental health and increase the likelihood that parents will raise and discuss concerns and seek treatment as needed.

Yet universal screening efforts can be hampered by logistical, systemic, and other barriers. Logistical barriers include issues like difficulty integrating screening into an already busy practice workflow. An additional barrier is pediatricians' self-reported lack of confidence and training in addressing mental health issues (Horwitz et al., 2007). Systemic issues include lack of adequate mental health resources, which is even more of an issue with early childhood mental health.

Despite these challenges, universal mental health screening in primary care has been shown to be feasible and effective in improving rates of referral (King et al., 2010; Schonwald, Huntington, Chan, Risko, & Bridgemohan, 2009). Not surprisingly, universal screening is gaining popularity within other early childhood settings, such as child care centers and women, infant, and children's offices. Given the many contexts in which children may be screened, it is important that states and local agencies work together to ensure that screening efforts are coordinated (e.g., discussing screening across settings, sharing results across agencies through a database or other means).

Screening Methods Characteristics of Screening Tools

Screeners should have several characteristics, especially if they are to be implemented widely. They should be brief and easy to administer, and most parents should be able to complete them independently. They should also be easy and quick to score and interpret. Ensuring these characteristics of a screener can ensure that a maximum number of screens are completed and that staff are not overly burdened. Advances in technology have led to moving screeners to an electronic format, which can further facilitate completion and scoring.

Screening tools vary in the scope of their assessment. Some screening tools are designed to detect a narrowly defined problem. For example, the Modified Checklist for Autism in Toddlers, Revised with Follow-Up (M-CHAT-R/F; Robins et al., 2014) is designed to detect ASD and would not be appropriate when the goal is to detect children with social-emotional or behavioral problems in areas outside of ASD. In contrast, more global screeners, such as the Ages and Stages Questionnaire: Social Emotional (ASQ-SE; Squires, Bricker, & Twombly, 2002) and the Brief Infant Toddler Social Emotional Assessment (BITSEA; Briggs-Gowan & Carter, 2006), are designed to identify children who may be evidencing problems in the broad domain of social-emotional/behavioral problems. Some screening tools, such as the BITSEA and the Strengths and Difficulties Questionnaire (SDQ; Goodman & Goodman, 2009), go a step beyond problems to also detect social-emotional competencies. Selecting a screening instrument that meets the goals of the screening process (narrow versus broad, problems versus competencies) is essential to ensure a successful screening initiative.

In recent years the number of screening tools available for the infant-toddler period has grown. However, many screeners now available focus on a specific area of social-emotional adjustment (e.g., behavior problems) and

do not provide comprehensive coverage of both problems and competencies. For example, the 35-item Eyberg Child Behavior Inventory (ECBI; Eyberg & Pincus, 1999), and the 40-item Toddler Behavior Screening Inventory (TBSI; Mouton-Simien, McCain, & Kelley, 1997) measure behavior problems in children 2 to 16 years of age and 1 to 3 years of age respectively whereas the Preschool Anxiety Scale (PAS; Edwards, Rapee, Kennedy, & Spence, 2010; Spence et al., 2001) measures anxiety symptoms in children 3 to 5 years of age. While these scales all demonstrate acceptable psychometric properties, they may be limited in their ability to screen for a wide range of problems and address social-emotional competencies. Additionally, screening tools that were designed for older children are often scaled down for use with younger children without adequate assurance regarding the developmental appropriateness of items nor the psychometric properties within a younger population.

Selected Screening Tools

Table 1.5 displays several commonly used, brief, parent-report social-emotional/behavioral screening questionnaires. We selected tools that cover an array of problems (and, in several cases, competencies) and that may be appropriate in settings in which wide-scale screening is occurring. These questionnaires are also described briefly. All the questionnaires selected can be completed by parents (and in some cases child care providers) on their own or with the assistance of a staff member. They all usually require 5–10 minutes to complete and are easy to score. Qualified individuals who have undergone appropriate training can score the instruments. Regarding interpretation, all the measures require knowledge of standardized assessment and supervised training in working with relevant clients.

The Ages & Stages Questionnaire–Social-Emotional Version (ASQ-SE; Squires et al., 2002), a screening tool that can be completed by parents of children 3 to 66 months of age, addresses seven behavioral areas: self-regulation, compliance, communication, adaptive functioning, autonomy, affect, and interaction with people. There are eight versions of the questionnaire that correspond with different child ages (6, 12, 18, 24, 30, 36, 48, and 60 months) and eight corresponding scoring sheets. The number of items varies depending on the questionnaire ranging from 22 to 36. For each question item, respondents are asked to indicate whether the behavior is something that the child does "Most of the Time," "Sometimes," or "Rarely or Never." In addition, respondents can indicate whether the behavior described by each item is something that is a "Concern." Several additional questions at the end of the questionnaire ask about parents' concerns about child social-emotional/behavioral functioning (e.g., "Do you have any concerns about your child's eating and sleeping behaviors or about her toilet training?"). An overall summary score can be compared with age-specific cutoff scores to identify children at risk for social or emotional difficulties. The ASQ: SE has strong internal consistency (.82), test–retest reliability (.94), sensitivity (.82), and specificity (.92) in detecting children with developmental delay or social-emotional diagnoses (Squires et al., 2002).

The BASC-2 Behavioral Emotional Screen System (BASC-2 BESS; Kamphaus & Reynolds, 2007) measures behavioral and emotional strengths and weaknesses from preschool through high school. In the early childhood age group (ages 2 to 5 years), tools are available for parents and teachers to complete. The tool asks about internalizing problems, externalizing problems, and adaptive skills, though questions in these domains are combined into a total score. Validity indexes can be used to identify overly negative or inconsistent responses. The BASC-2 BESS has demonstrated acceptable test–retest reliability (0.79–0.85), interrater reliability (0.76–0.90), validity with other measures of child behavior such as the Child Behavior Checklist (0.71–0.76), sensitivity (0.73–0.82), and specificity (0.97) in detecting children with social-emotional/behavioral problems (Kamphaus & Reynolds, 2007).

The Brief-Infant-Toddler Social-Emotional Assessment (BITSEA; Briggs-Gowan & Carter, 2006) is a forty-two-item measure for identifying social-emotional/behavioral problems and delays as well as child competencies in 1- to 3-year-old children. The BITSEA generates a Problem and a Competence score, each of which can be compared with age- and gender-specific cut points. The BITSEA has good psychometric properties, including test–retest reliability and interrater reliability. The BITSEA cut points have demonstrated high sensitivity in detecting children with social-emotional/behavioral problems according to other gold standards (diagnostic interview; Child Behavior Checklist) while maintaining acceptable specificity (Briggs-Gowan et al., 2013). In addition, the BITSEA is highly sensitive to autism spectrum disorders (Carter & Briggs-Gowan, 2005; Gardner et al., 2013). Finally, research suggests that BITSEA has acceptable sensitivity and specificity and predicts a majority (PPV of 67.9%) of children who meet the criteria for a psychiatric disorder, according to the Preschool Age Psychiatric Assessment (PAPA) interview (Briggs-Gowan & Carter, 2008b).

TABLE 1.5 Brief Checklist/Questionnaire Measures That Address Social-Emotional and Behavioral Problems Broadly

	ASQ-SE Ages and Stages Questionnaire Social-Emotional	BESS Behavioral Emotional Screen System	BITSEA Brief Infant-Toddler Social and Emotional Assessment	ECSA Early Childhood Screening Assessment	SDQ Strengths and Difficulties Questionnaire	SWYC Survey of Wellbeing of Young Children

	ASQ-SE Ages and Stages Questionnaire Social-Emotional	BESS Behavioral Emotional Screen System	BITSEA Brief Infant-Toddler Social and Emotional Assessment	ECSA Early Childhood Screening Assessment	SDQ Strengths and Difficulties Questionnaire	SWYC Survey of Wellbeing of Young Children
COVERAGE:						
Problem domains covered	Problems are combined into one total score, though it covers a range of areas including self-regulation, compliance, communication, autonomy, and interaction with others	Problems are combined into one total score, though it covers internalizing and externalizing problems	Problems are combined into one total problem score, though it covers internalizing, externalizing, dysregulation, and maladaptive behaviors	Problems are combined into one total score, though it covers a range of areas	Emotional Symptoms; Conduct Problems; Hyperactivity; Peer Problems	BPSC includes 3 domains (Irritability, Inflexibility, Difficulty with Routines); PPSC covers several domains (internalizing, externalizing, attention problems, parenting challenges) though problems are combined into one overall score
Competencies/skills covered	Competencies are assessed but responses are integrated into overall score. There is not a separate competency scale.	Competencies are assessed but responses are integrated into overall score. There is not a separate competency scale.	Includes separate Competence domain with separate cut point	No	Includes separate Prosocial Behavior Scale domain with separate cut point	No
Parent worry or concern addressed?	Parent can indicate concern about each item; plus open-ended questions about concerns; not used in scoring	No	Two questions gauge parent worry about child behavior and language functioning; not used in scoring	Parent can indicate concern about each item plus there is one question asking about overall concern regarding child's emotional or behavioral development; not used in scoring	Not explicitly, though Impact Supplement asks whether caregiver thinks child has difficulties in emotions, behavior, concentration, or ability to get along with others	Two questions regarding parent concerns about child's behavior and child's learning or development; not used in scoring though providers are encouraged to follow up on concerns raised
Additional notes		Ability for parents to complete forms by listening to audio recordings; includes Validity Index to identify responses that may be overly negative or inconsistent		Parent report form includes two questions about parent depression (PHQ-2) and two questions about parent stress	Impact supplement can be used to assess distress and impairment associated with symptoms	Charts showing normative curves (percentiles) available for BPSC and developmental milestones available, though PPSC and POSI have one cut point

[1]Many measures are available in other languages but are often not normed in those languages.

The Early Childhood Screening Assessment (ECSA; Gleason, Zeanah, & Dickstein, 2010) is a brief screening tool designed to identify emotional and behavioral problems in children 18 to 60 months of age. There are two versions of the questionnaire—a parent report form, which consists of 40 items, and a caregiver/teacher report form, which consists of 36 items. The 36 child-specific items are similar across forms. The parent report form also includes the U.S. Preventive Health Task Force recommended Patient Health Questionnaire—2 questions to assess for parent depression (though the time frame "over the past two weeks" is not included) and two questions that ask about parent stress. Items are scored on a 3-point Likert scale (Rarely/Not True, Sometimes/Sort-Of, and Almost Always/Very True), plus parents can circle the "+" next to each item if they are "concerned about an item and want help with it." Parents can also indicate at the end of the questionnaire whether they are worried about their child's overall behavior. Scores on the child questions and the adult questions are separately compared with clinical cut points to determine risk status. Though research on the ECSA is not as abundant as that on other screening tools, preliminary research suggests that the ECSA has adequate sensitivity (86%) and specificity (83%) as well as good internal consistency (0.91) and test–retest reliability (0.81) (Gleason et al., 2010).

The SDQ (Goodman & Goodman, 2009) is a 25-item behavioral screening tool composed of five items in each area: (1) Emotional Symptoms; (2) Conduct Problems; (3) Hyperactivity; (4) Peer Problems; And (5) Prosocial Behavior (strengths). A separate one- to eight-item scale assesses problem presence, level of severity, and impairment (impact supplement). For providers using the SDQ over time when interventions are put in place, a follow-up form is also available, which asks two questions about the use of interventions (whether the intervention reduced problems or helped in other ways). The SDQ can be used with children 24 months to 18 years of age. There are three age groups for which separate forms are available: 2 to 4 years; 5 to 10 years; and 11 to 17 years. Parent report and teacher report forms are available. Scoring can be completed in less than 5 minutes either by hand or online. Results yield scores for the five scales, plus a Total Difficulties score (sum of the four problem domains, excludes prosocial behavior scale), and an Impact score. However, the SDQ authors have reported that in low-risk or general population samples, it may be better to examine two problem scales, internalizing (Emotional Symptoms and Peer Problems) and externalizing (Conduct Problems and Hyperactivity) rather than the four subscales (Goodman, Lamping, & Ploubidis, 2010). The SDQ has been widely used and investigated cross-culturally with normative data obtained in various countries including the United States using a large sample. While the psychometric properties among of the SDQ among school-age children are strong (Sensitivity = 85%; Specificity = 80%; Goodman, Ford, Corbin, & Meltzer, 2004), its use among preschoolers is less common and rigorous studies among this age group are currently lacking.

The Survey of Wellbeing of Young Children (SWYC; Sheldrick, Henson, et al., 2012) is a comprehensive screening instrument for children under 5 years of age designed to be used easily in busy practice settings, particularly within primary care. There are 12 age-specific versions of the SWYC (2, 4, 6, 9, 12, 15, 18, 24, 30, 36, 48, and 60 months) that vary in question content. All versions of the SWYC include sections on developmental milestones (10 questions covering language, motor, social, and cognitive), family context (nine questions covering family risk factors such as parent depression and substance use), parent concerns (two questions), and child behavior. Regarding child behavior questions, parents of children up to 18 months children complete the Baby Pediatric Symptom Checklist (BPSC; 12 items) and parents of children 18 to 66 months complete the Preschool Pediatric Symptoms Checklist (PPSC; 18 items). The BPSC and the PPSC represent downward extensions of the Pediatric Symptoms Checklist, a behavioral screening tool that can be used with children 6 to 16 years of age. The SWYC also includes a seven-item autism-specific screener, the Parent's Observations of Social Interactions (POSI), which parents of children 16 to 30 months of age complete. Sections of the SWYC that have been examined (BPSC, PPSC, POSI, milestones) demonstrate acceptable psychometric properties, including reliability (test–retest, internal consistency) and validity (Sheldrick, Henson, et al., 2012; Sheldrick et al., 2013; Sheldrick & Perrin, 2013; Smith, Sheldrick, & Perrin, 2013).

Comprehensive Dimensional Tools for Assessing Social-Emotional/Behavioral Problems

When the goal of the assessment is to gather detailed information about the specific areas in which a child is manifesting problems, longer, more detailed assessments are generally most appropriate. Comprehensive checklists can provide a detailed and differentiated understanding of the areas in which a child is reported by the parent to be manifesting a problem and those in which the child's behavior falls in the typical range for his age group. These

types of tools ensure that parents are queried about a broad array of social-emotional problems including behaviors that parents may not be aware can be problems for young children. Comprehensive checklists usually gather information at the level of broad domains and subscales within each domain. The most common domains covered are the internalizing and externalizing domains first identified by Achenbach (Achenbach, 1966). Internalizing problems include fears, anxieties, and depressive and mood problems. Externalizing problems generally include aggressive, disruptive, and non-compliant behaviors, as well as problems of hyperactivity and inattention. Some tools, such as the ITSEA, also assess functioning in other domains, such as dysregulation and social competence (Table 1.7). Similarly, some tools assess functioning in a single domain; for example, the Multidimensional Assessment Profile of Disruptive Behavior (Wakschlag et al., 2014) focuses solely on ensuring a comprehensive assessment of disruptive behaviors, such as noncompliance, temper loss and low concern for others. In addition to providing domain-level scores that indicate a child's overall level of problems within a given broad area, these types of tools also provide subscale scores that indicate a child's functioning in more specific, narrowband areas of functioning. Clinically, having a profile that can pinpoint specific areas of difficulty can be more informative for guiding conversations with parents and treatment planning than broad domain scores. For example, on the ITSEA (Carter & Briggs-Gowan, 2006) and the CBCL/1.5-5 (Achenbach & Rescorla, 2000), the externalizing domain score is calculated by summing across a number of hyperactivity/impulsivity items as well as items describing aggressive and noncompliant behaviors. Given the frequent co-occurrence of disruptive and hyperactivity/impulsive behaviors clinically, a high score may reflect the presence of a wide array of problems throughout the domain. However, some children may display primarily hyperactive/impulsive problems without any elevation in aggression or noncompliance and others may behave in primarily disruptive ways with elevations in all areas. Thus, an elevated domain score provides an imprecise reflection of a child's problem behaviors. In contrast, subscale scores provide more specific information, enabling the clinical formulation to focus on the presenting problems.

Clinically, comprehensive checklists can be especially helpful when the goal is to profile a child's strengths and weaknesses to guide treatment planning. They also are best suited when the goal is to track treatment outcomes, because they provide a detailed assessment of functioning within the specific subareas that were identified as problems when the child began treatment and targeted by the treatment plan. In contrast, using a tool that captures behavior only at the level of the broad domain runs the risk of underestimating improvement. This is because so many behaviors influence domain-level scores. Taking the externalizing domain as an example, if a child entered treatment with problems with hyperactivity/impulsivity and aggression and made significant gains in the area of aggression but not hyperactivity/impulsivity, the externalizing domain score could remain elevated above a clinical cutoff even though the child's aggressive behavior had dropped to normative levels.

Scientifically, increasing evidence suggests that narrowband subscales that capture discrete sets of behavior are more effective than scales that are comprised of heterogeneous sets of behavior for linking behaviors with neurobiological risk factors. For example, efforts to identify genetic contributions to psychopathology have been strengthened by the use of narrowband measures of phenotypic expression (Krueger, 1999; Krueger et al., 2002; Tackett et al., 2013; Todd et al., 2005). As an illustration in young children, one of our studies recently revealed that maternal reports of preschoolers' difficulty learning from punishment (or "Punishment Insensitivity" on the Multidimensional Assessment Profile of Disruptive Behavior) was associated with poorer performance on a computerized task that assessed learning from punishment (Briggs-Gowan et al., 2013). However, mothers' reports of other types of disruptive behavior were not associated with task performance. This narrowband approach also is consistent with the National Institute of Mental Health's Research Domain Criteria framework, which calls for research that employs dimensional measures to characterize aspects of functioning that can be more precisely linked with underlying biological processes, such as genetic vulnerability and neural pathways (Casey, Oliveri, & Insel, 2014; Insel et al., 2010). For these reasons, when the goals of an assessment are to dig more deeply in an effort to drive scientific discovery, comprehensive tools that provide both broad and narrow measures of functioning are often most desirable and a close inspection of the items that contribute to subscales and domains is essential to ensure that the tool captures the constructs of interest.

Selected Dimensional Checklists

Several norm-referenced tools for assessing social-emotional and behavioral problems common in this developmental period are summarized in Table 1.6 and 1.7 and described briefly in this section. These measures are fairly comparable in their general format (as shown

TABLE 1.6 Comprehensive Checklist/Questionnaire Measures That Address Social-Emotional and Behavioral Problems Broadly

	ITSEA	CBCL	BASC-2	PKBS-2	Conners-EC Behavior Scales[1]

Available in Spanish?	Yes	Yes	Yes	Yes	Yes

[1]The Conners-EC also includes Developmental Milestones Scales (an additional 75 parent and 70 teacher/child-care items) for assessing Adaptive Skills, Communication, Motor Skills, Play, and Pre-Academic/Cognitive development.

in Table 1.6). They are written at a fourth- to sixth-grade reading level, are composed of 100–200 items, and require 15–30 minutes to complete. As normed instruments, these tools provide a means of comparing a given child with population-based means to determine whether the child's difficulties fall in a range that is considered clinically concerning. Despite these commonalities, these measures vary with respect to key factors including (1) whether they were explicitly developed for young children or are instead downward extensions of tools originally designed for older children; (2) the number and content of the domains they cover; and (3) the extent to which they provide insight into specific types of problems.

These tools have very detailed manuals with extensive information about the psychometric properties of each measure. Therefore, we do not attempt to summarize them here. Overall, each of these tools *generally* has acceptable reliability and validity; however, because these are very comprehensive measures with many possible scores, it is possible that an individual scale or even a domain *may not have inadequate* reliability or validity in a particular population or age or sex group. Therefore, a careful review of a tool's reliability and validity within the population to be assessed is critical.

Comprehensive, Multidomain Checklists

The BASC-2 Preschool (Reynolds & Kamphaus, 2004) measures behavior problems and adaptive skills for children ages 2 to 5 years of age. The BASC-2 Preschool version is a parent or teacher report measure that is composed of 100–134 items depending on the informant. The reliability and validity of this measure have been

evaluated. Norms are provided for 2- to 3-year-olds and 4- to 5-year-olds, with additional breakdowns for boys and girls, as shown in Table 1.7. The BASC-2 Preschool version provides four broad scores: Internalizing Problems, Externalizing Problems, Behavior Symptoms Index, and Adaptive Skills. It is important to understand the subscales that go into scoring each of these domains because some subscales are used in multiple domain scores. More specifically, the Externalizing score is based on the Aggression and Hyperactive scales. The Internalizing Problems score is based on Anxiety, Depression, and Somatic problems. The Behavior Symptoms Index is comprised of Hyperactivity, Aggression, Depression, Withdrawal, Attention Problems, and Atypicality. Thus, the Behavior Symptoms Index includes all Externalizing subscales, only one of three Internalizing scales, and three scales not included on either the Internalizing or Externalizing Problem scores. Therefore, it is important to be very careful to interpret patterns cautiously. For example, if the Externalizing and Behavior Symptoms scores are both elevated, it will be relevant to inspect the scales within each to determine whether both of these elevations are driven primarily by Hyperactivity and Aggression problems or whether other scales such as Attention, Withdrawal, Anxiety, or Atypicality are also elevated and contributing to the high Behavior Problem Index score. Caution will need to be taken when using the BASC-2 in research applications to ensure that this overlap in scale content does not lead to misinterpretation of findings.

The Child Behavior Checklist for 1.5-5 (CBCL/1.5-5) (Achenbach & Rescorla, 2000) is a checklist measure that is a downward extension of the CBCL, originally developed for older children. The reliability and validity of the younger child version has been evaluated in children from 18 months through 5 years. The CBCL/1.5-5 addresses social-emotional/behavioral problems in three domains (Internalizing, Externalizing, and Total Problems), with more specific subscales within the Internalizing and Externalizing domains. The CBCL can also be scored to obtain *DSM*-oriented scales, which are designed to parallel symptoms that fall within specific diagnostic areas. It is worth comment that items that go into scoring the DSM-oriented scales also go into scoring the Internalizing and Externalizing Domain scores and subscale scores. Therefore, to avoid double counting individual problem behaviors, it is best to use one or the other set of scores but not both. Social-emotional competencies are not rated in

the CBCL/1.5-5. This measure also has been used internationally, including in Denmark (Kristensen, Henriksen, & Bilenberg, 2010), China (Liu, Cheng, & Leung, 2011), Taiwan (Wu et al., 2012), and Columbia (Flink et al., 2013).

The Conners Early Childhood (Conners-EC) (Conners, 2009) is a checklist measure that assesses both social-emotional and behavioral problems and developmental milestones in young children ages 2 to 6 years. Earlier forms of the Conners were developed for older children and focused on ADHD and other types of behavior problems (Conners, Sitarenios, Parker, & Epstein, 1998). The current version is extended to include anxiety, mood/affective problems, and atypical behaviors. The Conners-EC Behavioral form includes 115 parent-report and 116 teacher report items. It was normed within six-month age bands for boys and girls separately, which should enhance the developmental appropriateness and accuracy of its norms. This measure provides scores in six areas as follow: (1) Inattention/Hyperactivity; (2) Defiant/Aggressive; (3) Social Functioning/Atypical; (4) Anxiety; (5) Mood/Affective Problems; and (6) Physical Symptoms. The Conners-EC does not, however, offer broad domain scores for Internalizing or Externalizing Problems or for Social Skills/Competencies. However, the separate Developmental Milestones scales portion of the Conners-EC (eighty parent items, seventy-four teacher items) includes assessment of Play, as well as Adaptive behavior, Communication, and Motor Skills.

The Infant-Toddler Social and Emotional Assessment (ITSEA) (Briggs-Gowan & Carter, 1998; Carter & Briggs-Gowan, 2006; Carter et al., 2003) is a 169-item questionnaire about social-emotional and behavioral problems and competencies in 1- to 3-year-old children. From its inception, the ITSEA was developed for use with very young children. Items were developed based on literature review, clinical and developmental theory, and input from a large panel of experts from the fields of infant mental health, developmental psychology, and developmental psychopathology. It was developed as a comprehensive tool that would be appropriate for profiling children's strengths and weaknesses in the social-emotional domain. There are four broad domains, Internalizing, Externalizing, Dysregulation, and Competence, with multiple subscales within each domain. In addition, the ITSEA includes three indices, Social Relatedness, Atypical Behaviors, and Maladaptive. These indices consist of low base rate, but clinically significant behaviors. Reliability and validity have been established in four independent samples and in a national norming sample in the United States (Briggs-Gowan & Carter, 1998, 2008a; Carter & Briggs-Gowan, 2006; Carter et al., 2003; Carter, Little, Briggs-Gowan, & Kogan, 1999). In international samples, a number of researchers have established the ITSEA's reliability and validity in other languages and cultures, including China (Jianduan et al., 2009), the Netherlands (Visser et al., 2010), and France (Bracha et al., 2004). Additional studies have shown that the ITSEA is sensitive to treatment change (Barlow et al., 2013; Lowell, Carter, Godoy, Paulicin, & Briggs-Gowan, 2011; Spittle et al., 2010).

The Preschool and Kindergarten Behavior Scales (PKBS-2) (Merrell, 2002) is a checklist measure of problem behaviors and social skills in 3- to 6-year-olds. This 99-item measure includes identical items for different informants. The exact same form is used for parents and teachers, but different norms are applied depending on the informant. The PKBS provides a somewhat less detailed set of scores about a child relative to other measures in this section. It offers Internalizing, Externalizing, and Social Skills scores. Standard scoring provides broad scores for the Internalizing, Externalizing, and Social Skills domains, as well as specific scores for three social skills subscales, Social Cooperation, Social Interaction, and Social Independence. Although they are not described in the scoring forms for the PKBS, the manual describes scoring for several subscales within the internalizing and externalizing areas, including Anxiety/Somatic Problems, Social Withdrawal, Attention Problems/Overactive, Self-Centered/Explosive, and Antisocial/Aggressive. A full understanding of the content of these scales is important however, as some scales include items that are not clearly described by the name of the scale. For example, the Attention Problems/Overactive scale includes some items that appear to be more disruptive in nature. Given the high levels of comorbidity within specific externalizing behaviors, it is likely that these items loaded best on this scale. However, interpretation should be informed by the content of the scales.

Dimensional Checklists That Focus on Specific Areas

In addition to previously described the comprehensive measures, a number of tools focus more narrowly on specific aspects of social-emotional/behavioral problems and competencies. The Preschool Anxiety Scale (Edwards et al., 2010; Spence et al., 2001) assesses anxieties in the areas of social anxiety, generalized anxiety, separation, and specific fears. The PAS has demonstrated fair to good internal consistency and factor structure (Broeren & Muris, 2008; Edwards et al., 2010; Spence et al., 2001). However, some scales have had poor internal consistency in some studies. For example, Separation Anxiety had

poor internal consistency in Chinese and Dutch samples (Broeren & Muris, 2008; Wang, 2014). As discussed earlier, this could reflect problems with the translation, cultural variation in how items are understood, or differences in our separation anxiety manifests in those cultures. The PAS has not to our knowledge been formally normed. Another tool, the Multidimensional Profile of Disruptive Behavior (MAP-DB) (Wakschlag et al., 2014), is a new 78-item parent report measure of disruptive behavior in the areas of Aggression, Temper Loss, Low Concern for Others (disregard, punishment insensitivity), and Noncompliance. The MAP-DB has demonstrated acceptable internal consistency (Cronbach's alphas of .92 to .97) and test–retest reliability (ICCs of .76 to .85) (Nichols et al., in press; Wakschlag et al., 2014). Evidence of validity has begun to emerge (Briggs-Gowan et al., 2013; Nichols et al., in press; Wakschlag, Choi, et al., 2012). A final example is the Social Skills Improvement System (SSIS) (Gresham & Elliott, 2008), a checklist measure for children ages 3 to 18 that emphasizes the assessment of social skills but also includes some scales for assessing problems in other areas (e.g., externalizing).

Variation in Emphasis of the Domains That Are Assessed

A review of the domains and subscales assessed by these different measures, summarized in Table 1.7, reveals variation in the areas assessed. There are three primary points to note.

First, most but not all of these measures provide domain-level scores for both internalizing and externalizing problems (Table 1.7). The Conners-EC does not provide summary scores at the broad domain level. While this may be appropriate in clinical settings, it may be a disadvantage for some research applications where it is sometimes advantageous to examine patterns at the broad domain level instead of (or in addition to) at the level of multiple subscale scores.

Second, only some of these measures assess social skills/competencies and there is considerable variability within these in the types of competencies that are assessed. The BASC-2, ITSEA, and PKBS all assess social competencies and include subscales that assess specific aspects of social-emotional competence. For example, the PKBS assesses skills in the areas of social cooperation, social interaction, and social independence, the BASC captures social skills and adaptability, and the ITSEA provides scores for empathy, compliance, prosocial peer play, mastery motivation, and imitation/play. In contrast, the CBCL/1.5-5 does not assess any social competencies.

Third, there is considerable variability across these measures in their coverage of behaviors that may be associated with autism spectrum disorder. For example, the ITSEA includes indices designed to characterize these types of problems and has also demonstrated an empirical profile that is associated with autism (Carter & Briggs-Gowan, 2006). This profile is characterized by high scores on the Atypical Index and Depression/Withdrawal and low scores on the Social Relatedness Index and the Imitation/Play and Empathy. Similarly, the CBCL/1.5-5 has identified a Pervasive Developmental Delay subscale for assessing problems in this area. Other measures, such as the Conners-EC, have identified profiles that are associated with pervasive developmental delays. As a profile of specific weaknesses may be expected with children who are on the autism spectrum, a careful review of the manual is warranted to ensure appropriate interpretation of the profile of findings, is important when ASD is a consideration in assessment.

Finally, these measures differ in how deeply and specifically particular types of problems are assessed. ADHD problems provide a good example. Two measures have separate subscales for attention problems and hyperactivity/impulsivity problems, whereas the remaining measures combine these behaviors into a single score. For anxiety, most of the measures have a single subscale for assessing anxiety or combine anxiety and somatic problems; the latter approach can be problematic if working with medically ill children. The ITSEA is unique in distinguishing different types of anxiety, with scales for separation distress and general anxiety.

A final point to consider is variation in how child age and sex were addressed in the norming process. For example, the Connors-EC and ITSEA derived norms for six-month age bands for boys and girls separately and thus provide very narrow comparison groups against which children are compared. In contrast, the CBCL and PKBS employ the same norms across the entire age group for which the tool is assessed and did not derive norms separately for boys and girls. The BASC-2 used an intermediate approach, with age bands that span 24-month periods for boys and girls separately.

Diagnostic Approaches

Diagnostic interviews are designed to gather the detailed information that is needed to establish whether all of the criteria for making a particular diagnosis are met. The criteria required for a diagnosis varies across disorders, but often includes a specific number of symptoms, a period of duration, age of onset, and impairment. Although mostly

used in research settings, structured and semistructured interviews with parents or caregivers offer a more in-depth examination of child problems than can be obtained from questionnaires and can be particularly useful for helping to determine the child's diagnostic status (Egger & Angold, 2004). For example, in the PAPA interview, described in detail in the following section, interviewers can obtain specific examples of child behavior and inquire about the onset, offset, frequency, duration, intensity, quality, and contexts in which behaviors occur through follow-up questions and probes. Thus, interviews can provide a means of obtaining a more comprehensive understanding of the child's behavior and gathering information necessary to assign diagnoses.

The decision to use diagnostic interviews in the assessment process brings added challenges, including the staff and family time for the interview itself and staff time for review and scoring to establish diagnostic status. Interviews also typically require a formal training in administration and ongoing monitoring of the fidelity of administration and any ratings that are made in the scoring process to minimize drift over time. Such procedures are crucial to ensure that children are being consistently and systematically assessed in the same way. In practice, however, these standards can be difficult to uphold, especially when funding is limited or staff change over time, necessitating a system for training new staff. These issues are pronounced in early childhood because all of the interviews that are available are semistructured. Semistructured interviews provide interviewers with a clear framework for the interview, but interviewers must use their judgment about what constitutes a symptom, when to probe further to establish symptom presence, and what phrasing to use to describe a symptom (Angold et al., 2012). While the interviews vary in the background training required, from lay interviewer to clinician, the fact that interviewer judgment is employed means that training and monitoring are always essential.

The reliability of an interview provides information about how consistently the interview elicits the same information. Test–retest reliability indicates how well the interview provides the same results when administered twice at a short enough interval (typically 1–4 weeks) that true change in the child is not likely to have occurred. As it is administered by different interviewers at the two time points, test–retest reliability can be affected by differences in how deeply each interviewer probes or differences in how they perceive the information obtained even if they probe exactly the same way. Test–retest reliability can be influenced by true change in the child over time and development. Changes in how the parent perceives the child's behavior, fluctuations in the parent's attention level or mood can also affect reliability. The experience of being interviewed may influence a parent's understanding of the child's behavior. For example, they may come to realize that some behaviors that they thought were normal may be symptomatic or they may watch their child's behavior and realize it occurs more or less frequently than they thought it had at the first interview. Parents often also learn that if they deny the presence of symptoms the interview will go faster, resulting in lower scores at the second interview. Indeed, Egger and her colleagues note that attenuation (reduction) of symptoms and disorders is a common problem in test–retest studies of diagnostic interviews (Egger et al., 2006). Interrater reliability is a second type of reliability that's important for interviews. It refers to how consistently different people rate the same interview. Interrater reliability is typically assessed by having raters watch videotapes of the same interview and code it independently. It also can be assessed by having one rater administer and code the interview and the second rater code from an audio or videotape. A constraint of inter-rater reliability it does not establish how well the interview was administered, only whether the information obtained yields comparable diagnostic and symptom data when rated independently. Together, test–retest and interrater provide complementary information about reliability. Internal consistency can also be assessed for symptom scores obtained from interviews, but this is often not reported.

Selected Diagnostic Interviews

In this section, we will review and discuss four interviews that have been used with young children (Table 1.8). First we will review two interviews that were explicitly developed for early childhood: the Preschool Age Psychiatric Assessment (PAPA) (Egger & Angold, 2004; Egger et al., 2006) and the Diagnostic Infant and Preschool Assessment (DIPA) (Scheeringa, 2004; Scheeringa & Haslett, 2010). Then we will review two interviews originally developed for older children—the Anxiety Disorders Interview Schedule (ADIS) (Silverman, Saavedra, & Pina, 2001) and the Schedule for Affective Disorders and Schizophrenia – Present and Lifetime (K-SADS-PL) (Kaufman et al., 1997; Kaufman, Birmaher, Brent, Rao, & Ryan, 1996)—which have been used in studies of preschool-age children.

PAPA

The PAPA (Egger et al., 1999) was developed for parents of 2- to 5-year-olds. It is designed to provide comprehensive and developmentally sensitive coverage of the

TABLE 1.8 Diagnostic Interviews Used with Young Children

	PAPA (Egger et al., 2006)	DIPA (Scheeringa & Haslett, 2010)	K-SADS-PL Preschool (Kaufman, Birmaher, Brent, Rao, & et al., 1997)	ADIS (Silverman et al., 2001)
Age (months)	2 to 5 years	<7 years	1 to 6 years	3 to 5 years

Time frame covered	Past 3 months (and lifetime as appropriate)	Past 4 weeks	Past 3 months (and lifetime as appropriate)	Not specified
DSM version	*DSM-IV-TR*/RDC?	*DSM-IV*	*DSM-IV*	*DSM-IV*
Scoring	Electronic database	Hand scoring	Diagnostic consensus or by expert review	Hand scoring
Developmental modifications	Developed for young children	Developed for young children	Developed for older children. Studies vary in their developmental modification.	Developed for older children. Developmentally inappropriate questions are excluded.
Diagnostic areas covered	Common childhood disorders	Common childhood disorders	In preschoolers, reliability and validity primarily available for anxiety, ODD, CD, and ADHD	Anxiety disorders, ADHD, ODD, sleep terror disorder, selective mutism
Impairment	Impairment in multiple domains is evaluated in an incapacity module at the end of the interview	Impairment in multiple domains is evaluated at the end of each diagnostic section	Assessed in the process of assessing symptoms	Impairment in multiple domains is evaluated at the end of each diagnostic section
Test–retest reliability data	Reported (Egger et al., 2006)	Reported (Scheeringa & Haslett, 2010)	Reported for ODD/CD (Keenan et al., 2007)	Not reported for young children
Interrater reliability data	Not reported	Not reported	Reported for ODD/CD (Keenan et al., 2007) and for anxiety, ADHD, ODD, Mood (Birmaher et al., 2009)	Reported (Edwards et al., 2010; Rapee et al., 2005; Shamir-Essakow et al., 2005)
Validity data	Not explicitly studied, but various studies provide support for validity	Construct validity (Scheeringa & Haslett, 2010)	Reported for ODD/CD (Keenan et al., 2007) and for anxiety, ADHD, ODD, mood (Birmaher et al., 2009)	Not explicitly studied

symptom, frequency, duration, and onset criteria necessary to generate diagnoses for the *DSM-IV*, ICD-10, and DC: 0-3 diagnostic classification systems. In developing the PAPA, the authors conducted thorough reviews of the infant mental health literature and solicited detailed input from many infant mental health experts (Egger & Angold, 2001). The PAPA assesses a broad set of internalizing disorders, externalizing disorders, and regulatory disorders (addressing, e.g., sleep, feeding, and emotion regulation) as well as PTSD and reactive attachment disorder. At the end of the interview, an "incapacity" section is used to determine the level of impairment that is associated with symptoms of each diagnostic area. Impairment can be endorsed in several areas, including in parent–child and sibling relationships, in school or early care and education settings, and with peers. The PAPA may be administered by clinicians and laypersons, provided they have received formal PAPA training (Egger & Angold, 2004). Notably, the PAPA includes many adaptations that enhance its developmental appropriateness for young children. For example, it includes an extensive set of questions about temper tantrums, including probes to establish the types of behaviors that are manifested during tantrums (e.g., stamping feet, throwing things, holding breath), the

contexts in which they occur (home, school, elsewhere), how long they last, and whether the parent can identify triggers for tantrums (e.g., frustration, fatigue, transitions) or reports that they are out of the blue. A unique feature of the PAPA is that in determining whether symptom criteria are met, the diagnostic scoring algorithm incorporates information about the frequency of individual symptoms in a normative population. Thus, the algorithms incorporate empirical data to help distinguish normative from non-normative behaviors. Given that parents and professionals often have difficulty knowing when a particular behavior is problematic, this is a potentially valuable feature of the PAPA.

DIPA

Like the PAPA, the Diagnostic Infant and Preschool Assessment (DIPA) (Scheeringa, 2004; Scheeringa & Haslett, 2010) also covers a full range of psychiatric disorders that are common in childhood. It was designed for parents of children from infancy through 6 years of age. It is intended to provide a relatively quick and practical method for assessing psychiatric disorders. The DIPA is both structured and semistructured. It is structured in the sense that the initial stem questions about a given symptom are read verbatim, but semistructured in that the interviewer must probe for examples to establish whether symptom criteria are met. The interview is laid out in such a way that the interviewer can determine whether diagnostic criteria are met without requiring time-consuming data entry or computerized scoring. The DIPA also has incorporated a number of helpful developmental adaptations. For example, to aid the parent and interviewer in establishing whether a child's sleep patterns are symptomatic, the sleep disorders section incorporates empirical information for children of different ages (12 to 24 months versus 24 months and older) concerning how long children in this age group typically take to fall asleep and how often they typically waken during the night.

Two interviews that were originally developed for older children, the ADIS (Silverman et al., 2001) and the K-SADS-PL (Kaufman et al., 1996, 1997) have been used in studies of preschool-age children (Birmaher et al., 2009; Keenan et al., 2007; Kennedy, Rapee, & Edwards, 2009; Rapee, Kennedy, Ingram, Edwards, & Sweeney, 2005; Shamir-Essakow, Ungerer, & Rapee, 2005). Because they were developed for older children, in their original forms, these interviews include some *DSM* symptom criteria and descriptors that are developmentally inappropriate for young children, such as sexually inappropriate touching, vandalism, and stealing (Wakschlag et al., 2010). Most studies that have used the ADIS and K-SADS with young children have simply excluded these developmentally inappropriate symptoms from the interview entirely (Birmaher et al., 2009; Shamir-Essakow et al., 2005). However, this approach may miss the opportunity to assess these symptoms in a developmentally meaningful and valid way. For example, Wakschlag and Keenan have shown that many disruptive behavior symptom criteria of the K-SADS can be operationalized in a developmentally appropriate way for preschool-age children. When they used the K-SADS disruptive behavior modules with preschool children, they excluded inappropriate items (e.g., forced sexual contact) and modified definitional examples of symptom criteria where developmentally relevant (Keenan et al., 2007). For example, an exemplar for "often bullies" could include threatening aggression to get a toy (Gray & Wakschlag, in press). As interviews vary in how they have handled these issues of developmental relevance, it is important to review the context of an interview carefully when deciding whether it suits your goals and when interpreting results.

Psychometric Properties of Diagnostic Interviews

A review of the literature reveals unevenness across interviews in the types of reliability that have been emphasized and reported. For example, test–retest reliability has been systematically assessed for the PAPA and DIPA, has been reported for only Disruptive Behavior Disorders in the K-SADS, and has not been reported for the ADIS. In contrast, interrater reliability has been reported in multiple studies that have used the ADIS with preschoolers.

Test–Retest Reliability

Our literature review identified studies that have reported test–retest reliability statistics in young children for the PAPA, DIPA, and the K-SADS Disruptive Behavior Disorders (K-DBDs) but not for the ADIS. As summarized in Table 1.9, this review suggests that test–retest reliability is generally better for symptom scores than for presence versus absence of disorder. The poorer reliability for disorders relative to symptoms may be explained by the fact that diagnostic status is less forgiving of modest change. For children whose difficulties fall right near the threshold for disorder, a minor change in number of symptoms can dramatically change diagnostic classification (from present to absent or vice versa) but have minimal impact on symptom scores. A detailed review of each interview is provided in the following sections.

TABLE 1.9 Test–Retest Reliability of Diagnostic Interviews Used with Young Children

	PAPA (Egger et al., 2006)		DIPA (Scheeringa & Haslett, 2010)		K-SADS (Keenan et al., 2007)	
	Disorders (Kappa) Normative Sample/ Screen Highs	Symptom Scores (ICCS)	Disorders (Kappa) With/ Without Impairment	Symptom Scores (ICCS)	Disorders (Kappa)	Symptom Scores (ICCS)

CD	.60/.54	.66	Not studied	Not studied	.73	.81

Note: SAD=Separation Anxiety Disorder; GAD=Generalized Anxiety Disorder; PTSD=Post-Traumatic Stress Disorder; MDD=Major Depressive Disorder; ADHD=Attention-Deficit/Hyperactivity Disorder; ODD=Oppositional Defiant Disorder; CD=Conduct Disorder

PAPA. The reliability of the PAPA was examined in a sample of 2- to 5-year-old children who were recruited from a normative, population-based sample (Egger et al., 2006). To ensure the presence of sufficient psychopathology to evaluate the PAPA's reliability, children with high scores on the CBCL/1.5-5 were oversampled. Reliability is reported both for these screen-high children, as an estimate of reliability in clinical populations, and in a subsample that was more similar to the original normative sample as an estimate of reliability in nonreferred populations. The PAPA generally demonstrated good test–retest reliability for disorders (Table 1.9). Of 18 kappas reported, nine fell in the "Good" range (.60 to .74) and six were "Fair." Three of eight kappas for anxiety disorders were "Poor." In discussing this low reliability, Egger suggested that this could reflect poor reliability of *DSM* anxiety disorders in young children (Egger et al., 2006). All symptom count variables were reported to have good to excellent reliability. As noted by Egger and her colleagues (2006), the test–retest reliability of the PAPA is comparable to what has been reported for diagnostic interviews of older children and adolescents.

DIPA. The test–retest reliability of the DIPA was evaluated in a sample of 50 outpatient children under the age of 7 (Scheeringa & Haslett, 2010). Review of the DIPA revealed generally fair to good reliability for separation anxiety, PTSD, ADHD, and Oppositional Defiant Disorder (Table 1.9). However, reliability could not be adequately assessed for other disorders because some disorders occurred too rarely to estimate reliability; a rule of thumb is that reliability should be estimated only if there are at least five children with the disorder in the sample. Specific and social phobias were not assessed due to time constraints and concern about burden on families and interviewers in this clinical sample. At the symptom level, similar to the PAPA, reliability for assessing ODD and ADHD symptoms was good to excellent. Reliability was excellent for Separation Anxiety and Post-traumatic Stress symptoms but fair for symptoms of Major Depression and Generalized Anxiety.

K-SADS. The test–retest reliability of the K-DBDs was evaluated in a study of 223 clinically referred and nonreferred children, ages 3 to 5 years (Keenan et al., 2007). The focus of this study was specifically disruptive behavior disorders. Test–retest reliability statistics for ODD and conduct disorder (CD) and symptoms were good to excellent (Table 1.9). To our knowledge, test–retest reliability has not been reported for other disorders assessed by the K-SADS in preschoolers.

Interrater Reliability

Much less information is available about the interrater reliability of these diagnostic interviews. A number of studies that have used the ADIS with preschool samples have

reported its interrater reliability in assessing presence or absence of anxiety disorders (Edwards et al., 2010; Rapee et al., 2005; Shamir-Essakow et al., 2005). Across these three studies, interrater reliability was consistently good to excellent for separation anxiety (K = .69 to .89), specific phobias (K = .69 to .83), and social phobia (K = .84 to .89). However, interrater reliability of generalized anxiety disorder has been only fair in two studies (K = .54 to .56) and excellent in one (K = .77). For the K-SADS-DBDS, Keenan and her colleagues (2007) reported excellent interrater reliability for ODD and CD symptoms (both ICCs = .98) and disorders (K = .96 and .98, respectively). Finally, although specific details were not provided for individual disorders, Birmaher and colleagues reported that the K-SADS demonstrated excellent interrater reliability for all disorders (all kappas >.80) in a study of preschool-age children (Birmaher et al., 2009).

Validity

Validity of diagnostic interviews in young children has rarely been tested explicitly. As a consequence, their validity in properly classifying children as having or not having psychiatric disorders is essentially unknown. This is at least partially a reflection of an inherent challenge in defining an appropriate gold standard for evaluating the validity of psychiatric diagnoses. While clinician-assigned diagnoses might be considered for this purpose, they can have poor reliability (Fisher et al., 1993). Thus, poor validity could arise from unreliability of the clinician diagnoses rather than a limitation of the interview. One approach to validate these measures is to demonstrate expected associations with checklist measures. This approach validates that the interview captures elevations in symptoms—it cannot validate that the diagnosis itself is valid because checklists cannot determine the presence or absence of disorder explicitly because they do not evaluate diagnostic criteria. Another approach is to demonstrate concordance between the interview and overall clinical status, that is that children referred for treatment are more likely to meet criteria for disorder than healthy controls.

The DIPA is unique in that Scheeringa and colleagues explicitly evaluated the validity of the continuous symptom scores in relation to the CBCL 1.5-5 (Scheeringa & Haslett, 2010). Results of these analyses indicated good validity for the externalizing symptom scores and for separation anxiety, with correlations from .44 to .59, but generally low validity for internalizing problems, such as generalized anxiety and depression, with most correlations below .25. However, this might be as much a limitation of the CBCL as it is of the DIPA. For the K-SADS-DBDS, ODD and CD diagnoses demonstrated good reliability relative to measures of impairment and referral status (Keenan et al., 2007). To our knowledge, the validity of the PAPA, ADIS, and other diagnostic areas of the K-SADS have not been studied explicitly.

Nonetheless, as researchers employ these interviews in their studies, we have opportunities to gain insights into validity. Various studies that have used these interviews suggest their value for characterizing preschool psychopathology. For example, the PAPA, ADIS, and K-SADS all have been used in multiple preschool studies for a variety of purposes, including as a means of validating another tool (Edwards et al., 2010; Wakschlag et al., 2008) and of documenting treatment outcomes (Comer et al., 2012; Rapee et al., 2005) and for characterizing psychopathology in young children (Briggs-Gowan et al., 2010; Bufferd, Dougherty, Carlson, & Klein, 2011; Shamir-Essakow et al., 2005; Sterba, Egger, & Angold, 2007). For example, one recent study demonstrated greater impairment in young children with anxiety or depressive disorders identified by the PAPA relative to healthy children without disorders (Otto, Andreas, von Klitzing, Fuchs, & Klein, 2014). Another demonstrated the predictive validity of irritability, assessed with the PAPA, for predicting later depression, oppositional defiant disorder, and functional impairment (Dougherty et al., 2013). Longitudinal prediction from PAPA diagnosis to school-age peer impairment also has been reported (Danzig et al., 2013). Yet another demonstrated significant functional impairment in children who meet criteria for disorders on the PAPA (Bufferd et al., 2011). Treatment studies that have used the ADIS to assess anxiety disorders with preschool-age children have been similarly fruitful, with evidence that the ADIS is sensitive to treatment effects on anxiety disorders (Kennedy et al., 2009; Rapee et al., 2005). While these studies do not explicitly demonstrate the validity of these interviews, they do suggest their value for studying emergent symptoms and disorders in this developmental period.

It is worth commenting that a consistent emerging pattern is that generalized anxiety disorder is less reliably assessed, with lower test–retest and interrater reliability in most studies. This may reflect a need for further research to establish the validity of this type of anxiety in young children. This type of anxiety also may be difficult to assess in young children because their more limited ability to verbalize their internal states may mean that parents and other caregivers are less consistently aware of worrying and apprehension in this age group.

Observational Assessment

Observation is routinely used to assess the quality of individual, dyadic, triadic, and family functioning in young child assessments. These methods include two components: the procedures that are used to create the context for the observational episodes, and the coding system designed to quantify the elements of interest. Interactional episodes vary along a spectrum from naturalistic observation to structured interactions. Coding systems vary from micro-analytic coding of discrete behaviors across very brief time segments of interaction to global coding that requires appraisal of multiple components of the interaction across the entire duration of the observation.

A number of methods for assessing child temperament originated from developmental psychology laboratories. These include behavioral inhibition paradigms in which children are observed in situations in which they are exposed to novel objects and social situations (Kagan, Reznick, Clarke, Snidman, & Garcia-Coll, 1984; Reznick et al., 1986). The more extensive Laboratory Temperament Assessment Battery (Gagne, Van Hulle, Aksan, Essex, & Goldsmith, 2011) is a series of 3–5-minute naturalistic episodes that include the introduction of specific presses designed to capture variation in emotional expression, activity level, approach and avoidance, and other regulatory behaviors. Other measures focus on dyadic or triadic interactions. For example, the Parent-Child Early Relational Assessment (PCERA) is designed to assess individual child and parent affective and behavioral patterns and dyadic behaviors in both unstructured free play episodes and in more structured interactions (e.g., reading a book, doing a mildly difficult task) Clark, Tlucek, & Gallagher, 2004. Observations of triadic interactions, in which aspects of caregivers, cooperation, competition, and conflict are rated in relation to a particular child, have become more common in recent years (McHale & Coates, 2014; McHale & Fivaz-Depeursinge, 1999). The Disruptive Behavior Diagnostic System (DB-DOS) (Wakschlag et al., 2007, 2008) is an example of an observational paradigm and coding system that were developed to characterize children's functioning on a clinical continuum from normal to atypical. The interactions include parent–child and examiner–child interactions. Building on methods used in the area of ASD (Lord et al., 1989, 2000), each interactional context is designed to press for the full range of behaviors relevant to preschool disruptive behavior. For example, episodes include a don't touch shelf, a (presumably boring) sorting task, and a frustrating puzzle. As the presses build across the contexts, they can elicit valuable insight into how a child responds when stressed or frustrated. For example, providing qualitative and quantitative information about the intensity, pervasiveness, and ease of escalation of negative affect as well as whether it is displayed with both the parent and the examiner. We are have recently developed and reported the preliminary reliability and validity of an extension of this method to anxiety, the Anxiety Dimensional Observation System (Anx-DOS) (Briggs-Gowan, Mian, Carter, & Wakschlag, 2011; Mian et al., in press).

Observational methods such as these offer an important means of capturing independent information about a child's functioning. In practice, however, they are typically costly and burdensome to implement. To be valid, the observational paradigm must be administered in a standard fashion. Thus staff must be well trained, and there should be ongoing quality control checks to ensure that they continue to administer the protocol reliably over time. Similarly, observational coders must be trained to apply the coding system reliably, and their reliability must be maintained over time. The process of training a coder to the point of acceptable reliability can require many hours of coding and feedback with an expert coder. Once a coder is reliable, ongoing monitoring of reliability is essential to prevent drift over time. Consequently, standardized, coded observational approaches are primarily used in research settings. For coding of discrete behaviors, new technological advances are developing in which computers and computer software can assume some of the burden of coding; for example, improvements in face recognition and machine learning enabling coding of discrete emotions such as pain (Lucey et al., 2011).

Finally, along with observation, several researchers have developed methods for directly eliciting information about symptomatology from children. A variety of measures have been developed focused on the free responses of children to story stems, puppet interactions (Measelle, Ablow, Cowan, & Cowan, 1998; Warren, Emde, & Sroufe, 2000; Warren, Oppenheim, & Emde, 1996), and simple picture-based questionnaire responses (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1993, 1995; Martini, Strayhorn, & Puig-Antich, 1990). However, in relation to other diagnoses, the questions of whether and how to incorporate observational measures, or such material elicited directly from the child, have not been settled.

Assessing Impairment

As in older children and adults, social-emotional and behavioral problems in young children can be associated with impairment in functioning (Briggs-Gowan &

Carter, 2008a; Briggs-Gowan et al., 2001, 2006; Egger & Angold, 2006; Keenan et al., 2007; Lavigne et al., 1996; Luby, Belden, Pausch, et al., 2009). Symptoms of psychopathology can interfere with a child's participation in age-appropriate activities, developmental progress or relationships with others. When evaluating impairment in a young child, it is important to consider how the child's developmental capacities in domains such as cognition, motor, or language affect functional impairment. Delays in other areas, such as language development, may impede progress in other domains. Consider for example, the challenges faced by a child with mixed language delays and gross motor delays when attempting to keep up with peers. It is important that challenges in functioning associated with the mixed language and gross motor delays not be attributed to the symptoms of psychopathology that the child may also be evidencing. Difficulties being understood by and understanding peers may impede opportunities to learn age-appropriate prosocial skills acquired through give and take with peers. Difficulties running and climbing may interfere with his efforts to join gross motor peer play, contribute to isolation, and interfere with the development of peer relationships. Thus, assessing impairment associated with psychopathology requires consideration of developmental trajectories in multiple domains and their impact on children's performance of daily routines and activities.

In older children and adults, impairment is typically assessed by evaluating the individual's interpersonal, academic, occupational, and adaptive functioning (Association, 2000; Organization, 2001). In contrast, working with young children necessitates shifting the emphasis from the child only to encompass both the child and the broader family system.

Very young children's functioning is dependent on parental scaffolding and support. Impairment may manifest in the extent to which parents make accommodations that ultimately impact their child's participation in age-appropriate activities or developmental progress. For example, although a parent may not be able to offer examples of *child* impairment, *the parent* may have quit his or her job and restructured the household to accommodate their child's special needs or social-emotional problems. The parent may also avoid situations that would trigger their child's problem behavior. For example, a parent with a very active child may refrain from taking her even to family-friendly restaurants or a parent with a socially anxious child may avoid even child-friendly activities in the community. Such minimization of the demands placed on the child may help to obscure the child's impairment (Clark et al., 2004) while at the same time limiting the child's ability to engage in and learn from age-appropriate activities and likely further compounding the problem. When conceptualized within a broader family framework, young child impairment may manifest as parental distress or low efficacy about the parent–child relationship or evidence that the child's behavior interferes with the parent's ability to maintain family routines (e.g., have family meals together, visit relatives), household activities (e.g., making phone calls), or employment (e.g., restrictions on work due to the challenges of obtaining appropriate care for the child) (Clark et al., 2004).

Thus, when evaluating functional impairment, it is often useful to consider how a child's social-emotional/behavioral problems may limit the child's participation in age-appropriate activities such as learning activities (e.g., listening to books, drawing, building); opportunities to acquire and practice social skills with peers and nonfamilial adults; and exposure to challenging situations key to practicing and acquiring self-regulation skills. In parallel with this, it may be very illuminating to query how the child's problems may strain the parent–child relationship, cause distress for child, parent, or other family members, interfere with family routines (meals, bedtime, getting ready for the day), impact siblings, limit parental employment, or be perceived as affecting parental well-being (e.g. lack of sleep, worry, fatigue) or straining family relationships (between parents or in the broader family context).

Many available assessments now include some gauge of impairment in child or family functioning, as noted in the aforementioned summary of assessments. In addition to these, a number of measures offer a means of gathering information about the impact of the child's behavior on family functioning, such as the Parenting Stress Index (Abidin, 1990) and the Family Life Impairment Scale (Briggs-Gowan, Horowitz, & Carter, 1998; Briggs-Gowan et al., 2006; Carter et al., 2010). Measures of adaptive behavior, such as various forms of the Vineland Adaptive Behavior Scales II (Sparrow, Cicchetti, & Balla, 2005) and the Adaptive Behavior Assessment System (ABAS-II) (Harrison & Oakland, 2003) are norm-referenced tools that provide comprehensive assessment of a child's adaptive functioning. Adaptive functioning that is significantly lower than cognitive functioning often reflects the child's inability to participate in age-expected activities or attain developmentally expected competencies. Thus, adaptive functioning may represent one important index of impairment.

CONCLUSIONS AND DIRECTIONS FOR FUTURE RESEARCH

There has been tremendous progress in developing new instruments that enhance assessment of young children's social-emotional and behavior problems and disorders. Specifically, an array of instruments now exist: parent-reported questionnaires are available for screening and more comprehensive assessments of social-emotional and behavior problem and competence dimensions; diagnostic interviews are available for parents of children 2 years and older; and observational assessments of temperament and specific symptoms (e.g., disruptive behaviors) have been shown to deepen understanding of children's development in relation to their peers. Yet, despite these efforts and successes, many challenges remain. First, integrating data across informants and methods continues to be a significant challenge in both clinical and research settings, particularly given the frequent occurrence of low correlations between informants and methods (i.e., questionnaires, interviews, and observations). Given that young children do not have the metacognitive capacities to report on their own symptoms until approximately 4 years of age (and then only when using developmentally appropriate interviews such as the Berkeley Puppet Interview (Measelle et al., 1998), greater variability in caregiver expectations for child behavior among very young children, meaningful variability in children's behavior in different contexts (Dirks et al., 2012), and lack of consistency in documenting impairment among young children, recommendations or guidelines for systematic and valid approaches for integrating data would be a major contribution to the field. Recommendations should be based on empirically supported methods for integrating of multimethod, multi-informant assessment data within the domain of social-emotional and behavior problems and disorders that often yield competing views of the child. Moreover, such methods should also address children's developmental functioning and contextual factors such as caregiver–child relationships, family functioning, culture, and broader contextual factors that may shape the behaviors and emotions that parents and other informants notice and the meanings that they attribute to these behaviors and emotions.

Second, with an increased push for screening children for social-emotional and behavioral problems early and often, it becomes imperative to know how repeated administration of the same instrument may influence psychometric properties over time. One could easily hypothesize attenuation effects due to repeated screening as parents pay less attention to items, or one could hypothesize increased rates of reporting as parents become familiar with items and may begin to pay more careful attention to the child behaviors associated with screening items. Repeated screening also offers an opportunity for developing new methods for determining screening thresholds. Specifically, it is plausible that a child whose screening score is at or is one point above the single time-point threshold score on a screening instrument should carry more weight in relation to follow-up assessment or referral if similarly elevated scores have been obtained on two earlier occasions and less weight if this is the first occurrence of a score that just exceeds the cut score that is routinely employed for this age group. Underscoring the potential value of new methods for integrating longitudinal screening information, emerging research has shown that repeated assessments of irritability enhance prediction of impairment in preschoolers (Wakschlag et al., in press).

Third, with increased global diversity, there is a striking need to improve the availability of social-emotional and behavioral measures that have culturally valid content and offer representative normative data that are appropriate to the diversity that currently exists within many countries. This work will likely require international collaborative efforts using mixed methods approaches (i.e., integrated qualitative and quantitative studies) to aid instrument developers to serve the diverse children and families whose children may be at risk for or exhibiting elevated social-emotional and behavioral symptoms or disorders. Excellent translations of instruments are insufficient to meet this challenge. We need information about the psychometric properties of widely used measures in the many cultural groups in which we are currently employing translated tools. Indeed, there may be opportunities to capitalize on ongoing large-scale longitudinal epidemiologic studies in various countries to establish cross-national norms and validation. Moreover, given the diversity within individuals who share a common language, in clinical settings it is always essential to follow up with parents to learn more about the meanings that they are attributing to screening and comprehensive assessment questions and the ways they see their children's behaviors transacting with family values, goals, and the child's broader contextual caregiving environment.

Fourth, the National Institute of Mental Health's new framework for advancing mental health research, the Research Domain Criteria (RDoC), emphasizes the importance of dimensional assessments that characterize problems along a normal to abnormal spectrum and chart the developmental trajectories of functioning over the

course of childhood (Casey et al., 2014; Cuthbert & Insel, 2013; Insel et al., 2010). A core goal of the RDoC initiative is to employ methods that strengthen efforts to link phenotypic manifestations with underlying biological processes (e.g., neural pathways, psychophysiology, genetic risk). Measures that capture discrete, narrowly specified aspects of mood or behavior (e.g., irritability, fear responses) will advance these goals. Such narrowband approaches have proven to be effective in genetics research (Krueger, 1999; Krueger et al., 2002; Tackett et al., 2013; Todd et al., 2005). In our recent work with preschoolers, narrowband dimensional assessments have proven to be effective for identifying linkages with neurocognitive indicators of risk—with evidence that mother-reported difficulty learning from punishment predicted task-based indicators of impairment in learning from punishment (Briggs-Gowan et al., 2013) and observed fear reactions in the Anx-DOS correlated with attention bias to threat, an attentional pattern commonly associated with anxiety (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van, 2007; Briggs-Gowan et al., in press). However, methods for integrating dimensional assessments of social-emotional and behavioral functioning with other methods of characterizing neurobiologic risk will be essential to fully capitalize on these innovative technologies.

Fifth, there is increasing knowledge about the impact of adverse environments and stress on young children (Cicchetti & Toth, 1995; Curtis & Cicchetti, 2011; Finkelhor, Turner, Shattuck, & Hamby, 2013; Finkelhor, Vanderminden, Turner, Shattuck, & Hamby, 2014; Shonkoff & Phillips, 2000; Shonkoff et al., 2012). There is particularly strong evidence that maltreatment and other forms of violence within families are associated with a wide array of social-emotional and behavioral problems in young children. However, we do not know why there is so much heterogeneity in the outcomes associated with apparently similar adverse experiences, ranging from no elevations in social-emotional problems to a heterogeneous set of frank, persistent, impairing, and often comorbid psychiatric disorders. As we become more sophisticated about enriching environments for children with specific social-emotional and behavioral deficits, delays and problems in the forms of early parent–child and child interventions, we need to ensure that the measures we are using are sufficiently sensitive to both maturational and intervention effects.

Given the increased attention to and understanding of the importance of early childhood in laying the foundation for lifelong mental health, it is a very exciting time to enhance the use of evidence-based psychometrically sound, validated tools. Such tools have been and will continue to be essential for early identification and comprehensive assessment. These also have enabled the scientific community to demonstrate the early problems matter, are persistent and predict functioning later in childhood and drive policy change. While there is still a great deal of work to be done, the extensive attention to measurement development in this developmental period over the past 20 years has enabled a sea of change in understanding of and attention to very young children's mental health needs.

SUMMARY 87
REFERENCES 88

Our chapter in the previous edition of this book culminated with an overview of future directions for the developmental study of psychopathology. These included advancing developmentally oriented research on adult psychopathology and extending such research to more diverse societies. In this chapter, we report numerous new research findings on the assessment of adult as well as child psychopathology in over fifty societies. (For brevity, we use *child* to include ages $1\frac{1}{2}$ to 18.) The research reveals similarities and differences in the patterning and levels of psychopathology at different ages in different societies. It additionally reveals similarities and differences in problems reported for males versus females of different ages, according to multiple sources of data. The research is also yielding practical methods for integrating *multicultural* assessment of children with assessment of their parents to advance *family-oriented* interventions.

A related focus is on progress in strengthening the empirical foundations for developmental understanding of psychopathology. Findings from multiple longitudinal studies that operationalize phenotypes for psychopathology in similar ways are advancing knowledge in terms of evidence-based assessment and taxonomy. In conjunction with life span and multicultural research, the longitudinal studies are expanding our knowledge of multisource assessment, the benefits it confers, and the challenges it raises.

In preparation for considering developmental aspects of assessment, taxonomy, and *diagnosis* of psychopathology, we first outline life span and multicultural perspectives that increasingly contribute to the developmental study of psychopathology. Thereafter, we address conceptual components of developmental psychopathology, the roles of assessment and taxonomy, the multiple meanings of diagnosis, life span, and multicultural findings, the benefits of quantification, and future directions.

LIFE SPAN PERSPECTIVES

Developmental approaches to the study of psychopathology originated with efforts to advance our understanding of maladaptive functioning between birth and maturity (Achenbach, 1974, 1982; Cicchetti, 1984; Rutter & Garmezy, 1983). It is now widely recognized that behavioral and emotional problems in the young need to be understood in relation to developmental sequences, norms, and processes. However, it is also becoming clear that developmental approaches are needed to understand psychopathology at older ages. In many countries, challenges posed by the growing legions of elders are raising awareness of the need to cope with developmental changes in functioning during the last decades of life. Equally important, developmental perspectives can illuminate adaptive and maladaptive functioning in the early and middle adult years, when many changes occur in social roles, relationships, responsibilities, careers, self-concepts, and biological characteristics, including health. Although developmental aspects of assessment, taxonomy, and diagnosis have received more attention regarding children than adults, life span perspectives argue for expanding our horizons to include developmental aspects of adult psychopathology as well.

A particularly important issue concerns the need to obtain multisource data for purposes of assessment, taxonomy, and diagnosis. Most practitioners and researchers now understand that no single source can serve as a gold standard for assessing children's functioning. Because agreement among informants is typically low to moderate (Achenbach, McConaughy, & Howell, 1987; De Los Reyes, 2011), it is widely recognized that assessment of children requires data from multiple informants. The data from multiple informants must then be systematically compared and integrated to identify both the consistencies and variations among reports of each child's functioning.

In the assessment of elders whose mental competence may be questionable, it is common to obtain information from other informants, such as a spouse or grown child. In the assessment of younger adults, however, data are typically obtained solely from the adults who are being assessed, mainly via interviews, tests, and questionnaires. Yet, meta-analyses of cross-informant correlations between reports of adult psychopathology have revealed only modest agreement between adults' self-reports and reports by others (Achenbach, Krukowski, Dumenci, & Ivanova, 2005). A major way to advance assessment, taxonomy, and diagnosis of adult psychopathology is therefore to apply to adults the principles and methods for obtaining multiinformant data that are now commonly applied to children. Other lessons learned from the developmental study of child psychopathology are also applicable to adults.

MULTICULTURAL PERSPECTIVES

Mental health professionals are increasingly expected to help people from diverse backgrounds. In some cases, the need to cope with diversity arises from influxes of foreign refugees and immigrants to host societies. In other cases, the need to cope with diversity arises from migrations within a society. And in still other cases, the need to cope with diversity arises from greater sensitivity to differences

among people who have long coexisted in a particular society.

Diversity raises a variety of challenges for mental health professionals. Perhaps the most obvious is differences in language. Because mental health professionals may not be fluent in the languages of all the groups to be served, interpreters may be needed. Even when language is not a barrier, however, differences related to ethnicity, religion, place of origin, and socioeconomic status (SES) may affect communications between mental health professionals and the people they serve.

For assessment, taxonomy, and diagnosis of psychopathology, a fundamental issue is whether the same standardized procedures can be used to assess people from different backgrounds. This issue raises questions such as the following:

1. Can mental health professionals use the same standardized procedures to assess the problems and adaptive functioning of people from different populations?
2. Do people from different populations accept the same assessment procedures as effective ways of communicating information?
3. What can we learn from comparisons of standardized assessment data obtained from members of different populations?
4. Can mental health professionals use standardized procedures to distinguish between characteristics that are specific to individuals versus characteristics thought to typify populations to which the individuals belong?

To answer these questions, systematic research is needed to compare the results of standardized assessment procedures applied to representative samples of people from different populations. As detailed later, a growing body of research is available to answer these questions for diverse populations. Such research can also help us distinguish between aspects of psychopathology that are relatively consistent across populations versus those that are more variable. Throughout this chapter, we highlight the importance of comparing findings for people who differ in background and developmental level, as they are assessed from different perspectives, to identify important consistencies and differences in patterns and levels of psychopathology.

DEVELOPMENTAL PSYCHOPATHOLOGY

Developmental approaches to the study of psychopathology have become increasingly pervasive over the past few decades. These approaches have greatly advanced our understanding of maladaptive functioning in childhood and adolescence. Developmental approaches to psychopathology have also helped to shape training and practice. However, much remains to be done to integrate the study, prevention, and treatment of psychopathology with the study of development across the life span.

Assessment, taxonomy, and diagnosis are central foci around which developmental approaches to psychopathology can be organized. As a preface to considering assessment, taxonomy, and diagnosis, it is first important to introduce what we mean by *development* and *psychopathology*. We use both of these concepts broadly, with a minimum of theoretical assumptions. Although particular theories of development and psychopathology may help us understand particular phenomena, the utility of these concepts would be diminished by limiting their meanings to the dictates of particular theories.

THE DEVELOPMENTAL COMPONENT

We use *developmental* to encompass processes, changes, sequences, and characteristics that are typically associated with age. Chronological age (CA) is the most obvious developmental metric, but it can serve as a proxy for many other developmental parameters. For some purposes, it may be preferable to use developmental metrics that do not necessarily correlate highly with CA. Mental age (MA) and other indices of cognitive developmental level, for example, would not correlate highly with CA in samples that included children with intellectual disabilities, whose cognitive levels are below their CAs, or very bright children, whose cognitive levels are above their CAs. Biological parameters may also provide important developmental metrics. Nevertheless, even when parameters other than CA provide metrics for developmental variables, CA remains an important common denominator because of CA-related differences in biological maturity, appearance, and social status. Our use of the term *developmental* is intended to stimulate new ideas rather than to mold thinking according to narrow definitions of development.

In addition to identifying characteristics that are associated with developmental parameters, a developmental perspective focuses on adaptation. By identifying adaptive and maladaptive processes, we can shed light on the origins of favorable versus unfavorable outcomes. This, in turn, provides a basis for inferring causal factors in psychopathology and for designing interventions to prevent or treat psychopathology.

Developmental Theories

Some of the most influential theories of human psychological functioning have been developmental. Psychoanalytic theory, for example, interprets adult psychopathology in terms of childhood precursors involving psychosexual stages, fixations, and regressions (Freud, 1940). Piaget's (1983) theory portrays adult cognitive functioning as an outgrowth of stage-like advances and reorganizations occurring from birth to maturity. Learning theories attribute deviant behavior to the environmental contingencies experienced throughout the individual's lifetime (e.g., Bandura, 1977). Theories about infants' attachment to their caregivers have been used to explain later interpersonal functioning in terms of attachment representations (e.g., Cassidy & Shaver, 1999). Epigenetic theories hypothesize biological sequences that start at conception and continue through the eventual emergence of psychopathology (Rutter, 2006). Such theories focus on how life events influence gene expression, which can then predispose a person toward more versus less adaptive ways of handling stress and challenges. Because different theories can help us understand different aspects of development and psychopathology, the developmental study of psychopathology should not be restricted to the tenets of any single theory.

It may seem obvious that an organism's behavior during a particular developmental period is in many respects an outgrowth of its previous history. It is much less obvious how and to what extent the organism's previous history determines successful adaptation versus pathological maladaptation during particular developmental periods. The differences among developmental theories attest to the variety of possible ways to view development and to the multitude of variables potentially associated with developmental periods and levels. Although this chapter cannot delineate all variables posited by all theories of development, the different theories are rich sources of clues and concepts for guiding the developmental study of psychopathology.

Developmental Considerations in Assessment, Taxonomy, and Diagnosis

Knowledge of development should guide assessment, taxonomy, and diagnosis of psychopathology. For example, knowledge of cognitive development would argue against using interviews that require children to communicate evaluations of their own behavioral and emotional problems before they are cognitively capable of making and communicating such evaluations. This may seem obvious. Yet Breton et al. (1995) found that even normal 9- to 11-year-olds failed to understand many questions on the Diagnostic Interview Schedule for Children (DISC; Shaffer, 1992), which is widely used to make psychiatric diagnoses. Knowledge of development is thus needed to tailor assessment methods to the abilities of those who provide the data. Assessment should also be designed to detect possible developmental differences that have not previously been identified.

In designing assessment procedures to detect developmental differences, it is important to be sensitive to developmental variations in the *content* and *patterning* of the relevant phenomena, as well as to parameters that can be measured in a uniform fashion across broad age spans. For example, height, weight, and IQ are expressed as similar parameters for people of all ages. Yet, the physical configurations underlying even the measures of height and weight change markedly across the life span. Thus, children who weigh 40 pounds at age 5 and 120 pounds at age 15 have not merely grown three times as large. Their body proportions have changed, pubertal development has occurred, and their adolescent appearance causes people to treat them differently.

Analogous to height and weight, the cognitive processes that underlie an IQ of 100 at age 5 differ from those that underlie an IQ of 100 at age 15. Unlike height and weight, however, the phenotypic variables that are assessed by IQ tests differ considerably at ages 5 and 15. By the same token, psychopathological conditions that bear the same diagnostic label at different ages, such as attention-deficit/hyperactivity disorder (ADHD), may be phenotypically quite different at different ages, may involve different underlying processes, and may have different consequences for the individual's adaptation. We should therefore be aware that when diagnostic terms such as ADHD are applied to people of different ages they may not actually represent encapsulated disorders that are the same at all ages.

We must also remember that certain behaviors may be considered normal during one developmental period but deviant at earlier or later developmental periods. For example, high levels of motor activity that are normal for preschoolers would be considered deviant in adolescents. Conversely, sexual interests that are normal for adolescents would be considered deviant for preschoolers.

Developmental Methodology

Developmental approaches contribute methodology that is essential for comparing functioning across different

ages and for linking variables assessed at one age with those assessed at other ages. Longitudinal research is a hallmark of developmental methodology that is essential for identifying relations between variables assessed at different ages. Certain classic longitudinal studies have helped to shape views of relations between childhood characteristics and broad aspects of later functioning (e.g., Bayley, 1968; Kagan & Moss, 1962). Other longitudinal studies have revealed developmental relations between childhood characteristics and adult psychopathology (e.g., Reef, Diamantopoulou, van Meurs, Verhulst, & van der Ende, 2010).

Despite their importance, *real-time* longitudinal studies are costly, seldom use broadly representative samples, and take many years to yield results. More practical methods for obtaining longitudinal data have therefore been sought. These include follow-up (or catch-up) studies, in which people assessed at one age are sought for reassessment at a later age, and follow-back studies, which seek to obtain records of the earlier history of people for whom outcomes are known. Follow-up and follow-back studies are usually quicker and cheaper than real-time longitudinal studies. Follow-up and follow-back designs may also be used to select individuals who have low-prevalence risk or outcome characteristics that would be difficult to study with real-time longitudinal designs because it is impractical to repeatedly assess large enough samples of such individuals.

Examples of influential follow-up studies of childhood disorders include Robins's (1966) study of adults who had been assessed at a child guidance clinic many years earlier and a long-term follow-up of autistic children by Kanner, Rodrigues, and Ashenden (1972). Follow-back studies that started with known adult outcomes include comparisons of the early school records of people who differed in adult psychiatric diagnoses (Lewine, Watt, Prentky, & Fryer, 1980).

Because longitudinal research is essential for linking early characteristics with later outcomes, we need practical, cost-effective strategies for longitudinal research on psychopathology. In later sections, we present research designs that are especially useful for illuminating the developmental course of psychopathology.

THE PSYCHOPATHOLOGY COMPONENT

We use the term *psychopathology* broadly to encompass persistent behaviors, thoughts, and emotions that are likely to impede the accomplishment of developmental tasks necessary for long-term adaptation. For children, the important developmental tasks include at least the following: Regulation of biological functions related to eating, sleeping, elimination, and energy expenditure; maintenance of close relationships with family and peers; acquisition of academic and social skills; preparation for adult occupational and social roles; and formation of a stable sense of personal identity. For adults, important developmental tasks include achievement of mature occupational and social roles; maintenance of close personal relationships; responsible citizenship; and for those who have children, responsible parenthood and creation of loving, healthy home environments. For older adults, important developmental tasks include constructive coping with the aging process; changing or giving up occupational roles; facing the loss of friends and loved ones, as well as one's own demise; maintaining a sense of independence; and preserving close attachments without becoming burdensome.

A key aim of this chapter is to advance our ways of thinking about psychopathology. Because psychopathology can be conceptualized in different ways for different purposes, it is important to consider the relative utility of various models for assessment, taxonomy, and diagnosis.

Nosologically Based Models

Nosological models for psychopathology originated in the nineteenth century with efforts to bring psychopathology out of the realm of demonology and into the realm of physical medicine. An important thrust of these efforts was to model the classification of mental disorders on classifications of diseases, which are called *nosologies*.

Contemporary psychiatric nosologies stem largely from Emil Kraepelin's (1883) efforts to construct categories of major adult disorders for which, Kraepelin hoped, different physical causes would eventually be found. Kraepelin's categories included schizophrenia (originally called dementia praecox, i.e., premature or early dementia) and manic-depressive (bipolar) disorder, which have remained cornerstones of psychiatric nosologies ever since. As revealed by the cartoon in Figure 2.1 that Kraepelin drew for the 1896 Heidelberg Bier Zeitung (Beer Newspaper), he did not want diagnoses to be taken too seriously. By the 1915 version of his nosology, Kraepelin included disorders thought to be of psychological origin. He also included personality disorders, which he viewed as occupying a border region between illness and eccentricity.

Kraepelin's nosology was intended to be descriptive in the sense of being based on observations of patients. Some disorders that were initially described in terms of both mental and physical abnormalities were eventually found

Figure 2.1 Cartoon by Emil Kraepelin in the 1896 Heidelberg *Bierzeitung* (Beer Newspaper). In English translation, the caption says, "Psychiatrists of Europe! Protect your most sacred diagnoses!"

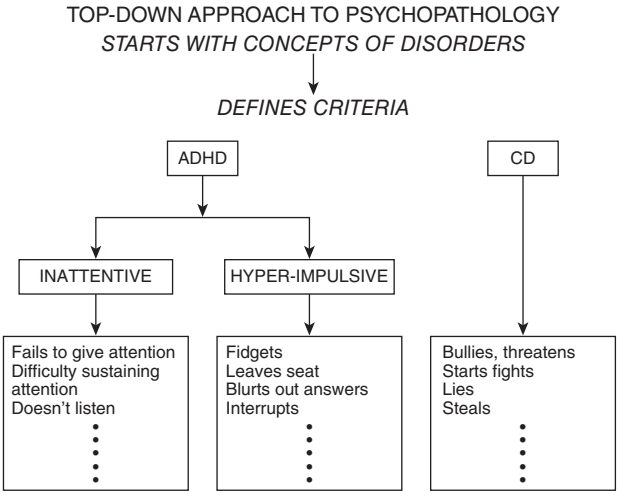

Figure 2.2 The top-down approach to assessment and taxonomy of psychopathology. *Source:* Copyright by T. M. Achenbach. Reproduced by permission.

to have specific physical causes. An example is general paresis, which involves mental and physical deterioration that by the late nineteenth century was found to be caused by syphilitic infection. Another example is Down syndrome, which Langdon Down described in terms of intellectual disability and physical abnormalities in 1866, although it was not until 1959 that the cause was found to be a chromosomal abnormality (Lejeune, Gautier, & Turpin, 1959/1963).

Efforts to describe disorders clinically and then to find physical etiologies have thus yielded some notable successes, especially the discovery that syphilis caused paresis, which supported the physical disease model for psychiatric nosology. On the other hand, discovery of the etiology of Down syndrome had to wait for nearly a century of advances in genetic research.

Kraepelinian diagnostic categories have long molded clinical practice, theory, training, and funding for research and services. In the United States, versions of Kraepelinian nosology have been embodied in successive editions of the American Psychiatric Association's (1952, 1968, 1980, 1987, 1994, 2013) *Diagnostic and Statistical Manual* (*DSM-I, DSM-II, DSM-III, DSM-III-R, DSM-IV, DSM-5*). At the international level, the *International Classification of Diseases (Ninth Edition, ICD-9; Tenth Edition, ICD-10;* World Health Organization, 1978, 1992) has also embodied versions of Kraepelinian nosology.

The Top-Down Strategy

In using nosological models for the *DSM* and *ICD*, experts formulate diagnostic categories and then choose criteria for defining the categories. In effect, the experts start at the top with their concepts of diagnostic categories and then work down to criteria for the categories, as illustrated in Figure 2.2. The diagnostic criteria for some disorders state that symptoms and impairment must be present in more than one context. However, except for including IQ tests in criteria for intellectual disability, neither the *DSM* nor the *ICD* specifies assessment operations for obtaining and using data. Instead, for each case, the diagnostician decides what data to obtain, what assessment methods and sources to use, and how to combine data into yes-or-no decisions about each symptom. The diagnostic data may thus differ greatly from case to case, but the same fixed decision rules are used to make diagnoses for different cases.

Empirically Based Models

For disorders having no known physical cause, an alternative to nosological models is to use statistical procedures to identify problems that tend to co-occur in large samples of people. Sets of statistically co-occurring problems are known as *syndromes*. (The original Greek meaning of *syndrome* was "the act of running together"; Gove, 1971, p. 2320.) The empirical identification of syndromes does not imply any assumptions about the cause of the syndromes. Some syndromes may ultimately be found to have physical causes, while others may be found to have experiential causes or combinations of physical and experiential causes.

Efforts to develop *empirically based models* for child psychopathology began during the 1940s in reaction to the lack of diagnostic categories for childhood disorders

(e.g., Hewitt & Jenkins, 1946). The advent of powerful computers in the 1960s facilitated factor analyses of large pools of problem items scored for large samples of children (e.g., Achenbach, 1966; Quay, 1964). Because the empirically based approach uses statistical analyses to aggregate problems that are then scored in terms of syndromes, it is also known as the *dimensional, quantitative,* or *multivariate* approach.

The Bottom-Up Strategy

The empirically based approach can be described as working from the bottom up because it starts with quantitative ratings of many specific problems obtained for many individuals from informants who see them under various conditions. The item ratings are then analyzed statistically to identify syndromes of problems that tend to occur together, as illustrated in Figure 2.3. Each syndrome is scored by summing ratings of the items that comprise the syndrome. Norms for syndrome scales are then constructed from ratings of large representative samples of people.

Variations on the Bottom-Up Strategy. In addition to empirically based syndrome scales, numerous scales have been constructed according to criteria other than empirically identified associations among problems, even though factor analysis may have been employed as well. As an example, the Behavior Assessment System for Children (BASC) was developed from an initial set of constructs chosen by Reynolds and Kamphaus (1992). Collections of items were written to conform to a priori definitions of the constructs. An item was assigned to a scale if it was "clearly linked in terms of content to the construct underlying its scale" (p. 72). Although factor analyses were performed, items were moved or deleted from the obtained factors on the basis of "reasonableness of content for the hypothesized scale dimension"; "consistency of item placement across age levels and . . . between parent and teacher respondents"; "the need for each scale to have a sufficient number of discriminating items to be reliable"; and "clinical judgment." As an example, of clinical judgment, Reynolds and Kamphaus (p. 73) stated, "The rating scale item "Says 'I want to die' or 'I wish I were dead'" was retained on the Depression scale despite low loadings because of its clear relevance." Also, "Several pairs of final scales initially were part of a single scale. Examples include Depression/Withdrawal and Hyperactivity-Attention Problems" (p. 80).

A FRAMEWORK FOR THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

To advance the developmental study of psychopathology, it is helpful to have a conceptual framework that highlights important issues to be addressed. Because no single research study can simultaneously address all the issues, programmatic research is needed to improve the assessment, taxonomy, and diagnosis of psychopathology.

Developmental Differences

We previously stressed the importance of developmental parameters in all research on psychopathology. To obtain an accurate picture of psychopathology, it is essential to gear assessment procedures to the developmental level of the participants, to determine what features are associated with clinical deviance at each level, and to construct taxonomies that reflect features characterizing each developmental level. The features that discriminate between different kinds of deviance are apt to change with development. It is therefore important for assessment and taxonomy to reflect developmental changes occurring in individuals, so that the same individuals can be studied longitudinally. Both the developmental differences and the links between developmental levels should be rigorously tested.

Sources of Data

Stemming largely from nosological models, clinical interviews have long been the main sources of data for assessing psychopathology. Beginning in the 1970s, standardized diagnostic interviews (SDIs) were developed to make yes-or-no decisions about whether adult patients met specific research diagnostic criteria (RDC) for major mental disorders, such as schizophrenia and bipolar disorders (e.g., Overall & Hollister, 1979). The SDIs included the

semistructured Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) and the highly structured Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan, & Ratcliff, 1981).

The explicit criteria embodied in various versions of RDC laid the foundations for *DSM-III* (American Psychiatric Association, 1980). Departing from the narrative-inferential format of *DSM-I* and *DSM-II* (American Psychiatric Association, 1952, 1968), *DSM-III* defined disorders in terms of lists of symptoms and other criteria, such as age-of-onset and duration of the symptoms. According to *DSM-III* and its successors, *DSM-III-R*, *DSM-IV*, and *DSM-5* (American Psychiatric Association, 1987, 1994, 2013), diagnosticians are to make yes-or-no decisions about whether patients meet each of the criteria required for a particular disorder. If a patient is deemed to meet the requisite criteria, the patient is diagnosed as having the disorder. Diagnostic criteria and decision rules are thus far more explicit than prior to *DSM-III*. However, neither *DSM-III* nor its successors specify assessment operations for determining whether the diagnostic criteria are met, except for including IQ tests in criteria for intellectual disability. As one approach to operationalizing *DSM* diagnostic criteria, the SDIs that had been developed in the 1970s to make RDC diagnoses were subsequently revised to assess *DSM-III*, *DSM-III-R,* and *DSM-IV* criteria (e.g., Shaffer et al., 2000).

Multi-Informant Data for Children

Some of the SDIs for adults were modified for diagnosing children. Examples include the Kiddie-SADS (Ambrosini, 2000; Puig-Antich & Chambers, 1978), which is a child version of the SADS (Endicott & Spitzer, 1978), and the Diagnostic Interview Schedule for Children (DISC; Costello, Edelbrock, Dulcan, Kalas, & Klaric, 1984; Shaffer et al., 2000), which is a child version of the DIS (Robins et al., 1981). When it became apparent that children cannot provide sufficient accounts of their own psychopathology, SDIs were developed to obtain diagnostic information from the children's parents (e.g., DISC-P; Costello et al., 1984; Shaffer et al., 2000).

Unfortunately, the parallel SDIs for children and their parents did not solve the problems of operationalizing *DSM* criteria for child psychopathology. Numerous studies have found little agreement between *DSM* diagnoses made from DISC interviews with children (including adolescents) and their parents (e.g., Costello et al. 1984; Jensen et al., 1999; Verhulst, van der Ende, Ferdinand, & Kasius, 1997). Furthermore, meta-analyses have revealed only low to moderate agreement between most diagnoses obtained from child, parent, and adult SDIs and clinical diagnoses based on other data (Rettew, Doyle, Achenbach, Dumenci, & Ivanova, 2009).

Perhaps we should not be surprised by the poor agreement between diagnoses made from SDIs of children and their parents, or between SDIs and diagnoses made by clinicians who use other data. When required to give yes-or-no answers to questions about psychopathology, children and their parents are apt to draw on different perceptions and memories of the children's functioning, to be differently motivated to report, distort, or withhold information, to understand questions differently, and to be differently affected by interviewers and the interview situation. When making diagnoses, clinicians are also apt to differ from children and parents with respect to their information about the children, their memories of it, how they interpret their information, and how they combine their information and impressions when selecting diagnoses.

Meta-analyses of many studies have yielded a mean Pearson correlation *(r)* of .60 between reports of children's problems by people who play similar roles with respect to the children, such as pairs of parents, pairs of teachers, pairs of mental health workers, and pairs of observers (Achenbach et al., 1987). Between pairs of informants who play different roles with respect to the children, such as parents versus teachers and teachers versus mental health workers, the mean *r* was .28. And between children's self-reports and reports by other people, the mean *r* was .22. Subsequent findings of informant discrepancies have been so consistent with the meta-analytic findings that they are regarded as being among "the most robust findings in clinical child research" (De Los Reyes & Kazdin, 2005, p. 481).

Detailed comparisons of parent versus self-ratings of the same problem items for youths in twenty-five societies and of parent versus teacher ratings of the same problem items for children attending schools in twenty-one societies have revealed great consistency across societies in the directions of discrepancies: Youths tend to rate their own problems higher than their parents rate them, and parents tend to rate their children's problems higher than their teachers rate them (Rescorla et al., 2013, 2014). Although the data for the Achenbach et al. (1987) meta-analyses came mainly from rather similar Western societies, the findings for parent-youth and parent-teacher discrepancies came from samples of very diverse societies in Africa, Asia, Australasia, Europe, Latin America, the Middle East, and North America. The directions of informant discrepancies were quite consistent across societies that vary greatly in culture, economic development, ethnicity, geographical region, language, political system, religion, and schooling.

Furthermore, particular kinds of raters (e.g., parents and youths) agreed very well about which problems were common (i.e., received high ratings) versus rare (i.e., received low ratings). Nevertheless, in each society the discrepancies within particular parent-youth and parent-teacher dyads varied greatly, with some dyads agreeing much better than other dyads. As addressed later in this chapter, numerous other multicultural findings reveal considerable similarity across very different societies, but major variations among members of each society. In any event, the evidence clearly shows that no one informant's reports regarding child psychopathology can substitute for all other reports.

Multi-Informant Data for Adults

Although the need for multi-informant data to assess child psychopathology is now widely recognized, assessment of adult psychopathology still relies mainly on data from the adults who are being assessed. Yet research shows that diagnoses based only on adults' self-reports are not likely to agree with diagnoses based on other sources of data. For example, studies of agreement between adults' self-reports of problems and reports by people who know the adults have yielded average correlations in the .20s to .40s (Achenbach et al., 2005; Meyer, 2002; Meyer et al., 2001). In reviewing research on diagnoses of adult psychopathology, Meyer et al. (2001) concluded that: "There was meager correspondence between diagnoses derived from a single clinician using (clinical interviews) and the diagnoses derived from the multimethod evaluations . . . after correcting for agreements due to chance, about 70% of the interview-based diagnoses were in error" (p. 151). Meyer et al. also found that the mean kappa between diagnoses based on self-reports versus multi-informant data was only .18. Furthermore, even when adults were interviewed twice, once by trained lay interviewers using the DIS and once by psychiatrists using the Schedules for Clinical Assessment in Neuropsychiatry (SCAN), agreement between the two interviews was extremely low, as exemplified by a kappa = .20 for major depressive disorder (Eaton, Neufeld, Chen, & Cai, 2000).

For elders whose mental competence is in question, it is generally recognized that data need to be obtained from people who know the elders, such as spouses, grown children, and caregivers. Consequently, parallel assessment instruments that obtain and systematically compare assessment data from multiple informants should be routinely used to assess elders' functioning (Achenbach, Newhouse, & Rescorla, 2004).

To advance our developmental understanding of psychopathology, we should apply lessons already learned about needs and methods for cross-informant assessment of children to the assessment of adults and elders. The aspects of functioning to be assessed, the sources of data, and the assessment instruments must, of course, be geared to the developmental levels of the people who are being assessed.

Epidemiological Aspects

Many studies of development and psychopathology employ samples chosen for convenience rather than for representativeness with respect to larger populations. This is understandable in light of the need to find people who are willing and able to participate in a particular study. However, convenience samples are often biased by selective factors that limit the generalizability of findings. If our knowledge of psychopathology is derived mainly from people who are conveniently available rather than from representative samples of people, we may be misled by findings for problems that do not actually distinguish people who do not need help from those who do need help.

As an example, both the early psychoanalytic and behavioral literature used children's fears of animals to model theories of the etiology and treatment of psychopathology. Sigmund Freud (1909/1953), for example, used a 145-page case study to illustrate the psychodynamics of Little Hans's horse phobia. In the behavioral tradition, Watson and Rayner (1920) experimentally conditioned Little Albert to fear a white rat, and Jones (1924) used Watson's principles to treat 2-year-old Peter's fear of a white rabbit.

Both the psychodynamic and behavioral traditions thus made children's fears paradigmatic for the subsequent literature on psychopathology. Yet, epidemiological studies have shown that fears of specific animals, situations, or places (other than school) are not necessarily more common among children considered to be clinically deviant than among representative samples of nonreferred children (Achenbach, Howell, Quay, & Conners, 1991; Achenbach & Rescorla, 2000, 2001). Epidemiological research has also shown that specific fears are reported for *fewer* clinically referred than nonreferred adults (Achenbach & Rescorla, 2003).

Other epidemiological findings have indicated that certain problems employed as criteria for nosological categories are not reported more often for clinically referred than nonreferred children. "On the go," for example, is a criterial symptom for the *DSM* category of ADHD (American Psychiatric Association, 1980, 1994, 2013). Yet this item was endorsed more often for a nationally

representative sample of *nonreferred* children than for demographically matched *referred* children (Achenbach et al., 1991). This may reflect favorable connotations of "on the go" as characterizing children who are energetic and busy in constructive ways. Other nosological criteria have likewise been chosen without epidemiological evidence that they validly identify individuals who need help.

Diagnoses of behavioral and emotional disorders seldom depend on a single deviant characteristic. Instead, most disorders involve problems that many people manifest to some degree at some time in their lives. To identify people as being clinically deviant, we therefore need to know the distribution of particular problems among people considered to be relatively normal, as well as among those who are considered to need professional help. Because many selective factors affect referral to a particular service, we also need data on people who are seen in different services and settings. And we need to know the outcomes of particular problems in both referred and nonreferred populations. This requires that epidemiological samples be reassessed longitudinally to determine which problems have relatively good versus poor outcomes when treated versus untreated and what other variables predict outcomes. Such research is important both to determine what problems distinguish people who need help from those who do not, and to identify risk and protective factors on which preventive and therapeutic efforts should focus.

Multivariate Aspects

Because so many different kinds and degrees of problems may evoke concern, it is important to standardize the scoring and analysis of problems. Because it is so hard to assess and aggregate multiple problems for large samples of people, multivariate statistical methods are needed. All scores obtained from self-reports, informants' reports, observations, and tests are subject to sampling and measurement error. However, by using multivariate statistical methods, we can aggregate scores on numerous problems from multiple sources to identify patterns of co-occurring problems. This is analogous to computed tomography (CT) scanning, whereby numerous low-grade x-ray pictures are integrated by computer to produce high-grade images. Once we identify patterns of problems, we can use the patterns to group people for research on the etiology, course, prognosis, and effectiveness of treatment for each pattern. Those multivariate patterns that are found to be reliable and to validly discriminate between people who differ in other important ways can then serve taxonomic functions, as detailed in later sections.

Operational Definitions

Operational definitions of variables provide basic tools for scientific research. Although scientific thought and theory also involve abstractions that are not operationalized, empirical tests of scientific ideas typically require specification of variables in terms of assessment operations. The assessment operations provide the empirical content of the science.

Discussions of psychopathology are replete with terms that are used as if their meaning were self-evident. Terms (and their abbreviations) such as conduct disorder (CD), oppositional defiant disorder (ODD), antisocial personality disorder (APD), and ADHD are common examples from the *DSM* nosology. Terms such as emotional disturbance (ED) and learning disability (LD) are used with similar aplomb in special education circles, reflecting the influence of Public Law 94-142 (P.L. 94-142), the Education of the Handicapped Act (*Federal Register*, 1977, 1981), which specifies eligibility for special education services (reauthorized as P.L. 101-476, Individuals with Disabilities Act, 1990; P.L. 105-17, 1997).

The need for operational definitions has long been recognized in efforts to improve nosologies. In a diagnostic classification of childhood disorders that was proposed half a century ago, the Group for the Advancement of Psychiatry (GAP; 1966) "attempted to set forth operational definitions of clinical categories" (p. 209). *DSM-III* and its successors have also been heralded as providing operational definitions (e.g., Narrow et al., 2013, p. 71; Rapoport & Ismond, 1996, p. 13). However, neither the GAP classification nor the *DSM* has defined behavioral and emotional disorders according to specific assessment operations. But what about the *DSM*'s criteria for each diagnosis? These criteria do not constitute operational definitions, because no assessment operations are specified for determining whether a person manifests each criterial feature. Nor are operations specified for combining often conflicting data from multiple sources. The lack of operational definitions for disorders may be one reason that poor reliability and low cross-informant agreement have been found for GAP and *DSM* diagnoses (e.g., Beitchman, Dielman, Landis, Benson, & Kemp, 1978; Jensen & Weisz, 2002; Lewczyk et al., 2003; Shaffer et al., 2000).

Categories such as those specified by the *DSM* and P.L. 101-476 serve important administrative functions, such as providing guidelines for reimbursement. However, these categories were not derived from empirical findings on distinctions among disorders in actual samples of troubled people. The categories should therefore not

be equated with types of people or types of disorders. Although people may indeed have the kinds of problems implied by such categories, people do not necessarily come packaged according to these categories. In other words, we should not automatically assume that individuals can be validly classified according to categories such as attention-deficit/hyperactivity disorder (ADHD), CD, ODD, APD, ED, or LD. Unless we empirically test (1) the associations among features that are used to define categories and (2) the power of the criterial features to discriminate between individuals who do versus do not need help for their problems, we cannot know how best to distinguish among kinds of disorders. To improve our ability to distinguish between individuals who do versus do not need help, as well as among patterns of clinical deviance, we need programmatic research that yields more valid groupings than most administrative categories provide. Such research is needed to advance our developmental understanding of psychopathology.

THE ROLES OF ASSESSMENT AND TAXONOMY IN THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

To improve our ways of distinguishing the normal from the deviant and one kind of deviance from another, it is helpful to distinguish between two related tasks. One task is to *assess individuals* to identify their distinguishing features. The second task is to *construct taxonomies* for grouping individuals according to their distinguishing features. These tasks are essential steps in targeting the disorders to be studied in each developmental period. They also form the basis for diagnostic decisions about individuals. To improve diagnostic decision making, we need reliable and valid procedures for identifying the distinguishing features of individuals, for grouping individuals according to their distinguishing features, and for effectively integrating all the relevant data into optimal conclusions. To clarify the different tasks, we first address assessment and taxonomy as scientific endeavors that can be better understood if we avoid confusing them with the term *diagnosis*, whose multiple meanings we address later.

Although diagnosis is an essential part of clinical services, scientific efforts are needed to improve both diagnosis and its links to services. The following sections therefore focus on the scientific process, which "proceeds in endless cycles of observation and measurement, hypothesis testing, and the development of theory, a process dependent on a valid system of classification or taxonomy" (McClellan & Werry, 2000, p. 19).

Assessment

Assessment refers to gathering data with which to identify the distinguishing features of individuals. Every individual can be distinguished from other individuals in many ways. Effective assessment requires selecting optimal features for the kinds of decisions to be made. To identify optimal features, we need data from representative samples of individuals with which to test the distributions, validity, and utility of various features.

Psychometric principles provide guidance for determining the methodological adequacy of assessment data. As applied to the assessment of behavioral/emotional/social problems, these principles can be summarized as follows:

1. Assessment should employ standardized procedures.
2. Multiple items should be used to sample each aspect of functioning.
3. Items should be aggregated to provide quantitative scores for each aspect of functioning.
4. Scores should be normed to indicate how an individual compares with relevant reference groups.
5. To be developmentally sensitive, the normative reference groups should be formed according to age levels or other indices of development.
6. To be considered psychometrically sound, assessment procedures must be reliable and valid, although the types of reliability and validity vary with the type of procedure.

In addition to these principles, psychometric theory prescribes specific standards for constructing sound assessment procedures. Psychometric theory does not, however, tell us *which* of the many features of individuals should be assessed. Instead, we should select features that are found to discriminate among individuals whose behavioral/emotional/social problems differ with respect to etiology, course, prognosis, or the most appropriate intervention. To determine which features specifically discriminate between individuals according to these variables, research is needed to test the discriminative power of various features. Rather than attempting to test every possible feature one-by-one, it is preferable to identify sets of features that tend to co-occur. Because assessment of each feature is subject to random variance, scores for sets of covarying features are likely to be more reliable than scores for each separate feature. Furthermore, sets of covarying features are likely to be more useful than separate features for generating and testing hypotheses, as well as for managing individual cases. The task of aggregating covarying features into sets

with which to identify similar individuals is the task of taxonomy, to which we now turn.

Taxonomy

It is helpful to distinguish between *classification* in general and *taxonomy* in particular. Classification refers to any systematic ordering of phenomena into classes, groups, or types. Many classifications are constructed merely for the convenience of users. Administrative classifications, for example, are designed to meet particular organizational needs. The people who design such classifications may start with knowledge of an organization's needs and the ways in which prospective users of a classification customarily view the phenomena to be classified. They then attempt to mesh the users' classificatory behavior with the needs that the classification must meet.

As an example, health insurers construct their own classifications of disorders to decide on reimbursements for mental health services. A key question is whether a particular classification scheme enables the insurer's actuaries to compute costs accurately enough for the insurer to charge rates that are competitive but high enough to be profitable after covering all costs. For third-party payers that are not funded by premiums based on costs, such as Medicaid, the problem is complicated by unpredictable changes in the size and nature of the covered population, variations in the services obtained, providers' techniques for coping with low reimbursement rates, and political vicissitudes. Considering the variety of factors that affect third-party payers' classification schemes, it is no wonder that so many classifications have been devised for reimbursement of mental health services.

In contrast to the broad concept of classification, taxonomy refers to a subset of classifications that are intended to reflect intrinsic differences between individuals assigned to different classes. Taxonomies of plants and animals, for example, are based on features that are intended to capture important differences among species. Various features can be chosen to distinguish among groups of plants and animals, such as physical characteristics, interbreeding, and hypothesized evolutionary history. Although the concept of species is so familiar as to seem self-evident, species is not an intrinsic property of living things. Instead, species is a taxonomic construct that is imposed on subsets of features, such as having four legs or laying eggs. Criteria for a particular species thus consist of certain features that are selected from all the features that could possibly be used to distinguish among individual plants and animals (Levin, 1979).

Are Behavioral and Emotional Disorders Natural Kinds?

Zachar (2000) distinguished between taxonomies that consist of *natural kinds* and those that consist of *practical kinds*. He defined a natural kind as "an entity that is regular (nonrandom) and internally consistent from one instance to the next" (p. 167). Examples include naturally occurring elements such as gold. By contrast, practical kinds "are stable patterns that can be identified with varying levels of reliability and validity" (p. 167).

Zachar argues that taxonomies of psychopathology involve practical kinds rather than natural kinds. Although some may believe that taxonomies of psychopathology should identify natural kinds, both the empirically based approach and the *DSM*'s nosological approach focus on practical kinds. In other words, they both define taxa in terms of sets of features no one of which is both necessary and sufficient to classify an individual's problems as belonging to a particular taxon. Both approaches are thus *polythetic*. This means that both the empirically based approach and the *DSM* specify sets of features from which various subsets of the features can qualify an individual for a taxon.

Constructing Taxonomies of Behavioral, Emotional, and Social Problems

In constructing taxonomies of behavioral/emotional/social problems, we should be aware that the problems can be aggregated according to different taxonomic models. Certain models may be useful for one stage of knowledge or for one developmental stage but not for other stages of knowledge or development. Furthermore, different models may be useful for different kinds of disorders or for different purposes at the same stage of knowledge. Models based on cognitive measures, for example, may be useful for grouping people according to educational needs, whereas models based on measures of behavioral/emotional/social problems may be useful for grouping the same people for management purposes.

We also need to be aware that the features chosen to characterize individuals are abstractions whereby we link individuals who we expect to be similar in other important ways. When we abstract a subset of features from the many features that could potentially be identified, we form a hypothetical construct of a case—a conceptual abstraction intended to capture useful aspects of the case. If our notion of the individual case and our taxonomic grouping of individuals according to certain shared features both involve hypothetical constructs, how should we match our

construct of the individual case to taxonomic models? To answer this question, we must take account of both the methodological possibilities for assessing individuals and the mental processes involved in matching the features of individuals to the features embodied in taxonomic models.

Effects of Categories on Taxonomic Thinking

Although taxonomies might be viewed as inherently categorical, the effects of classifying individuals in terms of categories need to be empirically evaluated. Cognitive studies have shown that training adult participants to classify pictures of people into experimentally manipulated categories caused the participants to exaggerate *similarities* between pictures of people within a category and also to exaggerate *differences* between pictures of people in different categories (Goldstone, Lippa, & Shiffrin, 2001; Queller, Schell, & Mason, 2006). Furthermore, research with preschool children has shown that labeling pictures of people categorically (e.g., "mean" vs. "nice") promoted stereotyped judgments that could be counteracted by showing the children pictures of people labeled in terms of continuous characteristics (e.g., ranging from "really mean" to "really nice") (Master, Markman, & Dweck, 2012). These findings indicate that, for both children and adults, classification of people categorically *reduces differentiation* and *increases stereotyping* of people's characteristics.

Prototypes as Taxonomic Models

Taxonomic categories have traditionally been defined in terms of criteria that are "singly necessary and jointly sufficient" for classifying individual cases (Cantor, Smith, French, & Mezzich, 1980, p. 182). In other words, a case was assigned to a particular category if, and only if, it met all the criteria for that category. Conversely, all cases that met the criteria for a particular category were ipso facto assigned to that category.

Cognitive research indicates that people's mental use of categories does not conform to the classical model whereby cases are categorized according to features that are both necessary and sufficient. As illustrated by familiar categories such as furniture, for example, the objects that people categorize together do not all share the same defining features (Rosch & Mervis, 1975). Instead, certain objects classified as furniture, such as tables and chairs, are unlike other objects that are also classified as furniture, such as lamps and rugs.

Objects that have the most features of a category are viewed as the most typical of the category and are more quickly and reliably categorized than are objects that have fewer of the category's features (Smith & Medin, 1981). For example, a sparrow is more typical of birds than an ostrich is. Furthermore, objects that have features of multiple categories are especially hard to categorize reliably. As an example, a tomato is hard to categorize as a fruit or vegetable because it has features of both categories.

Instead of being rigidly defined by criterial features that must all be present in all members of a category, mental representations of categories comprise sets of imperfectly correlated features known as *prototypes* (Rosch, 1978). Consequently, people judge category membership according to the degree of overlap between the features of a case and the set of prototypical features that define a category. In other words, people judge cases having many features of a prototype to be very typical of the category represented by that prototype. They judge cases that have few features of a prototype to be less typical of that category. Cases that manifest features of more than one prototype are judged to lie on the border between the categories represented by those prototypes.

According to the prototype view, people make quantitative judgments of the resemblance between particular cases and particular categories. That is, the degree of resemblance between a case and a category is judged according to the number of prototypical features that the case shares with the category. Furthermore, if each prototypical feature of a case and of a category can be scored for the intensity or certainty with which the feature is manifested, then the case's resemblance to the category can be quantified in terms of the sum or other aggregation of these scores.

If the human minds that must use taxonomies actually conceptualize categories in terms of quantifiable prototypes, why not use quantifiable prototypes in taxonomies of psychopathology? Quantification of taxa can help to mesh clinical thinking with taxonomies of psychopathology, as well as counteracting stereotypes promoted by categorical approaches. The possibilities for doing this will be presented after we consider conventional diagnostic thinking.

DIAGNOSIS

The term *diagnosis* conveys an aura of clinical authority, implying that it reveals an essential truth about what is really wrong with a patient. Yet the term has multiple meanings that sow confusion when we move from research tasks conceptualized in terms of assessment and taxonomy to clinical practice conceptualized in terms of diagnoses. To clarify relations between the research tasks and clinical practice, it is helpful to distinguish among the different meanings of diagnosis discussed next.

Diagnostic Processes

Diagnostic processes involve gathering the data needed for diagnostic decisions. Such processes are analogous to what we earlier defined as assessment. However, if data are gathered only to select diagnoses, *diagnostic processes* imply a narrower focus than assessment does.

Formal Diagnoses

Formal diagnoses involve assigning cases to the categories of a diagnostic classification. Accordingly, a leading psychiatric diagnostician, Samuel Guzé (1978), defined diagnosis as "the medical term for classification" (p. 53). This is the sense in which the categories of the *DSM* and *ICD* nosologies are diagnoses. When a clinician states that a child meets the *DSM* criteria for conduct disorder, for example, the clinician is making a formal diagnosis.

Diagnostic Formulations

Diagnostic formulations are efforts to elucidate multiple aspects of an individual's condition. When a clinician interprets a child's problems in terms of biological vulnerabilities, developmental history, family dynamics, stress, and rejection by peers, for example, the clinician makes a diagnostic formulation. A diagnostic formulation should weave all the findings of diagnostic processes into a comprehensive picture of the case. The diagnostic formulation thus provides a broader basis for developing treatment plans than a formal diagnosis does. Yet, it is by means of the formal diagnosis that the individual case is linked to others like it.

A formal diagnosis helps the clinician apply existing knowledge about a class of cases to a diagnostic formulation for a new case. For knowledge about a class of cases to be accurately applied to a new case, reliable procedures are needed for gathering data, integrating the data into a diagnosis, and selecting the appropriate formal diagnosis. Furthermore, the system from which the formal diagnosis is selected must be reliable, must be valid with respect to important correlates of its diagnostic categories, and must encompass cases like the one being diagnosed. To be credible, diagnoses should thus meet the same methodological standards as assessment and taxonomy do. Like assessment and taxonomy, diagnosis involves gathering data to identify the distinguishing features of individuals and grouping individuals according to their distinguishing features. Whichever terminology we use, the value of such procedures ultimately depends on whether they help people.

Comorbidity Issues

Since the introduction of explicit diagnostic criteria by *DSM-III* (American Psychiatric Association, 1980), many people have been found to meet the criteria for more than one diagnostic category (e.g., Costello et al., 1984; Weinstein, Noam, Grimes, Stone, & Schwab-Stone, 1990). Termed *comorbidity*, the tendency for people to meet criteria for multiple categories has a variety of implications. The apparent co-occurrence of two disorders could mean, for example, that one disorder results from the other; or that the same risk factors lead to both disorders; or that the two disorders are not really separate but are manifestations of the same underlying condition (Achenbach, 1991a; Caron & Rutter, 1991).

Neither the *DSM* nor the *ICD* provides evidence that each of their diagnostic categories validly represents a type of disorder that exists independently of disorders represented by other categories. Nor do the *DSM* and *ICD* specify assessment operations for reliably discriminating between disorders. When assessment procedures have been designed to operationalize *DSM* criteria for disorders, high rates of comorbidity have often been found. For example, two studies showed that 96% of boys who met *DSM* criteria for CD also met criteria for ODD (Faraone, Biederman, Keenan, & Tsuang, 1991; Walker et al., 1991). In addition, the *DSM-III-R* field trials found that 84% of clinic-referred children who met criteria for CD also met criteria for ODD (Spitzer, Davies, & Barkley, 1990). The very high rates of overlap between diagnoses suggest that the diagnostic criteria may not validly distinguish between different disorders.

Unidirectional Versus Bidirectional Comorbidity

The specific rates of comorbidity reported in many studies may be misleading, because they reflect computation of the overlap between diagnoses in only one direction. That is, they reflect the percentage of individuals having Diagnosis A who also have diagnosis B. If diagnoses A and B have different prevalence rates in a sample, this unidirectional computation yields a different rate of comorbidity than would be obtained by computing the percentage of individuals having Disorder B who also have Disorder A. For example, suppose that fifty children in a sample of one hundred obtain a diagnosis of CD (Diagnosis A) and that forty-eight of these fifty obtain a diagnosis of ODD (Diagnosis B). The unidirectional comorbidity of ODD (Diagnosis B) among children who have CD (Diagnosis A) is 48/50 = 96%. However, if eighty of the children have ODD and forty-eight of these have CD, the

unidirectional comorbidity of CD among children who have ODD is 48/80 = 60%. By recomputing published comorbidity rates bidirectionally (i.e., as the mean of the comorbidities of A to B and B to A), McConaughy and Achenbach (1994) obtained quite different rates from those based on the unidirectional comorbidities. When comorbidity is conceptualized in terms of the co-occurrence of two categorically defined disorders, it is thus important to consider the bidirectional rates of comorbidity between the disorders.

Berkson's Bias

Apparent comorbidity among disorders may also be misleading in other ways, as detailed elsewhere (Achenbach, 1991a; Caron & Rutter, 1991). Suppose, for example, that individuals manifesting a particular disorder have *X* probability of referral. Suppose, too, that individuals manifesting another disorder have *Y* probability of referral. Even if the disorders do not tend to co-occur in the population as a whole, people who have both disorders have $X + Y - XY$ probability of referral. This is obviously higher than the referral rate for individuals who have only *X* or *Y* probability of referral. If we study only referred people, we may conclude that the two disorders tend to occur together. Yet, if we study the entire population (including nonreferred people), we might find that the two disorders have no more than chance co-occurrence, because individuals having only one disorder without the other are much more common in the nonreferred population than in the referred population.

Known as *Berkson's bias* (Berkson, 1946), the tendency of apparent comorbidity to be inflated by referral biases is one of many artifactual ways in which findings of co-occurrence between even independently verifiable disorders can arise. The different effects of referral biases on different problems has been demonstrated by comparing comorbidities obtained among empirically based syndromes in demographically similar referred and nonreferred samples (McConaughy & Achenbach, 1994).

Implications of Comorbidity

If two disorders are operationally defined according to mutually independent assessment procedures, and if the two disorders are demonstrated to occur together with greater than chance frequency in unbiased samples of the general population, then the comorbidity of these particular disorders may be quite informative. However, if diagnoses are not based on operational definitions of empirically separable disorders, then findings of comorbidity may merely reflect a lack of clear boundaries between diagnostic categories or our inability to validly distinguish between disorders that do not really co-occur with more than chance frequency.

Rather than taking findings of comorbidity at face value as reflecting the co-occurrence of two distinct disorders, we should examine the diagnostic system itself for possible artifactual sources of apparent comorbidity. The high rate of overlap found between diagnoses of ODD and CD (Faraone at al., 1991; Spitzer et al., 1990; Walker et al., 1991), for example, invites scrutiny of the diagnostic system to determine whether ODD and CD truly represent separate disorders. The arbitrariness of the distinctions between the diagnostic categories of ODD and CD is highlighted by the major changes they underwent from *DSM-III* to *DSM-III-R,* with further changes in *DSM-IV*. *DSM-III* (American Psychiatric Association, 1980) listed five criteria for ODD, of which only two criteria needed to be met for the diagnosis. *DSM-III-R* (American Psychiatric Association, 1987), by contrast, listed nine criteria, of which five were needed for the diagnosis. *DSM-IV* listed eight criteria, of which four were needed for the diagnosis. Furthermore, the *DSM* criteria for diagnoses of CD also underwent major changes from *DSM-III* to *DSM-III-R*, with further changes in *DSM-IV*. *DSM-III* provided four distinct categories, plus a residual category of Atypical CD. *DSM-III-R*, by contrast, provided only one set of explicit criteria for CD, although once the prescribed number of criteria were met, the disorder could be categorized as "group type," "solitary aggressive type," or "undifferentiated type," according to the diagnostician's judgment. *DSM-IV* dispensed with these types in favor of "childhood onset type" versus "adolescent onset type." *DSM-5* retains the *DSM-IV* symptom criteria for ODD and CD (American Psychiatric Association, 2013).

Classification systems often need to incorporate changes based on new knowledge. However, the *DSM* revisions have not been derived from empirical tests of the co-occurrence of particular features or of whether the criteria for ODD and CD actually discriminate between distinctly different disorders in representative samples of children. Furthermore, no algorithms have been provided for calibrating diagnoses made from one edition of the *DSM* with those made from previous editions. It should therefore not be surprising that very different distributions of ODD and CD have been obtained when applying criteria from different editions of the *DSM* to the same children (Lahey et al., 1990).

DSM-III-R and *DSM-IV* specified that the diagnosis of ODD was not to be made if the criteria for CD were met.

Did this mean that ODD is a mild version of CD, a developmentally early version, or a by-product? Or did it mean that the two disorders are intrinsically related in some other way? Similar questions arise from overlaps among other diagnostic categories that are not derived from actual data on relations among problems. Based on a detailed examination of these and other issues, Lilienfeld, Waldman, and Israel (1994) cautioned that the application of the term "comorbidity" to psychopathology "encourages the premature reification of diagnostic entities" (p. 71) that have not actually been validated.

In an effort to consider the value of dimensional (quantitative) diagnostic criteria for *DSM-5*, the American Psychiatric Association appointed a task force on dimensional criteria. Evidence supporting dimensional criteria was presented by researchers and clinicians specializing in many areas of psychopathology (Helzer et al., 2008). Despite enthusiasm for dimensional criteria among members of the task force, *DSM-5* does not provide dimensional criteria (American Psychiatric Association, 2013).

LONGITUDINAL DESIGNS FOR THE DEVELOPMENTAL STUDY OF PSYCHOPATHOLOGY

Many kinds of research designs can be used in the developmental study of psychopathology. However, *longitudinal* designs, in which the same people are assessed at two or more points in their development, provide the most direct tests of relations between developmental parameters and patterns of problems. In the following sections, we illustrate some variations on traditional longitudinal designs that may be especially useful for developmental research related to assessment, taxonomy, and diagnosis.

Accelerated Longitudinal Designs

The ability of traditional longitudinal designs to shed light on psychopathology has been limited by the difficulty of maintaining participant samples, research teams, and funding over long periods. Moreover, most longitudinal studies have been handicapped by their failure to compare different birth cohorts and by their use of very different assessment procedures at different ages. Such limitations affect real-time, follow-up, and follow-back studies alike.

Life span developmental psychologists have emphasized the need to take account of differences related to birth cohorts and times of measurement, as well as differences related to age (e.g., Baltes, 1987). Unfortunately, it is difficult to include cohort and time-of-measurement comparisons in traditional longitudinal research designs.

One way to improve longitudinal research on psychopathology is to assess multiple birth cohorts by the same methods over several uniform intervals. Such designs have been variously called *convergence* (Bell, 1953), *mixed-longitudinal* (van't Hoff, Roede, & Kowalski, 1991), and *cohort-sequential* (Baltes, Cornelius, & Nesselroade, 1979). Because several birth cohorts are assessed in the same way over the same period, the longitudinal findings for each cohort can be compared with the findings for each other cohort. We can thus determine whether changes with age are similar in all cohorts or whether the changes differ between cohorts or times of measurement.

An additional strength of multiple birth cohort longitudinal designs is that they can be analyzed so as to reveal developmental sequences over a longer period of time than the real time spanned by the study. When analyzed in this way, they are called *accelerated longitudinal designs*. How can we perform the magic of accelerating longitudinal research? The logic is as follows:

1. At Time 1, individuals from several birth cohorts are assessed in a uniform fashion. For example, in June 2018, a test is administered to cohorts of children who are 6, 7, 8, or 9 years old (designated as Cohorts 6, 7, 8, and 9).
2. At Times 2, 3, and 4, the same children are assessed again in the same way. In other words, Cohorts 6, 7, 8, and 9 are reassessed in 2019, 2020, and 2021.
3. Individuals from one cohort are matched to individuals in another cohort. In our example, children from Cohort 6 are partnered with children in Cohort 7 with respect to demographic variables and to their assessment scores obtained at ages 7 and 8. That is, a particular Cohort 6 middle SES boy named Adam is matched to a particular Cohort 7 middle SES boy named Scott whose test scores at ages 7 and 8 were similar to the scores obtained by Adam at ages 7 and 8.
4. The accuracy of predicting scores obtained by individuals in one cohort from earlier scores obtained by matched partners in another cohort is then tested. In our example, we compute the correlation between scores obtained at age 7 by Cohort 6 children and scores obtained at age 9 by their matched partners from Cohort 7. For purposes of comparison, we then compute the correlation between the scores obtained at age 7 by the Cohort 6 children and their own scores at age 9. Suppose the correlation between age 7 and 9 scores within Cohort 6 is significant. Suppose also that the between-cohort correlation from

scores obtained at age 7 by Cohort 6 children to the age 9 scores obtained by their matched Cohort 7 partners is of the same magnitude as the correlation from age 7 to age 9 within Cohort 7. These findings would indicate that the score obtained at age 7 by a Cohort 6 child, such as Adam, can be used to predict the score obtained at age 9 by a Cohort 7 child, such as Scott, with as much accuracy as prediction of Scott's age 9 score from his own age 7 score.

5. If the findings outlined in Step 4 are replicated for the other combinations of cohorts in the study, it may become possible to create matched sets of partners across the four cohorts to predict scores obtained by Cohort 9 children at age 12 from scores obtained by Cohort 6 children at age 6. An accelerated longitudinal study that requires three years of real time (2018–2021) could thus yield results spanning six years of development (ages 6 to 12).

Although developmental psychologists have long discussed the cohort-sequential concept, its applications were limited mainly to identifying cohort and time-of-measurement effects on personality and cognitive tests (e.g., Nesselroade & Baltes, 1974).

The need for uniform assessment of multiple birth cohorts over several years might seem to make accelerated longitudinal studies of psychopathology prohibitive. On the other hand, accelerated longitudinal studies can be far more cost-effective than traditional longitudinal studies that require as many years to collect data as the developmental period spanned. But would the magic of predicting from early assessments of psychopathology in one cohort to later assessments in another cohort actually work? The answer depends on the specific assessment procedures, participant samples, and developmental periods spanned. The magic has, in fact, worked very well in accelerated longitudinal studies of psychopathology, as illustrated in the following section.

Accelerated Longitudinal Analyses of Aggressive Versus Delinquent Behavior

The nosological category of CD has typically included both aggressive and nonaggressive conduct problems. As an example, the *DSM-5* criteria for CD include 15 symptoms that are grouped under the headings "aggression to people and animals"; "destruction of property"; "deceitfulness or theft"; and "serious violations of rules" (American Psychiatric Association, 2013, pp. 221–222). Because only three symptoms are required for CD, some children may be diagnosed as having CD solely on the basis of three very aggressive behaviors, whereas others may be diagnosed as having CD solely on the basis of three nonaggressive behaviors.

In contrast to the single diagnostic category provided by *DSM* for different kinds of conduct problems, many factor analyses of diverse problem behaviors have shown that aggressive and nonaggressive conduct problems tend to load on different factors (e.g., Quay, 1993; Rescorla et al., 2012). Aggressive conduct problems may certainly be comorbid with nonaggressive conduct problems in many individuals, just as other kinds of problems may be comorbid. However, because the *DSM*'s nosological model places children in the single category of CD whether they manifest only aggressive conduct problems, only nonaggressive conduct problems, or both, the CD category obscures important differences between patterns of conduct problems.

One way to test for developmentally important differences between aggressive and nonaggressive conduct problems is to compare their developmental courses. Accelerated longitudinal analyses have been used to do this over ages 4 to 18 years in a population sample of Dutch children participating in the Zuid (South) Holland Longitudinal Study (Stanger, Achenbach, & Verhulst, 1997). The children were assessed with the Child Behavior Checklist (CBCL; Achenbach, 1991b) completed by their parents five times at two-year intervals. At each assessment, the parents rated their child on diverse behavioral and emotional problem items. Factor analyses of the problem items in other samples had previously produced eight syndromes that included a syndrome designated as *Aggressive Behavior* and one designated as *Delinquent Behavior* (subsequently designated as *Rule-Breaking Behavior*; Achenbach & Rescorla, 2001), which comprises nonaggressive conduct problems such as lying, stealing, running away from home, truancy, and hanging around others who get in trouble.

To compare the developmental courses of the Aggressive and Delinquent syndromes, Stanger et al. (1997) applied an accelerated longitudinal strategy as follows:

1. They used CBCL Aggressive and Delinquent syndrome scores for seven birth cohorts of children who were 4, 5, 6, 7, 8, 9, or 10 years old at Time 1. The children were 12, 13, 14, 15, 16, 17, or 18 years old, respectively, at Time 5, which was eight years later.
2. They matched each child in each of the youngest six birth cohorts to a child ("partner") in the cohort that was two years older. (Cohorts differing by two years of age were matched to take account of the two-year intervals between assessments.)

3. The matched partners were of the same gender and similar SES, and they obtained similar standard scores on the Aggressive and Delinquent syndromes at the two earliest ages at which both members of the pair had been assessed, i.e., at Time 1 and Time 2 for the older cohort of a pair and Time 2 and 3 for the younger cohort of a pair. In other words, Stanger et al. paired children who differed by two years of age, who were of the same gender, and who were similar with respect to SES, Aggressive syndrome scores, and Delinquent syndrome scores at two assessment points, two years apart.
4. Separately for the Aggressive and Delinquent syndromes, Stanger et al. then computed *r*s between children's scores from Time 1 to Time 2, Time 3, Time 4, and Time 5. These *r*s reflected the stability of the rank ordering of the children's own scores on a particular syndrome over periods of two, four, six, and eight years (i.e., the "within-cohort" stability of scores).
5. Stanger et al. also computed analogous *r*s between the syndrome scores obtained at Time 1 by children in the younger cohorts and the syndrome scores obtained by those children's matched partners in the two-year older cohorts at Times 2, 3, 4, and 5. These *r*s thus reflected the stability of the rank ordering of scores when *r*s were computed between one cohort of children at Time 1 and those children's matched partners in another cohort at Times 2, 3, 4, and 5 (i.e., the "between-cohort" stability of scores).

Separately for the Aggressive and Delinquent syndromes, Figure 2.4 displays the mean within-cohort and between-cohort *r*s obtained over intervals of two, four, and six years, plus the within-cohort *r*s over eight years for the seven cohorts of children. (The within-cohort *r*s extended two years beyond the ages that were included in the between-cohort *r*s.)

Figure 2.4 reveals two important findings:

1. Averaged across the seven birth cohorts, the mean between-cohort *r*s were as large as the within-cohort *r*s for both the Aggressive syndrome and the Delinquent syndrome over two-year and four-year periods and for the Aggressive syndrome over six-year periods. The sole exception was a mean between-cohort *r* that was only .01 lower than the mean within-cohort *r* over six years for the Delinquent syndrome, a trivial difference that was not statistically significant. Thus, later scores for the Aggressive and Delinquent syndromes were predicted as well from the early scores of children's matched partners from a different cohort as from the children's own early scores. This indicated that accelerated longitudinal analyses worked for the Aggressive and Delinquent syndromes.
2. At all data points for both the within-cohort and between-cohort *r*s, children's rank orders on the Aggressive syndrome were more stable than on the Delinquent syndrome. The greater stability of Aggressive than Delinquent syndrome scores was shown by mean within-cohort and mean between-cohort *r*s that were .21 higher ($p < .001$ computed by *z* transformation) for the Aggressive syndrome than for the Delinquent syndrome, averaged over all intervals.

To compare the developmental trajectories for the Aggressive and Delinquent syndromes, Stanger et al. averaged scores obtained by children in each cohort at each age for which the cohort was assessed. Separately for each gender, Figure 2.5 displays the mean Aggressive and Delinquent raw scores at ages 4 to 18 (because the seven cohorts were initially assessed at different ages, data were averaged for pairs of adjoining years, e.g., ages 4/5, up to age 18, when data were obtained for only one cohort). By looking at Figure 2.5, you can see that Aggressive syndrome scores declined steadily from ages 4/5 to 18. By contrast, Delinquent syndrome scores showed more complex relations to age, with increases at ages 12/13 for both genders. Girls' Delinquent syndrome scores then declined at age 18, although the data were based on only one cohort at that age.

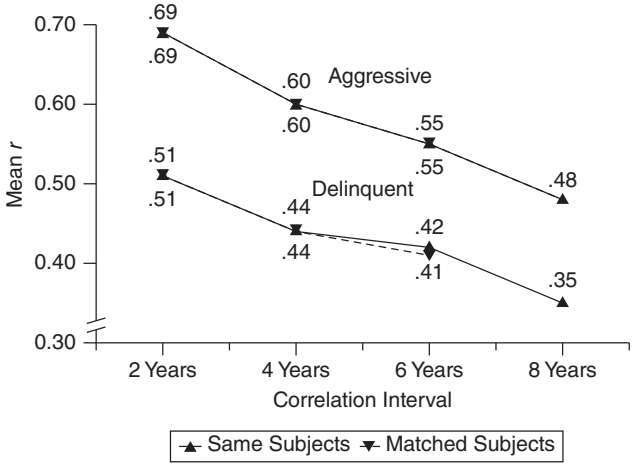

Figure 2.4 Within-cohort (same subjects) predictive correlations over intervals of two to eight years and between-cohort (matched subjects) predictive correlations over six years for Dutch children. Each predictive correlation for the Aggressive Behavior syndrome was significantly greater than for the corresponding Delinquent Behavior syndrome at $p < .001$. *Source:* Stanger, et al. (1997), p. 51. Reprinted with the permission of Cambridge University Press.

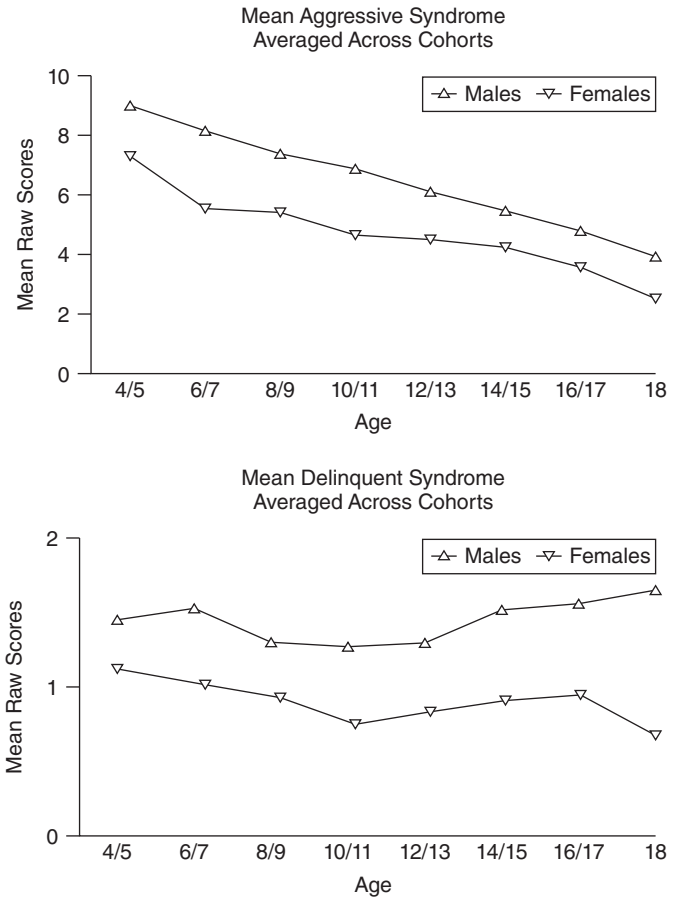

Figure 2.5 Mean Aggressive Behavior and Delinquent Behavior syndrome scores averaged across seven birth cohorts of Dutch children, separately for males and females. *Source:* Stanger et al. (1997), p. 54. Reprinted with the permission of Cambridge University Press.

The Stanger et al. data thus show more linear developmental trends, as well as greater developmental stability in individual differences, for Aggressive syndrome scores than Delinquent syndrome scores. Although Aggressive and Delinquent syndrome scores were significantly associated with each other (*r*s ranged from .53 at ages 4/5 to .63 at age 18), the findings revealed important differences in the developmental courses of aggressive versus nonaggressive conduct problems.

Based on the findings of strong between-cohort predictive relations, predictions could potentially be made from Time 1 scores obtained by one cohort to Time 4 scores obtained by its matched cohort when eight years older. For example, Time 1 scores obtained at age 4 by the Cohort 4 children could be used to predict Time 4 scores obtained at age 12 by their matched partners in Cohort 6. A study spanning six years of real time could thus be used to test predictive relations over eight years of development. Furthermore, tests of predictive relations can be extended to 12 years by matching individuals from successive cohorts to provide predictive correlations between age 4 scores obtained by Cohort 4 members at Time 1 with age 16 scores obtained by Cohort 10 members at Time 4. (To take account of developmental changes in mean scores, the scores need to be standardized within each cohort at each time of assessment.) The potential power of accelerated longitudinal designs greatly increases the value of short-term longitudinal studies, which are usually far more feasible than long-term studies.

Accelerated longitudinal designs are among the many potential methodological contributions of developmental approaches to psychopathology. They illustrate both the promise and the complexity of developmental perspectives for advancing the study of psychopathology. Cohort and time-of-measurement effects, as well as intraindividual developmental sequences, highlight the need for complex multivariate conceptualizations. The complexity should not deter efforts to cope with the challenges of interrelations between development and psychopathology, however,

because powerful research tools are available for coping with such challenges.

Path Designs

Path designs use regression statistics to test predictive pathways between variables assessed at developmentally early points and variables assessed for the same people at developmentally later points. Unlike accelerated longitudinal designs, path designs cannot test relations between variables over developmental periods that are longer than the real-time periods spanned by the assessment of the participants. However, path designs can test the degree to which multiple variables assessed at different early points in development individually and collectively contribute to the prediction of a particular outcome variable assessed at a later point in development. They can also test the indirect effects of developmentally early independent variables predicting subsequent variables that, in turn, predict the outcome variables of interest.

Various statistical techniques are available for conducting path analyses (Lleras, 2005). However, without going into the details of the various statistical techniques, we can illustrate some ways path analyses can contribute to developmental research on the assessment and taxonomy of psychopathology.

Six-Year Predictive Pathways for Aggressive Versus Delinquent Behavior

As reported in our illustration of accelerated longitudinal designs, factor analyses have yielded syndromes designated as Aggressive Behavior and Delinquent Behavior (also called Rule-Breaking Behavior). Both within-cohort and between-cohort correlations have shown significantly greater developmental stability for scores on the Aggressive syndrome than the Delinquent syndrome among Dutch children (Stanger et al., 1997). Another way to evaluate the developmental course of syndromes is via path analyses like those done in the U.S. National Longitudinal Study of a nationally representative sample of American children (Achenbach, Howell, McConaughy, & Stanger, 1995a, 1995b). Eight empirically based syndromes and numerous family variables were assessed at each of three time points, with three-year intervals between Times 1 and 2 and between Times 2 and 3, using methodology similar to that of the Dutch study on which the accelerated longitudinal analyses were based. In addition, at the second and third assessments, information was obtained about potentially important life events that had occurred since the preceding assessment, such as stressful experiences.

Figure 2.6 shows the pathways for Time 1 and Time 2 variables that significantly predicted Time 3 scores on the Aggressive and Delinquent syndromes. The Time 3 syndrome scores were computed by combining parents' ratings on the CBCL, teachers' ratings on the Teacher's Report Form (TRF; Achenbach, 1991b), and adolescents' self-ratings on the Youth Self-Report (YSR; Achenbach, 1991b). (The CBCL, TRF, and YSR are components of the Achenbach System of Empirically Based Assessment, abbreviated as ASEBA.) The Time 1 syndrome scores were computed from parents' ratings on the ACQ Behavior Checklist (Achenbach, Howell, Quay, & Conners, 1991), whereas the Time 2 syndrome scores were computed from parents' ratings on the CBCL.

The numerals on the predictive paths in Figure 2.6 indicate the effect sizes (ES) in terms of the percentage of variance in the Time 3 syndrome scores that was uniquely accounted for by each of the significant predictors, with the effects of the other predictors partialed out. Each ES for boys is printed above the solid and dotted lines, while each ES for girls is printed below the solid and dashed lines (solid lines = effects that were significant for both genders; dotted lines = effects that were significant only for boys; dashed lines = effects that were significant only for girls). For example, if you look under the Time 2 heading for the Delinquent syndrome in Figure 2.6, you can see that the topmost ES was 4% for the prediction of Time 3 Delinquent syndrome scores from Time 2 Delinquent syndrome scores for boys. Beneath the 4% ES for boys, you can see that the corresponding ES for girls was 8%. For both genders, there were also 1% ESs for prediction of Time 3 Delinquent syndrome scores from Time 2 Aggressive syndrome scores. For girls only, there were 1% ESs for prediction of Time 3 Delinquent scores from Time 2 Social Problems syndrome scores (low Time 2 Social Problems scores predicted high Time 3 Delinquent scores) and Attention Problems syndrome scores. There was an additional 1% ES for the number of unrelated adults living in the girls' homes between Time 2 and Time 3.

By looking under the Time 1 heading in Figure 2.6, you can see that, for boys, the following two predictors directly accounted for 1% of variance in Time 3 Delinquent scores: (1) The Time 1 marital status of the boys' parents (Time 3 Delinquent scores were higher if parents were single, separated, or divorced than if they were married or widowed); and (2) the Time 1 Delinquent scores. In summary, for both genders, more variance in Time 3 Delinquent scores was accounted for by earlier scores on the Delinquent syndrome than by any other variable. However, significant variance was also accounted for by other variables,

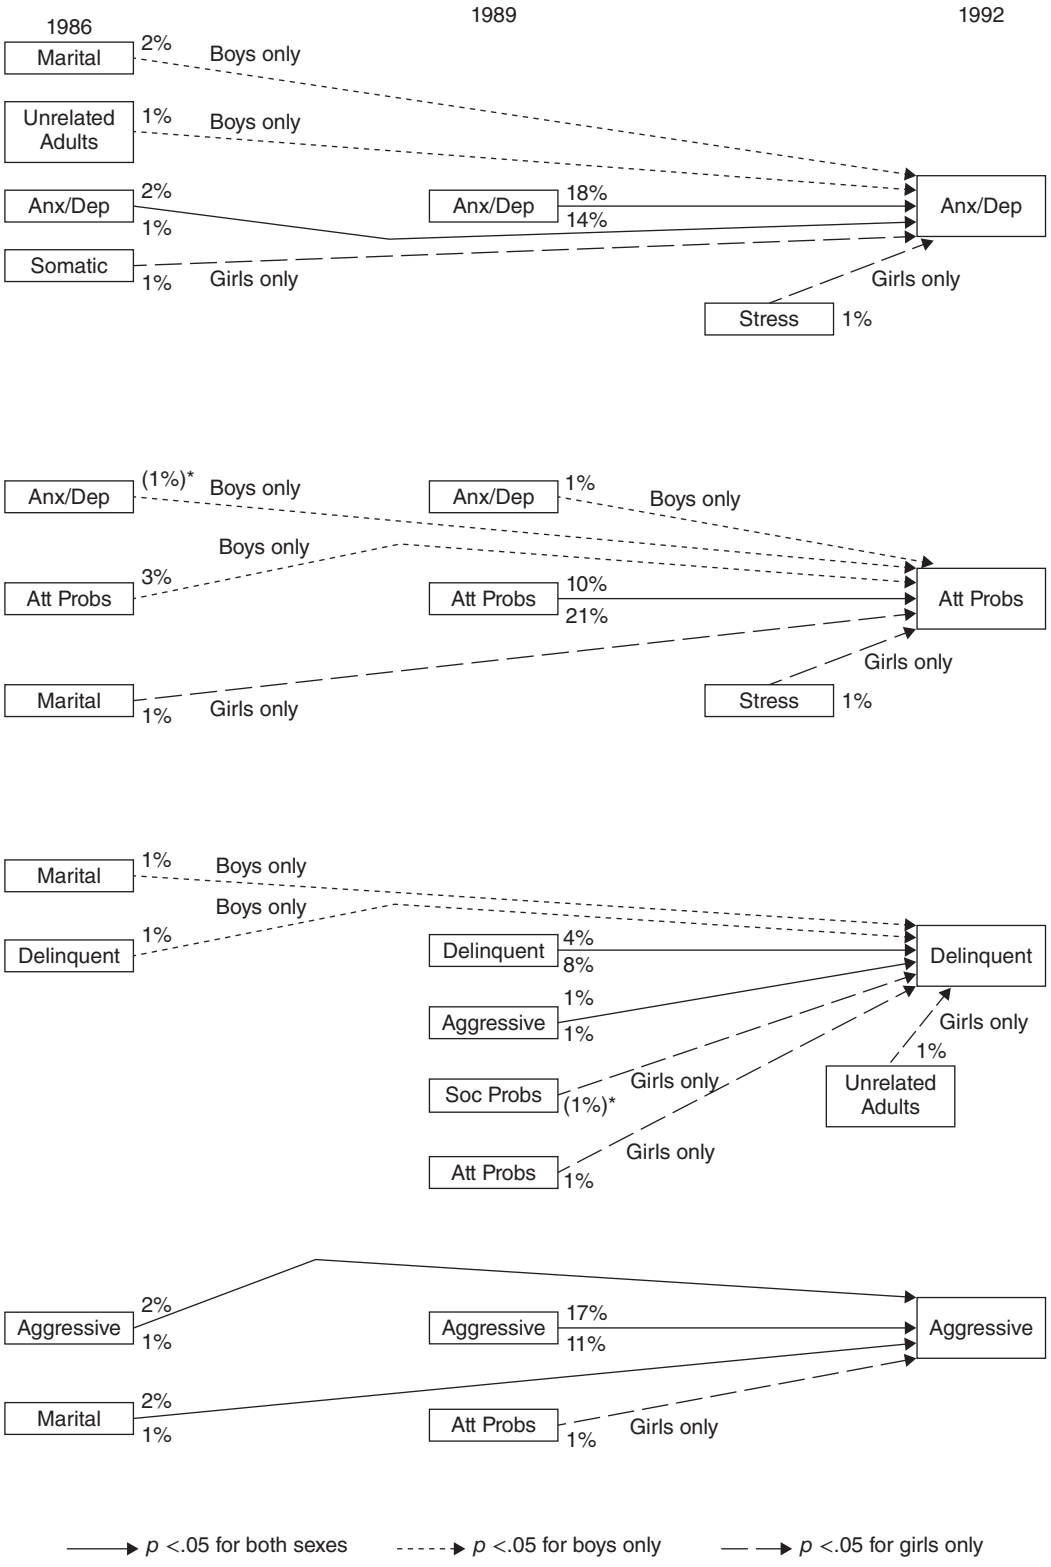

Figure 2.6 Predictive pathways to scores for Aggressive Behavior, Delinquent Behavior, Attention Problems and syndrome scores in an American national sample. *Source:* Achenbach et al. (1995a), p. 343. Adapted with permission of the *Journal of the American Academy of Child and Adolescent Psychiatry*.

including scores on the Aggressive, Social Problems, and Attention Problems syndromes, parents' marital status at Time 1, and the number of unrelated adults living in the home between Time 2 and Time 3.

If you look now at the lower portion of Figure 2.6, you can see that Time 2 Aggressive syndrome scores accounted for 17% of the variance in Time 3 Aggressive syndrome scores for boys and 11% for girls. Time 1 Aggressive syndrome scores accounted for an additional 2% of the variance in Time 3 Aggressive syndrome scores for boys and 1% for girls. The only other significant predictors were parents' Time 1 marital status (2% ES for boys; 1% ES for girls) and Time 2 Attention Problems syndrome scores (1% ES for girls only).

By comparing the predictive paths found for Time 3 Delinquent versus Aggressive syndrome scores, you can see that the ESs from earlier versions of the same syndrome were smaller for the Delinquent than the Aggressive syndrome: The ESs for the Time 1 and Time 2 Delinquent syndromes summed to 5% for boys and 8% for girls, whereas the ESs for the Time 1 and Time 2 Aggressive syndrome summed to 19% for boys and 12% for girls. In addition, more numerous other predictors were found for the Delinquent syndrome than the Aggressive syndrome. The other predictors included the Time 2 Aggressive syndrome scores for both genders, Time 2 Social Problems syndrome scores as negative predictors for girls, and the number of unrelated adults in the home between Times 2 and 3 as positive predictors for girls.

Although path designs differ markedly from accelerated longitudinal designs, findings from our examples of these different designs in the Netherlands and the United States suggest the following conclusions about the taxonomic properties of the Aggressive versus Delinquent syndromes:

1. Early scores on each syndrome are significant predictors of later scores on the same syndrome, indicating developmental stability in the degree to which individuals manifest each kind of problem.
2. The developmental stability of the Aggressive syndrome is greater than the developmental stability of the Delinquent syndrome; that is, individuals' rank orders remain more consistent for Aggressive than Delinquent scores over substantial periods of development.
3. The course of the Delinquent syndrome in relation to age, gender, and other kinds of problems is more variable than the course of the Aggressive syndrome.
4. Overall, the findings suggest that the Aggressive syndrome is more trait-like than the Delinquent syndrome in that individuals maintain more consistent rank orders in relation to peers of the same age and gender. Furthermore, later Aggressive syndrome scores are predicted more exclusively by scores on the same syndrome than is true for the Delinquent syndrome.

Path Analysis via Structural Equation Modeling

Path analysis can also make use of structural equation modeling (SEM) of hypothesized latent variables that are measured in terms of multiple manifest variables. The researcher specifies a model that includes relations between both the latent and manifest variables. Mediator variables are often specified as being affected by developmentally early variables but, in turn, as affecting developmentally later variables. As an example, path analyses were used to test predictors of the latent variable of adult aggression from a variety of measures obtained when the adults were children, 15 years earlier (Huesmann, Moise-Titus, Podolski, & Eron, 2003). The latent variable of adult aggression was derived by SEM from eleven manifest variables, including MMPI scores, plus self-ratings and informant ratings of various kinds of direct and indirect aggression. Childhood measures of peer-nominated aggression and violent television viewing were found to be significant direct predictors of adult aggression. In addition, an initial direct predictor of peer-nominated aggression and violent television viewing—poor school achievement—was found to be an indirect predictor of later adult aggression. Although the results indicated that viewing violent television can increase aggression over long periods, both the preference for viewing violent television and the continuity of aggression from childhood to adulthood may also reflect individual differences in achievement, plus the trait-like aspects of aggression indicated by the accelerated longitudinal and path analyses that we described previously.

Growth Curve Designs

The accelerated longitudinal and path designs illustrated in the preceding sections test changes over time via correlations computed for samples of individuals. In contrast, growth curve designs permit investigation of changes in individuals as well as changes in groups over time (Rogosa, Brandt, & Zimowski, 1982). Latent growth curve analysis uses longitudinal data for each individual to model a growth trajectory for that individual. In addition, an average growth trajectory for all individuals is obtained. Each individual growth curve and the group function are described by a set of parameters. For linear functions, these parameters are the intercept and the slope of the line. When growth is not monotonic, quadratic or cubic functions may

be fit to the data, resulting in parameters for these terms as well. The intercept of the function often represents the initial status of the individual on the dependent measure (i.e., at the first data collection point). The slope measures change in the dependent measure per unit of time over the time period from the first data collection point to the last. The variance estimates for intercept and slope indicate the degree to which individuals in the sample manifest differences in these parameters.

Researchers have developed many statistical procedures to analyze growth in individuals over time. Such procedures include *individual growth curve analysis* (Rogosa et al., 1982), *random effects modeling* (Laird & Ware, 1982), and *hierarchical linear modeling* (HLM; Raudenbush & Bryk, 2002). As HLM is one of the most widely used of these techniques, our summary will focus on this set of procedures.

Hierarchical Linear Modeling

HLM is called a hierarchical model because it describes the data in terms of at least two levels. For growth curve analysis, HLM uses Level 1 to specify a within-subject model for each individual in the sample, based on data collected at different points in time. For example, ordinary least squares (OLS) regression could generate a growth trajectory for each individual based on that individual's score on the CBCL Aggressive Behavior syndrome scale at four time points, such as at ages 9, 12, 15, and 18. If the best fit to the data points is a straight line, then an individual's growth over time will be described by his/her intercept (score at Time 1, or age 9) and his or her slope (rate of change in score per year starting at age 9 and ending at age 18). Because no fitted line perfectly captures all data points, each function also contains an error term. In its simplest form, each participant's growth over time is represented by Equation 2.1.

$$Y_t = a + bX + E \tag{2.1}$$

where Y_t is the dependent measure of the Aggressive Behavior syndrome score at time t, a is Participant A's score at age 9 (the initial data point), b represents the rate of change in scores over time, X represents the number of time units between the initial time point and time t (e.g., age 12 = +3), and E represents random error or residual deviation from the predicted score.

In HLM, the Level 2 or between-subjects model predicts the values of each individual's parameters. Thus, the parameters of the Level 1 model are the outcome measures of the Level 2 model. The first step in this analysis is to determine the total amount of variation in the intercept and slope parameters. When individuals have very different initial scores on the dependent measure and they show very different rates of change in the dependent measure over time, then variance in both the intercept and slope will be high. Variance in the intercept will be minimal when all individuals start at the same point, whereas variance in the slope will be minimal when all individuals decrease (or increase) in the dependent measure at the same rate over time. HLM uses chi-square to test whether the variances in the intercept and slope are significantly different from zero. If one of these parameters is not significantly different from zero, then the model is constrained or fixed so that individuals are not allowed to have their own values on this parameter in subsequent analyses.

In typical HLM analyses, the first Level 2 model has no predictors. This is called an *unconditional* model, because no additional factors, such as gender, SES, diagnosis, referral status, or life experiences, are used to predict individual growth. In this basic unconditional Level 2 model, the parameters from Level 1 (a and b) are predicted only by the population mean (derived from the data) and random deviation. The basic unconditional model at Level 2 appears in Equations 2.2 and 2.3:

$$a = \beta_{00} + \text{ random deviation} \tag{2.2}$$

$$b = \beta_{10} + \text{ random deviation} \tag{2.3}$$

Thus, the unconditional model states that the best estimate of an individual's slope or intercept is the population parameter plus some random deviation or error.

At the next stage in the analysis, HLM contrasts this unconditional model with a conditional model in which some additional factor is entered as a predictor to explain individual differences in either intercept or slope. For example, one might predict that clinically referred children would have higher Aggressive Behavior syndrome scores than nonreferred children (reflected in a higher intercept value). One might also predict that children being treated for aggressive behavior problems might show more improvement over time than children receiving no treatment (steeper negative slope). To test these predictions, the predictor of referral status or group is added to the Level 2 model. Because group in this example is a dichotomous variable, it would be coded using a dummy variable such as 0 = nonreferred and 1 = referred. Equations 2.4 and 2.5 depict the conditional model:

$$a = \beta_{00} + \beta_{01}(\text{group}) + \text{ random deviation} \tag{2.4}$$

$$b = \beta_{10} + \beta_{11}(\text{group}) + \text{ random deviation} \tag{2.5}$$

According to these equations, the individual differences in intercept and slope parameters at Level 1 are determined both by the population values for these parameters and by the child's status as nonreferred or referred (plus random deviation).

HLM next determines whether the conditional model with predictors is a significant improvement over the unconditional model with no predictors. Essentially, HLM determines the percent of total variance explained when predictors are added to the model relative to the total variance in the parameters with no predictors. It also tests the significance of each predictor using *t* tests.

Application of HLM to Developmental Psychopathology

For purposes of explication, we have presented HLM in its simplest form. However, HLM enables analyses that are much more complex. Multiple predictors can be entered at Level 2 and their main effects and interactions can be tested. For example, not only referral status but also gender and SES might be associated with both initial status and change over time in Aggressive Behavior syndrome scores. Some studies might necessitate a three-level model. For example, a study might compare Aggressive Behavior syndrome scores over time in individuals (Level 1) as a function of gender, SES, and referral status (Level 2) in three different countries, such as the United States, the Netherlands, and Korea (Level 3).

Growth curve analysis has become very widely used in developmental research. Because it preserves information about individual trajectories over time and permits examination of multiple predictors of those trajectories, it is very useful for answering major questions in developmental psychopathology. Furthermore, HLM can handle missing data in ways that traditional analysis of variance (ANOVA) and analysis of covariance (ANCOVA) procedures cannot. In a repeated-measures ANOVA, individuals who have missing data at one data point may be eliminated from the analysis or may have missing scores imputed to them. In HLM, however, individuals can remain in the analysis even if they have some missing data. That is, intercepts and slopes can be calculated for all individuals as long as they have scores for most of the data points (e.g., three out of four).

HLM Analyses Testing Moderation Effects

Laurent et al. (2013) used HLM to test whether child hypothalamic pituitary adrenal (HPA) activity moderated the effects of parental depressive symptoms on child CBCL/1½-5 scores over time in 210 adopted children. Mothers and fathers each completed the Beck Depression Inventory (BDI; Beck & Steer, 1993) and the CBCL when the children were 18, 27, and 54 months of age. To avoid possible effects of parental depression on CBCL ratings, each parent's BDI scores were tested as predictors of the child's CBCL Internalizing and Externalizing scores based on the spouse's ratings.

Laurent et al. (2013) measured HPA activity by obtaining morning and evening salivary cortisol over three consecutive days when the children were 54 months old. Because some cortisol data were missing, the authors used HLM to estimate each participant's typical cortisol levels for morning and evening and each participant's day-to-day variability in morning and evening cortisol levels at 54 months. These fitted values of morning and evening cortisol level and cortisol variability were used as markers of stress sensitivity in the child. Interestingly, the correlations between morning and evening cortisol levels (.09) and between morning and evening cortisol variability (.09) were low and not significant. However, cortisol level and variability were correlated modestly with each other in the morning (.31) and substantially in the evening (.81). These findings suggest that the various cortisol measures were not interchangeable or redundant but in fact tapped different aspects of HPA functioning.

In this study, HLM was used to see if variation in cortisol level or variability had a moderating effect on the impact of parental depression on child adjustment. Specifically, HLM modeled CBCL Internalizing and Externalizing scores at Level 1 with an intercept (b_0) and linear slope over time (b_1). Cortisol activity was used as a Level 2 predictor. The authors tested two basic kinds of models, which they called *within-family risk dynamics* and *between-family risk synergy*. The statistical difference between these two models depended on whether parental depression was treated as a Level 1 or Level 2 predictor, as explained below.

To examine within-family risk dynamics, parental BDI scores were added as a time varying covariate at Level 1 (b_2). This within-family risk model tested the effects of variation in parental depression on child adjustment over time as moderated by child stress reactivity measured by cortisol activity at Level 2. The baseline models of child Internalizing and Externalizing problems, which used age 54 months scores as the intercept, indicated that CBCL scores tended to increase from 18 to 54 months. Additionally, the baseline model indicated that there was sufficient within-child variability to add explanatory predictors at Level 1 and sufficient between-child variability in both intercept (54 months score) and slope (change in score from 18 to 54 months) to add explanatory predictors at Level 2.

Results of these analyses indicated that increases in maternal depression predicted increases in child's Internalizing and Externalizing scores over time, with no moderation by child's cortisol activity. In a contrasting pattern, increases in paternal depression showed no main effect on child CBCL Internalizing or Externalizing scores, but child's evening cortisol level and variability had a significant moderating effect. That is, only children who had higher evening cortisol levels and greater evening cortisol variability showed significant increases in Internalizing scores associated with increases in paternal depressive symptoms. In other words, greater child stress reactivity measured by evening cortisol activity increased the within-family effect of paternal depression on child Internalizing scores.

In the between-family risk synergy models, the mean of parent depressive symptoms averaged over the three data points was entered as a Level 2 predictor (rather than entering depressive symptoms as a time-varying covariate at Level 1). As in the within-family models, cortisol variables were entered as Level 2 predictors. The between-family risk synergy models tested whether children's CBCL Internalizing or Externalizing trajectories (intercepts and slopes) were predicted by the synergistic (interaction) effect of parents' average level of depression and the child's stress reactivity. For example, the authors predicted that the combination of high-risk parents and greater child stress reactivity would lead to higher levels of CBCL problems. It was found that Level 2 maternal depression predicted child Internalizing intercepts but the interaction (moderation) by cortisol was not significant. This means that children whose mothers had a high level of depressive symptoms in the period from 18 to 54 months had higher Internalizing scores at 54 months, regardless of their stress reactivity. On the other hand, the interaction of maternal depression and cortisol activity predicted child Internalizing slope, even though neither predictor was significantly associated with Internalizing slope on its own. Specifically, children with low levels of morning cortisol who had mothers with higher levels of depression tended to increase in Internalizing score from 18 to 54 months. For Externalizing, intercepts (i.e., 54 month score) and slopes (change from 18 to 54 months) were both predicted by the combination of high maternal depression and high evening cortisol levels.

Between-family risk synergy models for fathers showed quite similar patterns. Specifically, fathers with higher mean BDI scores had children with higher Internalizing scores at 54 months. The main effects of father's mean BDI scores on Externalizing intercepts and slopes were moderated by evening cortisol level and variability. That is, the combination of high paternal mean depression and high evening cortisol predicted higher child Externalizing scores at 54 months and greater increases in scores from 18 to 54 months.

This study illustrates several benefits of HLM for testing models of developmental psychopathology. Specifically, both linear growth (slope) and final level (intercept) of children's CBCL scores could be modeled in the same analysis. Second, HLM allowed parental BDI scores at 18, 27, and 54 months to be used either as a time-varying coordinate at Level 1 in the within-family risk model or as a mean value over time at Level 2 in the between-family risk synergy model. Additionally, HLM allowed simultaneous tests of within-child effects (what factors accounted for change over time in individual children's CBCL scores) and between-child differences (what factors accounted for individual differences between children in CBCL scores over time and in scores at 54 months). Finally, HLM allowed tests of stress reactivity's moderation of parental depression's impact on both within-child growth and between-child differences in Internalizing and Externalizing problems.

Growth Mixture Models

As described by Jung and Wickrama (2008), growth mixture modeling (GMM) is a person-centered statistical technique designed to capture individual differences in growth trajectories by identifying trajectory subgroups within a population. Like cluster analysis and latent class analysis, growth mixture models classify individuals into classes, categories, or subgroups such that within-class individual differences in scores are smaller than between-class differences in scores. Whereas HLM assumes that all individuals in a given population have the same growth parameters, GMM assumes that subgroups differ in their growth parameters.

A type of GMM described by Nagin (1999) has been called semiparametric mixture model fitting. Nagin points out that semiparametric mixture model fitting is a group-based strategy that can test whether developmental trajectories predicted by theories actually exist in a population. Nagin (1999) noted that unlike HLM and other forms of latent curve modeling that assume a continuous distribution of trajectories in a population, semiparametric mixture modeling aims to identify different groups of individuals within a population, with each group having its own distinct trajectory.

Like HLM, semiparametric mixture modeling uses a polynomial equation to represent the link between age and

the target behavior. For example, the model might assume a quadratic trajectory, which would be defined by an intercept, a linear slope term, and a quadratic term. However, unlike in HLM, the parameters in the equation (model) are left free to differ across groups. In other words, the various trajectory groups are free to differ from each other with respect to intercept, slope, or both, with the possibility that some groups have no growth (i.e., no change over time), others have only linear growth, and others have quadratic or cubic patterns.

The Bayesian Information Criterion (BIC) is typically used to select the optimal number of trajectory groups (i.e., the model with the highest BIC has the optimal number of groups) (Nagin, 1999). Comparison of BIC values for different models can reveal how much better the optimal model fits the data than various alternative models (Raftery, 1995). In addition, for each model solution (e.g., 2, 3, 4, and 5 group solutions), the output includes the probability that this solution is the "true model."

Also included in the output of semiparametric mixture model fitting are estimates of the probability that each individual belongs to each of the groups. This allows each individual to be assigned to the group he or she fits best. Once the groups are thus constructed, they can then be compared with respect to other variables of interest, such as demographic factors, IQ/educational status, biomarkers, or response to treatment.

Developmental Trajectories of Externalizing Problems

Bongers, Koot, van der Ende, and Verhulst (2004) used semiparametric mixture model fitting in a study involving 2,076 children in the Zuid-Holland longitudinal study who were first assessed in 1983. Data used for analyzing developmental trajectories were obtained from ASEBA forms administered at five points over 14 years. Four clusters of Externalizing problems distinguished by Frick et al. (1993) were studied, namely, *Aggression, Opposition, Property Violations,* and *Status Violations*. These constructs were operationalized by Bongers et al. (2004) using items from the CBCL that seemed to best tap the four clusters distinguished by Frick. CFAs were used to test the fit of the selected items to the Frick model at each CBCL time point. The data fit the model well for both males and females, and all item loadings on their respective cluster were significant and large (range from .50 to .91). Bongers et al. (2004) then used multilevel growth curve analysis to determine separately by gender the average trajectory of each of the four externalizing clusters over time as well as the variation around each average trajectory. Results revealed decreasing average trajectories for all clusters except Status Violations, which increased with age.

Following these steps, Bongers et al. (2004) applied semiparametric mixture model fitting. Based on comparison of the BICs, the authors concluded that the best fitting trajectory models were three classes for the Aggression cluster (all with linear slopes), six classes for the Opposition cluster (some with zero slope and some with quadratic slope), four classes for the Property Violations cluster (mix of linear and zero slopes), and four classes for the Status Violation cluster (all linear slopes). Males generally had higher scores than females but the shapes of the trajectories were similar. Trajectory classes were given descriptive labels. For example, within the Aggression cluster, the three classes were designated as "near zero" (71% of the sample), "low decreasers" (21%), and "high decreasers" (8%). The Aggression cluster high and low decreaser groups differed in their starting level of aggression as well as in their aggression scores in adolescence (moderately high vs. near zero). Only the Status Violation cluster had several "increasing" trajectories: 28% ("adolescence increasers") had no status violations before age 10 and then started increasing slightly as they moved into adolescence, 25% ("medium increasers") showed an increasing number of status violations throughout the whole age period, and 1% ("high increasers") showed an increasing number of status violations throughout the whole age period rising to very high levels in adolescence. The Opposition cluster also had one group that increased in adolescence (6%). Males were overrepresented in the more problematic trajectories in each cluster except for Opposition. Interestingly, 64% of individuals in the sample were deviant in only one cluster, leaving 36% deviant in two or more clusters.

The use of semiparametric mixture model fitting allowed the authors to empirically determine trajectory classes in each cluster, with the optimal number of classes (as determined by the BIC) varying across clusters. By using multilevel growth modeling, the authors could determine the average trajectory for each externalizing cluster (separately for males and females). Then, by applying semiparametric mixture model fitting, they could identify trajectory classes that differed in their pathways over time from the prototypic pattern. Some of these classes followed the average trajectory in shape (e.g., generally decreasing over time, but from different starting points, as in the Aggression cluster). However, other classes had a quite different shape (e.g., the average Opposition trajectory decreased over time, but 6% of the sample increased in adolescence).

As noted by Nagin (1999), semiparametric mixture model fitting can be used to test important developmental

hypotheses, such as the distinction between childhood onset and adolescence limited antisocial behavior (Moffitt, 1993). Bongers et al. stated that their model did not identify an adolescence-limited class such as Moffitt described. Although for Opposition and Status Violations there were classes whose scores increased during adolescence, the CBCL scores for these classes were not as high as the scores for the classes who had high scores throughout the 14-year period, which is inconsistent with Moffitt's typology.

LIFE SPAN APPLICATIONS

To apply developmental approaches to psychopathology across the life span, we should consider lessons learned from research on children. Changes in the prevalence, patterning, and possibilities for assessing problems do not end at maturity. Although the changes may be slower and less conspicuously linked with biological development than during childhood, adult psychopathology may be as closely linked to developmental changes as child psychopathology is. However, to test the developmental course of psychopathology, its correlates, and its outcomes, we need assessment procedures and taxonomic constructs that can take account of both the changes and the continuities in psychopathology from childhood to adulthood and old age. Furthermore, it would be desirable to quantify adult assessment and taxonomy in ways that lend themselves to powerful developmental research strategies, such as accelerated longitudinal, path, and growth curve designs.

The value of measures that can track changes and continuities over significant periods of adulthood has been demonstrated in studies of cognitive functioning. As an example, latent growth models were applied to 11 cognitive measures for 550 Swedish adults who were initially tested at ages 44 to 88 years and were then retested at intervals of three and six years thereafter (Finkel, Reynolds, McArdle, Gatz, & Pedersen, 2003). The results revealed different trajectories for different kinds of abilities, including stability into old age for crystallized ability, linear declines in other abilities, and acceleration of linear declines after age 65 for measures that depended on speed. Significant individual variations in growth curves were found for some of the measures.

Similar growth curve analyses can be applied to measures of psychopathology in adults, such as those derived from the ASEBA forms for adults: the Adult Self-Report (ASR) and Adult Behavior Checklist (ABCL) for Ages 18–59, and the Older Adult Self-Report (OASR) and Older Adult Behavior Checklist (OABCL) for Ages 60–90+ (Achenbach, Newhouse, & Rescorla, 2004; Achenbach & Rescorla, 2003). Several problem scales are common to the instruments for both adult age groups. Examples include the empirically based Anxious/Depressed, Somatic Complaints, and Thought Problems syndrome scales and the *DSM*-oriented Depressive Problems, Anxiety Problems, Somatic Problems, and Antisocial Personality Problems scales. One syndrome scale, named Intrusive, is specific to ages 18 to 59. Other scales are specific to ages 60 to 90+, such as the Irritable/Disinhibited, Memory/Cognition Problems, Worries, and Functional Impairment syndrome scales. Many scales for ages 18 to 59 have counterpart scales scored from the CBCL, TRF, and YSR for ages 6 to 18.

Longitudinal research has shown that high problem scores on the adult Intrusive syndrome, as well as on the adult Aggressive Behavior syndrome, are strongly predicted by high scores on the child/adolescent Aggressive Behavior syndrome (Achenbach et al., 1995c). These findings indicate that some aggressive children and adolescents are socially intrusive as adults whereas others remain more overtly aggressive. The same research shows that high child and adolescent scores on the Attention Problems syndrome predict high scores on the adult version of this syndrome. However, the adult version is characterized less by overactivity and more by irresponsibility than the child/adolescent version.

Because analogous assessment instruments are available for ages $1\frac{1}{2}$ to 90+ years, developmental analyses of psychopathology can be extended over lengthy periods of development. In addition, because many of the empirically based and nosologically based scales for adults and older adults are similar to those for children and adolescents, ASEBA instruments facilitate multigeneration family studies. Multigeneration family studies are particularly useful in behavior genetics research designed to identify genetic effects, environmental effects, and their interactions in parents and their children.

STANDARDIZED ASSESSMENT AND TAXONOMIC MODELS IN MULTIPLE LONGITUDINAL STUDIES

Longitudinal studies are essential for identifying and testing developmental courses of psychopathology. However, the payoffs yielded by the large investments, long-term commitments required of investigators and participants, and years needed to obtain results may be limited by a lack of clear generalizability from findings for longitudinal samples to larger populations. One kind of limitation on generalizability stems from unrepresentative samples of

participants who are chosen for their convenient availability and willingness to undergo repeated assessments over long periods. A second kind of limitation stems from assessment procedures that are designed for a particular study or are chosen because they are au courant when the study begins. Results obtained with assessment procedures that are customized for a particular study are of unknown generalizability to larger populations if the procedures are not applied to and normed for those populations. Furthermore, if assessment procedures used in a study go out of fashion by the time they yield results, the results may not be applicable to then-current assessment procedures.

As an example, diagnostic interviews and other assessment instruments based on the 1980 *DSM-III* became obsolete in 1987 with the publication of *DSM-III-R*, which then became obsolete in 1994 with the publication of the *DSM-IV*. The interval between the 2000 *DSM-IV* Text Revision (*DSM-IV-TR*) and the 2013 *DSM-5* has been longer. However, the years needed to develop assessment instruments for each edition of the *DSM* and then to test the *DSM* diagnostic criteria, as well as the lack of standardized algorithms for translating data based on early editions into the diagnostic criteria of later editions of the *DSM*, limit the value of findings based on obsolete diagnostic criteria.

Earlier in this chapter, we illustrated path analyses for testing predictive pathways from variables assessed at developmentally early points to developmentally later scores on Aggressive Behavior and Delinquent Behavior syndromes in the U.S. National Longitudinal Study. The syndromes were scored from age-appropriate versions of ASEBA instruments completed by multiple informants. The sample was representative of the U.S. population, attrition was low in the initial and subsequent assessments, age-appropriate versions of the same items and constructs were assessed at each age with instruments that continue to be widely used, and the scales have age, gender, and informant-specific U.S. national norms. Consequently, the results can be applied to the U.S. population with much greater confidence than if the sample was unrepresentative, or if the assessment instruments were customized for the study, became obsolete, or lacked norms.

Despite the high cost and great value of a longitudinal study on a nationally representative sample, no single study is likely to yield definitive answers by itself. Instead, multiple studies employing standardized assessment procedures and taxonomic models are needed to obtain widely generalizable and useful findings. The following sections provide an overview of four longitudinal studies in the Netherlands using Dutch translations of the assessment instruments that were used to assess the empirically based syndromes in the U.S. National Longitudinal Study.

Zuid Holland Longitudinal Study

The Zuid Holland Longitudinal Study began with assessment of a representative sample of 2,076 4–16-year-olds living in the Province of Zuid Holland. Parents completed CBCLs and reported on child and family variables like those assessed in the U.S. National Longitudinal Study. Teachers completed TRFs and 11–16-year-olds completed YSRs. Age-appropriate ASEBA instruments were subsequently completed by the participants and by various informants at four two-year intervals, followed by six-year and 10-year intervals, spanning a total of 24 years, until the oldest participants had reached the age of 40. Numerous other candidate predictor and outcome variables were also assessed, including *DSM* diagnoses made from SDIs.

Over the age ranges that were similarly assessed in the Zuid Holland and U.S. studies, similar predictive pathways and associations were found from developmentally early to developmentally later scores on the syndromes. Furthermore, despite more universal health insurance coverage for Dutch than U.S. children, as well as other differences between the societies and their mental health services, the developmental course of clinically elevated scores on the syndromes was found to be similar for Dutch and U.S. children (Van Oort, van der Ende, Wadsworth, Verhulst, & Achenbach, 2011). Tendencies for problem scores to be higher for both Dutch and U.S. children from lower than upper SES families were consistent with those found in a review of findings from 15 societies (Achenbach & Rescorla, 2007b).

Over the much longer span of the Zuid Holland than the U.S. study (24 years vs. 9 years), it was found that all the syndromes initially scored from parents' CBCL ratings significantly predicted syndromes scored from the participants' self-ratings on the ASR (Achenbach & Rescorla, 2003) 24 years later (Reef, Diamantopoulou, van Meurs, Verhulst, & van der Ende, 2009). The significant predictive relations revealed homotypic cross-informant (parent to self-ratings) continuity over 24 years for Anxious/Depressed, Withdrawn, Somatic Complaints, Rule-Breaking Behavior, and Aggressive Behavior syndromes. Heterotypic continuity was found for the Thought Problems and Attention Problems syndromes. The parents' initial ratings also significantly predicted *DSM* diagnoses made from SDIs administered to the participants 24 years later (Reef et al., 2010). Especially surprising were findings that parents' initial CBCL ratings also significantly

predicted the participants' CBCL ratings of their own children 24 years later (van Meurs, Reef, Verhulst, & van der Ende, 2009).

The TRacking Adolescents' Individual Lives Survey (TRAILS) Study

The TRAILS study started with a population sample (N = 2,230) and a clinical sample (N = 543) of youths residing in the northern Netherlands. Participants have been assessed at ages 10–12, 12–15, 15–17, and 18–20 and are being assessed again in their 20s (Ormel et al., 2012). Many measures have been used, including the CBCL and YSR, followed by the ASR after the participants' eighteenth birthday. Use of ASEBA instruments to operationalize phenotypes of psychopathology facilitates coordination of findings with other studies that use these instruments. Thus, as done in the Zuid Holland and U.S. longitudinal studies, correlations have been computed between ASEBA ratings of TRAILS participants at successive ages and have been found to be similar in all three studies.

As an example of the many TRAILS findings, parental internalizing disorders significantly predicted internalizing problems among TRAILS participants, while parental externalizing disorders predicted externalizing problems. As another example, maternal postpartum depression predicted internalizing problems, while pregnancy and delivery difficulties predicted externalizing problems. Stressful life events in adolescence were found to predict both internalizing and externalizing problems (Ormel et al., 2012).

Ormel et al. (2012) reported trajectories of scores averaged from CBCL and YSR ratings at ages 10–17 on the Aggressive Behavior, Rule-Breaking Behavior, Anxious/Depressed, and Withdrawn/Depressed syndromes. Significant decreases with age were found for Aggressive Behavior and Anxious/Depressed scores, whereas significant increases with age were found for Rule-Breaking Behavior scores. The decreases in Aggressive Behavior and increases in Rule-Breaking Behavior scores from age 10 to age 17 were consistent with the developmental trajectories shown in Figure 2.5 for CBCL scores averaged across seven birth cohorts. Ormel et al. found that mean Withdrawn/Depressed scores were stable from age 10 to 14, but increased somewhat from age 15 to 17. Gender differences were greatest for Rule-Breaking Behavior, with boys having substantially higher scores than girls at each age from 10 through 17, and for Anxious/Depressed, with girls having higher scores than boys at each age, plus a much smaller decline than boys from age 10 to 17. The authors concluded that "the study of developmental pathways needs to take into account the individual's gender, type of psychopathology, and age" (p. 1032).

Generation R Longitudinal Study ("R" = Rotterdam)

ASEBA instruments are being used to assess psychopathology in another Dutch longitudinal study that began with 8,880 pregnant women living in Rotterdam (Tiemeier et al., 2012). Among many other analyses of relations between developmentally early variables and subsequent psychopathology, Tiemeier et al. tested relations between mothers' self-reported anxiety during pregnancy and again after their child's birth, children's genotypes for the 5-HTTLPR polymorphism in the promoter region of the serotonin transporter gene (5-HTT, SLC6A4), and age 5 Internalizing scores averaged from mothers' and fathers' CBCL ratings. This test was especially important because of previous inconsistencies in findings of whether stressors raised risks for internalizing problems among carriers of the short allele of the 5-HTTLPR polymorphism. In a widely publicized article from a Dunedin, New Zealand, longitudinal study, Caspi et al. (2003) had reported that participants who carried the short allele were found to be at increased risk for developing depression after childhood maltreatment and other stressful experiences. This apparent gene x environment (GxE) interaction was of great interest because it appeared to support GxE mechanisms hypothesized to account for much psychopathology. Subsequent studies (e.g., Risch et al., 2009) failed to support the GxE interaction reported by Caspi et al. Moreover, Kraemer (2012) questioned the methodological basis for drawing either negative or positive conclusions about the GxE interaction from the existing data.

No single study can definitively resolve the very complex issues raised by possible GxE effects on psychopathology. However, the large representative Generation R sample assessed with many measures from the prenatal period onward, including assessment of psychopathology with the same kinds of standardized instruments at successive ages, provides exceptional opportunities for testing GxE effects. The inclusion of prenatal variables in testing the GxE interaction is of particular value, because serotonin appears about 5 weeks after conception. Consequently, individual differences in serotonin transporter availability related to the 5-HTTLPR polymorphism could affect vulnerability to prenatal stressors such as maternal anxiety.

Tiemeier et al. indeed found that children who carried the short allele of the 5-HTTLPR polymorphism and whose mothers reported high prenatal anxiety *or*

high postnatal anxiety (with prenatal anxiety controlled) obtained significantly elevated Internalizing scores at age 5. Furthermore, children who carried two short alleles obtained higher Internalizing scores than children who carried only one allele. However, these effects, as well as many other effects found to date in the highly sophisticated, cutting-edge Generation R study, were very small. The large number of very small effects led the authors to describe their research as representing "bit-by-bit efforts of integrative pluralism with many different perspectives" (p. 1124).

Netherlands Twin Registry (NTR)

The longitudinal studies summarized so far have repeatedly assessed particular birth cohorts of individuals as they developed. The NTR, by contrast, is a unique resource that enrolls large proportions of the twins born in the Netherlands each year. Since 1987, parents of newborn twins have been invited to participate in the NTR, with 40–50% of the parents accepting the invitation. Numerous standardized assessments of the twins and their families have made it possible to do hundreds of cross-sectional studies. Moreover, repeated assessments at successive ages with developmentally appropriate versions of ASEBA instruments have also made it possible to do hundreds of studies of genetic and environmental effects on the development of psychopathology operationalized via the instruments used in the United States, Zuid Holland, TRAILS, Generation R, and other studies.

As an example, Boomsma, van Beijsterveldt, and Hudziak (2005) analyzed Anxious/Depressed syndrome scores computed from mothers' and fathers' ratings of thousands of NTR twins when the twins were 3, 5, 7, 10, and 12 years old. For combined maternal and paternal ratings, heritability estimates for Anxious/Depressed syndrome scores were 76% at age 3, 60% at age 5, 67% at age 7, 53% at age 10, and 48% at age 12. Shared family environment effects were not significant at ages 3 and 7, 16% at age 5, 20% at age 10, and 18% at age 12. Discrepancies between maternal and paternal ratings reflected differences between each parent's information about their children's functioning, which, in turn, reflected significant genetic and shared environmental effects. In other words, rather than reflecting rater error, differences between mothers' and fathers' ratings validly captured different genetically and environmentally influenced variance in their children's behavior, as well as variance common to ratings by both parents.

Longitudinal analyses of NTR data have produced somewhat different findings for genetic and environmental effects on the CBCL Withdrawn, Attention Problems, and Aggressive Behavior syndromes (Hoekstra, Bartels, Hudziak, van Beijsterveldt, & Boomsma, 2008; Rietveld, Hudziak, Bartels, van Beijsterveldt, & Boomsma, 2004; van Beisjsterveldt, Hudziak, & Boomsma, 2003). Longitudinal analyses of mothers' and fathers' CBCL ratings of NTR twins have also been used to model distinctions between measurement error versus different genetically and environmentally influenced aspects of children's functioning captured by mother versus father ratings (Bartels, Boomsma, Hudziak, van Beijsterveldt, & van den Oord, 2007).

MULTICULTURAL FINDINGS AND APPLICATIONS

To avoid wrongly assuming that findings in a single society reflect universals, it is important to apply the same standardized assessment procedures for psychopathology to people from a variety of societies. If the assessment procedures are found to function similarly in different societies, they can be used to compare the course and correlates of psychopathology across those societies. Findings from multiple societies warrant more confidence than findings from a single society. An additional advantage of assessment procedures that function similarly in different societies is that they foster multicultural collaborations, which can greatly extend the reach of developmental research on psychopathology.

We use the term *society* in reference to populations living in a particular political jurisdiction in which a particular language is dominant. Many of the societies for which we report findings are countries, but some are regions within countries, such as Flanders (the Flemish-speaking region of Belgium), or are commonwealths or territories that are distinct from the country to which they belong, such as Hong Kong and Puerto Rico. We use the term "multicultural" in reference to findings and applications based on data spanning the cultural variations occurring across multiple societies.

Multicultural Tests of Syndromes

The previously described ASEBA syndromes were derived mainly from ratings of U.S. samples. To test the degree to which the ASEBA syndromes would be supported in other societies, indigenous researchers obtained ratings of samples of people residing in over 50 societies. The ratings obtained in each society were then subjected to confirmatory factor analyses (CFAs). The societies were located in

Africa, Asia, Australasia, the Caribbean, Europe, the Middle East, Central America, and South America. The ratings were obtained with the CBCL/1½-5, Caregiver-Teacher Report Form for Ages 1½-5 (C-TRF), CBCL/6-18, TRF, YSR, ASR, and ABCL, translated into local languages when necessary. CFAs supported the ASEBA syndrome structure in nearly every sample (Ivanova et al., 2007a, 2007b, 2007c, 2010, 2011, 2015a, 2015b; Rescorla et al., 2012b). The findings indicated that the syndrome models are sufficiently applicable in many societies to warrant scoring ratings of ASEBA problem items in terms of these models. Although additional problems might be important in some contexts and societies, the CFA support for the syndrome models in ratings by different kinds of informants in so many societies means that they can provide an evidence-based multicultural taxonomic framework for a broad spectrum of behavioral, emotional, and social problems assessable via self-ratings and collateral ratings.

Multicultural Comparisons of Scale Scores

The CFA support for the ASEBA syndrome models in so many societies justifies multicultural statistical comparisons of the syndrome scale scores. This has been done in age x gender x society ANOVAs of the syndrome scales scored from ratings on the ASEBA forms for ages 1½–5, 6–18, and 18–59 years. In addition to comparisons of syndrome scores, the comparisons have included scores for *DSM*-oriented scales and broad-band Internalizing, Externalizing, and Total Problems scales (Rescorla et al., 2011, 2012a, 2012b, 2015a, 2015b). Age and gender differences in scale scores have been very consistent across very diverse societies. Effect sizes for societal differences in problem scale scores have ranged from small to medium.

As another way of comparing problem ratings across societies, correlations have been computed between the mean ratings for all the problem items in each society and the mean ratings for all the problem items in each other society on the same instrument completed by the same type of informant. For example, the CBCL/6-18 was completed by parents of 69,866 children residing in 42 societies. Using the data from Society 1, Rescorla et al. (2012b) computed the mean of the 0-1-2 Society 1 ratings for each of the 112 problem items that were analyzed for the multicultural comparisons. The same was done for Society 2, Society 3, and so on through Society 42. The formula for Pearson *r* was then used to compute the correlation between the 112 mean item ratings for Society 1 versus Society 2, Society 1 versus Society 3, etc. for all pairs of societies. (In effect, such correlations are *Q* correlations, because they measure the similarity between the mean ratings on the 112 problem items for each pair of societies.)

Rescorla et al. averaged all the correlation coefficients obtained between all pairs of societies to obtain the overall mean correlation as a summary statistic for the degree of multicultural similarity in the items that were rated low, medium, or high. For the CBCL/6-18, the overall mean correlation was .74. For all the other instruments, the overall mean correlations were also in the .70s, indicating a high degree of similarity according to Cohen's (1988) criteria (Rescorla et al., 2011, 2012a, 2012b, 2014a, 2014c). In other words, for ages 1½–5, 6–18, and 18–59 years, informants' ratings were quite consistent with respect to problems that received low, medium, or high ratings across very diverse societies.

Construction of Multicultural Norms

Findings that hundreds of thousands of people in over 50 societies were willing and able to complete the standardized rating instruments indicates their acceptability for assessing members of those societies. The CFA support for the empirically based syndromes, the large multicultural correlations between mean item ratings, and the consistent age and gender effects also indicate that the scales and items function similarly in many societies. However, the small to medium effect sizes for cross-society differences in scale scores argue for different sets of norms with which to evaluate the scale scores obtained by individuals in different societies.

Comparisons of the mean Total Problems scores obtained on each ASEBA instrument in the societies in which the instrument was administered revealed normal distributions of mean Total Problems scores across those societies. Although there were statistically significant differences between the mean Total Problems scores from different societies, the range from the lowest to the highest mean Total Problems score spanned only about 13% of the possible range of Total Problems scores. Furthermore, about 68% of the societies had mean Total Problems scores within one standard deviation (*SD*) of the *omnicultural mean* (the mean of the mean Total Problems scores of all the societies having data for a particular form). The mean Total Problems scores of about 16% of the societies' were >1 *SD* below the omnicultural mean, while about 16% were >1 *SD* above the omnicultural mean. (The percentages were obtained by averaging the percentages found for each instrument.)

Following common psychometric practice, the societies were divided into groups demarcated by 1 *SD* below and 1 *SD* above the omnicultural mean (Achenbach &

Rescorla, 2007, 2010, 2015). Societies whose mean Total Problems scores are >1 *SD* below the omnicultural mean are designated as Group 1, societies whose mean Total Problems scores range from –1 to +1 *SD* from the omnicultural mean are designated as Group 2, and those whose mean Total Problems scores are >1 *SD* above the omnicultural mean are designated as Group 3.

Separately for each instrument, multicultural norms were constructed for Group 1 by computing cumulative frequency distributions of scores on each scale obtained by individuals in each Group 1 society, separately by gender within each age group. For each gender/age group, a new cumulative frequency distribution was then created for each scale by averaging the cumulative frequency distributions from all the Group 1 societies. Percentiles of scores in this mean cumulative frequency distribution were used as the basis for assigning normalized *T* scores to the raw scores. The same procedure was followed for Group 3 societies. Because the U.S. mean Total Problems score was at the middle of the distribution of Group 2 mean Total Problems scores for most instruments and because the U.S. norms had already been used in many research and clinical applications, the U.S. norms are used for Group 2 for those instruments.

Practical Applications of Multicultural Norms

To facilitate applications of the multicultural norms to individuals for both research and practice, the norms are incorporated into computer software for scoring the ASEBA instruments. This enables users to obtain *T* scores based on norms for societies relevant to assessment of each individual and also to display each individual's scale scores on profiles in relation to appropriate multicultural norms.

As an example, if a 14-year-old girl's mother came from Puerto Rico and her father came from Jamaica, scale scores obtained from her mother's CBCL/6-18 ratings could be displayed in relation to norms appropriate for Puerto Rico, while scale scores obtained from her father's CBCL/6-18 ratings could be displayed in relation to norms appropriate for Jamaica. If the girl attended a school in the United States, TRF scale scores from her teachers' ratings could be displayed in relation to U.S. TRF norms. And, if the girl had lived much of her life in the United States, her YSR scale scores could be displayed in relation to U.S. norms. The software would compare the scale scores from each informant's ratings on bar graphs, with each bar standardized for the girl's age, gender, the type of informant (parent, teacher, self), and the appropriate multicultural norms. The user could thus see whether any scale scores were clinically deviant in relation to any of the relevant norms.

ADVANCING ASSESSMENT, TAXONOMY, AND DIAGNOSIS

To set the stage for considering how assessment, taxonomy, and diagnosis can be advanced, Figure 2.7 illustrates the dynamic and continuous relations between them.

To be accurate, diagnosis requires valid ways of conceptualizing the phenomena that are to be diagnosed. Taxonomies provide frameworks for conceptualizing psychopathology in terms of similarities and differences between behavioral/emotional/social problems that can then provide targets for diagnosis. Taxonomic frameworks for problems are commonly conceptualized in terms of syndromes. The value of particular syndromes depends on the degree to which they are found to have important correlates, such as differences in etiology, prognosis, responsiveness to particular interventions, and long-term developmental pathways. To develop reliable, valid, and useful taxonomies, we need reliable and valid assessment data that can be obtained for diverse samples of people. After a taxonomy has been derived from assessment data, the taxonomy can be used to guide assessment of new cases to determine which taxa the cases resemble.

In Figure 2.7, *diagnosis* includes *diagnostic processes, formal diagnoses,* and *diagnostic formulations*. To avoid confusion about diagnosis, it is important to keep in mind these three different aspects of diagnosis. Assessment and taxonomy are important contributors to all three aspects

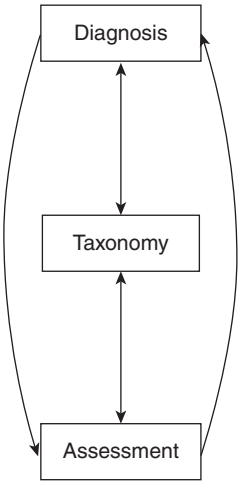

Figure 2.7 Relations between assessment, taxonomy, and diagnosis. As explained in text, *diagnosis* includes *diagnostic processes* (gathering data), *formal diagnoses* (classifying cases and disorders), and *diagnostic formulations* (integrating all relevant data for each case). *Source:* Copyright T. M. Achenbach. Reproduced by permission.

of diagnosis. Diagnostic processes clearly include assessment operations that should be guided by a taxonomy of syndromes. Formal diagnoses involve identification of the taxa that are most relevant to each case. And diagnostic formulations integrate information specific to the case with the type of information on which taxonomic decisions and formal diagnoses are based.

Challenges to Be Met

DSM-III (American Psychiatric Association, 1980) was an important milestone in advancing the nosological approach toward more explicit and testable criteria for psychopathology. Since 1980, *DSM-III* and its successors have generated a tremendous amount of research, as well as major changes in clinical training and practice. An especially important research goal has been to improve the diagnosis of *DSM*-defined disorders via SDIs. Accordingly, enormous resources have been invested in developing, testing, and revising SDIs as ways of operationalizing the *DSM-III*, *DSM-III-R*, and *DSM-IV* criteria (e.g., Costello et al., 1984; Shaffer et al., 2000). Further revisions and testing will be needed to operationalize *DSM-5* criteria.

Efforts to diagnose *DSM*-defined disorders via SDIs have molded research, training, and practice according to the *DSM*'s diagnostic model, which requires yes-or-no decisions about each criterial feature of each diagnostic category. SDIs, such as the DISC for children and DIS for adults, are viewed as quasi-gold standards for assessing psychopathology. However, studies of SDIs have revealed major challenges for assessment, taxonomy, and diagnosis of psychopathology. We first summarize these challenges at the level of specific methodological issues. We then consider possibilities for advancing assessment, taxonomy, and diagnosis to improve understanding, prevention, and treatment of psychopathology.

Challenges Revealed by SDI Studies

The challenges can be summarized as follows:

1. *Test–retest attenuation:* Fewer symptoms are typically reported at second interviews than at initial interviews, causing declines in the number of diagnoses over even very short periods such as a week (e.g., Roberts, Solovitz, Chen, & Casat, 1996).
2. *Low to moderate cross-informant agreement:* People report different symptoms about themselves than others report for them, causing disagreements between diagnoses based on self-reports versus informant-reports (e.g., Achenbach et al., 1987, 2005; Meyer, 2002).
3. *Diagnoses made from SDIs often disagree with clinical diagnoses:* Even when designed to operationalize *DSM* criteria, SDIs such as the DISC and DIS often produce different *DSM* diagnoses than clinical assessments (e.g., Jensen & Weisz, 2002; Lewczyk et al., 2003; Rettew, Doyle, Achenbach, Dumenci, & Ivanova, 2009).
4. *High rates of comorbidity:* Rates of comorbidity between some SDI diagnoses are so high as to raise questions about whether the diagnoses actually represent different disorders (e.g., Faraone et al., 1991; Walker et al., 1991; Wilens et al., 2002).
5. *Great variations in prevalence estimates of DSM diagnoses made from* SDIs *in epidemiological surveys:* When *DSM* criteria are operationalized via SDIs, the SDIs yield much greater variation in prevalence estimates than would be expected from sampling differences (e.g., Achenbach et al., 2012; Breton, Bergeron, Valla, Berthiaume, & Gaudet, 1999).

The challenges raised by SDI studies expose fundamental problems that cut across assessment, taxonomy, and diagnosis. These problems need to be addressed in efforts to improve understanding, prevention, and treatment of psychopathology. Some of the problems revealed by SDI studies may afflict other assessment procedures, as well. For example, test–retest attenuation, low to moderate cross-informant agreement, and high rates of covariation (i.e., comorbidity) among different kinds of problems are found in most procedures for obtaining information about people's problems (e.g., Achenbach & Rescorla, 2001, 2003; Krueger & Piasecki, 2002). Agreement between most assessment procedures and *DSM* clinical diagnoses also tends to be low, although this may be most troubling for procedures that are explicitly designed to correspond to *DSM* diagnoses (e.g., Gadow et al., 2002). If assessment procedures are not specifically designed to correspond to *DSM* diagnoses, their modest agreement with *DSM* clinical diagnoses is less surprising than if they are designed to correspond to *DSM* diagnoses.

Although some of the challenges faced by SDIs are quite general, the problems are exacerbated by the *DSM* requirement to make diagnoses by applying fixed rules to the criteria that must be met. For example, a decline in the number of symptoms endorsed from one occasion to another may reflect the general phenomenon of test–retest attenuation. However, according to *DSM*'s fixed rules for the number of symptoms required for each diagnosis, a decline of even one symptom can change decisions from sick to well for *DSM* diagnoses. Similarly, disagreements between informants' reports for even a single symptom

can cause major differences in diagnoses made on the basis of self-reports versus reports by other informants. Equally important, the dependence of *DSM* diagnoses on the precise definition, number, duration, and co-occurrence of reported symptoms may contribute to the great variations in prevalence estimates found in different epidemiological studies. For example, Roberts, Attkisson, and Rosenblatt (1998) found prevalence estimates ranging from 1% to 50% among epidemiological studies of diagnoses of child and adolescent disorders. Assessment procedures that uniformly operationalize a particular set of taxonomic constructs have yielded more consistent epidemiological findings than SDIs that are intended to operationalize *DSM* diagnostic criteria but that vary considerably in how they obtain judgments of whether each criterion is met (e.g., Achenbach et al., 2012; Rescorla et al., 2012b).

Other Types of Challenges

Assessment, taxonomy, and diagnosis also face challenges raised by the need to identify and combine optimal sources and kinds of assessment data for taxonomy and diagnosis; the need to take account of variations related to age, gender, society, and sources of data; and the need to distinguish between cultural differences versus individual differences. Table 2.1 summarizes the challenges. Progress in meeting the various challenges requires systematic research that can bridge the gaps between nosological and empirically based approaches to provide assessment procedures, taxonomic constructs, and diagnostic targets that can be used by both approaches.

TABLE 2.1 Challenges in Advancing Assessment, Taxonomy, and Diagnosis

1.	Test–retest attenuation: The decline in problems reported from initial interviews to subsequent interviews.
2.	Low to moderate cross-informant agreement: Different informants tend to report different problems.
3.	Limited agreement between diagnoses made from SDIs and clinical evaluations.
4.	High rates of comorbidity: Comorbidity between some diagnoses is so high as to raise questions about whether the diagnoses represent different disorders.
5.	Great variations in prevalence rates of *DSM* diagnoses made from SDIs in epidemiological surveys.
6.	The need to integrate multisource data.
7.	The need to take account of differences related to age, gender, society, and sources of data.
8.	The need to distinguish individual differences from cultural differences.

QUANTITATIVE AIDS TO MEETING THE CHALLENGES

DSM-III, *DSM-III-R*, *DSM-IV*, and *DSM-5* have brought significant advances in making diagnostic criteria more explicit. However, the *DSM*'s diagnostic criteria and categories are based on the assumption that each diagnostic category represents a separate disorder. The assumption that each diagnostic category represents a separate disorder may indeed be tenable for disorders for which specific pathogens or other physical abnormalities have been identified. For example, diagnostic categories for infectious diseases such as tuberculosis, diphtheria, and AIDS can be confidently defined in terms of pathogens that are necessary (though not always sufficient) for the disorder to occur. Diagnostic categories for cancer can be defined in terms of specific kinds and locations of tissue pathology, even if specific etiologies have not been identified.

Some forms of psychopathology may eventually be found to involve physical pathogens or other physical etiological factors. However, until physical etiologies are validated, it may be premature to require yes/no decisions for diagnoses of behavioral, emotional, and social problems. Because even physical disorders may not all be identifiable in terms of yes/no dichotomies (e.g., hypertension), the search for physical etiologies may also be more productive if diagnostic criteria and taxa are quantified. In fact, meta-analyses have indicated that quantitative assessments of psychopathology are substantially more reliable and valid than categorical assessments (Markon, Chmielewski, & Miller, 2011).

Even if a categorical diagnostic format is retained, cut points can be established on distributions of quantitative scores. Rather than being established a priori by committees of experts, the cut points can be based on scores that validly discriminate between representative samples of people who are judged to be relatively normal (i.e., healthy samples) versus people who are judged to need mental health services. To take account of age, gender, societal, and informant differences, cut points can be established on the basis of multicultural norms for people of each gender within particular age ranges, according to assessment data obtained from different kinds of informants. To avoid transferring the disadvantages of purely categorical diagnoses to diagnoses based on scores, the cut points should be based on empirical findings of variations related to age, gender, society, and type of informant. Moreover, levels of deviance can be identified for distinguishing between people who have extreme degrees of the problems encompassed by a diagnostic taxon versus people who have less

extreme degrees of the problems versus people who are in the normal range. Even if cut points are imposed on distributions of scores, the continuous scores should be retained to provide more precise measures of problems than are provided by categorization. Quantitative diagnostic scores also have advantages for measuring change over time, such as by comparing scores before, during, and after treatment and by comparing scores at different points in development.

Advantages of Quantification for Research

Quantification of the criterial features of diagnostic taxa and of the diagnostic taxa themselves offers multiple advantages for most kinds of research on psychopathology, as discussed in the following sections.

Preserving Information

One advantage is that quantification of features typically preserves more information about the features than yes/no categorization does. This is especially true when neither the boundaries of each feature nor of the diagnostic categories are well validated. When the boundaries of diagnostic categories are not well validated, imposition of unvalidated boundaries and categorical assessment procedures may cause both false positives and false negatives. Even if certain disorders are ultimately found to have categorical boundaries, measurement error will prevent assessment procedures from infallibly distinguishing between individuals whose problems fall within those boundaries versus individuals whose problems are not entirely congruent with the categorical boundaries.

Avoiding Forced Choices

Quantified assessment procedures avoid forced choices because they capture the degree to which individuals' problems approximate particular diagnostic taxa and because quantification can take account of measurement error. By indicating the degree to which individuals' problems resemble each relevant diagnostic taxon, quantified assessment can help to prevent the premature closure risked by placing individuals in diagnostic categories that may be wrong.

Increasing Precision

A further advantage of quantification is that it can improve research by increasing the precision of data obtained about each characteristic of each individual. It can also improve research by enabling the use of more varied and powerful analytic tools than are available for categorical data. These analytic tools are especially useful for the following research areas that are increasingly important for advancing assessment, taxonomy, and diagnosis: Identification of patterns of psychopathology and their correlates; life span developmental analyses of adaptive and maladaptive functioning; behavior genetics and epigenetics; epidemiology; efficacy, effectiveness, and outcomes of different kinds of interventions; pharmacokinetics of medications; biochemical correlates of behavioral and emotional problems; and multicultural applications.

Advantages of Quantification for Conceptualizing Psychopathology

Quantitative Aspects of Prototypes

In earlier sections, we outlined prototypes as models for taxonomy. Insofar as people mentally represent categories in terms of prototypes (sets of correlated features), mental representations of even categorical taxonomic constructs involve quantification. That is, a prototype for a category encompasses multiple features that are not perfectly correlated with each other. On the other hand, individuals who manifest many features of a prototype are more easily assigned to the category represented by that prototype than individuals who manifest fewer features of the prototype. Individuals who manifest multiple features of more than one prototype may be especially hard to classify into a single category. If such individuals have enough problems to need mental health services, then their problems can be described in terms of scores on multiple prototypes. According to *DSM*'s rules, individuals who manifest enough prototypical features of two categories to qualify for both categories are assumed to have the disorders represented by both categories, i.e., they have comorbid disorders. (Although some editions of *DSM* have included preemptive rules, such as CD taking precedence over ODD when criteria for both disorders are met, these rules are often suspended in research and practice.)

If diagnostic categories are quantified in terms of the number of their prototypical features, the categories would correspond more closely to people's mental representations in terms of prototypes. In other words, because people use the number of features corresponding to their mental prototypes to help them classify individuals and because the reliability and confidence with which individuals are classified depend on the number of prototypical features manifested, diagnostic categories may be used more effectively if they take advantage of the quantification that is inherent in mental classification processes. Because psychopathology often includes features of multiple diagnostic categories, quantification of each category would allow users of the categories to think about borderline cases and

comorbidity explicitly in terms of the scores obtained for each diagnostic category. Borderline cases, for example, could be operationally defined in terms of scores that are high enough to be somewhat above the normal range but not so high as to be clearly clinically deviant. Furthermore, manifestations of features of multiple categories could be explicitly documented in terms of profiles of scores for all the relevant categories without implying that each elevated score indicates a separate (or comorbid) disorder.

Conceptualizing Cross-informant Variations

Quantification of diagnostic taxa can also facilitate conceptualization of cross-informant variations in assessment data. By allowing for variations in the degree to which particular problems are manifested and reported, quantified taxa can help us use both the differences and the similarities in reports by different informants for determining the overall level of individuals' problems and how consistently they are manifested. For example, if all informants report high levels of attention problems for a child, this would provide consistent evidence for a disorder that involves attention problems, such as ADHD. On the other hand, suppose that a teacher reports attention problems but a parent reports that the child concentrates intently on video games. A purely categorical system forces us to choose between the teacher's and parent's reports to make a yes/no decision about whether the child has ADHD. However, quantified taxa enable us to integrate scores obtained from different informants into the scores for each relevant category. This can be done by considering the possible situational specificity of problems, using weighted means of scores, matching profile patterns from different informants to profile types, and matching scores from different informants to latent classes or latent profiles.

In summary, the quantitative aspects of mental prototypes provide a natural basis for conceptualizing psychopathology in terms of quantified taxa. Quantified taxa facilitate diagnostic decisions about individuals who need help but whose problems are too diverse or situation-specific to meet criteria for a single diagnostic category, as well as individuals who meet criteria for multiple diagnostic categories. Quantified taxa also facilitate thinking about individuals who have significant problems that correspond to a particular diagnostic category but that do not quite reach the threshold required for a categorical diagnosis. Equally important, when different informants report different problems for an individual, profiles of quantified categories scored from each informant can be used to document similarities and differences in how the individual is perceived.

Advantages of Quantification for Mental Health Services

For mental health services, a fundamental advantage of quantification is that decisions about who needs services and what kind of services they need can be based on clients' profiles of adaptive and maladaptive functioning rather than on whether they meet categorical criteria for a particular diagnosis. Excessive reliance on diagnostic categories as a basis for treatment decisions may exclude clients who need help but do not fit the categories. On the other hand, if clients meet criteria for a diagnostic category, it is then too tempting to assume that they are ill even if they are adapting well. Furthermore, excessive reliance on diagnostic categories may cause treatment to focus more narrowly on the categories than is warranted either by the client's needs or by the ability of categorically based treatments to ameliorate broad spectra of problems. This may be especially true when a mental health service specializes in a particular diagnostic category such as depression, anxiety, or ADHD. Because the diagnostic procedures, treatment modalities, and clinicians in such services tend to focus on the target category, clients and their problems may be viewed primarily through the lens of that category. Assessment of multiple quantified taxa can reveal the degree to which individuals' problems really are or are not concentrated in a particular taxon. Table 2.2 summarizes these advantages.

TABLE 2.2 Potential Advantages of Quantifying Criterial Features and Taxonomic Constructs

1.	Avoids yes-versus-no forced choices about the presence of features and diagnosis of disorders.
2.	Allows cut points on distributions of scores that can reflect age, gender, informant, clinical status, and other differences.
3.	Provides more precise measurement of psychopathology than categorization does.
4.	Allows use of more powerful analytic tools than categorization does for research on patterns of psychopathology, developmental trajectories, behavior genetics, epidemiology, effects of interventions, pharmacokinetics, biochemical variables, and cross-cultural variations.
5.	Corresponds to mental representations of taxa in terms of prototypes.
6.	Quantified covariation between problems avoids dilemmas of comorbidity between categorical disorders.
7.	Facilitates aggregation of multisource data in taxonomic constructs.
8.	Provides more precise basis for decisions about treatment and evaluations of progress and outcomes.
9.	Facilitates targeting of specific problems in relevant contexts.
10.	Measures specific problems independently of criteria for diagnoses.

EFFORTS TO QUANTIFY DIAGNOSTIC TAXA

The following sections outline efforts to bring the benefits of quantification to diagnostic taxa.

Rating Scales for *DSM* Categories

One approach to quantifying diagnostic taxa is to reproduce the symptom criteria for individual *DSM* categories in rating scales, such as those described next.

ADHD Rating Scale-IV

DuPaul et al. (1998) constructed the ADHD Rating Scale-IV, which consists of the *DSM-IV* symptom criteria for the Inattentive and Hyperactive-Impulsive types of ADHD. Parents and teachers rate each symptom as *0 = Never or rarely*, *1 = Sometimes*, *2 = Often*, or *3 = Very often*. The ratings are then summed to provide scale scores for Inattention, Hyperactivity-Impulsivity, and Total ADHD. DuPaul et al. (1998) reported that categorical diagnoses of ADHD correlated between .08 and .44 with scores on the scales of the ADHD Rating Scale-IV completed by parents and teachers. However, DuPaul et al. also reported correlations of .76 to .88 between teachers' ratings on the ADHD Rating Scale-IV and the corresponding quantitative scales of the Conners Teacher Rating Scale-39 (C-TRS; Conners, 1997).

Youth's Inventory-4

In an effort to quantify a broader range of *DSM* diagnostic taxa, Gadow and colleagues developed rating scales consisting of symptoms from multiple *DSM-IV* categories. As an example, the Youth's Inventory-4 (YI-4; Gadow et al., 2002) is a self-rating form consisting of *DSM-IV* symptoms that youths rate 0, 1, 2, or 3 according to gradations like those of the ADHD Rating Scale-IV. Symptom severity scores are obtained by summing the numerical ratings on each scale. Versions of a companion rating form, the Adolescent Symptom Inventory-4 (ASI-4), are designed to obtain parent and teacher ratings of many of the same *DSM* symptoms.

Using a sample of 11- to 18-year-olds whose parents requested an outpatient evaluation, Gadow et al. (2002) tested associations between symptom severity scores on the *DSM* scales of the YI-4 and *DSM* diagnoses in the youths' clinic charts. The diagnoses were analyzed in terms of the following five categories: ADHD, ODD, CD, depressive disorders, and anxiety disorders, although many youths qualified for multiple categories. Gadow et al. then identified the YI-4 *DSM* scales whose symptom severity scores had the highest point-biserial *r*s with each category. The highest *r*s ranged from .06 for the YI-4 ODD scale with *DSM* diagnoses of ODD to .38 for the Major Depressive Disorder scale with *DSM* diagnoses of depressive disorders, with mean point–biserial $r = .25$ (computed by Fisher's z transformation).

Although the authors did not report associations between diagnoses and parent or teacher ratings, the Pearson *r*s between the YI-4 and parents' ASI-4 ratings on corresponding *DSM* scales ranged from .05 to .50. All correlations between the YI-4 and teachers' ASI-4 ratings on the corresponding *DSM* scales were extremely low ($r < .18$). However, the YI-4 scales yielded many *r*s in the .60s and .70s with the youths' self-ratings on non *DSM*-based scales scored quantitatively from the Children's Depression Inventory (CDI; Kovacs, 1992), the Multidimensional Anxiety Scale for Children (MASC; March, 1997), and the YSR. Thus, although YI-4 *DSM* symptom severity scores did not yield much agreement with *DSM* clinical diagnoses nor with parent or teacher ratings, self-ratings on the YI-4 *DSM* symptom scales correlated highly with self-ratings on other quantitative measures of problems.

Findings for the ADHD Rating Scale-IV and the YI-4 thus suggest that parent, teacher, and self-ratings of actual *DSM* symptom items do not necessarily agree well with *DSM* diagnoses that are based on the same items. The obstacles to agreement between the *DSM* scales and *DSM* diagnoses could include variations in the data used by the clinicians who made the diagnoses, plus their use of additional criteria such as the duration of symptoms.

DSM-Oriented Scales

Another approach to quantifying *DSM* diagnostic categories is to start with items that are of proven value for obtaining ratings by the relevant informants and then to select those items that are very consistent with *DSM* diagnostic categories, whether or not the items have exact counterparts among the *DSM* symptom items. Because each *DSM* diagnostic category in effect represents a diagnostic construct, experts' understanding of the diagnostic constructs may provide a good basis for selecting items that are appropriately rated by informants, even if the items are not precisely the same as the *DSM* symptom criteria. However, because experts' judgments may vary with such characteristics as their professional training, the settings in which they work, the types of clients they see, and their cultural backgrounds, it is important to identify items on which diverse experts' judgments converge.

To make use of judgments by experts who varied greatly with respect to their training, work settings, clients, and cultures, Achenbach, Dumenci, and Rescorla (2001) invited 22 psychiatrists and psychologists from 16 cultures around the world to rate CBCL/6-18, TRF, and YSR problem items for their consistency with *DSM-IV* diagnostic categories for child and adolescent disorders. The experts had all published on psychopathology and had a mean of 19.1 years of experience since their first doctorate. Five had both an MD and a PhD. The experts were given the *DSM* criteria for nine categories of disorders that are defined largely in terms of behavioral, emotional, and social problems. They then rated each problem item as 0 = not consistent, 1 = somewhat consistent, or 2 = very consistent with each *DSM* category. Because the objective was to obtain the experts' judgments of the diagnostic constructs represented by the *DSM* categories, they could rate problem items as being very consistent with a category even if the items did not have precise counterparts among the *DSM* symptom criteria.

Items that were rated as very consistent with a *DSM* category by at least 64% of the experts were assigned to a scale for that category. The scales are designated as "*DSM*-oriented" because they capture what is common to diverse experts' understanding of the diagnostic constructs underlying *DSM* categories, rather than being verbatim statements of the *DSM* criteria. Enough items met criteria to form *DSM*-oriented scales that were designated as follows: affective problems (including dysthymia and major depression); anxiety problems (including generalized anxiety disorder, separation anxiety disorder, and specific phobia); somatic problems (including somatization and somatoform disorders); ADHD problems (including hyperactive-impulsive and inattentive types); oppositional defiant problems; and conduct problems.

To enable users to judge the degree of deviance indicated by scores on the *DSM*-oriented scales, normative data have been obtained for population samples of 6–18-year-olds living in 42 societies. Scores on the *DSM*-oriented scales are displayed on profiles in relation to multicultural norms for each gender according to particular age ranges, separately for parent ratings on the CBCL, teacher ratings on the TRF, and self-ratings on the YSR (Achenbach & Rescorla, 2001, 2007a; Rescorla, 2012b).

Relations to DSM Diagnoses

Point-biserial *r*s have been reported between *DSM-IV* clinical diagnoses and the *DSM*-oriented scales in a university psychiatry clinic sample (Achenbach & Rescorla, 2001, p. 130). Like the diagnoses reported by Gadow et al. (2002) for youths who completed the YI-4, the diagnoses were obtained from clinical records and were based on multiple sources of data. However, unlike the ages 11 to 18 spanned by the Gadow et al. data for self-ratings on the YI-4, the data for the *DSM*-oriented scales spanned ages 6 to 18 and were obtained from parents' ratings on the CBCL/6-18. For the same diagnostic categories as Gadow et al. used, the correlations between *DSM* clinical diagnoses and the corresponding *DSM*-oriented scales ranged from .34 for CD to .60 for ADHD, with mean point-biserial $r = .45$ (computed by Fisher's z transformation).

As another way of assessing *DSM* diagnoses, clinicians administered the *DSM-IV* Checklist (Hudziak, 1998) to family members who were involved in the clinical evaluation of the children. The *DSM-IV* Checklist consists of questions corresponding to each of the criterial symptoms for each diagnostic category. Although the questions are quoted from the *DSM-IV* symptom criteria, clinical interviewers are free to rephrase the questions for the benefit of the interviewees. The score for each diagnostic category is the sum of symptoms judged to be present. For the same diagnostic groupings as Gadow et al. used, the Pearson *r*s with the corresponding *DSM*-oriented scales ranged from .43 for anxiety disorders to .80 for ADHD, with mean $r = .63$ (computed by Fisher's z transformation). Recall that the *DSM*-oriented scales do not consist of items reproduced verbatim from the *DSM* symptom criteria. Nevertheless, their mean *r* of .45 with *DSM* clinical diagnoses and .63 with scores for *DSM* diagnoses on the clinician-administered *DSM-IV* Checklist were significantly higher ($p<.05$) than the mean *r* of .25 between *DSM* clinical diagnoses and the YI-4 scales that did consist of verbatim *DSM* symptom criteria. This suggests that quantification of *DSM* diagnostic constructs may not be most effectively done by obtaining informants' responses to the verbatim *DSM* symptom criteria. The *DSM*-oriented scales have since been slightly revised on the basis of *DSM-5* diagnostic criteria (Achenbach, 2014).

Bridging Gaps Between Nosologically and Empirically Based Constructs

The top-down and bottom-up strategies that characterize nosologically and empirically based constructs, respectively, are arguably the most common approaches to taxonomy of psychopathology. Each makes use of existing knowledge and concepts in different ways. Both may help to advance assessment, taxonomy, and diagnosis, especially if the potential strengths of both can be combined. One way to combine their strengths is to use a common set of

assessment procedures for nosologically and empirically based constructs. Such a combination is exemplified by the *DSM*-oriented scales that are scored from the same pool of items from which empirically based syndromes are scored (Achenbach, 2014; Achenbach & Rescorla, 2000, 2001, 2003). For children and adults, scores for both types of scales are displayed on profiles in relation to age-, gender-, and informant-specific multicultural norms (Achenbach & Rescorla, 2007a, 2010, 2015). The two types of scales have similar psychometric properties, and there are medium to strong associations between some scales of the two types (Achenbach, Bernstein, & Dumenci, 2005; Achenbach, Dumenci, & Rescorla, 2003b). The ability to score both types of scales from the same items—which are rated by the people being assessed and by informants in about 15 minutes—makes it easy to compare nosologically and empirically based findings in many research and clinical contexts for many purposes.

Longitudinal Research Designs

In previous sections, we presented accelerated longitudinal, path, and growth curve designs as examples of research designs that may be especially useful for developmental research related to assessment, taxonomy, and diagnosis. Some longitudinal studies, such as the Dunedin, New Zealand project (Newman et al., 1996), have reported *DSM* diagnoses for the same participants at different ages. However, application of powerful longitudinal designs to nosological constructs has been limited by the difficulty of operationalizing nosological constructs via SDIs that must be tailored to the different developmental levels of large representative samples of participants repeatedly assessed over long periods. Additionally, major changes in diagnostic criteria from one edition of the *DSM* to another make it hard to link diagnoses based on the different editions. Equally important, although longitudinal growth models can utilize categorical variables such as diagnoses, these categorical variables do not capture as much information about individual differences between people as quantitative scales do.

DSM-oriented scales that can be scored quantitatively from the same brief assessment instruments as empirically based scales facilitate research on nosologically based constructs and comparisons of results obtained for empirically based constructs. Scores on quantitative *DSM*-oriented scales based on ratings from multiple informants can also serve as indicators for latent variable analyses. Latent variables estimated from such indicators can then be tested as predictors, moderators, mediators, and outcomes in path or growth curve analyses. It is thus possible to use accelerated longitudinal, path, and growth curve designs to track relations between developmentally early and later measures of nosologically based constructs to test their developmental stability and the degree to which they predict various outcomes.

Genetic and Other Biological Research

Quantified phenotypic measures of nosological constructs make it possible to test complex quantitative models for genetic and environmental effects on psychopathology. Because these measures can be economically obtained for very large samples of twins and other genetically informative samples, they yield much more powerful genetic analyses than do structured diagnostic interviews, which would be financially prohibitive for such large samples (e.g., Boomsma et al., 2001).

In addition to genetic research, studies of other biological variables can be strengthened by using quantitative measures of nosological constructs. For example, several studies have found significant correlations between the empirically based Aggressive Behavior syndrome and a variety of biochemical measures (e.g., Gabel, Stadler, Bjorn, Shindledecker, & Bowden, 1993; Hanna, Yuwiler, & Coates, 1995; Scerbo & Kolko, 1994). Quantitative scales for measuring nosologically based constructs can provide more powerful and differentiated tests of associations between biochemical variables and diagnostic constructs than categorical diagnoses can.

Research on Secular Trends in Psychopathology

It has been widely noted that the previously rare diagnoses of pervasive developmental disorders (PDD; now called autism spectrum disorder in *DSM-5*), including autism and Asperger's disorder, have become more common (e.g., Chakrabarti & Fombonne, 2001). Reviews of documents have also led to the conclusion that adolescent conduct disorders, substance abuse, depression, and suicide have increased (Rutter & Smith, 1995). Secular (i.e., long-term) changes in rates of psychopathology are apt to be very important, because they may provide clues about etiological factors and protective factors. Secular changes in rates of psychopathology may also argue for new efforts at prevention and treatment. Unfortunately, changing rates of diagnoses may reflect changing diagnostic criteria, diagnostic categories, and even the willingness of mental health workers to make certain diagnoses. As an example, autism was previously blamed on unconscious parental attitudes (e.g., Wolman, 1970, p. vii), which meant that it was a very undesirable diagnosis. Autism has since come to be

regarded as a developmental disability for which intensive services are now provided. Even documentation of suicide may reflect cultural changes, as there is evidence that suicides by young people were previously underreported on death certificates (Males, 1991).

To measure changes in the behavioral and emotional problems on which diagnoses are based, it is necessary to assess representative samples of populations with the same standardized procedures at different points in time. Problem rates can then be compared to measure changes, whether or not there have been changes in diagnostic criteria, categories, or willingness to make certain diagnoses. As an example, studies in the United States and the Netherlands have used the same standardized procedures to obtain CBCL and TRF ratings of different representative samples of children at intervals separated by as much as 23 years (Achenbach, Dumenci, & Rescorla, 2002, 2003a; Tick, van der Ende, & Verhulst, 2007b). In the American samples, empirically based syndromes and *DSM*-oriented scales both showed small but significant increases in problem scores in the 1980s, followed by small but significant decreases in problem scores in the 1990s. From 1983 to 2003, the Dutch samples showed small increases in some kinds of problems. For CBCLs completed by parents of 2–3-year-olds in 1989 and 2003, another Dutch study found little change over the 14-year interval (Tick, van der Ende, Koot, & Verhulst, 2007b). The percentage of children who obtained clinically deviant scores on the *DSM*-oriented pervasive developmental problems scale actually declined slightly, which argues against a general increase in autism spectrum problems.

A study in the United Kingdom (UK) compared parents' reports of problems for 15- and 16-year-olds in cohorts that were assessed in 1974, 1986, and 1999 (Collishaw, Maughan, Goodman, & Pickles, 2004). The assessment instruments differed somewhat among the three studies and only 11 problem items were similar enough for comparison across the three cohorts. Significant increases in conduct problems were found from the 1974 to the 1986 and the 1999 cohorts. Emotional problems and hyperactivity were also significantly higher in 1999 than 1974 or 1986. Although it is certainly possible that secular trends differ among countries, it is difficult to draw firm conclusions from the UK data, because of differences in the assessment instruments and because the completion rates were evidently only 62% in 1974 and 45% in 1986 (Collishaw et al., 2004, p. 1353). The 1999 completion rate was evidently not reported, but samples with high attrition rates often include smaller proportions of people with many problems than do samples with low attrition rates.

DIRECTIONS FOR CONTINUED RESEARCH

Important advances are being made in the developmental study of psychopathology, but much remains to be done. In this section, we outline directions in which assessment, taxonomy, and diagnosis can continue to advance. Although these are not the only directions, they are particularly important for extending the developmental study of psychopathology to adults, to elders, and to more diverse cultures.

Family-Oriented Assessment and Interventions

There are many studies of child/adolescent psychopathology and of adult psychopathology. Research on psychopathology among the elderly is also growing rapidly. However, there is far less research on the developmental course of psychopathology from childhood into adulthood and from adulthood into old age. Several factors may account for the dearth of research that bridges major developmental periods. One factor is that clinicians and researchers tend to specialize in work with children and adolescents, or adults, or the elderly, rather than spanning these different periods. A second factor is that concepts of psychopathology tend to be formulated separately for children and adolescents, for adults, and for the elderly. And a third factor is that assessment, taxonomy, and diagnosis tend to be segmented according to these major life periods.

To fully understand both adaptive and maladaptive functioning within each life period, as well as the continuities and discontinuities between periods, we need assessment procedures that provide continuity across broad age spans. Much of the research on prediction of adult psychopathology from childhood variables has used very different measures of child and adult problems. Because certain behaviors that are considered deviant in childhood would not be deviant in adulthood and vice versa, assessment must be tailored to the developmental level of the people assessed. However, methodologically similar assessments of similar variables for people of different ages are likely to provide better pictures of continuities and discontinuities between developmental periods than are assessments that differ with respect to both the methodology and the variables assessed. Our section on Life Span Applications illustrated some ways in which similar standardized methodology has been used to assess psychopathology across major periods of life. However, far more needs to be done to systematically compare and contrast findings for different life periods and to bridge

the gaps between them with longitudinal research. Use of similar standardized methods to assess people as they grow older makes it possible to apply accelerated longitudinal designs, which can yield developmental findings more quickly and cost-effectively than traditional longitudinal designs.

For clinical as well as research purposes, similar standardized methods can be used to assess different generations within families, such as parents and their children, to identify cross-generational similarities and differences. As an example, factor analyses of ratings of ASEBA problem items have yielded seven similar syndromes for ages 6–18 and 18–59, plus similar broadband Internalizing and Externalizing groupings of syndromes. This makes it possible to compare ratings of 6–18-year-olds and their parents on nine empirically derived scales, as well as on *DSM*-oriented scales that are similar for ages 6–18 and 18–59. The Multicultural Family Assessment Module (MFAM; Achenbach, Ivanova, & Rescorla, 2015) enables researchers and practitioners to display bar graph comparisons of scores for parents and their children on the seven counterpart syndromes, Internalizing, Externalizing, and *DSM*-oriented scales, standardized by age, gender, informant, and multicultural norms. Practitioners in child and family services can show these bar graphs to parents to highlight similarities and differences between self-reported and collateral-reported problems vis-à-vis both the parents themselves and their child. Helping parents see both the variations in problems reported for themselves and for their child and helping them identify parallels between their problems and their child's problems can greatly facilitate family-oriented services.

Multicultural Directions

Globalization has many facets. Although economic globalization may be the most publicized facet, cultural globalization is also important. Cultural globalization stems partly from increasing access to a common set of media for information and entertainment. However, it also stems from mass movements of immigrants and refugees from their indigenous societies to very different societies. Host societies are often ill prepared to provide mental health and related services to immigrants. In addition to language barriers, challenges arise from differences in attitudes toward mental health services, as well as from differences in what is deemed to be normal versus abnormal. Other challenges arise when mental health professionals from developed societies seek to help people in developing societies.

Both to build a more comprehensive science of developmental psychopathology and to use that science to help more people, it is important to use assessment instruments and data that extend across multiple societies. Our section on Multicultural Research reviewed multicultural findings for psychopathology in children and adults, using both bottom-up and top-down assessment procedures.

Quantification of Diagnostic Taxa

Nosological approaches typically require categorical yes/no judgments of each criterial feature of each diagnostic category. These approaches also require yes/no decisions as to whether an individual meets the overall criteria for a diagnosis. However, the categorical, yes/no format is not necessarily an immutable part of the nosological approach. A dimensional approach, whereby symptoms are summed to obtain a score for a diagnosis, is often viewed as the main quantitative alternative to the categorical approach. Yet, summing the number of symptoms is only one of many ways to reap the benefits of quantification for increasing precision, reliability, validity, and statistical power. For example, allowing diagnosticians to rate symptoms and other diagnostic criteria on 3-step scales rather than requiring yes/no forced choices could make the diagnostic process easier, more reliable, and better differentiated. Categorical cut points can still be retained for deciding whether an individual meets criteria for a diagnosis by specifying diagnostic thresholds in terms of the sum of three-step ratings, rather than the number of symptoms. Further benefits of quantification can be obtained by providing age, gender, and multicultural norms for the distributions of scores within each diagnostic category. For categories in which the distributions of scores differ significantly by age, gender, or society, diagnostic thresholds can be chosen to mark a similar degree of deviance for each group, if desired. Quantification can also be used to combine data from multiple sources as a basis for making diagnostic decisions.

As an alternative to dimensional approaches, person-centered quantification can be used to identify categories of individuals who have similar patterns of problems. Methods for using quantitative diagnostic data to identify types or categories of individuals include latent profile analysis, cluster analysis, and latent class analysis. A particularly important use of quantification for individual patterns is known as *patient-focused analysis*. This involves repeated measurement of individuals' scores during and after interventions to detect statistically reliable changes in magnitudes or slope parameters (e.g., Lambert, Hansen, &

Finch, 2001). In short, even elementary quantification, such as rating diagnostic criteria on 3-step scales, would enable the nosological approach to capitalize on the many benefits of quantification that have long been utilized by other approaches to assessment and taxonomy.

Use of Norms to Evaluate Interventions

Numerous studies have been designed to improve prevention and treatment of psychopathology (e.g., Kazdin & Weisz, 2003; Roberts, Kane, Thomson, Bishop, & Hart, 2003). However, when prevention and treatment are targeted on diagnoses that are assumed to reflect enduring characteristics of the individuals who meet diagnostic criteria, as implied by diagnoses such as ADHD and personality disorders, it is difficult to evaluate the effects of the interventions, because the diagnoses are not expected to change. Whether or not particular forms of psychopathology actually involve such enduring conditions, accurate evaluation of intervention effects requires measurement of change from clinical deviance toward the normal range of functioning. To determine whether interventions do produce statistically significant improvements, controlled studies are needed in which norms are used to measure the degree to which participants' preintervention scores move from being clinically deviant to postintervention scores that are more typical of representative normative samples of peers (Achenbach, 2001; Sheldrick, Kendall, & Heimberg, 2001). Because successful adaptation requires not only an absence of problems but the presence of positive competencies, the effects of interventions should be evaluated in relation to norms for competencies as well as for problems.

Use of Multisource Data

Low levels of agreement between clinical diagnoses and SDI diagnoses, as well as the modest correlations between reports by different informants for both adult and child psychopathology, indicate that no single source of data is likely to suffice for comprehensive assessment of psychopathology. Although assessment of children usually includes data from multiple informants, multi-informant data are also needed for adults. Even when multi-informant data are obtained, challenges remain with respect to documenting specific similarities and differences between reports by different informants. As an example of ways to compare reports by multiple informants, we have developed computer software that displays data from multiple informants in terms of side-by-side comparisons of item scores and bar graphs of scale scores (Achenbach & Rescorla, 2015). The software also displays the degree of agreement between informants in terms of *Q* correlations and compares the *Q* correlations obtained for each case with those obtained for large samples of informants. However, much more research is needed on how best to integrate data from different sources as a basis for decisions about diagnoses, interventions, and outcomes.

SUMMARY

Numerous advances are occurring in knowledge and methods related to developmental issues in assessment, taxonomy, and diagnosis of psychopathology. In this chapter, we defined *psychopathology* as persistent behavior, thoughts, and emotions that are likely to interfere with developmental tasks necessary for long-term adaptation. The major themes of our chapter are summarized below.

First, it has become clear that developmental approaches are needed to understand psychopathology across the life span. This means that we need assessment procedures, taxonomic models, and diagnoses geared to the problems characteristic of each developmental period. At the same time, to track developmental sequences and outcomes, continuity is needed between assessment procedures from one developmental period to another.

Second, the developmental study of psychopathology has demonstrated the importance of multisource data for adults as well as children. Research has revealed that correlations between adults' self-reports and reports by other informants are as low as those found for children.

Third, multicultural perspectives are essential. By applying the same standardized multi-informant assessment procedures in different societies, we can identify similarities and differences in patterns of reported problems to learn whether the same assessment procedures, taxonomic constructs, and diagnoses are applicable across societies. Procedures that are found to perform similarly across societies can be used to compare the course and correlates of psychopathology in different societies.

We described developmental methodology that is applicable to the study of psychopathology across the life span. Real-time longitudinal, accelerated longitudinal, path, and growth curve designs are especially useful.

We contrasted nosologically based models of psychopathology that employ a *top-down* strategy (whereby experts formulate diagnostic categories and then choose criteria for the categories) with empirically based models that employ a *bottom-up* strategy (whereby problems rated

for large samples of people are analyzed statistically to derive syndromes of co-occurring problems). We explained that *assessment* refers to gathering data to identify the distinguishing features of individual cases, whereas *taxonomic* models group cases according to their distinguishing features. Prototypes, which represent categories quantitatively in terms of sets of imperfectly correlated features, provide taxonomic models that mesh well with human information processing. We also discussed three different meanings of the term *diagnosis*: *diagnostic processes, formal diagnoses,* and *diagnostic formulations*. In this context, we suggested that the high rates of comorbidity found for *DSM* diagnoses raise questions about whether each diagnostic category truly represents a separate disorder.

To advance assessment, taxonomy, and diagnosis, we need to meet the following challenges: test–retest attenuation, i.e., the tendency for more problems to be reported at initial than subsequent assessments; limited cross-informant agreement; limited agreement between clinical diagnoses and diagnoses made from SDIs; high rates of comorbidity; great variations in prevalence rates of *DSM* diagnoses made from SDIs; the need to integrate multisource data; the need to take account of differences related to age, gender, and data sources; and the need to distinguish individual differences from cultural differences. We suggested that quantification of nosologically based constructs can help to meet many of these challenges. Quantification can also make nosologically based constructs more amenable to powerful longitudinal research designs, genetic and other biological research, and research on secular trends in psychopathology. To continue advancing the developmental study of psychopathology, we outlined directions for further research.

WHAT IS EPIDEMIOLOGY?

Epidemiology is the study of patterns of disease in human populations (Kleinbaum, Kupper, & Morgenstern, 1982). Patterns, or nonrandom distributions, of disease occur in both time and space. The task of epidemiology is to understand observed patterns of pathology along these two dimensions and to use this understanding as a basis for prevention and treatment. For example, a pattern has been observed linking exposure to environmental lead in infancy with the development of behavioral and learning problems in later years (Needleman & Bellinger, 1991). The causal relationship appears to be sufficiently strong to justify primary preventive measures to remove lead from gas and domestic paint to protect those children who might otherwise be vulnerable to such exposures (Kleinbaum et al., 1982).

Epidemiology, "an exact and basic science of social medicine and public health" (Earls, 1979, p. 256), emerged as an influential branch of medicine in the nineteenth century. Like the rest of medicine, it is an action-oriented discipline, whose main purpose is intervention to control disease, but which is also concerned with understanding causes. Epidemiology has both similarities to and differences from clinical medicine. Scientific knowledge about the cause and course of disease is one of the tools that both share. Epidemiology reflects clinical medicine also in using two methods of attack: a tactical method, concerned with the practical and administrative problems of disease control at the day-to-day level; and a strategic method, concerned with finding out what causes disease so that new weapons of control and cure can be engineered (Earls, 1980; Susser, 1973). Thus, epidemiologists can be found, in their tactical or public health role, reporting on the

prevalence of AIDS and advising on how to control its spread while simultaneously, as part of a wide strategic plan to control the disease, carrying out multicenter clinical research trials of new vaccines and treatments.

Epidemiology is also like clinical medicine in its understanding of the concept of disease in broad terms. In this chapter, we adopt the definition of *disease* as a pathological process that may have biological, psychological, and social dimensions (Kleinbaum et al., 1982; Susser, 1973). Disease in this sense includes identified syndromes of known etiology. The unifying theme is that, at some point, a decision is made that a pathological process is present in an individual, who is then regarded as a *case*. The thorny problems of case identification in child and adolescent psychopathology are discussed later in this chapter.

Epidemiology diverges from clinical medicine to the extent that it concentrates on understanding and controlling disease processes in the context of the population at risk, whereas the primary focus of clinical medicine is the individual patient. This does not mean that epidemiology is not concerned with the individual; on the contrary, it is very much concerned with understanding the individual's illness and the causes of that illness. The difference lies in the frame of reference. Put at its simplest, clinical medicine asks, What is wrong with this person, and how should I treat him or her? Epidemiology asks, What is wrong with this person, and what is it about him or her that has resulted in this illness? Why is this child depressed, but not her brother? If her mother is also depressed, is the child's depression a cause, a consequence, or an unrelated, chance co-occurrence? Such questions immediately set the individual child within a frame of reference of other children, or other family members, or other people of the same sex or race or social class. As we shall discuss later, this approach to understanding pathology has important effects on the way information is collected, the kind of information collected, the methods used to analyze it, and the conclusions that can be drawn from it.

As the study of patterns of disease distribution in time and space, epidemiology thus encompasses a great deal more than simply counting how many people have smallpox or AIDS. Epidemiology counts (Freedman, 1984), but it does far more than that (Insel & Fenton, 2005). The methods developed to count cases are useful for many purposes; for example, to estimate the need for and probable cost of mental health services or to monitor the effect of a new treatment. However, these methods provide only one part of the information needed to understand the course, causes, and prevention of disease. Figure 3.1 (Kleinbaum et al., 1982) shows how the study of disease patterns in time and space informs both public health and scientific epidemiology (Susser, 1973).

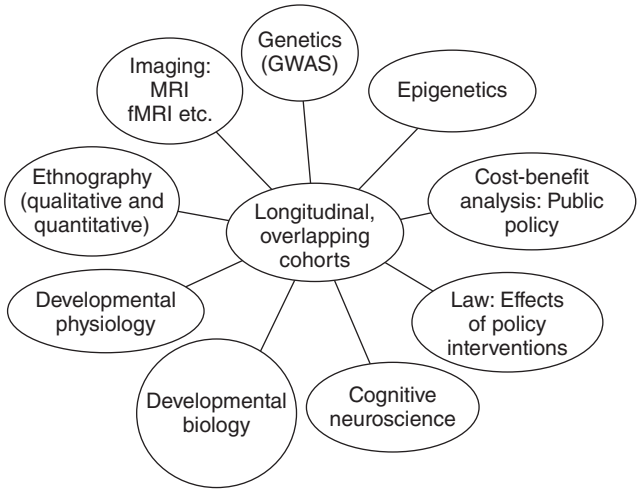

Figure 3.1 Contributions of developmental epidemiology to translational science. *Source:* Kleinbaum et al. (1982).

Scientific Epidemiology

From the strategic or scientific point of view, the issues at each level have to do with identifying the stages by which a disease progresses through its natural course, generating and testing hypotheses about causal pathways, and inventing and testing methods for prevention to be implemented by the tactical, public health arm of the health care professions. The success or failure of attempts to prevent a disorder can then provide important information about the causes of the problem. The course of disease can be divided into three stages: (1) exposure, dealing with causes; (2) disorder, dealing with the manifestation of a disease in clinical signs and symptoms; and (3) outcome, examining what leads to different outcomes for different patients. These three stages invite different kinds of preventive intervention: (1) primary, or universal, prevention tries to reduce the risk of exposure to agents promoting the disease; (2) secondary, or targeted, prevention is directed at saving those who have been exposed from developing the disease; and (3) tertiary, or indicated, prevention focuses on reducing the damage caused when people actually become ill. Tertiary prevention encompasses both reducing the residual damage from an illness and, where necessary, protecting the rest of society from harm, either through infection or from a sick person's dangerous behavior.

Although this approach to disease prevention was first articulated at a time when acute, infectious diseases such as cholera and smallpox were the chief preoccupation of epidemiology, it applies with minor modifications to chronic or episodic diseases, such as heart disease and cancer, which are the main causes of mortality in industrialized countries today. Applied to psychopathology, it also provides a model for exploring the development of psychiatric disorders (Rutter, 1990).

Public Health Epidemiology

At the tactical level, public health and primary care workers are often involved in what has been called *shoe-leather epidemiology* (Kleinbaum et al., 1982). This might take the form of tracing the pathways by which a cluster of suicides spreads through a high school or isolating the source of a neurotoxic element in the water supply, or teaching lifestyle changes to cardiac patients to reduce the risk of stress-related disease. The aim is to identify key points in the development and transmission of a disease at which intervention can act to reduce the prevalence of the disease or harm caused by it. Such interventions may be directed at preventing exposure to the causes of the disorder, at preventing the onset of the disorder in those who are vulnerable to it, or at minimizing death rates or residual impairment in those who survive. Taking depression as an example, primary prevention might include antibullying programs in schools; secondary prevention might be directed at the children of depressed parents, who are known to be a high-risk group (Clark et al., 2002); and tertiary or indicated prevention might examine the ability of adequate treatment to prevent relapse.

There is a great deal of interchange between the public health aspects and the scientific aspects of epidemiology, and also between different levels of investigative and preventive effort. At each of these levels, both strategic and tactical efforts are needed. Indeed, the real-world nature of epidemiology means that the answers to many scientific questions, such as the paths of disease transmission, have at some stage to be tested by regarding a preventive intervention as a scientific experiment. The classic example is the story of how John Snow (1855), by having the handle removed from the Broad Street water pump during the 1853 cholera epidemic in London, tested his hypothesis that (1) cholera was caused by an invisible, self-reproducing agent living in water; (2) the agent flourished in water heavily contaminated with sewage; and (3) therefore, if a community drawing its water from a contaminated supply was forced (by his action in disabling the pump) to use water from a different water company, drawn from a purer source, the rate of disease would fall.

CHARACTERISTICS OF RESEARCH IN PSYCHIATRIC EPIDEMIOLOGY

Epidemiology, as this brief introduction demonstrates, is less a body of substantive knowledge than it is a way of looking at problems. The great historical victories over infectious diseases and the recent achievements in helping to reduce mortality and morbidity from chronic illnesses such as cardiovascular disease (Dawber, 1980) came as a result of looking at clinical problems in a new way. Here we introduce the basic requirements for studying the epidemiology of any disorder (Kleinbaum et al., 1982) and discuss their implications for developmental psychopathology.

Epidemiologic research presupposes the ability to (1) measure disease frequency in the population of interest; (2) make valid generalizations from samples to populations, that is, to avoid sampling or ascertainment bias; and (3) measure the impact of risk factors on disease without confusion among multiple competing risks, that is, to avoid confounding among risk factors. We discuss each of these challenges in turn.

Measuring the Frequency of Disease

The question of how many people exposed to a risk factor for a disease actually become sick, how many avoid disease, and how many die or recover is central to epidemiological research. The most frequently used measures involve the concept of a rate, "an instantaneous potential for change in one quantity per unit change in another quantity" (Kleinbaum et al., 1982, p. 100). Timing is implicit in the idea of a rate. Epidemiology deals most often with incidence rates, which measure the extent to which new cases of a disorder appear in the previously healthy population over a specified period of time, and prevalence rates, which measure all the cases, whether new or previously existing, observed during a specified period. Usually, the epidemiologist is concerned with relative rates of disease onset in two or more groups of people who differ on exposure to a risk or preventive factor. For example, in a Swedish study, the prevalence of drunkenness in adolescence among girls who reached menarche earlier than the norm for the population was found to be high, relative to the rate found in girls of the same age whose menarche occurred within the normal age range (Stattin & Magnusson, 1990). Relative rates thus become the metric for answering questions about a

possible causal role played by putative risk factors in the onset of disorder. In this example, Stattin and Magnusson found that, at age 14, 75% of girls who had reached menarche before age 11 had been drunk at least once, compared with only 29% of girls who reached menarche after age 13. Furthermore, the rate of frequent drunkenness remained higher across adolescence for early than for later maturing girls. This led to speculations about the mechanism by which early puberty could put girls at risk (Moffitt, Caspi, Belsky, & Silva, 1992).

Defining a Case

In any context where decisions have to be made leading to action to prevent or treat illness, categories have to be created. Making a diagnosis means putting an individual into a category: "Has Disorder X" or "Does not have Disorder X." Even if the goal is to eliminate a risk factor that potentially affects everyone in the community, such as environmental pollutants or unsafe automobiles, it is still necessary to define categories of affected and nonaffected individuals to measure the effectiveness of a primary prevention or to calculate costs and benefits. For example, how many cases of learning disability were prevented by reducing environmental lead? How much does it cost to prevent one case of learning disability, and how much is saved by doing so?

The relationship among symptoms, diagnosis, and the concept of disease has exercised many brains (Meehl, 1992; Pickles & Angold, 2003). A diagnosis encapsulates a mixed bag of information: the number and severity of symptoms, the duration of symptomatology, the date of onset, the likelihood of exposure to a causal factor, and the level of functional impairment. All of these have implications for a decision about whether intervention is indicated. For some forms of pathology, there is little ambiguity about how the diagnosis should be made; either it is fairly self-evident, like a broken bone, or the rules have been sanctified by use, like the stages of cervical cancer, or there is a clearly identifiable pathogen that acts as a marker for the disease, as in tuberculosis. Few types of psychopathology can invoke any one of these as a decision rule for diagnosis. There are no reliable pathognomic markers; the boundaries between one disorder and another, or between normality and disorder, are generally ill defined (Pickles & Angold, 2003), as Kendell (1976) demonstrated in his classic exploration of the boundaries of depression. Classification systems arise and pass away, while older classifications may still retain some of their sway. To confuse matters further, psychiatry often makes use of familiar language in its diagnostic terminology (e.g., *depression, anxiety*), not necessarily in the vernacular meaning of the term. In his review of childhood depression, for example, Angold (1988) identified eight different ways the term depression is used in the description of psychopathology:

- As the low end of normal mood fluctuations
- As a description of psychic pain felt in response to some unpleasant situation
- As a trait
- As an individual symptom
- As a syndrome
- As a disorder
- As a disease
- As a cause of handicap or disability

The implications for treatment are likely to differ depending on which definition is being used.

Taxonomy, Instrumentation, and Mechanisms

In identifying cases of a disorder, it is important to distinguish between the problems that can be solved by a well-designed diagnostic instrument and those that have to be solved at the level of the taxonomic system that defines what a case is (Meehl, 1992; Wing, Bebbington, & Robins, 1981). Robins (1989), for example, using both clinical and epidemiological methods, presented evidence that some *DSM* disorders are consistently diagnosed more validly (using several criteria of validity) than others. This, Robins believed, suggests that "part of the source of invalidity lies in the diagnostic grammar of the systems whose criteria standardized interviews evaluate" (p. 57). She used the phrase *diagnostic grammar* because "[diagnosis] is much like a language. The criteria include elements that have special relations to each other like parts of speech—symptoms (nouns?); severity (adjectives?); clustering (verbs?); age of onset, frequency, and duration (adverbs?)" (p. 61). If the grammar is wrong, the sentence will not make sense, however clearly it is articulated. Much of the process of developing a good diagnostic grammar is carried out through careful clinical work. Epidemiology, however, can contribute in several ways. It provides feedback about the relationship between symptom patterns seen in clinical and community samples, which can throw light on possible biases affecting the results (see later discussion). It can also provide information about the prevalence of different disorders in the community, and their patterns of distribution by age, sex, and so on. This information can then influence clinicians' expectations about the relative likelihood that a given patient has one disorder rather than another.

In practice, it is well known that physicians make diagnostic judgments on the basis of very few items of information (Cantwell & Baker, 1988; Meehl, 1954). Good prevalence information can be a very important part of the clinician's database.

Psychiatric epidemiologists have long been active collaborators with clinicians in the work carried out around the world to improve psychiatric taxonomies (Robins, 1989). However, the task facing psychiatric epidemiology is even more difficult than that facing clinical psychiatry. The clinician can assume a certain level of suffering in a patient who has come seeking help; the problem is to figure out exactly where the suffering lies. Epidemiologists, working most of the time in the community, have to identify cases among people most of whom are not seeking treatment. They have to convince themselves and others that the criteria they use are valid: that a clinician would identify this as a case of a given disorder whether or not the individual came seeking treatment. They also have to distinguish between the normal range of feelings and psychopathology; between, for example, what Freud described as *hysterical misery* and *common unhappiness* (Breuer & Freud, 1895).

For child psychiatry, this problem of case definition is even more complex. Children rarely refer themselves for treatment, even when severely symptomatic. Thus, the rule of thumb that equates illness with seeking treatment is even less accurate for children than it is for adults. Referral for treatment may have more to do with characteristics of a child's mother, teacher, or pediatrician than with the child's own behavior or feelings (Costello & Janiszewski, 1990; Dulcan et al., 1990; Shepherd, Oppenheim, & Mitchell, 1971).

A third aspect of case identification is the discovery of mechanisms that underlie the development of psychiatric disorders. These mechanisms exist at many different levels, from genes to brain structure and functioning. Despite much exciting progress in identifying mechanisms (discussed later), none is yet ready for use in everyday clinical or epidemiologic diagnosis. Child psychiatry is still largely dependent for case identification on inferences from responses to verbal questions.

Using Question-and-Answer Methods to Identify Cases

Psychiatry confronts two problems that make it particularly difficult to develop reliable and accurate measures of symptoms and diagnoses using question-and-answer methods. One is that no gold standard measures can be used to evaluate the accuracy of a test (Angold et al., 2012): a postmortem or magnetic resonance image (MRI) will not tell us whether a child really has separation anxiety disorder. The second problem is with the standard procedure for assessing the reliability of a question-and-answer measure. This is known as the test–retest reliability procedure, which uses two interviewers to interview the same subject on two different occasions about the same period of time. Whereas one can take someone's temperature repeatedly without appreciably altering body temperature, interviewing someone at length about emotionally sensitive topics can hardly be done without affecting how the individual thinks or feels about these issues. The first interview is thus likely to affect how the subject responds to the second interview. For example, in a test–retest study in which children were interviewed twice, we found that boys who, at the first interview, admitted that they told a lot of lies, were much more likely than other boys to deny, at the second interview, other kinds of deviant behavior to which they had previously admitted (Angold & Costello, 1995). However, a lot is now known about how to improve accuracy in child psychiatric interviewing, and current methods are remarkably reliable (Shaffer, Lucas, & Richters, 1999).

Classifying Cases in the Clinic and the Community

The problem of equating cases found in community studies with referred cases has been addressed in several ways in child psychiatric epidemiology. First, diagnostic instruments have been developed that meticulously translate clinical diagnostic criteria into methods for identifying the same symptoms in nonreferred cases (Angold & Costello, 2000; Chambers et al., 1985; Costello, Edelbrock, Kalas, Kessler, & Klaric, 1982; Herjanic & Campbell, 1977; Hodges, McKnew, Cytryn, Stern, & Kline, 1982; Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000).

Second, most measures for community use now include, or are used with, measures of functional impairment so that the relationship between symptoms and a child's ability to carry out the normal tasks of daily life can become the subject of empirical review (Canino, Costello, & Angold, 1999). At the same time, current attempts to classify psychiatric disorders into a coherent taxonomy have adopted a multiaxial system by which a clinician is encouraged to describe the patient from several points of view, of which psychiatric diagnosis is only one (American Psychiatric Association, 1994, 2013; Rutter et al., 1969, 1979). Several current epidemiological assessment instruments adopt the same multiaxial approach (Angold & Costello, 2000).

Third, the psychometric studies that are carried out as part of the process of instrument development include

studies of referred and nonreferred samples and interviews using both clinicians and trained lay interviewers. Instruments can then be revised so that caseness has the same meaning wherever or by whomever a child is recruited or assessed.

Developmental Issues in Case Identification

One reason why establishing rates of disorder is even more of a problem for child psychiatric epidemiology is that there is a need to reconcile a nondevelopmental psychiatric taxonomy, such as the *DSM* system, with the realities of child development. The *Diagnostic and Statistical Manual, 5th Edition* (*DSM-5*) includes a section on the development and course of each diagnosis that replaces the previous edition's sections on course. However, *DSM-5* uses *development* to refer to the developmental course of the illness, not of the individual. It sticks closely to an implicit medical model according to which a disease, although it has a developmental course along the lines sketched earlier, is defined as a disease by virtue of the fact that every case has roughly the same etiology, pathogenesis, risk factors, presentation, course, and treatment response. Measles is measles is measles. For example, the diagnostic criteria for *DSM-5* major depressive episode are described as being similar in their essential features in children, adolescents, and adults (American Psychiatric Association, 2013); the only differences specified are additions to two of the symptoms: (1) depressed mood. "In children and adolescents, can be irritable mood" (p. 160) and (3) significant weight loss or weight gain. "In children, consider failure to make expected weight gain" (p. 161). Apart from the statement that "the likelihood of onset increases markedly in puberty" (p. 165), no reference is made to any aspect of children's cognitive, social, and bodily development that might influence a child's ability to experience or respond to different symptoms. Neither the similarities nor the differences specified by the *DSM* have a firm basis in developmental data about the manifestation of depression at different stages of life (Angold & Worthman, 1993; Cicchetti & Schneider-Rosen, 1984, 1986; Costello et al., 2002; Digdon & Gotlib, 1985; Ladouceur, Peper, Crone, & Dahl, 2012).

Since 2009, the National Institute of Mental Health has been working on a new way to classify mental illnesses by linking the various layers of systems that contribute to mental function. Called the Research Domain Criteria (RDoC), the goal is to cut across traditional diagnostic categories to identify relationships between behavior and neurobiology. It is too early yet for epidemiologic studies to incorporate RDoC measures, but this is likely to be an important pathway for the future.

In summary, epidemiology shares with clinical psychiatry a concern for and involvement in the problems of case identification. These problems occur at two levels: the level of defining the characteristics of a disorder and the level of developing methods for identifying those who have the disorder so defined. Arguments about the reliability and validity of psychiatric assessment have frequently confused these two levels, as Robins (1985) so clearly demonstrated. Only when we can plainly describe the causal pathway for each disorder, from exposure through onset to outcome, as in Figure 3.1, will we be in a position to be satisfied with the validity of our taxonomy and the reliability of our diagnostic tools.

Ascertainment Bias in Case Identification

Once researchers are able accurately to identify cases of the disorder of interest, the next concern is to ensure that the sample of cases that they recruit for research purposes accurately represents the distribution of cases in the community. This is important because the relationship between the disorder and its putative risk factors needs to be the same in the sample as in the general population. It is the nature of epidemiological research that questions of causality can rarely be answered by laboratory studies in which all but the key variable are carefully controlled or randomly varied. It is not feasible to test the causal role of poverty, for example, by randomly assigning newborns to be raised in high- and low-income households, or the role of maternal temperament by the sort of cross fostering studies that are considered ethical with other primates (Suomi, 1991). One way to compensate is to pay very careful attention to the characteristics of the population from which the study samples are drawn; that is, not only to the numerator of a rate of disease (the number of cases within a given period) but also to the denominator of the rate (the population at risk). Only when we know that the sample selected for study accurately mirrors the population from which it is drawn (or when we know exactly what the biases are and how to control for them) can we specify exactly to whom our causal analyses apply.

This necessity usually rules out samples of convenience and mandates very careful thought about the choice of population for a study. For example, if the question has to do with the causal role played by the peer group in adolescent delinquency, and the sample consists of young people recruited from tenth-grade classrooms, neither the denominator nor the numerator can, by definition, include

persons who have dropped out of school. Thus, the conclusions about causal processes that can be drawn from such a study are limited to those relevant to tenth graders who attend school, not to the age group in general. Because dropping out of school and delinquency are known to be associated, the selection of a school-based sampling frames results in a sample that may be biased in important ways.

The problem of ascertainment bias is even more acute when clinic-based samples are used. There are many reasons people get into treatment, and reasons they do not; these may mislead the researcher trying to understand risk factors for disease. For example, Berkson (1946) used Mayo Clinic records to show that, among people with two illnesses, "each disease is itself aggravated in its symptoms and more likely to be noted by the patient … [the] effect would be to increase relatively the representation of multiple diagnoses in the hospital and in general to increase the discrepancy between hospital and parent population" (p. 50). This led to a spurious belief that cholecystic disease was causally related to diabetes, when in fact, in the general population the association between the two diseases was zero.

Berkson (1946) argued from these analyses that it is more cost-efficient to carry out representative community studies earlier rather than later in the process of studying comorbidity and etiology because bias-free studies have to be done at some point in any case. Meehl (1992) also pointed out that millions of dollars of tax money have been wasted performing studies in clinical settings where the biases inherent in case selection mean that the studies cannot answer the questions about causal association that they are designed to address.

The danger of ascertainment bias is one reason why many epidemiological studies use samples that are carefully selected to be representative of the general population. The disease of interest may be quite rare in the community, which often means that the case-identification stage of such studies is expensive; large numbers of people must be surveyed to identify a relatively small number of cases. With child psychiatric disorders, the issue is compounded because reports from different informants—parents, children, teachers, peers—may identify very different children as cases (Achenbach, McConaughy, & Howell, 1987; Foley et al., 2004, 2005). Depending on the question being studied, it may be necessary to interview three or more people to establish whether a child is or is not a case according to the study criteria. The risk factors for a disorder identified by one informant may also be quite different from the risk factors for the disorder as identified by another informant. For example, in a study of children with symptoms of hyperactivity, inattention, and impulsivity (Costello, Loeber, & Stouthamer-Loeber, 1991), 61% of children identified as hyperactive by both parents and teachers were boys; however, boys made up 77% of children identified as hyperactive by teachers alone but only 38% of children identified by mothers alone.

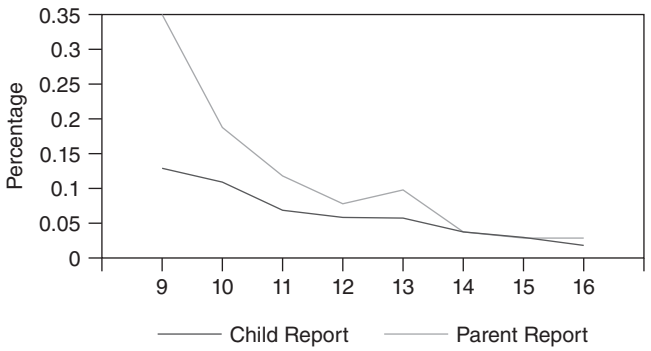

Figure 3.2 Mean separation anxiety symptoms by age and source of information.

For the researcher interested in developmental influences on the expression of psychopathology, the situation becomes even more complex. For example, Figure 3.2 shows the rate of separation anxiety symptoms reported by children between the ages of 7 and 16 and by parents about their children. The parents' report data showed low rates of symptoms and a modest effect of the child's age on the rate of symptoms. The rate of symptoms reported by the children, in contrast, fell sevenfold as the age of the child increased. If the purpose of the study had been to select a sample of cases of separation anxiety disorder, the bias caused by relying exclusively on one informant or the other would have varied depending on the age of the children surveyed.

Controlling Bias in Estimating the Influence of Risk Factors

The third set of threats to the validity of a causal link has to do with competing risk factors or confounders. In most etiological studies, more than one risk factor is involved. The problem is to figure out the relative importance of various risk factors so that decisions about intervention can be focused where they will be most effective. It is useful to distinguish between two distinct characteristics of factors that influence the probability of disease: confounding and effect modification (Miettinen, 1974).

Confounding distorts the impact of a risk factor on the risk of disease because of the presence of some extraneous variable. A factor may act as a confounder in one study but not in another. Consider, for example, two groups

at high and low levels of genetic risk for a disease that is also affected by poverty. If everyone in one group was at high genetic risk, a real relationship between poverty and disease might be obscured in that community; almost everyone who was poor would also be at genetic risk, so it would not be possible to say which factor was causing the disorder. In the second community, where not all the poor were at high genetic risk and not all the group at high genetic risk were poor, it would be possible to look separately at the rates of disorder in four groups (poor nonaffected, rich nonaffected, poor affected, rich affected) and figure the risk associated with poverty.

Effect modification, or synergy, refers to the different impact of a risk factor at different levels of another variable (Rothman, 1976). This relationship is not specific to any particular study; it is a real relationship among two or more risk factors. For example, if both the gene for phenylketonuria (PKU) and a diet high in phenylalanine are necessary for PKU to occur, rates of the disorder will vary in different communities depending on how many people inherit the gene and how many eat a high-phenylalanine diet. The relationship between gene and diet remains constant across sites, but diet will act as an effect modifier, controlling the expression of the gene. Another example is the relationship among peak height velocity (PHV, the growth spurt of early adolescence), change of school, and depressive symptoms. The period of PHV may be a time when youngsters are particularly vulnerable to symptoms of depression (Simmons & Blyth, 1987), particularly when they have to deal with stressful events. It happens that, in the American school system, most children move from middle school to high school between eighth and ninth grades. This coincides with the time when many girls, but few boys, are at PHV. School change could thus be acting as an effect modifier, increasing the risk of depression in girls but not in boys.

Clinical as well as epidemiologic research has to deal with confounders and effect modifiers. Lively debates are in progress about whether and how to derive causal inferences from observational studies with many potential confounders (Kaufman & Cooper, 1999; Pearl, 2013; Robins, 2000). Sometimes it is possible to narrow down the list of potential causes using careful study design. When standard experimental designs are inappropriate or infeasible, quasi-experimental methods may be found that reduce the risk that cases and noncases differ not only on the putative risk factor but also in lots of other ways (Shadish, Cook, & Campbell, 2002). For example, in our study of all 9-, 11- and 13-year-old American Indian children living on a federal reservation, it happened that after we had assessed the children for four years, a casino was opened that gave every enrolled tribal member a sizable income supplement. After another four years, we looked at children's psychiatric symptoms before and after the intervention. We found that children whose families moved out of poverty had reduced conduct disorder symptoms but that the intervention had little effect on depression, anxiety, or attention-deficit/hyperactivity disorder (ADHD; Costello, Compton, Keeler, & Angold, 2003). Because every man, woman, and child on the reservation received the income supplement, there was no possibility that the effect of an increased income could be confounded with the sort of qualities (e.g., hard work, thrift) that could cause both an income increase and a reduction in behavioral symptoms.

The other set of methods to deal with competing risk factors is statistical. Epidemiologists have always been careful to make it clear that nonexperimental studies can show associational but not causal relationships between risk factors and outcomes. They are, however, coming closer to claiming the ability to talk about *causal associations* (Robins, 1997, 2000). Some have gone so far as to claim that properly designed observational studies can produce results that are superior to those based on experimental designs because they often have a level of ecological validity that experimental studies lack (Benson & Hartz, 2000; Hernán, Hernández-Díaz, & Robins, 2013).

The idea that some effect modifiers could operate as protective factors has been widely discussed (Garmezy, 1988; Loeber, Farrington, Stouthamer-Loeber, Moffitt, & Caspi, 1998; Stouthamer-Loeber, 1993). As Rutter (1985) pointed out, there are logical problems in identifying something as a protective factor, except in the presence of a risk or vulnerability; the concept of protection implies the presence of risk. However, in terms of Figure 3.1, it is reasonable to talk about protection from risk factors for a disease.

Measuring the Impact of Risk and Protective Factors

One implication of this discussion of risk factors is that it is possible to rank risk (and protective) factors in terms of their relative importance to the rate of an observed disorder, and thus to make decisions about the most cost-efficient preventive strategies. There are several ways to calculate the importance of a factor's contribution to the prevalence of a disease. Two of these are risk ratio or relative risk and excess or attributable risk. Relative risk is a ratio comparing two risks of disease, often, the risk of a disease in a group exposed to a risk factor compared with the risk in a nonexposed group (e.g., the risk of depression in children of divorced parents compared with the risk to children in intact families). Attributable risk is

an estimate of the extra cases of disease (above the rate in the nonexposed population) attributable to exposure to a particular risk factor. Attributable risk is a function of two factors: the relative risk in groups exposed and not exposed to the risk factor and the frequency of the risk factor in the population. Thus, even if the relative risk associated with a risk factor is high, the attributable risk, and thus the decrease in incidence of the disease if that risk factor were removed, may be low if the proportion of people in the population exposed to that risk factor is low. For example, there might be a high relative risk for lung cancer associated with exposure to a chemical used only in one particular industry, but the attributable risk would be low if only a few people worked in that industry and were exposed to that chemical. From a public health viewpoint, a greater reduction in the number of cases of lung cancer might be achieved by removing a risk factor with a lower relative risk but to which more people are exposed; for example, asbestos or cigarette smoke (Lilienfeld & Lilienfeld, 1980; Rothman, 1976). Measures of relative risk are particularly important for the scientific aspect of epidemiology because they are a way of estimating the causal impact of risk factors. Measures of attributable risk are of particular interest from the practical point of view because they can generate an estimate of the impact of a risk or protective factor in real or proportional terms.

This discussion of causality begs an underlying question: Does it make any sense to think about human behavioral development in terms of continuity and causes? Some developmental psychologists have argued that prediction is not only difficult but also is unnecessary for the study of psychopathology (Lewis, 1990). Epidemiology has not adopted this approach; on the contrary, it has put its money on its ability to control disease through the prediction of causal pathways, and historically this has been an immensely successful bet. The interesting question is whether it is an approach that will prove to be as effective in the area of developmental psychopathology as it has been for infectious diseases.

Summary

In this section, we discussed three functions of epidemiology: (1) to measure disease frequency and risk exposure; (2) to make valid generalizations from samples to populations; and (3) to control bias in relating risk factors to disease. The next question is whether, and how, the methods and ideas that have evolved over the past century, primarily to tackle infectious diseases, can be adapted to the moving target that is developmental psychopathology.

WHAT IS DEVELOPMENTAL EPIDEMIOLOGY?

Epidemiology is inherently a developmental discipline, as shown in Figure 3.1, in the sense that it is concerned with the development of disease and how to intervene in that process. However, we talk about developmental epidemiology as a special variety of epidemiology when we are dealing with child psychopathology. The reason is that in this case, we have to take account of another developmental model: the model that describes the development of the individual. From this point of view, developmental epidemiology can be seen as concerned with the interaction between two developmental processes: of the organism (the child) and of the disease. The importance of understanding this interaction was pointed out by Anna Freud (1965; see also Cicchetti, 1990a; Rutter, 1988), but her view of what develops was somewhat different from the view of both developmental psychology and developmental psychopathology today. In this chapter, our use of the concept of development, which follows that of developmental psychology and biology, will be familiar to developmentalists but may carry different implications for child psychiatrists and pediatricians trained to use the term development either in the context of psychodynamic theories of personality (Dare, 1985) or in reference to specific, mainly physical or cognitive, stages of development (American Psychiatric Association, 1994). For clarification, we offer a brief review of what we understand by development.

The Concept of Development

Earlier in this chapter, we discussed epidemiology as a scientific method of understanding the development of disease (Figure 3.1). This approach shows marked similarities with the way the word development is applied to biological organisms (Hay & Angold, 1993). As Nagel (1957, p. 15) defined it:

> The concept of development involves two essential components: the notion of a system possessing a definite structure and a definite set of preexisting capacities; and the notion of a sequential set of changes in the system, yielding relatively permanent, but novel increments not only in its structure but in its modes of operation.

The process of disease progression has much in common with development: It is programmed by the nature of the transformation of the organism that begins the process, and in general it follows a reasonably regular course, although with wide variations in its rate. Furthermore, there is hierarchical integration as diseases develop. Each stage in the

progress of a given disease builds on the previous stages, and many of the manifestations of earlier stages are integrated into later symptomatology.

This has much in common with the idea of *epigenesis,* as developed by Gottlieb (1991a). Individual development is characterized by an increase of complexity of organization (i.e., the emergence of new structural and functional properties and competencies) at all levels of analysis (molecular, subcellular, cellular, and organismic) as a consequence of horizontal and vertical coactions among the organisms' parts, including organism–environment coactions. Horizontal coactions are those that occur at the same level (gene–gene, organism–organism), whereas vertical coactions occur at different levels (cell–tissue, behavioral activity–nervous system) and are reciprocal, meaning that they can influence each other in either direction, from lower to higher or from higher to lower levels of the developing system.

For example, the genome controls cell structure, but environmentally induced cytoplasmic changes are capable of switching genes on and off (Ho, 1984; Jollos, 1934); neural differentiation in the mammalian visual cortex is dramatically affected by sensory experience (Black & Greenough, 1986); and neuroendocrine mechanisms are powerfully influenced by sociocultural factors (Mineka, Gunnar, & Champoux, 1986; Worthman, 1987). Recent longitudinal epidemiologic studies showed that a functional polymorphism in the gene encoding the neurotransmitter-metabolizing enzyme monoamine oxidase A (MAOA) moderated the effect of early maltreatment so that maltreated children, if they owned the allele conferring high levels of MAOA expression, were less likely to develop antisocial problems in adolescence (Caspi et al., 2002; Kim-Cohen et al., 2006). Thus, the concept of development used here (1) presupposes change and novelty, (2) underscores the importance of timing in behavioral establishment and organization, (3) emphasizes multiple determination, and (4) leads us not to expect invariant relationships between causes and outcomes across the span of development (Cacioppo & Tassinary, 1991; Cairns, 1991).

Behavior is seen as resulting from the dynamic interaction of multiple interdependent systems in both the individual and the environment. As summarized by Eisenberg (1977), "The process of development is the crucial link between genetic determinants and environmental variables, between individual psychology and sociology." It is characteristic of such systems that they consist of feedback and feed-forward loops of varying complexity. Organism and environment are mutually constraining, however, with the result that developmental pathways show relatively high levels of canalization (Angoff, 1988; Cairns, Gariépy, & Hood, 1990; Gottlieb, 1991b; Greenough, 1991; McGue, 1989; Plomin, DeFries, & Loehlin, 1977; Scarr & McCartney, 1983). For example, consider the well-established path to substance abuse (Kandel & Davies, 1982):

$$\text{Beer or wine} \rightarrow \text{Cigarettes or hard liquor} \rightarrow \text{Marijuana} \rightarrow \text{Other illicit drugs}$$

It is characteristic of this pathway that the number of individuals at each level becomes smaller but that those at the higher levels continue to show behaviors characteristic of the earlier stages. Having described such a pathway, the task is to understand the process by which it is established and to experiment with preventive strategies appropriate to the various stages of the developmental pathway. Such strategies must be appropriate to the developmental stage of both the individual at risk and the disorder.

Research based on this view of development has been going on for several decades, as these volumes attest, but has taken some time to influence child psychiatric epidemiology (Angold & Costello, 1991; Bale et al., 2010). Conversely, until recently developmental psychopathology has paid less attention to some of the key concerns of epidemiology—in particular, the importance of representative samples and controls for confounding. But this is beginning to change.

Implications of a Developmental Approach to Child Psychiatric Epidemiology

Child psychiatry, in its current manifestation in the United States, has modeled its nosology and its concepts of health and disease on adult psychiatry, using the same nomenclature and static assumptions about causality, risk factors, course, and outcome. But children are not scaled-down adults, and this approach causes serious problems for the epidemiologist concerned with explaining patterns of disease distribution in the community. Why, for example, do rates of depressive disorders, which are low in prepubertal children of both sexes, continue low in postpubertal boys but rise very sharply in postpubertal girls (Angold, 2003; Angold, Costello, Erkanli, & Worthman, 1999)? Is the increase causally associated with age, or with pubertal status, or with something else entirely? To understand these phenomena, it seems reasonable to postulate that children are organisms developing at a different rate from adults, organisms in whom developmental changes dramatically alter both the ways they can manifest their

genetic endowment and the nature of their interactions with their surroundings. Here we consider the implications of some basic principles of developmental theory for the epidemiology of child psychiatric disorders.

Implication 1: Development Implies Change

This may seem to be an obvious statement, but child psychiatric epidemiology has not always taken the idea of change very seriously. This is partly the result of the current systems for the classification of diseases, which are essentially nondevelopmental. Most disorders have definitions that take no account of age or developmental level, sometimes in spite of overwhelming evidence that age-dependent changes are a central feature of the phenomenology of the disorders involved. Conduct disorder is a good example. Loeber and colleagues (Loeber & Homish, 2005; Loeber, Keenan, & Zhang, 1997) identified three different developmental pathways involving antisocial behavior. If a cross sectional, snapshot view was taken of behavior at any point in time, children who pursued any of these three pathways shared many characteristics. Longitudinal studies, however, revealed different patterns. Children who followed the authority conflict path tended to show conduct problems early in life, to have trouble at school because of hyperactivity and learning difficulties as well as conduct problems, to explore a wide range of different deviant behaviors, and to remain deviant well into adulthood.

Some of the same behaviors could be found in other children at any given time, but a second group of these followed a different, covert pathway, with a higher remission rate. These children tended to have started showing deviant behavior later in childhood than the first group and to have had fewer problems at school or with peers. Longitudinal studies also suggested the existence of a third group who, like the first, were aggressively deviant in adolescence but who showed little or no early conduct disorder. The evidence for these different developmental patterns has been pieced together from a multitude of different studies, using both clinical and population samples, and is much stronger for boys than for girls (Loeber & Baicker-McKee, 1990). The *DSM,* in contrast, ignores strong evidence that conduct disorder in children is a precursor of antisocial personality disorder in adults (Robins & Price, 1991; Robins & Wish, 1977), to the extent of coding conduct disorder on Axis I (Clinical Disorders) and adult antisocial personality disorder on Axis II (Personality Disorders and Mental Retardation).

Questions about development and change can be addressed using methods developed to identify developmental trajectories (Land & Nagin, 1996; Nagin & Tremblay, 2001). These methods have been used, for example, to show that there are important differences between children who show persistent, rather than time-limited, conduct problems (Nagin & Tremblay, 2001) or obesity (Mustillo et al., 2003).

Implication 2: Development Is Goal Directed

If we accept what Ernst Mayr (1982) called the biological metaphor or heuristic of development, then we accept a teleonomic, goal-directed explanation as part of that metaphor. In Mayr's words:

> A physiological process or a behavior that owes its goal-directedness to the operation of a program can be designated as teleonomic. All the processes of individual development (ontogeny) as well as all seemingly goal-directed behaviors of individuals fall in this category, and are characterized by two components: they are guided by a program, and they depend on the existence of some endpoint or goal that is foreseen in the program regulating the behavior. Each particular program is the result of natural selection and is constantly adjusted by the selective value of the achieved endpoint. (Mayr, 1982, p. 48)

Teleonomic activities are distinguished by Mayr from other types of teleological processes—most important, for our purposes, from those performed by adapted systems (e.g., the cardiovascular or respiratory systems) that owe their adaptedness to a past selectionist process (Hay & Angold, 1993).

A teleonomic approach has particular advantages for developmental epidemiology, given its concern with disease elimination and service provision. It enables us to conceive of disease states in terms of inability to achieve one or more of the goals of development, and it points preventive efforts in the direction of those situations in which a particular process or task seems to be particularly salient at a certain phase of life. For example, Sroufe and Rutter (1984, p. 22) outlined "a series of developmental issues . . . based on the collective experience of numerous developmentalists . . . cutting across affective, cognitive, and social domains":

> Age 0–1: Biological regulations; harmonious dyadic interaction; formation of an effective attachment relationship.
> Age 1–2.5: Exploration, experimentation, and mastery of the object world (caregiver as secure base); individuation and autonomy; responding to external control impulses.
> Age 3–5: Flexible self-control; self-reliance; initiative; identification and gender concept; establishing effective peer contacts (empathy).
> Age 6–12: Social understanding (equity, fairness); gender constancy; same-sex chumships; sense of "industry" (competence); school adjustment.

Age 13+: "Formal operations" (flexible perspective taking; "as if" thinking); loyal friendships (same sex); beginning heterosexual relationships; emancipation; identity.

Sroufe and Rutter's (1984) list has two major implications for epidemiology. First, it implies that if we want to prevent, for example, conduct disorder, we need to define the goal of orderly conduct and the various systems (affect, cognition, impulse, and muscular control) that are most involved with regulating conduct at different developmental stages. This means that we need research to address such questions as the following: Do children who have achieved the goal of forming secure attachments around 1 year of age find behavioral control at age 5 easier than insecurely attached children (Greenberg, Speltz, & DeKlyen, 1993; Lyons-Ruth, 1996)? Intervention designs can be used to test a hierarchical, causal relationship among the various stages (see Cicchetti, 1990b; Cicchetti & Toth, 1992 for a more detailed discussion of this point).

A second, linked implication is that pathology that looks very different at different stages may be causally linked; for example, the *anxious attachment* of a 1-year-old may be causally linked to the emotional lability and superficial friendliness of the same child at age 5 and to an inability to form lasting intimate relationships as an adult. If this were the case, then, from a public health point of view, efforts to support secure attachments in infants would be justified, not just by the manifest anxiety of some 1-year-olds but also by the chance of preventing the social disruption caused by those same children as adolescents and adults.

Implication 3: The Goal of Development Is Normality

Normality is a state not requiring intervention. We would argue the value for developmental epidemiological research of taking the position that the goal of development is normality. That is, among the multiple outcomes of any developmental process there exists a wide range that are not likely to cause a child any serious problems in moving to the next developmental phase or task; any of these outcomes should be defined as normal. Normality and pathology in an epidemiological context can thus be defined in terms of decision making: Is some sort of intervention indicated?

In this respect, epidemiology moves along a different track from much of developmental psychopathology. The latter has tended to adopt the viewpoint of developmental psychology, that many phenomena of interest are best measured on some sort of continuous scale, representing a hypothesized underlying distribution of symptoms or capacities in the population. This makes sense for disciplines whose aim is to map out the pathways by which children's thoughts, feelings, and actions change over time under different internal and external controls (Pickles & Angold, 2003). The specific concern of epidemiology, however, functioning as it does at the interface between scientific understanding and public health, is with those patterns of thought, feeling, and action about which something must be done at a given stage for the sake of the child's present or future well-being or in response to pressures from families, schools, or society in general. Thus, we define a developmental abnormality from an epidemiological point of view as a state in which intervention is indicated, and normality as a state in which intervention is not indicated. These definitions do not necessarily require that an intervention be available or effective, only that pathology has a social meaning as well as a medical and a developmental one, and that a corollary of defining a syndrome as pathological is that one would intervene if it were feasible. In this, public health and clinical medicine are alike.

This view of normality and abnormality requires us to take into account not only the symptom or behavior, but also the developmental stage at which it occurs, in deciding whether to devote major efforts to prevention. Taking an example from externalizing behaviors, Loeber & Le Blanc (1990) pulled together evidence from many studies to argue that behavior that is not highly predictive of later conduct disorder in most children at a certain stage may be highly predictive in a specific child if (1) it first occurs earlier than in normal children; (2) it occurs with greater frequency than in normal children; and (3) it forms part of a more diversified symptom cluster. These developmental abnormalities frequently go together (Cohen, 1990; Farrington, 1983; Tolan, 1987). This implies that, for example, boys younger than 12 who commit minor acts of theft, vandalism, and substance abuse should be treated as showing a serious problem for which intervention is needed, whereas boys who first commit such acts after age 12 should not be taken so seriously. This is based on evidence that children who begin such acts early are likely to show a much higher rate of delinquency in their late teens than those who begin later (Fréchette & Le Blanc, 1987; Tolan, 1987) and to continue showing delinquent behavior for a longer period of time (Le Blanc & Fréchette, 1989).

Thus, the concept of goal-directed change toward developmentally appropriate, normal behavior provides a framework within which to study patterns of pathology in time and space and links the study of human development to the study of disease under the heading of developmental epidemiology.

FROM CHILD PSYCHIATRIC EPIDEMIOLOGY TO DEVELOPMENTAL EPIDEMIOLOGY: A BRIEF HISTORY

In this section, we trace the history of developmental epidemiology from the earliest days of child psychiatry to the present.

The Origins of Child Psychiatric Epidemiology

Work on the epidemiology of child and adolescent psychiatric disorders was first undertaken in the late nineteenth century to answer the most pressing question that faced the emerging discipline of child psychiatry: how to classify and care for children with severe disabilities, many of whom were likely to be a public expense for much of their lives. In this context, the main concerns were to identify the nature of the deficits shown by severely impaired children and to find out how many such children there were.

In the nineteenth century, the disease concept of psychiatric illness replaced the earlier view of psychiatric illness as *moral insanity* (Prichard, 1837). Mental disease was regarded as a thing residing within the affected individual; cases could therefore be counted in the same way as in the epidemiology of physical disease. At the same time, reforms in the administration of psychiatric services (e.g., the assumption by the state of responsibility for mental hospitals) increased the need for statistics and paved the way for epidemiological studies (Jablensky, 1986).

There appear to have been few children in mental hospitals or asylums in the nineteenth century (von Gontard, 1988), but an analogous problem arose here, too: how to identify children who could never be expected to become self-sufficient adults and for whom long-term care, probably at public expense, would be needed (Grob, 1985).

Distinguishing Psychiatric Disorder from Severe Mental Retardation

An important and basic distinction made by the end of the nineteenth century was one between *imbeciles* and *lunatics*. As universal education spread across Europe and the United States in the second half of the century, children who could not handle the demands of the educational system became a visible and troubling group. In their historical overview of child psychiatry, Chess and Habibi (1978) pointed out that the distinction between, and division of responsibility for, idiots and lunatics was far from clear until the twentieth century; in 1876, all the charter members of the American Association on Mental Deficiency were psychiatrists, and the child guidance movement in the United States began at the University of Pennsylvania in a clinic set up by Winner in 1894 primarily to care for the feebleminded. Gradually, over the course of the nineteenth century, specific groups of children were described, and causes for their disabilities were identified. J. L. Down (1867), a psychiatrist and superintendent of a large asylum for idiots, described Down syndrome, and J. C. P. Williams, superintendent of the Scottish National Institution for Imbecile Children, developed a classification into such categories as epileptic, microcephalic, and inflammatory idiocy, demonstrating that the same phenomenon of idiocy could result from many different causes (Ireland, 1877). Mental retardation slowly became recognized as a problem to be treated separately from behavioral and emotional problems. Children with severe developmental deficits began to be seen as lying on a continuum of disability with children who were struggling to survive the new compulsory education system, rather than as simply part of the general class of severely dysfunctional children (although, of course, some children might have both intellectual and psychiatric problems). For example, special classes for the feebleminded were mandated in England by the Elementary Education Act (Defective and Epileptic Children) of 1899. Throughout the industrialized world, as the right of all children to education was acknowledged, the care of the mentally retarded largely moved out of the sphere of psychiatry, unless emotional or behavioral problems were also severe. Causal theories focused on genetics, perinatal insults, and early environmental adversity; treatment centered on pinpointing precise deficits and maximizing children's potential rather than curing them as the pioneers in the treatment of idiocy had hoped to do (von Gontard, 1988).

Distinguishing Among Psychiatric Disorders

From the same period, descriptions can be found of children whose cognitive development was normal but who showed serious emotional or behavioral problems. In 1835, the physician James Prichard (1786–1848) wrote that idiotism and imbecility are observed in childhood, but "insanity, properly so termed, is rare before the age of puberty" (1837, p. 127). Following Pinel, the French psychiatrist who first described *mania without delirium* (Pinel, 1806, p. 150), Prichard distinguished *moral insanity* from, on one hand, "mania, or raving madness … in which the mind is totally deranged" (p. 16)—and which he

attributed to physical causes such as convulsions—and, on the other hand, imbecility or mental retardation. He thus used *moral* in its eighteenth-century sense of pertaining to personality or character. Henry Maudsley (1868), writing 30 years later, used the term in its nineteenth-century sense, referring to ethics and norms. He distinguished between instinctive insanity, which was "an aberration and exaggeration of instincts and passions," and moral insanity, which was a defect of the moral qualities along a dimension of "viciousness to those extreme manifestations which pass far beyond what anyone would call wickedness" (p. 289). In the process, he broadened the realm of child psychiatry to include problems of conduct previously seen to be the responsibility of religion and the law. Maudsley preferred to use the term *affective* (where Prichard used moral) as being "a more general term and expressing more truly the fundamental condition of nerve-element, which shows itself in affections of the mode of feeling generally, not of the special mode of moral feeling only" (p. 280).

When writing about etiology rather than classification, however, Prichard and Maudsley followed the French tradition in distinguishing between moral and physical causes of mental disorder, using moral in the sense of what came to be called exogenous causes. Prichard (1837), quoting Georget, listed among moral causes of insanity domestic grief, disappointment in love, political events, fanaticism, jealousy, poverty or reversal of fortune, reading romances, and excessive study. Mental retardation was seen as stemming exclusively from physical causes: either convulsions of some type in the early years, or some defect transmitted from the parent. This defect might itself be inherited, or it might be "traceable to parental intemperance and excess" (p. 44; see Maudsley, 1879).

The dominant causal theory of psychopathology in the second half of the nineteenth century was genetic: heredity and degeneration caused disease, which started with scarcely perceptible signs in early childhood but took a progressive and irreversible course and would probably be transmitted to future generations if the affected individual were permitted to breed. Even when the proximal cause of insanity was a moral one, "the different forms of insanity that occur in young children . . . are almost always traceable to nervous disease in the preceding generation" (Maudsley, 1868, p. 245).

Psychiatrists in the nineteenth century thus had a developmental causal theory about psychopathology, but it was a narrow form of developmental theory. The development of the disease was progressive and irreversible, tied to the development of the child only in that it manifested itself differently as the child grew, but impervious to other influences, such as treatment or learning. "All one could do was to prevent the most extreme manifestations by strict punishment and to protect those not affected" (von Gontard, 1988). The most effective defense for society was to prevent the procreation of the insane, and eugenics and lifelong segregation in asylums were seen as more effective intervention strategies than attempting treatment or cure. Although a continuum of severity was documented in child psychiatric disorders, as it was in mental retardation, the continuum was interpreted quite differently. It took the form of a continuum of degeneration caused by the disease within the individual across time, rather than a distribution of severity that would remain fairly constant in an individual over time, as was the case for mental retardation. Thus, the prognosis, even for children who presented with mild symptoms, was believed to be gloomy.

Psychoanalytic Theory and Developmental Psychopathology

One of the strengths of the psychoanalytic approach to psychopathology, as its theory and treatment methods developed around the turn of the twentieth century, was that it rejected the therapeutic pessimism of much contemporary child psychiatry. Although Sigmund Freud accepted that individuals had innate or constitutional characteristics, he developed what his daughter, Anna (Freud, 1965), described as an "etiological formula of a sliding scale of internal and external influences: that there are people whose sexual constitution would not have led them into a neurosis if they had not had (certain) experiences, and these experiences would not have had a traumatic effect on them if their libido had been otherwise disposed" (see Freud, 1916–1917, p. 347). Children whose libido disposed them to pathology could be saved by the right environment, or therapy, or both. Thus, although even mild symptoms could be ominous, the course was not inevitable.

Psychoanalytic theory was fundamentally developmental at a time when the term had no place in mainline child psychiatry; as an example, the entries under the heading "Development" in the index of Anna Freud's *Normality and Pathology in Childhood* (1965) take up two columns, whereas there is not a single entry under that heading in two of the classics of mid-twentieth-century American child psychiatry (Chess & Habibi, 1978; Kanner, 1945). Psychoanalytic theory was also developmental in the multiple senses discussed in this chapter and throughout

this volume: It emphasized the multiple determination of outcomes, the transformation and hierarchical integration of behavior, and the emergence of novelty. In the words of Anna Freud (1965, pp. 166–167):

> As we abandon thinking in terms of specific causes of dissociality we become able to think increasingly in terms of successful or unsuccessful transformations of the self-indulgent and asocial trends and attitudes which normally are part of the original nature of the child. This helps to construct developmental lines which lead to pathological results, although these arc more complex, less well defined, and contain a wider range of possibilities than the lines of normal development.

This approach held sway over child psychiatry for almost a century, despite a lack of empirical evidence supporting its interpretation of the etiology of mental disorders (Grunbaum, 1977). In the past two decades, Freudian developmental psychopathology, with its emphasis on etiology, has largely been replaced, particularly in the United States, by a more phenomenological approach whose goal has been to follow the example of medicine, which looks for diseases that have a standard etiology and set of manifestations, and of some branches of psychology, which seek to pin down concepts like intelligence in forms that are deliberately designed to transcend differences that are a function of developmental factors (Cairns & Cairns, 1991). However, although the *content* of psychodynamic theory has not stood up to empirical research, the *form* of the theory, with its emphasis on how the development of the child and of the disease are intertwined, retains considerable attraction as a model for developmental psychopathology and epidemiology.

Distinguishing Normal from Abnormal

One of the great psychiatric dilemmas of our time is the decision as to what is normal and what is abnormal in human behavior. Lacking specific tests to make the distinction, the diagnostician has recourse mainly to clinical judgment which rests on training, experience, perceptiveness, and theoretical persuasion. In child psychiatry, Leo Kanner (1945) pointed out that recorded symptoms "are of necessity those of selected groups and not of the total population of children" (quoted in Lapouse & Monk, 1958). He continued, "This selectiveness, in the absence of 'normal controls' has often resulted in a tendency to attribute to single behavior items an exaggerated 'seriousness' with regard to their intrinsic psychopathologic significance. The seriousness becomes attached to the signal regardless of what it announces and who announces it. The high annoyance threshold of many fond and fondly resourceful parents keeps away from clinics and out of reach of statistics a multitude of early breath holders, nail biters, nose pickers and casual masturbators who, largely because of this kind of parental attitude, develop into reasonably happy and well-adjusted adults" (Lapouse & Monk, 1958, p. 1134).

By 1970 a number of older general population studies (Cullen & Boundy, 1966; Cummings, 1944; Griffiths, 1952; Haggerty, 1925; Lapouse, 1966; Lapouse & Monk, 1958, 1964; Long, 1941; McFie, 1934; Olson, 1930; Wickman, 1928; Young-Masten, 1938; Yourman, 1932) reported prevalences of individual problem behaviors reported by parents and teachers of older children and adolescents. One of the achievements of these early child psychiatric epidemiologists was to document just how common individual abnormal behaviors are in the general population of children. For example, in their survey of a random sample of 6- to 12-year-olds in Buffalo, New York, Lapouse and Monk (1958) found that 43% of children were reported by their mother to have seven or more fears or worries, 49% to be overactive, and 48% to lose their tempers twice a week or more. Similarly, Shepherd et al. (1971) found that, on their scale of 25 deviant behaviors, only 40% of a population sample of elementary school children in Buckinghamshire, England, was not deviant. However, only 2.6% of the children were deviant in seven or more areas. Some of these studies (Cummings, 1944; Griffiths, 1952; Macfarlane, Allen, & Honzik, 1954; Macfarlane et al., 1954) also illustrate a point that seems often to have been forgotten until recently (Loeber & Stouthamer-Loeber, 1997; Tremblay et al., 1999): that some conduct problems now associated with *DSM-5* conduct disorder, such as lying and some forms of aggression, actually have their peak prevalence before age 5.

Measuring Child and Adolescent Psychopathology

The problem with the approach to measuring the prevalence of child psychopathology used in these two studies was illuminated by a review of prevalence studies commissioned for President Carter's Commission on Mental Illness (Gould, Wunsch-Hitzig, & Dohrenwend, 1980). Prevalence estimates of childhood psychopathology varied widely, depending on whether parents or teachers were surveyed (at that time, children were rarely asked about their own problems). Estimates of the prevalence of maladjustment varied widely even when they were based on data from the same informant group: from 6.6% to 22% according to teachers and from 10.9% to 37% according

to mothers. It is difficult either to plan service delivery systems or to examine causal factors if the rate of the disorder itself is so imprecise.

The questionnaires used in the 1950s and 1960s had three other disadvantages for epidemiological research: (1) they were not designed to distinguish clearly among different syndromes or diagnostic clusters of symptoms; (2) they did not take developmental changes into account; and (3) they did not, as a rule, differentiate symptoms of a disorder from any impairment in functioning that might accompany those symptoms but not be a part of the syndrome itself. For example, failing to perform at age-appropriate levels in school could be a symptom of general mental retardation, a specific learning difficulty, or attentional problems associated with ADHD or depression, or it could result from repeated absence from school because of acute separation anxiety or a chronic physical illness. General maladjustment scales did not make it easy to study the relationship between symptoms and impaired functioning in a way that might illuminate causal relationships.

Epidemiologists and clinical researchers have tackled this problem in several different ways in recent decades. The goal of all these approaches is to elicit information that will identify children with psychiatric syndromes or disorders, but the methods differ substantially. Some have developed survey-type questionnaires consisting of questions designed to mirror the symptoms described in a psychiatric taxonomy such as the *DSM* or ICD. Others, wanting to capture more of the detailed information about symptom severity, duration, age at onset, and associated impairment that is needed, together with symptom reports, to make a diagnosis or devise a treatment plan, have developed structured psychiatric interviews (Shaffer et al., 1999). The goal (Angold et al., 2012) has been to mirror as closely as possible the diagnostic skill of experienced child psychiatrists while overcoming the twin problems that clinicians are notoriously unreliable (Zubin, 1978) and are usually too expensive to be used in large or longitudinal community studies. Here we discuss one or two issues about the use of questionnaires that have implications for developmental epidemiology; the area is covered in detail elsewhere (Angold, 2002; Shaffer et al., 1999).

Questionnaires for Assessing Child Psychopathology

There are hundreds of questionnaires designed for the child, teacher, or parent to complete, covering psychopathology in general or specific syndromes. We discuss just one set of these as examples of the strengths and weaknesses of this approach for developmental epidemiology. Achenbach and his colleagues set out to develop a set of interrelated symptom questionnaires (now called the Achenbach System of Empirically Based Assessment [ASEBA]; Achenbach & Rescorla, 2000; Rescorla & Alley, 2001), whose items were selected using a mixture of clinical and epidemiologic methods. The original set of behavioral and emotional problems was compiled from clinical sources, but the process of reducing the list to the number finally selected was based on studies using general population samples. The first of the questionnaires, the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983), was designed for use by parents whose children were 4 through 16. Items endorsed by fewer than 5% or more than 95% of parents were rejected, and language was simplified to be understandable by anyone with a fourth-grade education. Achenbach and Edelbrock carried out extensive factor-analytic studies of how items clustered together in children of different age groups and genders. Many of the syndromes identified in this way showed clear links to the standard diagnostic labels used in psychiatry (Verhulst, van der Ende, Ferdinand, & Kasius, 1997). This is not surprising, as the original set of items was submitted by clinicians familiar with how children's symptoms tend to present. However, the CBCL proved to have much higher test–retest reliability than clinicians did, and items were quick to administer and score.

The work of Achenbach and his colleagues has provided some powerful tools for developmental epidemiology, both practically and conceptually. First, the extensive data collection and careful standardization on large samples set high standards for instrument development. Second, the team developed a closely integrated set of scales associated with the original CBCL, covering infancy to adulthood and available in versions for parent, teacher, and self-report. Third, the list of emotional and behavioral problems is set in the context of questions about the child's social competencies and school performance; basic sociodemographic information also is collected. Fourth, a lot of work has gone into language and layout, and the four-page questionnaires collect a great deal of information in a brief time (about 20 minutes). As a result of these virtues, the instruments are very widely used for both clinical and epidemiological purposes. They have been translated into many languages, encouraging cross-cultural studies of the generalizability of the identified symptoms and syndromes and their correlates (Broidy et al., 2003; Ivanova et al., 2007; van Eldik, Treffers, Veerman, & Verhulst, 2004; Verhulst, Achenbach, Althaus, & Akkerhuis, 1988; Weisz, 1989).

The many virtues of the questionnaire approach adopted by Achenbach and colleagues make it even more

important to recognize its limitations (Achenbach, 1985). First, the strategy of omitting rarely endorsed symptoms means that this method cannot be used to describe some of the most severe and disabling problems, for example, those seen in children with bipolar disorder. Second, it is important to note that the questionnaire method is predicated on the assumption that the respondent knows the child well enough to be able to make ratings on items like "Feels too guilty" or "Lying or cheating." A checklist is thus a very well-designed form for recording information about a child that the respondent already knows, but the data that it provides can only be as good as the respondent's knowledge of the child in question. Third, this method produces a series of scale scores for each child, standardized relative to a population sample matched for age, sex, and social class. These scores cannot be used to answer such public health questions as, "How many children need treatment?" unless certain decision rules are applied to them. A clinical cut point has been identified for the global behavioral problem score of the ASEBA checklists, based on a comparison of the scores of children referred for mental health services during the previous year with the scores of nonreferred children (Achenbach, 1991). However, as we discuss later, there is reliable evidence from national data and community surveys that receipt of services is a poor criterion for defining need for services (Burns et al., 1995; Costello, Burns, Angold, & Leaf, 1993; Costello, Pescosolido, Angold, & Burns, 1998). It is also worth emphasizing that scale scores are standardized to identify a priori a certain percentage of the population as being in the clinical range. Thus, they cannot be used to provide prevalence estimates.

Interviews for Identifying Psychiatric Disorders in Children and Adolescents

The checklist approach does not provide the detailed information about symptom severity, duration, age at onset, and associated impairment that is needed, together with symptom reports, to make a diagnosis or devise a treatment plan. Alternative approaches are needed, ones more closely related to the process of clinical decision making. Beginning with the work of Michael Rutter in the 1960s, a large number of structured psychiatric interviews have been developed. They have much in common. All structured interviews aim to:

- Structure information coverage so that all interviewers will have collected all relevant information (both confirmatory and disconfirmatory) from all subjects
- Define how relevant information is to be collected
- Structure the process by which relevant information is combined to produce a final diagnosis

Interviews vary widely in how they go about these tasks. However, a general distinction can be made between interviewer-based (or investigator-based) interviews, respondent-based interviews, and best-estimate interviews (Angold et al., 2012).

Interviewer-Based Interviews. These interviews require the interviewer to make an informed decision based on what the respondent says. Interviewers are expected to question until they can decide whether a symptom meeting the definitions provided by the interview (or known to them from their training) is present or absent. This group of interviews includes the Anxiety Disorders Interview Schedule (Silverman & Rabian, 1995); the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000); the Child Assessment Schedule (Hodges, 1993; Hodges et al., 1982); the paper-and-pencil (not the computerized) versions of the Diagnostic Interview Schedule for Children and Adolescents (DICA; Reich, 2000) and the Missouri Assessment of Genetics Interview for Children (MAGIC; Reich, 2000), the Interview Schedule for Children and Adolescents (Sherrill & Kovacs, 2000); various versions of the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS; Ambrosini, 2000); and the Pictorial Instrument for Children and Adolescents (Ernst, Cookus, & Moravec, 2000).

Three of these interviewer-based interviews (the K-SADS-P IVR, the DICA, and the CAPA) provide extensive sets of definitions of symptoms or detailed guidance on the conduct of the interview. Such glossaries are particularly important when an interviewer-based interview is to be used by nonclinician interviewers because they provide detailed guidance as to what the interviewer is supposed to be looking for in making symptom ratings. Nonclinician interviewers have been shown to be able to make such clinical judgments with high reliability when they have received adequate training with such glossaries (Angold & Costello, 1995).

Respondent-Based Interviews. In other psychiatric interviews, it is the respondent who makes the final decision about whether a symptom is present, typically by answering yes or no to each question. The interviewer makes no such decisions but simply reads the questions. Because the decision as to the presence or absence of psychopathology lies with the respondent in such interviews, we refer to them as respondent-based. The DISC (Shaffer et al., 2000), the computer-assisted version of the DICA (Reich, 2000), and the Dominic-R (Valla, Bergeron, & Smolla, 2000) are the three representatives of this approach.

A variant on these two approaches to interviewing is taken in the Development and Well-Being Assessment (Goodman, Ford, Simmons, Gatward, & Meltzer, 2000), which is widely used around the world. Here the interviewer uses a respondent-based approach first and then supplements the information by asking additional questions. The responses to these are integrated with the structured responses by an experienced clinician, who formulates the diagnosis.

The distinction between interviewer- and respondent-based interviews is not hard and fast in actual practice because there has been considerable cross-fertilization between these approaches. For instance, CAPA, which has its roots in the interviewer-based tradition, includes a subset of questions that are to be asked verbatim of all subjects, as in a respondent-based interview, but then allows further questioning for clarification. The DICA, which had previously been a respondent-based interview, now requires interviewers to question much more flexibly and is currently an interviewer-based instrument (Reich, 2000). Although the distinction between interviewer- and respondent-based interviews provides a useful rough-and-ready typology, it is really better to consider interviews as lying at various locations along three dimensions: (1) degree of specification of questions; (2) degree of definition of symptom concepts; and (3) degree of flexibility in questioning permitted to the interviewers (Angold, 2002).

Summary

In this section, our goal has been to see where developmental epidemiology came from and how it got to be where it is today. The problems that had to be formulated and solved were of two kinds: how to conceive of the nature of childhood psychopathology and how to measure it. Progress in the past century has been extraordinary in both areas. However, as we discuss later, this progress has brought developmental epidemiology to a point where radically new concepts, and new methods, are now needed. Before we get there, however, we look at how epidemiologists in other areas of medicine have thought about developmental questions, and give some examples from psychiatry.

EPIDEMIOLOGY AS A DEVELOPMENTAL METHOD

Much of this section is inspired by Breslow and Day's (1980, 1987) two-volume *Statistical Methods in Cancer Research*. As those authors point out: "Most chronic diseases are the result of a process extending over decades, and many of the events occurring in this period play a substantial role" (Breslow & Day, 1987, p. 2).

In the study of physical growth, of mental and hormonal development, and in the process of aging, the essential feature is that changes over time are followed at the individual level. Longitudinal surveillance and recording of these events is therefore a natural mode of study to obtain a complete picture of disease causation.

Many psychiatric disorders fall into the category of chronic diseases, and the methods developed by cancer and cardiovascular epidemiologists to explore causal relationships in such diseases can, we believe, provide at least a useful starting place for thinking about psychiatric disorders.

Chronic disease epidemiologists view the diseases that they study as having inherent developmental processes of their own; processes that obey certain laws and follow certain stages even as they destroy the individual in whom they develop (Hay & Angold, 1993). Developmental epidemiology asks what happens when developmental processes embodied in pathogenesis collide with the processes of human development.

Risk, Exposure, and the Meaning of Time

Many questions can be answered only by methods that take into account temporal characteristics of risk factors, including their onset and the "dose," or level of exposure, over time. Age at first exposure, time since first exposure, duration of exposure, and intensity of exposure are all interrelated aspects of timing that may have different implications for causality and thus for prevention. The kinds of questions we are thinking of include the following:

- Does physical abuse by parental figures cause psychiatric disorders in children? Is a single blow a sufficient cause or does abuse have to go on for a period of time, or happen at a certain level of severity, before it constitutes a risk factor? Are children of different ages or developmental stages differentially vulnerable to physical abuse as a risk factor? What risks are associated with removing children of different ages from home because of physical abuse?
- Why are depressive disorders rare in both prepubertal girls and boys, but much more common in postpuberal girls? What causes the observed sex difference to develop? Is it associated with hormonal, morphological, or social changes occurring around puberty? Why is earlier-than-average maturation apparently a positive event for boys but a negative one, associated with increased risk of behavioral and school problems, for girls?

A risk factor may have a different impact on the risk of disease, depending on when it first occurs, how long it is present, and the level of intensity at which it occurs. For example, insulation workers exposed to asbestos had a cumulative risk of dying of mesothelioma over a 20-year period (controlling for other causes of death) that was the same irrespective of age at first exposure (Peto, Seidman, & Selikoff, 1982). Here, *length of exposure* was the critical aspect of risk. In contrast, the risk of breast cancer following irradiation appears to be highest in girls exposed at ages 0 through 9, falling with age until there is little excess risk for breast cancer associated with exposure to radiation after age 40 (Howe, 1982). Cases of breast cancer attributable to irradiation begin to occur some 10 years after exposure and continue thereafter at a roughly constant level, suggesting that the absolute excess risk increases with time since exposure. Thus, *timing of exposure* is the critical aspect of the risk exposure.

However, different sorts of radiation can have different durations as risk factors for cancer; for example, bone sarcomas occurring after exposure to the radioisotope 224Ra, which has a half-life of 3.6 days, cluster in a period of 5 to 10 years following first exposure, whereas bone sarcomas following exposure to 226Ra, which has a half-life of 1,600 years, occur at a constant rate beginning 5 years after first exposure (Mays & Spiess, 1984). In the latter case, exposure to the decay products of the radioisotope continues at virtually constant levels after absorption of the radium.

A longitudinal study of British male doctors' smoking provides an example of dose-related risk: The annual death rate per 100,000 men, between 1951 and 1971, standardized for age, was 1,317 for nonsmokers, 1,518 for those currently smoking 1 to 14 cigarettes a day, 1,829 for those currently smoking 15 to 24 a day, and 2,452 for those smoking over 24 a day (Doll & Peto, 1976). This was true inspective of age, and risk fell quite rapidly in those who gave up smoking (Breslow & Day, 1987). In this case, *amount of exposure* was the critical factor.

Examples from Developmental Psychopathology

These examples illustrate the importance for developmental epidemiology of thinking about different aspects of development: age at first exposure, time since first exposure, duration of exposure, intensity of exposure. Here we present some examples of how child psychiatric researchers have used ingenious designs to tease out the same issues.

The importance of *age at first exposure* has been studied most intensively of all the aspects of risk over time in child psychopathology because of the theoretical importance attached to early experiences in the Freudian and other psychodynamic models of development. For example, researchers investigating the role of attachment in children's development have concentrated on the very early months and years of life as the crucial period during which the inability to form one or more such relationships may have damaging effects that last into childhood and perhaps even into adulthood (Sroufe, 1988). The critical date of onset of risk appears to occur after 6 months, but the duration of the risk period is not yet clear. Hay (1985) presented evidence that maternal depression, which presumably interferes with mothers' ability to form normal relationships with their infants, affects motor development if it occurs during the 1st year of life, and language development but not motor development if it occurs during the 2nd year of life. This is a case where age at first exposure appears to interact with the developmental processes most salient at a particular age. In another example of the importance of timing, Rutter (1985) pointed out that once children have achieved urinary continence at around age 2, there is a period of risk for relapse into incontinence that appears to coincide with starting school. Once this period of risk is over, the chance of developing enuresis is very slight. In this case, age at exposure is clearly the critical developmental risk factor because no parallel increase in functional enuresis occurs at later times of stress, such as moving to middle or high school, and there is no delay between the stress and the symptoms.

Timing of exposure has rarely been treated separately in studies of child psychopathology. Brown and Harris (1978), in their work on the social origins of depression, argued that women who lost their mother in the 1st decade of life were more vulnerable as adults to depressive episodes in the face of severe life events. However, theirs was a retrospective study that did not address the question of whether these women were also at greater risk of depressive episodes during later childhood and adolescence. It is not clear whether the crucial factor was the length of time since exposure to the risk factor of mother's death, or the age of the child at the time of exposure, or some combination of the two.

Timing of puberty has emerged as an important aspect of risk in relation to both depression and behavioral problems. In a longitudinal study that measured not only age at menarche but also morphological development, Tanner staging (Marshall & Tanner, 1969), and levels of gonadal and steroidal hormones, high levels of testosterone, not timing of puberty, predicted female adolescent depression (Angold et al., 1999). On the other hand, many studies show that girls who are early in developing the morphological signs of puberty, indexed by Tanner stage

or menarche, are at risk for behavioral problems if they have unsupportive families (Ge, Brody, Conger, & Murry, 2002; Ge, Conger, & Elder, 1996; Magnusson, Stattin, & Allen, 1985; Moffitt et al., 1992).

Duration of exposure to poverty was examined by Offord and colleagues (1992) in their repeated surveys of a representative sample of children in Ontario. They showed that children whose families were living below the poverty level at two measurement points were at increased risk of behavioral disorders, compared with children whose families were below the poverty level on one occasion only, or never. In a longitudinal study from New Zealand, Moffitt (1990) found that children identified at age 13 as both delinquent and hyperactive had experienced significantly more family adversity (poverty, poor maternal education, and poor mental health), consistently from the age of 7, than children who were only delinquent or only hyperactive at age 13:

> The most striking increase in the antisocial behavior of ADD+delinquent boys (diagnosed at age 13) occurred between the ages of 5 and 7, when they attained a mean antisocial rating that was not reached by other delinquent boys until 6 years later. School entry and reading failure coincided temporally with this exacerbation of antisocial behavior. These data suggest that the problem behavior of this group, despite being generally persistent, is responsive to experience. The data also reveal a key point of vulnerability that could be a target for intervention: reading readiness. (p. 906).

Another example comes from the Great Smoky Mountains Study. Children who had been assessed over an eight-year period were classified into four groups on the basis of their body mass index (a ratio of weight to height) at each assessment: no obesity (72.8%), childhood-only obesity (5.1%), adolescent-only obesity (7.5%), and chronic obesity (14.8%). Only the chronically obese group was at increased risk of psychiatric disorder (Mustillo et al., 2003). This is an example of *duration of exposure* as the key risk characteristic. It is also an example of the impact of *intensity of exposure* because no effects were found of overweight that fell below the threshold of obesity.

Intensity of exposure to lead (Needleman & Bellinger, 1991) provides an example of a definite dose–response relationship. Another aspect of intensity is the number of different risk factors to which a child is exposed (Seifer, Sameroff, Baldwin, & Balwin, 1989). Rutter (1985) and others have pointed out that children exposed to one risk factor are at increased risk of exposure to others (e.g., no father in the home and poverty) and that the dose–response relationship to an increasing number of different risk factors is not a simple linear one. Most children appear to be able to cope with a single adverse circumstance, but rates of psychopathology rise sharply in children exposed to several adverse circumstances or events (Seifer et al., 1989).

These examples show that it is possible to design studies that at least begin to allow us to tease out the respective roles played by time since first exposure, age or developmental stage at first exposure, duration of exposure, and intensity of exposure. Multistage models of risk, which have been developed to address the complexities of causality in chronic disease, are one way of putting the pieces together. Several such models have been proposed, particularly in the context of carcinogenesis (Peto, 1984), and have been reviewed in terms of developmental psychopathology (Pickles, 1993). Statistical techniques for exploring causality in such multistage models have made great strides recently (Pearl, 2013; Robins, 2001). The challenge is to incorporate all the various aspects of risk into a single model and distinguish the ones that carry the tune from those that are just noise.

FUTURE DIRECTIONS: DEVELOPMENTAL EPIDEMIOLOGY

We have described how child psychiatric epidemiology has developed over the past 50 years as a collaborative activity of basic, clinical, and public health scientists working together to understand the magnitude of the problem of child mental illness and to identify key risk factors. Many of the fundamental problems of conceptualization and measurement have been solved, or at least reduced to manageable proportions.

Up to this point, the role of epidemiology has been mainly a descriptive one: addressing the basic questions, How many? Who? Where? When? We are now in the position of being at least as capable of answering these questions reliably and accurately in child psychiatry as are chronic disease epidemiologists in other areas of medicine. However, child psychiatry is changing, and epidemiology will change as well. The goal is now to understand how risk exposure and vulnerability change over the life course, and how the requirements of so-called normal development at each developmental stage shape the types of psychopathology that emerge if these requirements are not met. The term *developmental epidemiology*, first coined by Kellam in the 1970s (Kellam, Ensminger, & Turner, 1977), is useful to describe what epidemiology is doing these days.

In this concluding section, we describe some rapidly growing research areas that will contribute to the next generation of studies to the shift from child psychiatric epidemiology to developmental epidemiology. The different approaches overlap in many areas, but we discuss the future under three broad headings: longitudinal research; impact studies of burden, cost, and prevention; and studies of mechanisms.

Longitudinal Research

Longitudinal research is almost the sine qua non for testing developmental hypotheses about causes and risks. Here we consider three types: longitudinal studies, life-course studies, and intergenerational studies.

Longitudinal Studies

Although there have been many longitudinal developmental studies, some of them beginning at birth (or even before), longitudinal studies of psychiatric disorders had to await the development of appropriate technology, specifically, data collection methods that validly and reliably translated a given psychiatric taxonomy into instruments that could be used repeatedly with the same subjects (see earlier discussion).

An example of how longitudinal studies can be used to address developmental questions can be found in a recent paper on the Great Smoky Mountains Study (Copeland, Shanahan, Costello, & Angold, 2011). Annual interviews with 1,420 young people over a period from age 9 through 21 provided data to address such questions as the following: Does the prevalence of different disorders increase or decrease with age? Do children with a disorder continue to have the same disorder (homotypic continuity) or a different disorder (heterotypic continuity)? Longitudinal analyses showed that, although the average annual prevalence of psychiatric disorder was around 18%, over the period of the study more than 60% had one or more disorders. Some disorders (ADHD, separation anxiety, functional enuresis) dominated the picture in childhood but had almost disappeared by age 16. Depression and drug abuse were predominantly disorders of adolescence. Anxiety disorders in general had a U-shaped distribution, falling to their lowest point at age 12. Although wave-to-wave continuity was not very high, over the course of the study there was a high degree of continuity of diagnosis (Table 3.1). The increased likelihood of an episode of a disorder following an earlier episode was statistically significant for every diagnosis except specific phobia.

In contrast, there was relatively little prediction from one disorder to another (heterotypic continuity), and it was almost entirely restricted to girls. Anxiety predicted depression, and depression predicted anxiety. Anxiety and conduct disorder predicted substance abuse, and there was some movement among the disruptive behavior disorders,

TABLE 3.1 Homotypic and Heterotypic Continuity, with and Without Controls for Comorbidity

Predicting to	Past depression	Past anxiety	Past conduct disorder	Past oppositional defiant disorder	Past ADUD	Past substance abuse
Depression	7.0 (3.1, 15.9)[c]	3.0 (1.7,5.4)[c]				
Controlling for comorbidity	4.2 (2.1,8.3)[c]	2.7 (1.8, 5.2)[b]				
Anxiety	5.7 (2.2. I4.5)[c]	2.4 (1.6,3.7)[c]				
Controlling for comorbidity	2.8 (1.2,6.5)[a]	2.0 (1.2,3.4)[a]				
Conduct disorder			11.2 (5.9, 21.1)[c]			
Control ling for comorbidity			10.3 (4.3, 24.7)[c]			
Oppositional defiant disorder				3.7 (2.2, 6.2)[c]	2.0 (1.1,3.8)[a]	
Controlling for comorbidity				4.7 (2.7,8.1)[c]	2.1 (1.1, 4.2)[a]	
ADHD			2.2 (1.0.4.5)[a]		10.7 (5.2. 22.3)[c]	
Controlling for comorbidity			1.8 (0.9. 3.9)		9.6 (4.4, 21.2)[c]	
Substance abuse		2.0 (1.2,3.5)[a]	2.7 (1.2,6.5)[a]			21.3 (6.3, 72.5)[a]
Controlling for comorbidity		2.0 (l.l, 3.7)[a]	1.7 (0.6.4.7)			25.7 (7.8, 85.4)[a]

Note: [a]$p < .05$; [b]$p < .01$; [c]$p < .001$; NS = Not significant.
Adapted from "Prevalence and Development of Psychiatric Disorders in Childhood and Adolescence," by E.J. Costello, S. Muslillo, A. Erkanli, G. Keeler, & A. Angold, 2003, *Archives of General Psychiatry, 60,* pp. 837–844.

perhaps suggesting that the *DSM* taxonomy fits boys better than it does girls.

Several research groups have now used their longitudinal data to look at continuities and discontinuities in mental illness from childhood into adolescence and beyond. Some of the longitudinal studies have followed their subjects into adulthood (Caspi, Moffitt, Newman, & Silva, 1996; Cohen, 1996; Fergusson & Woodward, 2000; Reinherz, Giaconia, Hauf, Wasserman, & Silverman, 1999; Rohde, Lewinsohn, Kahler, Seeley, & Brown, 2001). These are beginning to show indications of continuity between temperamental characteristics in early childhood and the onset of psychiatric disorders in late adolescence and young adulthood (Caspi et al., 1996). Two examples come from the Dunedin study, a birth cohort of around 1,000 children from New Zealand who have been evaluated every two years since birth.

The first set of analyses (Jaffee et al., 2002) started from hints in the literature that juvenile-onset major depressive disorder (MDD) may be etiologically distinct from adult-onset MDD. In these analyses, early childhood risk factors covered the period from birth to age 9 years. Diagnoses of MDD were made according to *DSM* criteria at three points prior to adulthood (ages 11, 13, and 15 years) and three points during adulthood (ages 18, 21, and 26 years). Four groups were defined: individuals first diagnosed as having MDD in childhood, but not in adulthood ($n = 21$); individuals first diagnosed as having MDD in adulthood ($n = 314$); individuals first diagnosed in childhood whose depression recurred in adulthood by age 26 years ($n = 34$); and never-depressed individuals ($n = 629$). By the time of an age 32 follow-up, 44% of the cohort had experienced at least 1 episode of depression (Moffitt et al., 2007).The two juvenile-onset groups had similar high-risk profiles on the childhood measures. Compared with the adult-depressed group, the juvenile-onset groups experienced more perinatal insults and motor skills deficits, more caretaker instability, criminality, and psychopathology in their family of origin, and more behavioral and socioemotional problems. The adult-onset group's risk profile was similar to that of the never-depressed group with the exception of elevated childhood sexual abuse. These analyses made it clear that the distinction between juvenile- and adult-onset MDD is important for understanding heterogeneity in depression. Similar findings have been seen in clinical samples (Zisook et al., 2004).

A second example from the same study revisited the theory that there are two types of adolescent delinquency, childhood-onset and adolescence-limited; that their manifestations in adolescence are indistinguishable; but that their consequences for persistence into adulthood are different (Moffitt, 1993). At the age-26 follow-up (Caspi et al., 2002), the childhood-onset delinquents were the most elevated on psychopathic personality traits, mental health problems, substance dependence, numbers of children, financial problems, work problems, and drug-related and violent crime, including violence against women and children. The adolescent-onset delinquents were less extreme at age 26 but showed elevated impulsive personality traits, mental health problems, substance dependence, financial problems, and property offenses. A third group of men who had been aggressive as children but not very delinquent as adolescents emerged as low-level chronic offenders who were anxious, depressed, and socially isolated and had financial and work problems. A follow-up at age 32 showed that a family history of behavioral problems distinguished males with persistent problems from those whose behavioral problems were limited to childhood or adolescence (Odgers et al., 2007).

A third line of research from the Dunedin study has begun to link early mental health problems with the early onset of poor physical health and, possibly, risk factors for early mortality. For example, early social isolation had persistent and cumulative detrimental effects on adult health, mediated by childhood overweight, low IQ, and lack of exercise (Caspi, Harrington, Moffitt, Milne, & Poulton, 2006).

These examples serve to show how as developmental epidemiology grows up it can contribute to developmental psychopathology and also shine new light on some of the accepted verities of adult morbidity and mortality.

A next step in the use of descriptive longitudinal studies for developmental epidemiology must be to work out ways of releasing data from these studies for public access so that future researchers can take advantage of these incredibly valuable resources. There are many issues to be worked out, not the least of them the protection of participants' privacy and the rights of the scientists who labored for so many years to collect the data. But these are soluble problems, and the benefits of bringing fresh minds to bear on issues in developmental epidemiology are likely to be tremendous.

Life-Course Studies

Psychiatric disorders are increasingly showing themselves to be chronic diseases. For example, across childhood and adolescence, for every psychiatric disorder except specific phobias, the likelihood of an episode has been shown to be significantly higher in youth with a history of the same disorder than in those with no previous history (Copeland et al., 2011). As data accumulate from prospective studies,

it is becoming clear that the onset of most adult psychiatric disorders lies much further back in childhood than had been suspected from adult studies relying on retrospective recall of onset (Kim-Cohen et al., 2003).

Life-course epidemiology is the study of long-term effects on chronic disease risk of physical and social exposures during gestation, childhood, adolescence, young adulthood, and later adult life. It includes studies of the biological, behavioral, and psychosocial pathways that operate across an individual's life course as well as across generations, to influence the development of chronic diseases (Ben-Shlomo & Kuh, 2002; Kuh & Ben-Shlomo, 1997).

In many ways, life-course and developmental epidemiology mirror one another. Life-course epidemiology, however, has taken on a special concern with the embodiment of social phenomena into the biological (Krieger, 2001), encapsulated in the concept of *health inequalities*. This concern arose historically from work showing that mortality from many diseases is spread unequally across the population (Wilkinson, 1994; Wilkinson & Pickett, 2009) and that these differences in risk can be linked to social inequalities that often go back to infancy or even to the parental generation (Barker, 1998; Davey Smith, Gunnell, & Ben-Shlomo, 2000; Leon, 2000). This body of work has had enormous significance for international thinking about social policy and is having a direct effect on the allocation of public resources in some countries.

Developmental epidemiology needs to take on board the social, economic, and political implications of the fact that children are born with different levels of risk for psychiatric disorder, that their family's socioeconomic status is part of the predictive equation, and that community-level interventions as well as individual treatment can influence how well individuals are able to function (Costello et al., 2003). Future studies will include health disparities (in the broad sense of medical and psychiatric health) as part of their remit.

Global Mental Health

A major shift in the focus of psychiatric epidemiology in the past decade has been from the parochial issues of a single country or continent to the whole world. There are several reasons for this: first, immigration and world travel have opened our eyes to other people's problems. Second, huge multinational studies such as the World Health Organization's World Mental Health Survey (Kessler et al., 2007) have (1) created and tested instruments for use in many language and cultures (Kessler & Üstün, 2004) and (2) permitted comparisons of prevalence rates and risk factors around the world (Demyttenaere et al., 2004). Third, two reports on the global burden of disease, from 1996 (Murray & Lopez, 1996) and 2012 (Lozano et al., 2012), both placed mental illnesses very high in terms of morbidity and disability around the world. Fourth, psychiatry in general is, as noted earlier, beginning to wake up to the reality that most cases of mental illness have their onset or first episode in the first two decades of life (Jaffee, Harrington, Cohen, & Moffitt, 2005). As a result of this confluence of thought and data, the major funding agencies are paying more attention to global mental health, especially of mothers and children (Collins et al., 2011; Patel, Flisher, Hetrick, & McGorry, 2007). This means, for the next generation of epidemiologists, new challenges in developing measures that are usable worldwide, a task that has been tackled for adults but not yet for children (Goodman et al., 2012). Several instruments have been translated into many languages (e.g., the Child Behavior Checklist (Ivanova et al., 2007) and the Development and Well-Being Assessment (Heiervang, Goodman, & Goodman, 2008)), but the hard work of sorting out real and methodological differences between instruments has yet to be done (Angold et al., 2012).

Intergenerational Studies

A life-course approach to developmental epidemiology is not limited to individuals in a single generation but can intertwine biological and social transmission of risk across generations, recognizing that geographic and secular characteristics may be unique to that cohort of individuals (Cairns, Elder, & Costello, 1996; Power, Kuh, & Morton, 2013; Stein, Susser, Saenger, & Marolla, 1975).

Experiences of the previous generation can operate at many different levels of generality. They may be specific to the mother–child dyad (e.g., the effect of drug use during pregnancy) or may affect everyone living in a certain neighborhood (e.g., poverty or exposure to an environmental toxin). All mothers and children may be affected by a particular event, such as a period of famine or disease, or children may be affected by their mother's developmental stage (e.g., children of teen mothers or elderly mothers).

Models for intergenerational research have recently developed (Cairns, Cairns, Rodkin, & Xie, 1998; Rossi, 1989), and statistical methods have become more tractable (Muthen & Muthen, 2000; Robins, 1992; Zeger & Liang, 1992). Undertaking transgenerational studies requires a level of commitment from both researchers and funding agencies that is hard to sustain over the necessary length of time, especially in the United States with its five-year funding cycles. Many American researchers have looked

abroad to find countries that have nurtured such studies and governments that understand their importance (Chasiotis, Scheffer, Restemeier, & Keller, 1998; Granger et al., 1998; Krueger, Caspi, Moffitt, & Silva, 1998). However, we can hope that as policymakers become more aware of the overlapping pattern of risk factors among chronic diseases and the risks associated with very early exposures they will come to understand the immense returns from investment in multigenerational research.

Impact Studies

Prevention Science

The strongest test of a developmental theory about causes of disease and its impact on society is an intervention that manipulates a core etiological factor and tests the outcome. Prevention science is the discipline that has arisen to put this principle into practice. Its strongest growth has been in the area of AIDS prevention, but it has also been an important force in developmental psychopathology, with its own academic societies and research journals.

Prevention science uses theory about the causes of disease to generate interventions, which when tested provide information not only about the effectiveness of the intervention, but also about the etiology of the disease (Dodge, 2001). The famous Broad Street pump intervention described earlier (Snow, 1855) is a classic example of prevention science: If dirty water caused cholera, then removing access to dirty water should both prevent new cases and support the etiologic hypothesis.

Epidemiology traditionally divides prevention into three categories, depending on the mean level of risk in the population of concern. Primary prevention programs like clean water, car seat belts, and parental leave programs are examples of primary or universal prevention. The scientific questions at this level have to do with what is prevented downstream by universal programs upstream. For example, the "Just Say No" drug abstinence program was introduced as a primary prevention for all children in school, designed to stop drug use before it began. Unfortunately, the developmental science behind it was inadequate, and the results were null, if not negative (Lynam et al., 1999). In another careful study of a primary prevention program for school-age children, Stattin and colleagues (Mahoney & Stattin, 2000) evaluated the youth recreation centers that are a ubiquitous feature of Swedish towns. Usually, these are places where young people can hang out, with very little adult supervision or structured activity. Participation in activities with low structure was associated with high levels of antisocial behavior for boys and girls, whereas participation in highly structured leisure activities was linked to low levels of antisocial behavior. Despite several studies, however, community leaders still strongly support these recreation centers: an example of how long it takes for research to influence policy.

On the other hand, primary prevention with children (e.g., the Good Behavior Game; Kellam, Koretz, & Moscicki, 1999), and families (e.g., a family income supplement; Costello et al., 2003) can be effective and suggest etiologic pathways that could be explored in further research. But prevention science has done relatively little in the way of *primary* prevention for mental health problems. It is highly likely that primary prevention programs that improve early nutrition or provide more family leave have effects on the development of psychopathology, but they have not been treated as scientific tests of theory, and so we do not know.

Secondary, or high-risk, intervention programs are much more likely to be subjected to scientifically informative testing, and this is where the bulk of prevention science has been done. A large number of interventions are based on high-risk children, schools, and communities, and many of them have survived the trial by fire of National Institutes of Health review committees and are both theory driven and scientifically sound. This is not the place to review this literature; the main issue for developmental epidemiology is that such studies should be epidemiologically sound. This means that it should be clear how far their results can be generalized. Does an intervention to reduce bullying (Olweus, 1987) work with girls as well as boys? In which age groups? In which ethnic groups? What can we learn about what drives bullying?

A good example of a secondary intervention that yields insights for developmental epidemiology is the Fast Track program for aggressive children in grade school. This was based on clearly articulated theory about cognitive difficulties that could interact with environmental risk to produce aggressive behavior in socially ambiguous situations (Dodge, Pettit, & Bates, 1994). High-risk youth were randomly assigned to an intensive intervention that lasted for 10 years. Hostile attributional bias was indeed found to be a partial mediator of the effect of the intervention on reductions in aggressive behavior. Two years after it ended, youth assigned to preventive intervention had significantly lower use of general and outpatient mental health services but not of inpatient mental health services (Jones et al., 2010). As adolescents and adults, they had fewer arrests (Group, 2010). The intervention was effective but clearly expensive, lasting as it did over 10 years.

Tertiary interventions have hardly been explored in the context of tests of developmental theory. Once children have developed clinically defined psychiatric disorders, interventions focus on clinical treatment rather than tertiary prevention, although pediatricians (Kendrick, 1999), psychologists (Williams, Holmbeck, & Greenley, 2002), and psychiatrists (Pols et al., 1996) are beginning to talk about the need for a focus on tertiary prevention. Given the early onset of most psychiatric disorders, this is clearly a vitally important area for future work.

Within this broad framework there is a wide variety of intervention strategies, some of which may take developmental issues into account. A good example is suicide prevention, which was comprehensively reviewed by Gould and colleagues (Gould, Greenberg, Velting, & Shaffer, 2003). Among the primary prevention efforts they discuss are gun control programs at the national and local level and school-wide suicide awareness curricula. Secondary prevention efforts have included skills-training programs for youth, whether identified through screening or self-referred, screening programs to try to identify children with suicidal ideas, training for gatekeepers such as primary care pediatricians, peer counseling programs, crisis centers, and hotlines. Other approaches include training the media on how to report suicide to minimize copycat behavior, and postsuicide counseling in schools and among the friends of youth who have killed themselves. Tertiary care programs focus on following up suicide attempters in an effort to reduce repeat episodes. Research on the effectiveness of all these strategies is patchy, and some continue to be used despite doubts about their developmental appropriateness and effectiveness (Gould et al., 2003; Gould, Cross, Pisani, Munfakh, & Kleinman, 2013). However, suicide is one of the few areas in child and adolescent mental health in which one can see the skeleton of an integrated prevention strategy beginning to emerge.

It sometimes feels as though progress in implementing prevention programs in the mental health area has been glacially slow, and public policy is often impervious to evidence. But prevention scientists are determined people, and they are building a powerful set of weapons in the form of statistical methods, meta-analytic studies, and cost-benefit analyses that will help them to get their message across in the next decade.

Burden of Illness and Costs and Effectiveness of Interventions

As we described earlier, epidemiology (the study of where, when, why, and to whom diseases occur) has a dual role: to increase our understanding of what causes an illness (scientific epidemiology) and to help institute policies to prevent or control it (public health epidemiology). Implementing policies to prevent or control disease costs money. Before allocating resources to any disease, policymakers need to know how big the problem is, what interventions are available, how useful they are, and how much they cost. So epidemiology has historically been concerned with estimating the burden of disease and the cost and effectiveness of interventions (Angold & Costello, 2000).

Developmental epidemiology has a new role to play in this area, for all the reasons discussed in the section on life-course epidemiology. It is becoming increasingly clear that we cannot afford to wait to intervene until, for example, a child develops conduct disorder. Treatment at that stage is expensive, labor intensive (Costello et al., 2007; Henggeler, Melton, Brondino, Scherer, & Hanley, 1997), and of modest effectiveness (Lipsey & Wilson, 1998). It is imperative that we apply what is known about early predictors to develop interventions that can be used earlier in the development of the disorder. This is an enormous research program and is addressed elsewhere in these volumes.

The role of the developmental epidemiologist is often that of record keeper: to measure the burden of disease (World Health Organization, 1996), the need for (Costello et al., 1993; Rice, Woolston, Stewart, Kerker, & Horwitz, 2002), cost of, and barriers to services (Flisher et al., 1997; Leslie, Rosenheck, & Horwitz, 2001; Owens et al., 2002) at different developmental stages, and the changes in disease incidence as new interventions are introduced (Brown, van Os, Driessens, Hoek, & Susser, 2000; Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1993; Kellam, Rebok, Mayer, Ialongo, & Kalodner, 1994).

None of these activities is new to epidemiology in general, but they have been a long time coming to the area of child psychiatric disorders. The next decade will see a significant expansion of cost, cost-benefit, and cost-effectiveness studies, either as new studies or as additions to ongoing ones.

Mental Health Surveillance

Tracking the prevalence (ongoing cases) and incidence (new cases) of diseases over time is essential if we are to study both the societal impact of a disease, and that of treatment or prevention programs. This is a program of work that has hardly begun in the area of child psychopathology. We rely on agencies of the Centers for Disease Control and Prevention (CDC) to tell us how many cases of SARS there were last year in the United States and whether the incidence of AIDS is increasing or decreasing. Until recently, it would have been of no use to ask CDC the same questions

about prepubertal depression or early-onset schizophrenia, although their social cost may well be as high (Lozano et al., 2012; Murray & Lopez, 1996). Areas where the CDC takes an interest in prevalence include drug use and abuse, on which annual surveys of the school-age population have been available since 1975 from the University of Michigan's Institute for Social Research. Thirty years of data can be tracked to show the rise and fall in use of different drugs. Another exception is the CDC's Youth Risk Behavior Surveillance System, an anonymous population survey set up in 1990 to monitor priority health risk behaviors that contribute markedly to the leading causes of death, disability, and social problems among youth and adults in the United States. These behaviors, often established during childhood and early adolescence, include tobacco use, unhealthy dietary behaviors, inadequate physical activity, alcohol and other drug use, sexual behaviors that contribute to unintended pregnancy and sexually transmitted diseases (e.g., HIV infection), and behaviors that contribute to unintentional injuries and violence.

These data can be used to show, for example, a small but steady decline in the proportion of high school students who report currently using alcohol, from 50.8% in 1991 to 34.9% in 2013 (the latest data available). On the other hand, the proportion making a suicidal attempt serious enough to need medical attention has increased from 1.7% in 1991 to 2.7% in 2013 (http://www.cdc.gov/healthyyouth/yrbs/overall.htm). Because the data come from different (anonymous) samples each year, they cannot be used to track an individual's progression. They do, however, provide hints of what legal or cultural changes might be doing to the development of risk behaviors across adolescence.

Other areas in which CDC has begun to involve itself are autism spectrum disorder (ASD), ADHD, and developmental disabilities. However, the CDC does not publish information on the most common childhood mental disorders: anxiety, depression, oppositional defiant disorder or conduct disorder, or many other disorders.

Clearly, a major task for developmental epidemiology in the next decade will be to help the CDC to shoulder the task of charting national rates of child and adolescent psychiatric disorders over time, as it has done for national rates of other serious conditions. Work is currently in progress to integrate brief psychiatric measures into national surveys such as the National Health Interview Survey (NHIS) and the National Health and Nutrition Examination Survey (NHANES-IV). NHANES has recently been using some modules of the DISC and the DISC Predictive Screener, and the NHIS is using a short questionnaire, the Strengths and Difficulties Questionnaire (Goodman et al., 2000), that is also used in several other countries. This will make international comparisons feasible. More work is needed to evaluate the validity of these measures across the age range and to assess their usefulness as a measure of the burden of child mental illness in the community. It is clear, however, that in the next decade it will be possible to stop treating assessment issues as research problems to be funded by federal research agencies and move them over to being issues to be dealt with by surveillance and monitoring agencies such as the CDC. This will have many advantages. First, it will make it possible to treat psychiatric disorders as on a par with other medical conditions. Second, it will produce national data sets, such as those produced by NHIS, which can be used to look at the sorts of questions raised by life course epidemiology: what environmental, political, and social conditions breed psychiatric disorders, and how societies should address these problems. Third, it will relieve the National Institute of Mental Health scientific research budget of the responsibility for basic prevalence studies and free up research dollars for questions on the scientific side of epidemiology, questions about causes and consequences.

Mechanisms: Genetic Epidemiology

In the past decade genetic epidemiology has become a driving force in the epidemiology of child psychiatric disorders. Three recent revolutions in genetic epidemiology will have a tremendous impact on developmental psychopathology in the next decade: behavior genetics, molecular genetics, and epigenetics.

Psychiatric Behavioral Genetics

The first revolution occurred when the methods of psychiatric epidemiology were applied to behavioral genetics. Psychiatric interviews like those described earlier were used in studies with genetically informative designs, such as twin, adoption, family, and migrant studies. For the first time, researchers explored not only the genetics of scalar characteristics, such as intelligence, but also of categorical disorders such as depression, measured in ways that approximate clinical diagnosis. Furthermore, behavioral geneticists began to take seriously issues of sampling so that they could talk about the contribution of genes to disease in the population as a whole, rather than in highly selected families or groups. Some longitudinal studies have also looked at how genes can have different effects at different developmental stages (Eaves & Silberg, 2003; Jacobson, Prescott, & Kendler, 2002).

An example of this approach is the work emerging from the Virginia Twin Study of Adolescent Behavioral Development (VTSABD), a population-based sample of twin pairs followed through adolescence into adulthood. One set of analyses investigated the role of genetic and environmental factors in the association between depressive symptoms and symptoms of overanxious disorder (OAD), simple phobias, and separation anxiety in 8- to 13-year-old and 14- to 17-year-old girls (Silberg, Neale, Rutter, & Eaves, 2001). There were distinct patterns underlying the association between depression and the different anxiety syndromes during the course of development. First, specific genetic influences on depression after age 14 reflected liability to symptoms of earlier OAD and simple phobias. Second, aspects of the shared environment that influenced symptoms of depression before age 14 contributed to symptoms of separation anxiety and simple phobias later in adolescence. Third, the shared environmental influence on depression in older girls also affected liability to symptoms of concurrent OAD and persistent separation anxiety. These results suggest that depression before and after age 14 may be etiologically distinct syndromes. Further analyses including several other longitudinal twin data sets reinforced the view that environmentally driven differences in stable levels of anxiety and depression continue to increase throughout the life cycle (Kendler et al., 2011).

Molecular Genetics

The second genetic revolution occurred when it became feasible to apply the methods of molecular genetics to epidemiologic samples. This development opens up the opportunity to use not only twin or adoption studies but a wide range of samples to test theories about candidate genes for specific symptoms. Even more exciting is the new opportunity to use the treasure-house of data from longitudinal studies to test for gene–environment interactions. Such studies can answer questions about which genes interact with which environmental factors, at what developmental singe. Two examples provide first glimpses of what is likely to be one of the most fruitful areas of developmental epidemiology in the next decade.

Investigators studied the male children from the Dunedin longitudinal study sample (Caspi et al., 2002) from birth to adulthood to determine why some children who are maltreated grow up to develop antisocial behavior whereas others do not. A functional polymorphism in the gene-encoding MAOA was found to moderate the effect of maltreatment. Maltreated children with a genotype conferring high levels of MAOA expression were less likely to develop antisocial problems. These findings provide epidemiological evidence that genotypes can moderate children's sensitivity environmental insults. The finding has since been replied in the VTSABD (Foley et al., 2004).

In other analyses, the Dunedin team investigated why stressful experiences lead to depression in some people but not in others (Caspi et al., 2003). A functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene was found to moderate the influence of stressful life events on depression. Individuals with one or two copies of the short allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events than individuals homozygous for the long allele. Again, an individual's response to environmental insults is moderated by his or her genetic makeup. The publication has aroused considerable controversy, but a meta-analysis of 55 studies found strong evidence to support the finding (Karg, Burmeister, Shedden, & Sen, 2011).

Geneticists have for generations been telling us that genes express themselves only in an environment, and that the key questions have to do with the relationships between the two over time. Developmental epidemiology and genetic epidemiology are already merging, and the process will continue in the next decade.

In the future, no epidemiologic study will fail ask participants to consent to the collection of biomaterial for DNA. In the immediate future, existing studies are going back and obtaining blood or saliva, or asking participants to consent to a new use of already collected biodata. Collaboration between molecular geneticists and epidemiologists with longitudinal data on representative samples offers an amazing opportunity for progress in understanding the biological and social origins of disease.

Epigenetics

Epigenetics is the study of the way the expression of heritable traits is modified by environmental influences or other mechanisms without a change to the DNA sequence, operationally defined as a stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence (Berger, Kouzarides, Shiekhattar, & Shilatifard, 2009).

Epigenetics can be divided into predetermined and probabilistic epigenesis. Predetermined epigenesis is a unidirectional, scripted, and predictable movement from structural development in DNA to the functional maturation of the protein. Probabilistic epigenesis, on the other hand, is a bidirectional structure-function development with experiences and external molding development. Most of what psychiatric researchers are interested in involves probabilistic epigenesis (Gottlieb, 1991a; Gottlieb

& Willoughby, 2006). A recent methylome-wide association study of blood biomarkers of environmental insults in schizophrenic patients and controls (Aberg et al., 2014) demonstrates that methylation studies can capture signatures of environmental insults even in peripheral tissues. Longitudinal epidemiologic studies with repeated blood samples will find a new use, testing for changes in the methylome associated with identified events.

SUMMARY: TRANSLATIONAL EPIDEMIOLOGY

This chapter has covered a lot of ground: from the first stirrings of understanding about childhood psychiatric disorders to the possibility of using epigenetics to identify gene–environment interactions that can generate psychiatric disorder. There are fuzzy boundaries between developmental epidemiology and developmental psychopathology, life-course epidemiology, genetic epidemiology, services research, and several other areas. Turning this fuzziness into a strength, we suggest adopting the language of *translational epidemiology* (Khoury, Gwinn, & Ioannidis, 2010; Weissman, Brown, & Talati, 2011). Translational science aims to move from bench to bedside, but translational epidemiology looks further, aiming to combine what is learned at the bench and bedside with the results of community-based studies and public health interventions (Khoury et al., 2010).

There is another dimension that current accounts of translational epidemiology omit: development. We have only to look at the age curve of alcohol dependence as an example to see that translation from mechanisms to interventions will be impeded if the effects of development are ignored. In this instance, conduct disorder is a strong predictor of early onset alcohol abuse or dependence only until age 15. Once alcohol misuse becomes developmentally normal, conduct disorder is no longer predictive (Sung, Erkanli, Angold, & Costello, 2004). This developmental pattern has implications not only for bench (molecular genetics) and bedside (high-risk interventions) but also for public policy. Figure 3.1 sketches just some of the ways developmental epidemiology, of which longitudinal community studies are an example, can grow translations across many branches of science.

INTRODUCTION

The chapter begins by considering what is meant by a cause—noting both equifinality and multifinality. Noncausal alternative explanations for a statistical association are discussed in terms of genetic mediation, social selection, reverse causation, misidentification of the risk feature, and a confounding variable. Unmeasured confounders are discussed by considering propensity scores, growth curve trajectories, structural equation modeling, direct acyclic graphs (DAGs), mediation analyses, and sensitivity analyses. The different varieties of natural experiment are reviewed with respect to many genetically sensitive designs. These include multivariate twin designs, discordant twin pairs, discordant sib pairs, children of twins (CoT) designs, the extended children of twin (eCoT) design, the longitudinal twins and parents (LTaP) design, adoption studies, assisted reproduction technologies (ART), maternal versus paternal smoking contrasts, and migration strategies. The contrasting of two environmental risk factors is discussed with respect to twin–singleton comparisons, adoption as a radical change of environment, time-series designs, and inverse probability of treatment weighting. Designs to deal with social selection involve circumstances that entail either universal introduction of risk or its removal. Instrumental variables are discussed in relation to early puberty, Chinese one-child policy, the sex of the co-twin, and Mendelian randomization (MR). The regression-discontinuity design is examined as the only design that deals adequately with unmeasured confounders. Adoption/fostering is considered as one means of separating prenatal from postnatal effects. Finally, we look at research indicating that natural experiments are truly needed.

This chapter is based on Rutter's (2007, 2012) papers on natural experiments and it includes substantial sections that appear in the same form as they did in those papers. Both authors contributed equally to this chapter. We are most grateful to Camilla Azis-Clauson for great help in searching the literature and in drafting.

WHAT IS MEANT BY A CAUSE?

At first sight, it might be thought unnecessary to ask what is a cause when discussing causal hypotheses. Thus, surely, a cause can simply be considered as anything that brings about whatever outcome is being examined? However, there are several different reasons that the issue is not quite as straightforward as that. First, with respect to either psychopathology or psychological traits, multifactorial causation is the rule. There are very few simple direct

determinative causal effects on any outcome. MacMahon, Pugh, and Ipsen (1960) suggested the metaphor of a web of causation, and Rothman and Greenland (2002) similarly argued that any causal effect will have been brought about by a constellation of components acting in concert. With very few exceptions, there is no such thing as a single necessary and sufficient cause.

Several different causal pathways may all lead to the same end point (Rutter, 1997), what Cicchetti and Cohen (1995) referred to as *equifinality*. Equally, any single starting point may lead to a diverse range of outcomes—what Cicchetti and Cohen called *multifinality*. There can be no single cause of any outcome, for these reasons and also because each causal element is likely to be reducible to a pathway that starts with some other element. Mackie (1965, 1974) referred to causes that are insufficient but necessary components of unnecessary but sufficient causes—now usually referred to as INUS (Schwartz & Susser, 2006). That sounds complicated, but actually it is not. It is simply a way of stating that the overall causal nexus in its entirety is a sufficient causal condition being considered without needing to invoke the operation of any other influences. On the other hand, it is unnecessary because it represents only one of several possible causal pathways. The clear implication is that changing a causal factor will actually reduce the population's burden of disorder (if the outcome being investigated concerns a disorder) (Robins & Greenland, 1996). Hill (1965) famously outlined a set of guidelines that might be used to consider the possible validity of a causal inference. These were helpful, but the most important requirement is the need to consider alternative explanatory hypotheses (Cochran & Chambers, 1965). Simply providing supporting evidence that might bolster the causal inference should never be acceptable (National Research Council, 2002).

Holland (1986) argued that attributes of units can never be causes because causes must be, in principle, open to manipulation. That sounds reasonable, but it is important to note that what seemed to be fixed attributes can often be broken down in a more meaningful way. For example, sex is a fixed attribute, but it is reasonable to pose the question as to whether any effect is a consequence of the person's chromosomes, prenatal hormonal influences, contemporary hormonal influences, and so forth.

The two most influential causal models in recent times have been those of Campbell and of Rubin. Campbell's approach focused on the identification to threats to validity and the inclusion of design features that might prevent those threats from occurring or might render them implausible (Shadish, 2010; West & Thoemmes, 2010). By contrast, Rubin focused on precise specification of possible outcomes and assumptions that are mathematically sufficient to estimate the causal effect. Both have a preference for design over statistical analysis, although analytic approaches are crucial to both. See Berzuini, Dawid, and Bernardinelli (2012) and Foster (2010) for a fuller discussion of the different statistical perspectives needed in studying causality. Pearl (2000) argued for the helpfulness of directed acyclic graphs (DAGs) as a way of making statistically explicit the causal process that is being examined and the assumptions that are involved in its testing (Robins, 2001; Robins, Hernán, & Brumback, 2000).

NONCAUSAL ALTERNATIVE EXPLANATIONS FOR AN ASSOCIATION

Five possibilities have played the greatest role in the development of natural experiments. First, there is the possibility of genetic mediation of the risks stemming from an environmental feature. This possibility arises as a consequence of both passive and active gene–environment correlations. Passive in this connection refers to the fact that parents who pass on their risky genes may also have a tendency to create risky environments. Because a risk factor clearly refers to an environmental feature (as would be the case with poverty or social disadvantage or family conflict and probably also applies to the rearing provided by parents with a mental disorder; Rutter et al., 1997), the causal mediation may, nevertheless, be genetically mediated. Pike, McGuire, Hetherington, Reiss, and Plomin (1996) provided an example of how effects of family conflict are partially genetically mediated. Gene–environment correlations refer to the tendency for individuals (both children and adults) to shape and select their environments. As a consequence, there is evidence of genetic influences on individual variations within a range of different types of risk exposure (Kendler & Baker, 2007). To deal with these possibilities researchers have devised a range of genetically sensitive designs to test environmental–risk mediation hypotheses.

Second, there is the possibility of social selection or allocation bias (Caspi, 2003)—meaning that the association between the risk experience and the outcome reflects the *origins* of the putative risk factor rather than its effects. The possibility arises, for example, in terms of the risk for a variety of psychopathological outcomes for children born to a teenage mother (Maynard, 1997; Moffitt & Team, 2002). Is this a reflection of the causal impact of rearing by a teenage mother, or, rather, does it reflect the qualities of

individuals who have a pregnancy as a teenager? In other words, would the same be found for individuals born to an older mother who, at an earlier point in her life, had a pregnancy as a teenager? Designs using twins or adoptees have been developed to determine the possibility of social selection. Also, designs have been used that capitalize on circumstances in which total populations have been exposed without the opportunity of choice or selection.

Third, there is the possibility of reverse causation. In a now classic article, Bell (1968) argued persuasively that some of the supposed effects of socialization experiences might reflect the effect of children on their social environments (as indexed, for example, by parents and teachers) rather than the effects of the children's rearing environment on them. Thomas, Chess, and Birch (1968) argued much the same when considering children's temperamental features. Such reverse effects have been shown in both experimental (Anderson, Lytton, & Romney, 1986) and naturalistic studies (Bell & Harper, 1977) as well as in studies of the effects of children on their adoptive parents (Ge et al., 1996; O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998). The notion of reverse causation has also been extended to associations between one form of psychopathology and another type of disorder (McGue & Iacono, 2005).

The fourth possibility is that the risk feature has been misidentified. Most famously, this was the case with the postulate that broken homes were a major cause of antisocial behavior (see Wootton, 1959, for a critique). Research went on to show that the main risk stemmed from either family discord or poor parenting rather than from a family change or breakup as such (Brown, Harris, & Bifulco, 1986; Fergusson, Horwood, & Lynskey, 1992). Similarly, designs using adoptees have been used to separate prenatal from postnatal effects and to differentiate among different possible sources of environmental risk.

Fifth, there is the very real concern that any association might reflect nothing more than some confounding variable—meaning any variable that both differentiates between the groups to be compared and is statistically associated with the outcome being investigated. Traditional multivariate statistical analyses make adjustments for confounders that have been measured. Unfortunately, these methods involve several serious problems (Rutter, Pickles, Murray, & Eaves, 2001). It is evident that statistical adjustments cannot solve the problem. Therein lies the need for natural experiments. First, there is the logical problem of having to use an invariant set of associations to infer what would happen if a key association was different or was changed (McKim & Turner, 1997). That necessitates the assumption that the effect within the existing sample would apply to a different set of circumstances (i.e., without the confounder). The general statistical strategies for dealing with possible confounding variables are discussed in Rosenbaum (2002); Rothman and Greenland (1998); Shadish, Cook, and Campbell (2002); and Susser, Schwartz, Morabia, and Bromet (2006). It would be inappropriate to control for factors that are intermediate on the pathway between exposure to the risk factor and the outcome or those that are caused in part by exposure to the risk experience (see Weinberg, 1993, for a discussion of this issue).

The problem of assuming that effects within the existing sample would apply to a different set of circumstances is particularly great if the two groups being compared do not overlap in key cells (see Melhuish, Belsky, Leyland, & Barnes, 2008, for an example of this kind). They found that scarcely any children in the comparison group came from high-risk families, whereas these constituted a high proportion in the intervention group. Propensity scores are particularly useful in identifying where there is a lack of overlap and the problem can be partially circumvented by dropping the overlap cells before undertaking the statistical controls. They are also helpful in reducing the biasing effects down to a single balancing factor. Note that it is often assumed that if a multivariate analysis shows an effect of A on some outcome that is maintained after taking account of the effects of B or C, this means that necessarily there is a true effect of A in the absence of B or C, but it does not (Rutter, 1983).

An even greater problem is presented by the uncertainties regarding unmeasured confounders (Academy of Medical Sciences, 2007). The main problem does not lie in the control for confounders that have been conceptualized and carefully measured. Rather, the main difficulty arises from unmeasured confounders. The problems in dealing with confounders may be reduced in five main ways (Rutter, 2009). First, propensity scores can be used to determine the features associated with *exposure* to the putative causal influences. They can then be employed to calculate an inverse probability to treatment weighting (IPTW) to create two comparable groups (Robins et al., 2000). The technique involves a minimum of statistical assumptions and Sampson et al. (2006) provided a particularly clear account of its use. Nevertheless, its value is critically dependent on the identification of all the most important features influencing risk exposure.

A second approach is to use growth curve trajectories to take in account of an individual's overall liability to the outcome being considered (Nagin, Barker, Lacourse, & Tremblay, 2008). The logic here is that if the putative causal

influence alters a person's growth curve with respect to the outcome being considered, a causal influence is more probable. The use of this approach requires at least four measurement points over a substantial period of time to create a valid growth curve and requires a time-specific exposure to the putative causal influence. Nagin et al.'s (2008) example showed its value in testing for the effects of gang membership on criminal behavior. Furthermore, as with any other form of cluster analysis the curves represent a model (rather than a real phenomenon at an individual level). The number of curves selected for analysis is a matter of judgment on their likely meaning rather than the result of some single statistical solution, although naturally, statistical criteria should play a crucial part in the choices.

Third, structural equation models (SEMs) can be used to treat confounders as a latent variable, hence allowing a better assessment of their effects after taking into account measurement error. If multimeasurement longitudinal data are available, a two-stage approach can be employed: the first step involves the regression of effects on exposure, and the second step uses the predicted values of the exposure covariate in a regression of the putative cause on outcome (Dawid & Pickles, 2007). Fourth, as already noted, DAGs can use preexisting background knowledge to indicate the ways a possible confounder might operate. The value of this approach is crucially dependent on the plausibility of the model.

The fifth method is provided by mediation analyses (Baron & Kenny, 1986; Fairchild & MacKinnon, 2009; MacKinnon, Fairchild, & Fritz, 2007). On their own, they do not provide a test of causation, but what they do is to isolate a putative key mechanism that could account for the observed statistically significant association. The logic is that when the postulated mediator for C with respect to the effects of A on B is introduced into the overall model, the original correlation of A on B should drop to zero if there is complete mediation or be substantially reduced if there is partial mediation (see Kumsta, Rutter, Stevens, & Sonuga-Barke, 2010, for a discussion of the issues). Care in mediation analyses is required to ensure that there is no confounding between the mediator and the outcome.

Whatever the approach used, there is value in using sensitivity analyses to quantify how strong a confounding effect would have to be to overturn a causal inference based on a case–control comparison. For example, Cornfield et al. (1959) used such an analysis to show that if the association between smoking and lung cancer was due to a confounder, such a confounder would have to be nine times as frequent in heavy smokers as in nonsmokers to undermine the causal inference. Clearly, that was extremely implausible.

Last, it is necessary to consider the mistaken view that randomized controlled trials (RCTs) provide the gold standard for testing for causal influences. RCTs do constitute the gold standard for assessing the effect of a planned intervention. They provide much the best way for providing an unbiased measurement of intervention effects within that sample in relation to a particular intervention. There are three important limitations, however, with respect to studying causation. To begin with, the fact that an intervention has a significant effect does not necessarily mean that this can be generalized to what caused the problem in the first place. Second, RCTs often apply to rather specialized groups that may not be directly relevant to the population of interest. Third, attrition or nonparticipation may be a substantial problem in an RCT, particularly when it is dealing with long-term effects. It has been suggested that prevention trials allow for a good opportunity to test hypotheses about etiology (Howe, Reiss, & Yuh, 2002). However, as Howe et al. (2002) pointed out, for them to be used in this way certain key design features are essential, and these are usually not available.

Propensity scores, growth trajectories, structural equation modeling, mediation analyses, and RCTs provide important elements in the research process, but none constitutes an adequate substitute for natural experiments.

NATURAL EXPERIMENTS

Natural experiments differ fundamentally from many of the conventional statistical approaches in that they do not adjust or control for confounders. Instead, they use naturally occurring circumstances that serve to separate variables that ordinarily go together and, by this means, provide manipulations and not just analysis of crucial variables. Cook and Campbell (1979) and Shadish et al. (2002) were pioneers in developing quasi-experiments or natural experiments. They discussed the vital interplay between designs and statistical analysis. It is important to appreciate that natural experiments are not just a list of designs because the principles may be applied to the analysis of data sets gathered for other purposes. Thus, this may arise, for example, with cohort studies in which it is possible to construct estimators that exploit natural experiments that happen to be embedded within the sample (e.g., siblings and twins). With each of the natural experiments to be described, we consider their possible limitations and the assumptions they have to rely on that may or may not be

justifiable. Each design carries its own threats to internal and external validity and progress is best achieved when different studies, using different designs with different limitations, converge on similar findings.

Genetically Sensitive Designs

There are some nine types of natural experiments designed to differentiate between genetic and environmental mediation of risks through a variety of twin and adoptee designs, through offspring conceived with assisted reproduction technologies, and migration strategies. Twin designs use the contrast between monozygotic (MZ) and dizygotic (DZ) twin pairs to partition the population variance into additive genetic and shared or nonshared environmental effects. This contrast is predicated on the fact that MZ pairs share 100% of their segregating genes, whereas DZ pairs share on average just 50%. By treating some postulated environmental causal factor as a trait or phenotype, it is possible to estimate the heritability of the risk factor trait. By means of cross-twin, cross-trait analyses (the cross being between the risk factor and the outcome), the extent to which mediation is genetically or environmentally mediated can be quantified. Longitudinal data will be required to check the temporal order.

Multivariate Twin Designs

The longest established twin strategy is the use of multivariate twin analyses (see Kendler & Prescott, 2006). Findings using this approach raised doubts with respect to the causal inference made with respect to the substantial association found between an early age of first drinking alcohol and the later development of alcoholism (Grant & Dawson, 1997). Multivariate twin analyses showed no environmentally mediated effect deriving from the age of first drinking. Rather, both the early age of drinking and the alcoholism reflected the same genetic liability. Similarly, Jaffee et al. (2004) used the same strategy to examine the observed association between both corporal punishment and physical child abuse and children's propensity to engage in antisocial behavior. The findings confirmed environmental mediation in the case of abuse but not for corporal punishment, for which the mediation was largely genetic. That is, the implication was that corporal punishment probably mainly occurred as a result of responding to the child's genetically influenced behavior. By contrast, physical abuse did not show this effect and presumably arose from either features in the abusing parent or from features in the social or physical environment. On the other hand, analyses also showed that the regular use of severe physical punishment did involve a propensity for this to escalate into child abuse. The strength of the design is that it allows a means of disentangling different effects but, equally, allows detection of more complex two-way associations.

Much research has proved the value of multivariate twin analyses, but there are several important limitations. For example, the equal environments assumption is probably violated, at least in part, when studying an outcome such as depression or antisocial behavior (Rutter, 2006). But there are three other rather different hazards. First, the operation of parsimony in modeling sometimes means that potentially important features are dropped from the model because they just fail to reach significance. This arises most frequently with shared environmental effects. On occasion, the consequence may be a misleading model (see Maes et al., 1999, for an example of where this occurred). Second, twin studies assume that mating is random, whereas often it may not be. Third, there is rarely the power to deal with the confounding of genetic effects by the inclusion of GxE (when the E involves shared environmental effects).

Discordant Twin Pairs

Discordant same-sex twin pairs reared together represent a rather different twin strategy. The rationale in this case is that by examining pairs that are discordant for both the hypothesized environmental risk factors and the outcome being studied, it will be possible to determine how the two coincide. The design provides a substantial degree of control for shared genetic and environmental liabilities (Kendler & Prescott, 2006). Prescott and Kendler (1999) used this design to examine the supposed causal effect of early drinking on later alcoholism. Statistical modeling showed that the association largely reflected a shared genetic liability, although there was some effect from shared environmental factors. There are two important limitations. First, the discordance within MZ pairs raises the question of *why* they were treated differently within the family or had different experiences outside the family. No robust findings on this important matter are available in the published literature. Second, although the design provides a strong pointer that the within-pair difference in risk exposure exerted a causal influence it cannot completely rule out the possibility that some *other* experience was responsible (Jaffee, 2011; Vitaro, Brendgen, & Arseneault, 2009). Note, too, that, because MZ twins share 100% of their DNA, differences in their experiences cannot logically arise from differences in the structure of their DNA. Nevertheless, it could result from epigenetic differences within a pair (Fraga et al., 2005; Mill et al., 2006;

Wong et al., 2010). This does not invalidate the design, but it does complicate the interpretation because the epigenetic differences are likely to reflect environmental influences but these may operate through effects on gene expression rather than a direct effect of the environment itself.

In dealing with the discordant twin design, Lynskey (Lynskey, Vink, & Boomsma, 2006; Lynskey et al., 2003), first using the Australian twin register and then the Netherlands twin register, examined the so-called gateway hypothesis that the early use of cannabis led, by some form of causal mechanism, to an elevated risk of other elicit drug use. Both studies showed a significant gateway effect—with a two- to fourfold increase in other drug use. Retrospective reporting at age 30 was required to obtain assessments of lifetime use, and the comparisons were based on all twins. The numbers were too small for a full control of genetic influences by focusing on monozygotic pairs. Contrary to the early alcohol study (Prescott & Kendler, 1999), both the Lynskey et al. studies confirmed the likely environmentally mediated causal gateway effect. On the other hand, the mechanisms involved were quite uncertain. They could reflect attitudes induced by early pleasurable cannabis effects or a social effect operating by means of cannabis use providing an entry to groups using other drugs and bringing about contact with drug dealers.

Rutter (2007, 2012) used a study by Caspi et al. (2004) to illustrate how a combination of design features can substantially increase the power of a discordant MZ twin design to test for causal effects. The risk feature being investigated was maternal negative emotion focused on one twin, this having been assessed when the twins were aged 5 years using standardized ratings based on audio-taped interviews with mothers. Outcome was assessed two years later using teachers' reports. This removed the possibility of rater bias, and it also examined effects that spanned a radical change in environment (namely, starting school). The prospective longitudinal design provided measurement of within-individual change and determined the temporal sequence. Because the analysis took account of the children's behavior at age 5, the prospective strategy effectively ruled out any mediating effect of the child's behavior on the mother's emotional expression. The main limitation, as with other quasi-experimental designs, is the uncertainty as to whether the psychopathological risk stemmed from the negative expressed emotion per se or rather from some associated environmental feature impacting one twin only in the MZ pair. Hence, the natural experiment convincingly showed a significant environmental effect, but it could not sort out whether the maternal negative expressed emotion exerted the causal effect as against the possibility that it simply indexed some other environmental influence. In addition, the findings leave open the question of what set of features led the mother to respond so differently to the two twins.

Discordant Sib Pairs

Discordant twins cannot be used to examine prenatal risk effects, but discordant sibling pairs can serve the same purpose. Obel and colleagues (2011) used this design to examine the effects of the fetus' exposure to maternal smoking. Smoking was assessed from maternal report at the time of the child's birth, and attention-deficit/hyperactivity disorder (ADHD) was determined from clinical record register data. In the sample as a whole there was a highly significant odds ratio of 2.2, but the discordant sibling comparison showed a much reduced, statistically non-significant ratio of 1.2, which cast serious doubt on the causal inference with respect to ADHD but again confirming the causal effect on birth weight (which had been supported by all research strategies). It is noteworthy that if a natural experiment had not been used there would be the strong inference of a causal effect because supposedly there had been an adequate statistical control for confounders. Because there is random allocation of genes across sibs, there was good control for genetic liability. See D'Onofrio et al. (2010) for another example of the use of a discordant sib pair design.

Nevertheless, although this is an excellent design for studying prenatal risk factors, three limitations may be relevant. First, sibling comparisons involve the assumption of a stable unit treatment value (SUTVA)—meaning that the effect of each participant's exposure to the risk factor does not influence other unexposed participants (Lahey & D'Onofrio, 2010). That is not a plausible problem with respect to prenatal maternal smoking exposure, but it could well be relevant when examining postnatal influences. Second, the design involves the assumption that any differences between women who quit smoking when they become pregnant and those who continue smoking heavily is unrelated to any risk factors for the child outcome being considered. Although this possibility has been examined in relatively few studies, the large sample (over 18,000) in the UK Millennium Cohort study did provide the possibility of examining this issue (Pickett, Wilkinson, & Wakschlag, 2009). The findings showed that heavy smokers had the most problematic psychosocial context, and the implication is that this could reflect postnatal influences on child outcomes.

This was examined directly by Boutwell and Beaver (2010) using what they called a propensity score approach.

The maternal features used included antisocial behavior, substance abuse, depression, lower level of education, younger age, and family adversity. Three paternal features were also included. Unfortunately, the authors appear to have misunderstood the logic of propensity scores in that they included the child's Apgar score, delivery complications, and labor complications. Not only was it the case that none of these were associated with maternal smoking, but also in the case of first-born children the features will have followed (not preceded) maternal smoking. The paper argued that the propensity score approach reduced the effect of confounders but failed to appreciate that it was an error. The same problem also appears to have applied to a comparable study by McCrory and Layte (2012).

Third, the design does not provide unbiased estimates if the risk factors are not static over time (Jaffee, Strait, & Odgers, 2012). Jaffee and colleagues (2012) used the example of single motherhood as a possible risk factor for children's antisocial behavior. Sibling comparisons might be biased if the mother was younger than 20 years and single when her first child was born but older than 20 years and married when her second child was born. As in all natural experiments, it is crucial to consider the assumptions that have to be made and then decide whether these are actually likely or unlikely to bias the design with respect to the risk factor and outcomes being examined.

Harden et al. (2007) used sibling comparisons to examine whether children born to adolescent mothers had more mental health problems as a result of being reared by an adolescent mother. The alternative possibility is that any such effect was a consequence of the factors associated with being an adolescent mother rather than rearing by such a mother. To address that possibility, children of teenage mothers were compared with the firstborn children of older mothers. There was no difference between children born to teenage mothers and children born to older mothers who had had a birth as a teenager some years previously. A novel feature of this study was its integration with a children of twins (CoT) design. The key comparison here, then, is whether the children born to teenage mothers showed more mental health problems than their first cousins born to older mothers. The findings showed that they did have more problems, and this was consistent with the causal effects of early motherhood rather than the operation of genetic or environmental third variables. It is important to note that Jaffe, Caspi, Moffitt, Belsky, and Silva (2001) using the Dunedin longitudinal study found both an effect of rearing by an adolescent mother and an effect of being born to a mother who had been a teenage parent when younger. Why these two studies produced somewhat different findings is not clear. So far as use of the CoT design is concerned, there is the usual problem of no information on the fathers.

Children of Twins Design

The CoT design provides a useful extension of twin strategies (D'Onofrio et al., 2003; Rutter et al., 2001; Silberg & Eaves, 2004). The rationale of this design is that the offspring of adult MZ twins will be social cousins but genetic half-siblings (half because one parent is part of an MZ pair and the other is not). By contrast, the offspring of DZ twins are cousins both genetically and socially. If the postulated causal parental feature involves a genetically mediated risk, it should apply as much to the offspring of both the MZ twins regardless of whether one is providing the social rearing and the other is not. This will not apply as much to the offspring of DZ twins because, on average, they share just 50% of their segregating genes. The CoT design has been used with good effect to show that harsh forms of physical punishment have an environmentally mediated influence on disruptive behavior and substance use and abuse in the children (Lynch et al., 2006) and have shown that prenatal exposure to maternal smoking does not have an effect on ADHD, at least not in alcoholics (Knopik et al., 2006). The CoT design constitutes a potentially useful strategy for testing for environmental mediation, but it has several limitations. First, as is obvious from the necessity of using the rather small genetic differences between cousins and half-siblings, it requires very large samples. Second, it is quite difficult to take adequate account of the unknowns in both the genetic background and rearing environment provided by the parent who is not a twin. Third, unless the spouse background and rearing behaviors are measured and included in the analysis, the findings for behaviors that involve dyads (as would be the case, e.g., with marital conflict) could be misleading (Eaves, Silberg, & Maes, 2005). To deal with these and other related issues, two extensions of the CoT design have been developed.

ECoT Design

First, the extended children of twins (ECoT) design includes data from adult twins and their offspring and child twins and their parents (Narusyte et al., 2008). The ECoT model has the special advantage of being able to distinguish passive genotype–environment correlations from evocative genotype–environment correlations. The Narusyte study used only cross sectional data, and it would definitely be advantageous to attempt the same with

longitudinal data. Combining two different samples necessarily involves the assumption that the combined samples be comparable in terms of size, participant characteristics, and measured constructs. Because the model excludes the spouse of the parent, assortative mating cannot be taken into account. Also, it appears from simulations that the model performs less well when it includes parental traits influenced by the shared environment.

LTaP Design

The other extension is the longitudinal twins and parents (LTaP) design. An earlier version of the use of combination of twin and family data was described by Meyer et al. (2000). It showed an environmentally mediated effect of family adaptation, but the model used had the substantial disadvantage that the measurement of conduct disorder in the parents had to be reliant on retrospective measurement. The LTaP development obviated that problem by availability of a follow-up into early adult life of child twins. In other words, there was information about twin behavior prior to adulthood and in adulthood with the availability of measures in both age periods. The model upheld the assumption that the same genes influenced parent and offspring phenotypes, provided that there were no sizeable cohort effects. The design also estimated the degree of phenotypic assortment.

Silberg et al. (2010, 2012) used the LTaP design very well to examine the effects of parental depression and parental antisocial behavior on three different forms of psychopathology in the children: ADHD, conduct disturbance, and depression. The findings were striking in showing that the impact of parental antisocial personality on ADHD in the child was entirely genetic. Conversely, the association between parental antisocial behavior (ASB) and child depression was largely environmental. On the other hand, both genetic and family environmental mediation accounted for the association between parental ASB and children's conduct disturbance. The pattern of findings with respect to conduct disorder and depression in the children was much the same when studied in relation to parental depression. Specific parenting behaviors were not included in the published analyses, but separate analyses from the same data set showed the important mediating role of parental neglect on child conduct disturbance over and above any indirect genetic correlation between parents and their children (Eaves, Prom, & Silberg, 2010). As will be appreciated, particular assumptions are involved in several elements in the modeling; however, the main limitation for the design as a whole concerns the lack of information about the twins' spouses and environment, although such information can in principle be obtained and modeled (Jacob et al., 2003).

Adoption Studies

As Rutter et al.'s (1990) review of research strategies clearly showed, there are many different variants of the adoption design. However, all rely on the fact that adoption separates genetic heritage (and prenatal effects) from the rearing environment. In much of the literature, the emphasis has been on the detection of genetic effects, but here we are concerned only with the design as a means of testing environmental mediation. Duyme, Dumaret, and Tomkiewicz's (1999) research may be taken as an example because of its innovative use of measurement of the adoptive environment together with the availability of longitudinal data. The study was designed to examine the effects of the socioeconomic (SES) level of the adoptive family on the IQ gains following adoption between the ages of 4 and 6 years of children who had been compulsorily removed from their families during infancy because of concerns about abuse or neglect. Not surprisingly, there was an overall group increase in IQ following adoption (as would be expected because of the overall environmental improvement). What was novel was the determination of whether the degree of rise in IQ varied according to the SES of the adoptive families. The findings showed that the gains were significantly greater for those placed in high SES families than for those placed in low SES families. It is that finding that was novel in that it provided the best evidence that the gain in IQ was indeed a consequence of the qualities of the adoptive home.

There are, nevertheless, important limitations to adoption designs. First, there may have been selective placement. However, because that can be measured and because it is a relatively straightforward matter to take it into account in data analysis, that is not the main issue. What is a greater concern is the lack of comparability of the biological families and the adopting (rearing) families. In most countries, adopting parents tend to be better educated and more socially advantaged than the rest of the population, and, conversely, biological parents who have given up their children for adoption are much more likely to include a disproportionately high percentage of individuals with genetic risk characteristics.

Stoolmiller (1998, 1999) drew attention to the restricted range of family environments in adoptive families (as a result of the screening of families for what are thought to be environmental risk features). McGue et al. (2007) used a sample of 409 adoptive and 208 nonadoptive families from the Minnesota Sibling Interaction and Behavior

Study (SIBS) to examine this possibility. They found that, relative to nonadoptive families, adoptive families showed a 41% reduction of variance in what the authors called disinhibitory behaviors such as alcohol and substance abuse, plus 18% less variance in socioeconomic status. In short, the findings confirmed the Stoolmiller claims, but, contrary to Stoolmiller, there was no effect of the restricted range on adoptive sibling correlations for delinquency, drug use, and IQ. In other words, perhaps the consequences of the restricted range might have less effect than one would have thought on testing of environmental mediation through adoption designs.

However, as McGue et al. (2007) pointed out, it appears that adoption practices have changed over the last generation in Minnesota, with less screening than there had been in the past. The findings from other independent studies are needed before firm conclusions can be drawn on this particular limitation of the adoption design. From a practical point of view, the limited value of adoption designs, at least in the United Kingdom, is provided by the marked reduction in the number of healthy babies put up for adoption in the infancy period. Also, there are restrictions in many places on the use of adoptee samples for research.

Assisted Reproduction Technologies

Yet another way to exclude genetic mediation of risk, to identify environmental mediation where it occurs, is provided by the use of ARTs (see Thapar et al., 2007). ARTs retain the genetic link between mother and child (as with homologous in vitro fertilization and sperm donation, whereas others do not as with egg or embryo donations). If the maternally provided prenatal risk factor has an environmentally mediated effect on the child's outcome, this should give rise to the same associations irrespective of whether the mother and child are genetically related. Conversely, if the risk is genetically mediated, it should be evident only where there is a genetic link between mother and child. This method has been used to investigate the postulated prenatal risk from maternal smoking associated with both antisocial behavior (Rice et al., 2009) and ADHD (Thapar et al., 2009). Findings showed genetic mediation in relation to both outcomes, but there was environmental mediation in relation to birth weight (as found by animal models as well as by other human research). Importantly, as with other studies the findings showed that statistical control for confounders (including parental ADHD and maternal alcohol consumption) was inadequate to deal with the possibility of genetic mediation. The same design has also been used to test for environmental mediation of hostile parenting on antisocial behavior in the children (Harold, Elam, Lewis, Rice, & Thapar, 2012).

The main practical limitation of this design is the need for an adequate sample size to make the required comparisons. Some have expressed concern as to whether the women who use ARTs are systematically different from those who do not, in ways that might bias the design. We do not see that as a likely problem because the key thing is whether there is a systematic difference between those who have sperm donations compared with those who have egg or embryo donations. Theoretically, that is a possibility, although it is difficult to see how it could arise. With respect to the use of the design to look at the effects of smoking, there is the further problem that secular trends have meant that the number of women smoking in pregnancy is low, with an inevitable reduction in the size of key cells. On the other hand, the sample size was adequate to show a true causal effect of prenatal maternal smoking on the child's birth weight. In the studies undertaken, analyses were based on symptom counts rather than clinical diagnoses and, ideally, it would be useful to have adequate clinical assessment. Nevertheless, in our view the implausibility of biases in this particular design make it a potentially useful one to use, provided there can be the acquisition of appropriate ART samples of adequate size.

Maternal Versus Paternal Smoking Effects

Another way to test the possible causal effect of exposure to maternal smoking during pregnancy is to compare the effects with those of paternal smoking during pregnancy (as the latter cannot have had the same prenatal effect). Langley, Heron, Smith, and Thapar (2012) made this comparison using the Avon Longitudinal Study (ALSPAC) of some 8,000 children. The outcome examined was, again, ADHD. Because of the extensive evidence both from human and animal models that maternal smoking has a causal effect in leading to a reduced birth weight, this comparison was made between maternal and paternal smoking. In line with previous research it was found that maternal smoking was associated with a substantial and significant reduction in birth weight but that paternal smoking was not when the mother did not smoke. Conversely, however, both maternal and paternal smoking was associated with ADHD symptoms in the offspring, and there was no significant difference between the two. This suggested that the prenatal effect was not representing a causal association. It was possible, however, that paternal smoking might have had an intrauterine effect of on the fetus through passive smoking, but there was no evidence to show that this was the case. It is surprising that rather more use has not

been made of this comparison, but presumably it has not because so few studies have examined paternal smoking during the pregnancy on the grounds that it could not have a direct causal effect. The point to make here is that it is a pity to pass up the possibility of using this comparison as an informative natural experiment.

Migration Strategies

The last strategy to control for genetic mediation to mention is provided by migration. Expressed simply, the natural experiment arises because when people move from country to country they carry their genes with them but they may encounter quite different environmental circumstances. The natural experiment therefore is determining what happens when high-risk or low-risk ethnic groups move to a different country and adopt entirely different lifestyles. Two medical examples illustrate the point most clearly. The Pima Indians have long been observed to have an unusually high rate of obesity and obesity-connected conditions. It seems very likely that genetic factors play a role in this but the experimental contrast was provided by comparison of the outcomes between Pima Indians living in affluent circumstances and those living in areas with quite different (less adequate) nutritional opportunities. The findings were striking in showing that, when the lifestyle and dietary conditions varied, so did the rate of medical conditions arising from obesity (Ravussin, Valencia, Esparza, Bennett, & Schulz, 1994; Valencia et al., 1999).

A somewhat parallel, although less dramatic, example is provided by an early study of coronary artery disease in people of Japanese origin living in Japan, Hawaii, and California (Marmot & Syme, 1976). The findings showed that when the Japanese people adopted a Californian lifestyle their rate of coronary artery disease rose to much the same levels as those of Caucasian individuals living in California. In other words, although it is likely that there were genetic factors involved in the vulnerability, the prime risk factor lay in lifestyle features, including diet. Interestingly, in this instance, smoking was not implicated in the migration difference because smoking levels were very high in Japan as well as in California. It should be noted that the findings with respect to hypertension were rather different, and much remains to be explained in the causal nexus in relation to different outcomes.

The best-documented psychopathological example concerns the raised rate of schizophrenia spectrum disorders in people of Afro-Caribbean origin living in either the United Kingdom or the Netherlands—the two countries in which the phenomenon has been most extensively examined (Coid et al., 2008; Jones & Fung, 2005). The design relies on two key comparisons: first, the rate of disorder in migrants compared with the rate of the disorder in their country of origin; and second, the rate in migrants compared with the rate in nonimmigrants in the host country to which they migrated. In the case of schizophrenia spectrum disorders (and, to a lesser extent, some other psychoses) it was found that the rate was substantially higher in people of Afro-Caribbean descent living in the United Kingdom or the Netherlands than in Caucasians living in the same two countries and compared with people of presumably the same ethnic origins living in one of the islands in the Caribbean. A very detailed, carefully controlled study showed that the difference in the incidence of schizophrenia spectrum disorders was not an artifact of recognition or diagnosis but rather seemed to reflect some aspect of environmental adversities associated with migration to the United Kingdom or the Netherlands. Migration as such is not likely to constitute the causal factor because the findings applied to both second- and first-generation migrants and because in other circumstances migration may even bring benefits (Stillman, McKenzie, & Gibson, 2009).

Recently, a parallel study in the United States showed a somewhat similar ethnic difference, with African Americans about three times more likely to be diagnosed with having schizophrenia than White Americans (Bresnahan et al., 2007). The causal inference with respect to some kind of environmental influence is strong, but it would be much stronger with evidence of environmental factors differentially operating within ethnic groups. So far, various possibilities have been ruled out, but the key environmental risk factor has yet to be identified. Fu and Van Landingham (2012) used a migration design in a novel way by comparing Vietnamese immigrants to New Orleans in the United States to never-leavers in Ho Chi Minh City and returnees. These juxtapositions provided a net comparison of selection effects and immigration effects.

Strategies to Identify the Key Environmental Risk Feature

Twin and adoptee strategies have usually been considered solely in terms of their power to examine genetic mediation of what seemed to be environmental risk effects. However, there are circumstances in which they provide the natural experiment opportunity to compare two or more contrasting postulated environmental causes by holding genetic influences constant rather than by determining the possibility of genetic mediation.

Twin–Singleton Comparisons

The starting point for this strategy was the well-established finding that as a group twins lagged behind singletons

in their language development by about three months at 3 years of age (Rutter, Thorpe, Greenwood, Northstone, & Golding, 2003; Thorpe, Rutter, & Greenwood, 2003). The question to be investigated is why there was this language delay. The two leading contenders for the postulated environmental cause were obstetric complications (because they are known to be much common in twins) and altered patterns of parent–child interaction arising from having to deal with two children of the same age at the same time (Rutter & Redshaw, 1991). To focus on influences likely to be important in the general population, children born before 34 weeks of gestation were excluded on the grounds that other research had shown that this was associated with a substantial increase in brain damage (Rutter et al., 2003). As ever, sample selection was crucial in enabling a focus on features that were likely to operate in both twins and singletons as well as in the general population as a whole.

The natural experiment opportunity derived from two main features. First, although genetic influences will operate on individual differences in language, there is no reason to suppose that they will differ in either strength or type between twins and singletons. This meant that the problem of possible genetic mediation could be set aside. Second, overall social disadvantage, which is associated with language impairment in the overall population, is not particularly associated with twinning. Accordingly, the comparison virtually rules out the two major confounding factors found in the general population.

Focus on within-individual change provides a much better assessment of a causative influence than relying entirely on between-group differences. Accordingly, analysis of language performance at 3 years took into account the children's language at age 20 months. In other words, the outcome at 3 years was a reflection of changes between 20 months and 3 years. In this and other connections it is important that both the twins and singletons came from the same general population sampling frame—namely, the Avon Longitudinal Study of Parents and Children (ALSPAC). The findings showed no effect of obstetric complications but a significant effect of parent–child interaction and communication. When a composite score of the latter was introduced into the overall model, it eliminated the twin–singleton difference; that is, it showed complete mediation (Baron and Kenny, 1986). Several methodological steps made the causal inference plausible. Nevertheless, the design involved the limitation stemming from the uncertainty over the measurement of the key features of parent–child interaction as well as from the uncertainties over the generalization of the findings to populations of singletons. There is no reason to doubt the evidence showing the exclusion of any major effect of obstetric complications, but questions remain on the key causal elements of mother–child interaction, particularly as father–child interaction was not measured.

Adoption as a Radical Change of Environment

The English and Romanian Adoptees (ERA) study set out to examine the long-term effects of profound institutional deprivation (Rutter & Sonuga-Barke, 2010). This constituted a natural experiment for at least five different reasons. First, the children were admitted into institutional care in early infancy (thereby eliminating the usual confound of children being admitted when older because of identified impairment). Second, scarcely any children were adopted or returned to their biological families before the Ceauşescu regime fell in 1989 (thereby avoiding the usual biases associated with which children remained and which left institutional care). Third, it was possible to pinpoint accurately the timing of leaving institutional care. Fourth, the move from profoundly depriving institutional care to generally well functioning involved an exceptional marked environmental change. Fifth, the design involved a follow-up to at least the age of 15 years, with multimodal assessments at 6, 11, and 15 years.

Although the adoption created a quite exceptional natural experiment, it was necessary to go on to check whether there could be a bias resulting from variations in the parents' main reasons for adoption (altruism versus a response to infertility). Because none of these variations were associated with outcome, it appeared unlikely that these could constitute a significant bias.

In the 2010 Monograph, the institutional care, as defined, included a few children who had spent short periods of time in institutional care, and main analyses were done with both institutional deprivation and subnutrition. Both of these limitations were dealt with by a further study, based on the same sampling and data, of children who spent the whole of their period prior to adoption in institutional care and who had not shown subnutrition as indexed by body weight at the time of leaving the institution to enter the adoptive family (Rutter, Kumsta, Schlotz, & Sonuga-Barke, 2012). The findings of this group were closely comparable to those in the 2010 Monograph, with the effects of institutional care being, if anything, rather more marked.

The postulated causal effect of institutional deprivation can be tested in two different ways. First, there was the test of developmental recovery following adoption. Findings showed major recovery; these indicated that the initial deficits at the time of leaving institutional care were likely

to have been caused by the institutional deprivation. By the nature of the design, it was not possible to differentiate between the benefits being due to the cessation of a depriving institutional environment or the positive benefits of rearing in an adoptive home. The follow-up to age 15 indicated that variations in outcome were unassociated with variations in the quality of the adoptive home, at least as measured. Nevertheless, it does not rule out the possibility that the massive gains after leaving institutional care were in part contributed to by the quality of the adoptive family environment.

Second, because the recovery was incomplete in many instances, it was necessary to determine whether the deficits were a function of the preadoption institutional environment or variations in the qualities of the postadoption family environment. Several key findings pointed strongly to an institutional effect. First, the associations with institutional deprivation lasting beyond the age of 6 months were as strong at 15 years as they had been at 11 years and before that at 6 years. Second, the deficits were largely of a kind (such as quasi-autism or disinhibited attachment) that is rare in children not experiencing institutional deprivation. Third, the variations in outcome were not accounted for by variations in the postadoption environment. Fourth, institutional deprivation, even in the absence of subnutrition, was associated with a large and significant reduction in brain size that showed partial mediation with respect to the psychological outcomes. Various other methodological checks were also undertaken to rule out nondeprivation causes. As a result of these multiple design features, a causal inference seems well justified. Nevertheless, limitations remain. To begin with, no valid evidence on the biological parents was available, making it difficult to rule out all possibilities of genetic mediation. Also, although the findings were compellingly consistent, there was noteworthy heterogeneity in outcome, and the causes of this variation remain uncertain. Most crucially, although there is good reason to judge the internal validity as very high, questions remain on the extent to which the findings can be generalized to other forms of deprivation in other populations (Rutter & Azis-Clauson, 2011).

Time-Series Designs

Interrupted time-series designs played a major role in the development of quasi-experiments. They required a treatment that could be deliberately manipulated and implemented. In other words, their power lay in the investigation of treatment effects. Shadish et al. (2002) argued that concomitant time-series designs that did not involve introduction of an intervention element were inadequate for testing of causal inferences. That is because, in essence, they simply provide a correlation between two variables that have varied over time, and, on its own, this correlation certainly provides no justification for a causal inference. However, in recent years, improvements and both design and analysis have provided a way of using these as a natural experiment. Two rather different examples illustrate what can be achieved.

The first example examined the question of whether gang membership had a causative environmentally mediated influence on the level of delinquent activities. Many cross sectional studies have documented that gang members have higher delinquency rates than nonmembers (see, e.g., Spergel, 1990), but the question was whether that was a consequence of variables associated with selection into gang membership or socialization as a result of gang membership. Thornberry, Krohn, Lizotte, and Chard-Wiershem (1993) were the first to use longitudinal data to contrast these two hypotheses. They used contrasts between periods when the youths were members of gangs as against those before they entered the gang and after they left the gang. This pioneering early study relied on simple descriptive measures without adjusting for measured or unmeasured characteristics of the boys that might bias the findings. A similar approach had been used earlier by Kandel (1978), who determined whether the similarities in behavior and interest among friends were a reflection of selection or socialization. More recent research has used standard regression models to adjust for measured controls and random effects models to adjust for unmeasured stable characteristics of the boys (Thornberry, 1998; Thornberry, Krohn, Lizotte, Smith, & Tobin, 2003).

Gordon et al. (2004) extended the methodology by estimating fixed effect models to adjust for unmeasured biases, and the possibility that the approach did not control for age. It was possible that a failure to control for age had led to either an over- or underestimate of the effects of gangs. Also, the earlier studies had not considered gang membership that occurred prior to the onset of the study. Gordon et al. dealt with that by using retrospective reports of gang membership before the study began.

Their analyses were based on the Pittsburgh Youth Study. They also looked at whether peer delinquent activity had effects on delinquency that differed from those on drug use. The findings showed that boys who joined gangs were more delinquent before entering the gangs than those who did not join. Nevertheless, even with such selective differences the period of gang membership was associated with a substantial increase in both delinquency

and drug use. Moreover, delinquent activities reduced markedly when the individuals left the gang, although not necessarily right down to the pregang membership level. As the authors point out, the models they employed could not adjust for time varying effects brought about by some third variable associated with both gang participation and increased delinquency in a particular time period. On the other hand, models did adjust for such variables associated with the boys' age, with season and year, or with peer delinquency.

The findings provided convincing evidence that gang membership did have an environmentally mediated effect on delinquent activities. However, in order to understand the mechanisms involved, it would be necessary to have much more detailed data on the boys' peer networks. So it is not possible to rule out entirely the possibility of reverse causation. For example, a boy might exit a gang and reduce his own delinquency because the opportunities for delinquency had diminished. A combination of trajectory analyses and propensity score matching provided a powerful alternative approach (Haviland, Nagin, & Rosenbaum, 2007). This gave rise to similar findings, but it was notable that it was not possible to create matches for the tiny group who showed severe chronic delinquency prior to joining a gang.

Rather comparable parallel issues arise in testing the hypothesis that marriage leads to a reduction in delinquent activities. Again, the question is whether the difference found in other studies reflected selection into marriage or a causal effect of marriage. Using their long-term follow-up to age 70 of the Gluecks' serious adolescent delinquency sample (Glueck & Glueck, 1968), Sampson et al. (2006) addressed this issue by determining whether individuals were less likely, over time, to engage in crime during their periods of being married than during their periods of nonmarriage. The natural experiment aspect arose from the fact that in the United States, there was a very high rate of divorce and also of remarriage. Accordingly, there was a substantial sample of individuals who could be studied before they married, during their marriage, and after their marriage had broken up. In some instances, there were replications of this series of experiences.

The starting point was the use of 10 individual-specific and 10 family and parental background features and a range of adult time-varying covariates to assess selection into marriage. They used an inverse probability of treatment weighting (IPTW), devised by Robins et al. (2000), to weight each person and period by the inverse of the predicted probability of receiving the experience (i.e. marriage) that they actually received in that period. In other words, the model in effect created a pseudo-population of weighted replicates allowing a comparison of status (married versus unmarried) without making distributional assumptions about counterfactuals. The model also allowed age effects to be taken into account and thereby a quantitative estimate of marriage effects on crime.

The findings showed an average crime reduction of some 35% in periods of marriage (using a conservative approach rating ruling out reciprocal effects and imposing a strict causal order). The robustness of the estimate was shown by the demonstration that it was broadly similar across both the shorter time span of 17–32 years and the longer time span of 17–70 years. As with any other nonexperimental study it was impossible entirely to rule out the possibility of the operation of some unconceptualized and unmeasured confounder. Nevertheless, as the authors argued, given the unusually rich range of measures available, it is difficult to imagine what time-stable or time-invariant covariate could overcome the magnitude and robustness of the marriage effect. Propensity scores provide a powerful tool but they can only be as effective as the variables that go into the propensity score. The key predictors are omitted then that will inevitably reduce the benefit of the propensity score approach.

Another example of a time-series approach is provided by Rutter, Maughan, Mortimore, Ouston, and Smith's (1979) study of school effects using changes over time to assess possible environmentally mediated causal effects. The hypothesis being tested was that the qualities of schools influenced the attainments and behavior of the children attending these schools. A competing alternative hypothesis was that any associations found reflected either variations in the intake of pupils to each school or the influence of the pupils on school functioning. The natural experiment element was provided by the fact that the transfer from elementary to high schools in London at that time involved a marked lack of continuity between the two so that the children at any one elementary school moved to a large number of different secondary schools. Data were available for pupil functioning pretransfer (at ages 11–12), at the end of compulsory schooling, and at the end of compulsory schooling five years later. There was also a later follow-up after leaving school. To test the hypothesis, it was of course essential to have detailed measurement of school qualities and these were obtained through observations, interviews, questionnaires, and the like. It was argued that if the within-schools variations observed for pupil outcomes were truly a function of school influences, then the differences should not be accounted for by intake differences. Instead, they should be a function of measured

features in school quality and the effect should increase over the course of schooling.

In other words, the association between school qualities and pupil behavior should be greater at the time of leaving school than it had been at the time of intake. The findings supported this argument. The causal inference was further strengthened by comparable findings in other longitudinal studies and by the beneficial effects on pupil outcomes with the appointment of school principals in two out of three failing schools on the point of closure (see Rutter & Maughan, 2002). The main, substantial limitation is the need to rely on group tendencies rather than within-person change at the individual level for specifics of school experience. That was not available in the research, but, in principle, it could be available and if that were the case it would greatly strengthen the natural experiment.

Designs for Dealing with Selection Bias

Ordinarily, selection biases seriously interfere with any attempts to test environmental causation. That is because most risk experiences derive from situations influenced by people's behavior in selecting or shaping their environments. The strategy for dealing with this relies on the study of experiences that are not open to personal choice because the influences of personal choice have been excluded. These may involve either the introduction of risk experiences or their removal.

Universal Introduction of Risk

Both the examples here concern famine. The first concerns the Dutch famine during World War II (Stein, Susser, Saenger, & Marolla, 1975). The famine was both severe and time limited, and it was imposed on the total population and not just on a socially deprived subgroup. With respect to psychopathology, the main interest derived from the finding of a twofold increase in the risk for schizophrenia (as assessed on a national registry) that was associated with exposure to famine conditions in early gestation. Causal inference was substantially strengthened by a similar effect on congenital anomalies of the central nervous system—thereby suggesting a possible biological pathway (McClellan, Susser, & King, 2006). In addition, studies comparing the epigenetic findings for individuals prenatally exposed to famine and their unexposed same-sex siblings (Heijmans et al., 2008; Tobi et al., 2009, 2012) found that famine exposure resulted in a lower level of methylation of the locus for the insulin-like growth factor II. Again, the possible biological effect supported the causal inference. Causal inferences were also strengthened by the gestational period specificity and the diagnostic specificity. The main limitation of this study concerns the reliance on group exposure, rather than individual exposure. The possibilities for selection bias and selective survival were examined in detail and no support for their operation was found. Nevertheless, it is likely that a few individuals were able to use their initiative in obtaining some food. This could have introduced a very small amount of bias but what it would mean is that it would give rise to a reduction in the case–control difference. Thus, in so far as such a bias occurred, it would lead to an underestimate of the famine effect, and not an overestimate.

The second example is provided by the Chinese famine in 1959–1961 (St Clair et al., 2005), which showed a very similar twofold increase in the risk for schizophrenia. The causal inference was again strengthened by the biological parallels, that is, the reduction in birth weight and the increase in mortality rate associated with the famine. However, as in the Dutch example, there was the limitation of reliance on group differences but with the additional uncertainty in the Chinese case regarding the exact timing of the prenatal exposure. Both of these were good studies, and they provide a strong causal inference regarding environmental mediation of famine effects on child outcomes. Moreover, although not able to show a biological effect at the individual level, the finding did suggest a probably relevant biological pathway.

Universal Removal of Risk

The same basic strategy may be applied to the removal of risks. Costello, Compton, Keeler, and Angold (2003) used a natural experiment in which a casino was opened on an American Indian reservation to determine if the alleviation of poverty brought mental health benefits. Federal law in the United States required that a particular proportion of the profits of all casinos set up on a reservation had to be distributed to all those living on the reservation without any actions by individuals. By good fortune, the casino was set up during a prospective longitudinal study of child mental health—the Great Smoky Mountains study. The natural experiment involved several different elements. First, it was possible to check whether changes over time in the rate of poverty in American Indians were paralleled by similar changes in the White population. It was found that it was not. Second, the change over time allowed for a comparison between those who were not in poverty before or after the casino was set up, those who were poor before and who remained poor afterward, and those who started poor but ceased to be below the poverty line after the

casino was established. The interest, obviously, concerned the third group. The findings showed that the substantial reduction in poverty was followed by the reduction in the rate of some (but not all) kinds of child psychopathology. More detailed post hoc analyses were undertaken to try to identify what were the changes in the family brought about by the reduction of poverty. These showed that the relief of poverty had been accompanied by an increase in parental employment but also by an increase in time spent with the children, with associated greater supervision. Because these family effects were not part of the design, the causal inference is necessarily less certain. However, there was the implication that what mattered was what the relief of poverty did for the family rather than any direct effect on the child.

A further follow-up was undertaken at ages 19 and 21 years, with child interview plus criminality data from the courts and schooling and education information (Akee, Copeland, Keeler, Angold, & Costello, 2010; Costello, Erkanli, Copeland, & Angold, 2010). As is often the case, the much increased duration of follow-up allowed the use of cohort differences to examine the effects of the age of the individual during the period of income supplements and the duration of receiving them to be examined. In addition, mediation analyses in relation to within-individual changes over time became possible. Appropriate detailed analyses were undertaken to check whether findings might have resulted from general secular change; the analyses showed that they were not explicable on these grounds. In brief, it was found that the income supplements led to higher levels of education in early adult life and a lower rate of convictions for minor offenses. Furthermore, income supplements were associated with a lower rate of alcohol abuse and dependence and cannabis abuse and dependence. There were no effects on nicotine or other drug abuse or on emotional or behavioral disorders. The effects were greatest for those who were initially the poorest and for those that experienced the longest time of income supplements. There were no detectable benefits of income supplements that began only after childhood. The findings suggested (but did not prove) that mediation was provided by improved parent–child relationships. There was no indication that families used the lump sums received to buy different levels of long-term benefits.

The findings were striking with respect to the size of effects and their persistence into adult life. Two features stood out as different from other studies. First, the income supplement was very large—amounting to some quarter to a third of the original income—and, second, there was no expected end to the income supplements so that the individuals treated them as permanent. The authors noted that the study was undertaken in a mixed urban–rural area, and it is not known if similar results would occur in deprived inner-city settings. What is clear is that this natural experiment design provided compelling evidence of the causal effect of relief of poverty. As with other designs, the findings are less definitive on the precise mechanisms involved in the causal effect. From a practical point of view, too, the importance of a huge permanent increase in income makes it uncertain whether similar, albeit lesser, benefits might accrue from smaller, less-lasting income increases.

Another example of strategy of a universal intervention applying to the removal of risk is provided by Honda et al. (2005) with the natural experiment concerning the hypothesis that measles, mumps, rubella (MMR) vaccine was responsible for the marked rise in the rate of diagnosed autism spectrum disorder (ASD). The experiment derived from the fact that Japan stopped using the vaccine (because of the concern over the mumps component, which was not any part of the hypothesis about the adverse effects of MMR) at a time when its use was continuing in other parts of the world. The strength of this natural experiment lay in the availability of systematic standardized diagnostic data for a defined geographical area and an exact timing of the total withdrawal of the use of MMR vaccine in the follow-up to age 7 years (to ensure that no cases of autism were missed) and in the fact that the ASD rates elsewhere were still rising. The findings showed that the withdrawal of MMR had no effect on the rising trajectory in the rate of ASD. In addition to a variety of other methodological checks, the findings made the universal causal effect of MMR on ASD implausible, especially in light of the fact that other research strategies all gave rise to the same negative conclusion (Rutter, 2005). Note that, although the finding virtually rules out the possibility of MMR causing an overall rise in ASD, it cannot rule out the possibility of an idiosyncratic effect in a small minority of individuals, although there was no indication that this was the case and there was a complete absence of any known means of identifying such an idiosyncrasy.

Much the same strategy was used, with similarly negative findings, on the withdrawal of Thimerosal (a mercury preservative) from vaccines in Scandinavia in the early 1990s, at a time when the preservative continued to be used in the rest of the world. The initial negative finding (Madsen et al., 2003) was open to the objection that account had not been taken of the change of registry procedures. However, a further later study, on the same data set (Atladóttir et al., 2007), confirmed the negative

finding. With both of these studies, the key thing was that the decision as to whether or not to have the vaccine was a governmental decision with respect to the population as a whole and it was not open to individual choice. Indeed, without getting the vaccines from abroad, the removal of the vaccines would have effectively prevented personal choice.

Instrumental Variables

The use of an instrumental variable as a means of testing causal inferences involves two key design features. First, the instrumental variable must be outside the control of the individual (to avoid allocation bias), and, second, it must affect the outcome by some means that is independent of the usual liability to that outcome (to avoid both possible genetic mediation and possible social confounding). In other words, instrumental variables refer to circumstances that do not affect the outcome being studied but do influence the putative risk factor being considered (Foster & McLanahan, 1996). Instrumental variables are often used as part of a statistical approach designed to deal with omitting confounding variables, two-way influences, and imprecision in measurement (Angrist & Evans, 1996; Angrist, Imbens, & Rubin, 1996). However, here we are considering instrumental variables only in the narrower framework of their role being used in a natural experiment. Two examples are used to illustrate the strategy.

Early Puberty

An unusually early puberty constitutes a natural experiment because it has been associated with an increased rate of drinking alcohol and of drunkenness during the teenage years (Grant & Dawson, 1997). In the general population, early use of alcohol has been strongly associated with an increased risk of alcoholism in adult life. The causal hypothesis, therefore, is that early alcohol use contributes to the causation of later alcoholism. Early puberty constitutes an instrumental variable because it is outside the control of the individual. If early use of alcohol truly predisposes a person to alcoholism, the same early-use effect should be found even if the early use was a result of early puberty rather than an overall alcoholism liability. The findings across three large-scale general population epidemiological studies in Sweden, New Zealand, and Finland are consistent (Caspi & Moffitt, 1991; Pulkkinen, Kaprio, & Rose, 2006; Stattin & Magnusson, 1990), and all showed that early puberty was indeed associated with an increased rate of drinking alcohol and with drunkenness during the teenage years. The test, however, lies in what is found in early adult life. All three studies are consistent in showing that, although there was an effect on alcohol use in adolescence, this was no longer apparent by the mid-20s. In other words, the effects were quite different from those found in ordinary circumstances, carrying the implication that early use was not a causal factor despite its strong correlation. Rather, it reflected the same underlying liability. Longitudinal studies tell the same story. Thus, McGue and Iacono (2005) showed that early alcohol use was associated not only with later alcoholism but also with smoking, the use of drugs, involvement with the police, early sexual activities, conduct problems, and educational underachievement. The inference is that in the case of the timing of first alcohol use it is likely that there is not a causal effect; rather, the early use reflected a shared liability to a broader range of problem behavior.

China's One-Child Policy

A rather different instrumental variable was provided by China's one-child policy (Cameron, Erkal, Gangadharan, & Meng, 2013), which was introduced in 1979. Before that time, the psychological effects of being an only child were confounded by family features associated with a decision to have just one child. This became obsolete post-1979 because the government made the decision. Cameron et al. (2013) compared young people living in Beijing and born in 1975 or 1978 with those from the same area born in 1980 or 1983. Because the one-child policy was anticipated just before its introduction, the 1975 cohort provides a cleaner comparison. The proportion of only children rose from 27% of those born in 1975 to 91% for those born in 1983, and the average number of siblings fell from 0.97 to 0.12. By contrast, there was little difference in the size of the extended family as indexed by the number of cousins. The psychological effects of being an only child had been thought to include self-centeredness, lack of cooperativeness, and difficulty getting on with peers. Cameron et al. (2013) used two standard economic games (i.e., Dictator and Trust) as well as questionnaires to tap the psychological traits. Using the one-child policy as an exogenous instrument, the findings showed that the psychological effects of being an only child were valid and not just a consequence of parental choice. One strength of the study was the use of experimental methods to assess altruism and trustworthiness.

A somewhat comparable approach was used with the Argentine draft lottery to study the effects of military service on later criminal activities (Galiani, Rossi, & Schargrodsky, 2011). The opportunity to make this a natural experiment arose from the practice of random

assignment by lottery to determine who actually was conscripted for compulsory military service. The findings were clear-cut in showing that military service increased the likelihood of a later criminal record.

Sex of Co-Twin

Atterman et al. (2012) used the sex of a co-twin as the instrumental variable for prenatal exposure to testosterone in a study to examine effects on ADHD and ASD traits. The findings went in the opposite direction to prediction, and it seems likely that this reflected either parental reporting bias or confounding. The idea was a good one, but the findings are not really interpretable.

Mendelian Randomization

Mendelian randomization (MR) was first described as a natural experiment strategy by Katan (1986) and then by Gray and Wheatley (1991), but it has been more fully developed by Davey Smith and Ebrahim (2003, 2005). At first sight, the term MR sounds misleading because genes are, of course, not randomly distributed in the sense of everyone having the same chance of receiving particular genetic variants. Nevertheless, the allelic variations in the parental genes are randomly distributed among offspring at the stage of meiosis, as noted in Mendel's second law. What this means is the inheritance of any one trait is independent of the inheritance of other traits. The ingenious point with respect to using MR to test a hypothesis regarding environmental causation is that the allelic variations are likely to be randomly distributed with respect to the environmental risk hypothesis being tested. Cases where the pathway from genotype to phenotype is relatively well understood, and, when the gene in question has functionally varying alleles, allelic status can be used as a randomly distributed proxy for the behavioral differences that emerge from it (Irons, McGue, Iacono, & Oetting, 2007). In other words, the groups defined by the allelic variation known to affect exposure to some intermediate phenotype (such as drinking behavior) can be used to study the effects of variation in that phenotype on some disease or disorder hypothesized to be caused by the intermediate phenotype. The design was employed originally to rule out reverse causation; it does that because the genotype is unaffected by the disease, disorder, or trait being studied. The design is also not invalidated by confounding, provided there is no pleiotropic effect of the regulatory allelic variation (Keavney, 2004).

The design was originally developed for use in internal medicine to determine if the disease being studied had caused the environmental risk factor rather than the other way around. It has had some success both in providing support for a causal hypothesis (Casas, Bautista, Smeeth, Sharma, & Hingorani, 2005; Jokela et al., 2012) and in casting doubt on its validity (Keavney et al., 2006; Lawlor et al., 2011). Nevertheless, it usually requires huge samples, and it is weak if the risk effect is small, if there are difficulties in measuring the intermediate phenotype, or if the risk operates only above some threshold (Meade, Humphries, & De Stavola, 2006).

The strength and limitations of the MR design, compared with randomized controlled experiments, have been well discussed by Nitsch et al. (2006) and by Tobin and colleagues (2004) (see also Davey Smith, 2010; Kivimäki et al., 2011; Tobin, Minelli, Burton, & Thompson, 2004). Glymour, Tchetgen, and Robins (2012) usefully noted the key assumptions of the MR design (and other instrumental variable approaches) as follows: (1) the genotype is associated with the intermediate phenotype (the IV); (2) there are no unmeasured common causes of both the phenotype and the outcome being examined; and (3) every directed pathway from the genotype to the outcome passes through the phenotype (the IV0). They argue for the value of DAGs for spelling out the assumptions and for suggesting ways in which they may be tested. They conclude that usually it is not possible to prove the assumptions, but it is often possible to show that the putative IV is invalid.

Irons et al. (2007) used the MR design to examine the hypothesis that heavy early alcohol use had a gateway effect leading to the later use of hard drugs such as cocaine or heroin and to a broader range of antisocial behavior. That there is a substantial overall statistical association in the general population is not in doubt, but the query is whether it derives from the general liability to disinhibited behavior (whether influenced by either genetic or environmental factors) or whether the intermediate phenotype of heavy drinking causes the other problems. The opportunity to employ the MR design was provided by an allelic variation of a gene that leads to greatly reduced aldohyde dehydrogenase (ALDH) enzyme activity. Individuals with ALDH2 enzyme deficiency have an unpleasant flushing response to any ingestion of alcohol. The relevant gene is found almost exclusively in East Asians and, in this ethnic group, it is associated with a substantially decreased rate of alcoholism compared with those having normal enzyme activity.

Irons et al. (2007) were creative in realizing that the design could be used in their study of adoptees born in Korea and placed in adoptive homes in the United States in infancy, none of the adopting parents being of East Asian descent. Findings showed (as expected) a substantial genetic effect on alcohol abuse, but there was

no significant difference between the ALDH2 deficient and nondeficient groups in either drug abuse or antisocial behavior. The implication was that the association derived from a shared general liability for problem behavior and not from the causal effect of the intermediate phenotype of early alcohol drinking.

As with all natural experiments, it is desirable wherever possible to include more than one design element to separate variables. Adoption provided that further opportunity here. The results showed no effect of adoptive parental alcoholism, which confirmed the twin studies' conclusions of a genetic influence that will not apply when the parentage is nonbiological. On the other hand, it did show a significant effect of drinking by siblings, suggesting that it may well represent an environmental effect. Irons et al. (2007) emphasized that, although the ALDH2 allelic variation has a strong effect on alcoholism, it is not determinative. Not only do some individuals with ALDH2 deficiency become alcoholic, but also there is a gender difference in effect and a secular trend. It was necessary for Irons et al. to take account of these limitations in their analyses, as they did. Caution is needed even when the genetic effect is strong (as it clearly is the ALDH2) if environmental influences also affect the genetic pathway to the phenotype. MD works best when the relevant gene has a strong, highly focused effect; when pleiotropic effects are slight; and when there is a well-defined intermediate phenotype (Katan, 2004; Keavney, 2004).

We conclude that MR constitutes a useful addition to the natural experiments armamentarium, but equally it is likely to be practical in only a few circumstances. When it is necessary to combine samples to obtain the necessary sample size (which it was not in Irons et al., 2007), there are the further problems of ensuring comparability across samples in all relevant respects.

Regression Discontinuity Designs to Deal with Unmeasured Confounders

The only actual natural experiment that can fully deal with unmeasured confounders is the regression discontinuity (RD) design. This was first introduced by Thistlethwaite and Campbell (1960) over half a century ago as an alternative to randomized controlled trials. The key defining feature is that allocation for some planned intervention is by means of an assignment variable that uses a strict predetermined cutoff rather than randomization. In other words, the design capitalizes on a major selection bias, provided, and only provided, that it is under strict control. The basic point is that assignment cannot be caused by the intervention. It does not matter whether or not it is related to the outcome. It does, however, require that all participants belong to the same population prior to assignment. Moreover, the statistical analysis also requires accurate specification of the intervention effect (e.g., whether it is linear or curvilinear) and inclusion of an interaction term when that is appropriate. Unlike an RCT, effects are measured in terms of a discontinuity in regression lines (hence its name) instead of a difference in means. Although, at first sight, it is not obvious that RD allows an unbiased estimate for causal effect, it has been shown mathematically that it does (Rubin, 1977; Shadish et al., 2002) and this constitutes its major advantage (Laird & Mosteller, 1990). Because RD was designed as an alternative to RCT for planned experimental interventions, there is rather limited use as a natural experiment to test prior causes of a nonexperimental variety.

Use of RD to Assess Schooling Influences

Cahan and Cohen (1989) showed the applicability of RD in their study determining whether the amount of formal education, as opposed to increasing chronological age, had an effect on cognitive performance. The design was possible because all children in Jerusalem's Hebrew-language, state-controlled elementary schools (i.e., other than those providing only special education) in 1987 had a single admission date in December. This meant that, within each school year, there was a 12-month age span from the oldest to the youngest child (all of whom would have received the same amount of schooling), and between school classes there was a 12-month difference in duration of schooling (but a similar within-group variation in age). There was a potential problem with the key assumption that there could be no exceptions to the age cutoff. Although grade retention and grade skipping were rare, admission was sometimes delayed and sometimes accelerated. Most crucially, this variation was nonrandom (with variation greatest near the cutoff point) and with delayed admission students tending to be less able, whereas accelerated admission students were more able. To keep this bias to a very low level, Cahan and Cohen (1989) excluded all overage and underage children in each of the three age-specified year classes studied. It also excluded all children born in November and December.

To allow direct comparison between tests, researchers standardized effect sizes by using the pooled within-age standardization in Grade 4 (the youngest age group). The findings were striking in showing that the school effect exceeded the age effect for 10 of the 12 cognitive measures used. The two exceptions were both figural tests.

The greatest school effects were found for verbal tests and also for the one numerical test employed. There was no reason to expect anything other than a linear effect, although it might have been different in a less standardized school system. It should be noted that, although the data were not individually longitudinal, they did represent changes over time. Thus, although technically a cross sectional comparison, the RD design (by ensuring strict comparability of groups) allowed the strong inference of within-individual change.

We have described the study in some detail to emphasize the crucial importance of ensuring that the RD design assumptions are truly met and to illustrate a few of the practical steps that need to be taken to bring this about. The one key assumption that was not explicitly tested was the absence of an age x schooling interaction but the figures provided for the three-grade study gave no indication that there was an interaction. It should be noted that the findings are in keeping with a somewhat different form of natural experiment provided by forced school closure (Rutter & Madge, 1976). None of these schooling experiments tested the possibility of an interaction between schooling effects and the quality of family influences. Nevertheless, the findings from studies of gains and losses in the long U.S. summer school vacation indicated that this was highly likely (Entwisle, Alexander, & Olson, 2004; Heyns, 1978).

Use of RD to Study the Effects of Head Start

The second example of an RD design is provided by a retrospective assessment of the effects of Head Start using a discontinuity in program funding across counties in the United States as the research lever (Ludwig & Miller, 2005). During spring 1965, the US Office of Economic Opportunity provided technical assistance to the 300 poorest counties to develop Head Start funding proposals. Funding rates were found to be 50 to 100% higher in counties with poverty levels just above the cutoff. The treatment group comprised those just above the cutoff, and the control group comprised those just below. Because the cutoff was on a predetermined variable, the design was operative, and it allowed little opportunity for strategic behavior by individuals that could invalidate the required assumptions. The findings derived from somewhat rough county-level funding data and from the National Educational Longitudinal study, which tracked a national sample of eighth graders in 1988. The funding difference persisted through the late 1970s. The findings showed a substantial effect of Head Start on children's health, a lesser but still significant effect on school graduation, but no significant effect on reading or math scores or on noncognitive outcomes.

The validity of the findings was tested by determining whether similar effects were found in age groups that could not have benefited from Head Start (finding that they were not) and whether the health benefits applied to outcomes that could not plausibly be influenced by Head Start (they did not). The important limitation stemmed from reliance on countywide measures, from reliance on residence at follow-up rather than at program initiation, and from the lack of satisfactory data on in and out migration. The study demonstrates the uncertainties that usually operate when seeking to apply the RD design to naturally occurring circumstances outside of experimental control. The RD design provides an important alternative to RCT, but it is quite limited in its applicability to naturally occurring prior risk or protective factors.

McCall and Bielby (2012) provided a useful review of the use of fuzzy RD designs in the educational arena. They indicated that RD can be applied even when requirements are not fully met provided that stringent tests of the assumptions are employed. Whilst we admire the ingenuity of the design we remain very cautious over its general applicability because it has rarely given rise to clear-cut conclusions.

Adoption and Fostering as a Means of Separating Prenatal from Postnatal Effects

With many supposedly prenatal effects, there is the problem of differentiating between risks mediated during the pregnancy and risks that stem from the postnatal environment. For example, some longitudinal studies have shown that fetal cocaine exposure was followed by adverse effects on neurodevelopment and cognitive performance (see, e.g., Jacobson, Jacobson, Sokol, Martier, & Chiodo, 1996; Singer, Arendt, Minnes, Farkas, & Salvator, 2000). However, mothers who take cocaine during the pregnancy are highly likely to take cocaine postnatally, and the sequelae could derive from mother's overall liability to take cocaine. Equally, it could derive from environmentally mediated postnatal effects stemming from adversities in rearing that tend to be more common in drug dependent mothers.

One way forward is to compare drug-exposed infants who are reared by their biological mothers and those reared by a foster or adoptive parents. Thus, Singer et al. (2004), as part of a longitudinal study from birth, compared the outcome at 4 years of age of 48 prenatally cocaine-exposed infants reared by their biological families and 42 reared by adoptive or foster parents. The fostered and adopted children had only a very slightly higher mean IQ, but there was a parallel substantially lower proportion of them

with an IQ below 70 (37% versus 10%). The implication was that the cognitive deficit might be due to the prenatal cocaine exposure—as that will not have been corrected by the postnatal rearing in adoptive and foster families. It was important to check, however, whether the fostered and adopted children had less prenatal cocaine exposure. The findings rule that out because prenatal cocaine exposure was actually twice as high—probably because this was the reason the children had been removed from the biological mother. Genetic risk could not be excluded, but it seemed unlikely to constitute a sufficient explanation. On the other hand, what was problematic is that the prenatal cocaine exposure was also accompanied by a greater use of other drugs (including alcohol and tobacco), so the risk might involve substances other than the cocaine itself.

Moe (2002) used a somewhat similar design in her focus on prenatal drugs and alcohol exposure, but she used a matched control group that had not experienced prenatal exposure. She found that the cognitive functioning at 4.5 years of age in substance-exposed children who were adopted or fostered in infancy was substantially and significantly lower than that in the control group. The findings supported the inference that the adverse effects on cognition and development were primarily a function of prenatal substance exposure rather than an exposure to an adverse rearing environment.

The strategy in these studies provides a useful means of separating prenatal and postnatal effects, but, on its own, it is much less informative regarding either the precise risk feature (because prenatal exposure will often involve several substances) or the particular risk mechanisms.

ARE NATURAL EXPERIMENTS REALLY NEEDED?

We have argued that there are serious limitations to relying on statistical control to deal with confounders. However, we still have to ask what difference it makes in practice. With respect to the effects of exposure in utero to maternal smoking, three studies have used natural experiments (employing three different designs), each of which showed that the effect was likely to be largely, if not entirely, due to genetic mediation. The same three studies also sought to compare the findings using the standard regression techniques for dealing with confounders. All three showed that the effect that the natural experiment results found to be a function of genetic mediation was wrongly shown to be a true environmentally mediated effect using the standard regression approaches.

However, we need to turn to other research to see how far this is a general problem. Duncan, Magnuson, and Ludwig (2004) did a systematic comparison of experimental and nonexperimental estimates for effects of school class size on student test scores. The findings as a whole showed an average bias of the order of about 10 percentile points. This is about the same as the average experimental estimate for the effects of smaller classes and clearly constituted an important bias (Wilde & Hollister, 2002). A further example came from the moving to opportunity (MTO) housing voucher experiment: this randomly assigned residence in a high-poverty neighborhood to either a group that was offered a housing voucher or a control group that received no ability assistance. Because of the well-implemented random assignment it was possible to generate comparisons of nonexperimental and experimental estimates (Ludwig, Duncan, & Hirschfield, 2001).

A third example is provided by a randomized experiment designed to evaluate welfare to work programs in seven sites across the United States. Magnuson and McGroder (2002; cited in Duncan et al., 2004) showed that the nonexperimental estimate did not closely reproduce experimentally based estimates. A systematic review by Glazerman, Levy, and Myers (2002) concluded that regression methods only occasionally produced findings comparable to experimental studies.

While appropriately noting that natural experiments involve problems, Duncan et al. (2004) concluded much greater use needed to be made of them, and they give half a dozen examples of ingenious use of natural experiment strategies—although only some of these used that terminology. Plus, Joy, Kimble, and Zabrack (1986; cited in Duncan et al., 2004) took advantage of the fact that a town in northwestern Canada had a delayed introduction to television because its valley location blinded it to channel transmitters for several years. Two years after the introduction of a television channel, children of all ages showed increased verbal and physical aggression. Rosenbaum (1991; cited in Duncan et al., 2004) compared the effects of relocation to city and suburban addresses for families involved in the Gautreaux program, where favorable outcomes were found for suburban compared with city-based moves. Girotto and Peterson (1999; cited in Duncan et al., 2004) took advantage of the fact that high school students with summer birthdays took drivers' education during the summer (in addition to course work during the academic school year). They found that one additional yearlong academic course was associated with a 0.25 standard deviation increase in standardized test scores. Green, Hoffman, Morse, Hayes, and Morgan

(1964; cited in Duncan et al., 2004) took advantage of the effects of forced school closure as a way of avoiding racial integration and found that a missed year of school resulted in an IQ score that was six points lower. See DeGroot (1951) and Jencks et al. (1972) for other examples of using forced school closure to examine the effects on children or a loss of educational input.

What the studies have done effectively is to make it unlikely that social selection played any part in the effects, thereby doing much to strengthen the causal influence. However, the studies dealt only with the overall effects of schooling, and they were not able to determine what aspect of the schooling it was that made the difference. They made the point that it is important for researchers to be on the look out for natural experiment opportunities to take advantage of opportunities provided. While it is important to make maximal use of approved statistical techniques, it is also crucial to recognize, as pointed out by Shadish and Cook (1999), that design is the key element in natural experiments of all kinds.

OVERVIEW OF NATURAL EXPERIMENT METHODOLOGY

As we indicated in the introduction to this chapter, several rather different methodological hazards can lead to misleading inferences from observational studies that involve no kind of experimental approach. The natural experiments that we have considered differ in which of these hazards they mainly seek to deal with. No strategy is equally appropriate for all the different hazards. Similarly, all research designs involve a range of crucial assumptions. Natural experiments are no exception to that rule. We have sought to note some of the most important assumptions with the different designs and have indicated, where possible, what may be done to test the assumptions. Fortunately, the different forms of natural experiment vary in the assumptions they require. What this means is that conclusions are always likely to be more robust when the same answers are given by several quite different types of natural experiment. The consistent evidence, for example, that prenatal exposure to maternal smoking does not have a causal effect in leading to ADHD or conduct disorder well illustrates that point. Kendler and Gardner (2010) provided another example in which they use both co-twin control and propensity score matching to consider the possible causal impact of stressful life events on major depressive disorder. All natural experiments require appropriate statistical methods, but in some cases statistics are crucial in adding additional means of testing the process being investigated. The example of the effects of membership of a delinquent gang on an individual's engagement in crime constitutes a good example of this kind.

A key limitation of almost all the natural experiments that we have discussed is that the designs are much stronger in showing whether or not there has been environmental risk mediation than they are in showing which particular aspect of the environment provided the mediation. Different designs and different forms of statistical analysis are required to take that absolutely crucial step from identifying a truly causal risk environment to a much more difficult issue of precisely which aspect of the environment provided the risk. That is especially the case when dealing with complex environments and when, as is usually the case, there are bidirectional effects that may vary over time. However, it should no longer be acceptable for researchers (or clinicians) to avoid considering whether a causal inference is justified. Both Rutter (2007) and Foster (2010) pointed out that a high proportion of the literature ignores this important question. Some deal with the problem by arguing that they are dealing only with statistical associations and not causation. However, why anybody should be in the least bit interested in statistical associations, if they carry no implications for causation, remains a mystery. Others make explicit that their research methods cannot test causation; nevertheless, in discussing findings at the end of the paper they suggest that the findings do mean causation. Natural experiments do not provide anything approaching a complete answer to the dilemma of determining when correlation can rightly imply causation, but they do take the field forward in a most important way.

Most crucially, natural experiments should not be thought of as a discrete number of strategies. Rather, they represent an ever-extending list of opportunities open to the alert researcher. Thus, the American Casino Study, the Chinese One Child Policy Study, and the Argentine National Lottery Policy were not designed for the purpose of a natural experiment, but the key researchers spotted that they provided an invaluable natural experiment opportunity. Doubtless, other opportunities are out there waiting to be discovered and acted on.

INTRODUCTION

A rudimentary set of hypotheses in developmental psychopathology seeks to describe the degree to which and to explain the mechanisms by which early exposures and experiences shape psychological development. Many new leads and some changes are evident in this area of research since the publication of the last edition of this volume in 2006. This chapter seeks to provide an updating and integrating of the models and mechanisms that explicitly or implicitly underlie developmental research on normal and abnormal psychological function. More specifically, the aims of the chapter are to (1) outline and differentiate some key developmental models—especially those concerning early experience—for testing hypotheses concerning normal functioning and psychopathology; (2) identify leading mechanisms for these models; (3) articulate methodological challenges for research in this area; (4) review select model systems and research paradigms that have risen to prominence; and (5) discuss how developmental models shape clinical and public health debates and intervention strategies. Concluding comments and future directions end the chapter.

It may be instructive to note some of the major changes in this area of study since the last edition of this volume at the outset of this chapter, to set the stage for the subsequent

discussion and to underscore the pace of change and areas of particular scientific growth. Perhaps the most obvious is that the greater understanding of how genetic mechanisms may modulate and be modulated by (early) experience has stimulated further interest in developmental studies. Epigenetics is a prime example, but evidence suggests that there may be genetic influences on plasticity, developmental timing and susceptibility to environmental exposures. A second major change is a shift toward greater emphasis on integrative or multidisciplinary research. That is seen in the research findings emphasizing how early psychological stress exposure predicts cardiovascular, metabolic, and other physical health outcomes (Felitti et al., 1998); the reverse is also true, reflected in a greater emphasis now on how early diet, inflammatory conditions, and physiology shape neurodevelopment and later psychological outcomes (Brown & Susser, 2008). Findings from these lines of mechanistic research have helped to reformulate broader models of development. A corollary is that this kind of approach will begin to extinguish artificial boundaries in how research is conducted, moving from a perspective derived from medical or scientific disciplinary traditions to an approach that instead focuses on mechanisms of interest across many disciplines. A third change is the increased interest is the intersection of early experience on psychological development and economics, embodied in the increasing interest in a neuroscience-informed social policy agenda. Research evidence in this area is the final theme of the chapter.

Several further preliminary comments are in order. The first is that relevant and allied areas of research on early experience and developmental mechanisms extend too broadly for a single chapter, and so the focus is on exemplary paradigms and findings rather than an exhaustive review. Second, while acknowledging the seminal influence of experimental animal studies, the focus of this chapter is, wherever possible, on human psychological development. Certain areas of research that require mention, such as a consideration of microglia and brain development, are inevitably limited to animal studies. On the other hand, the number and quality of human studies is now substantial and sufficient in some areas to compose a majority of the reviewed research. Third, although the emphasis of the chapter is on psychological development, it is necessary to refer to multiple systems that are linked with psychological development given the inexorable trend toward integrative, multidisciplinary hypotheses in development and psychopathology.

ALTERNATIVE DEVELOPMENTAL MODELS AND HYPOTHESES IN PSYCHOLOGICAL RESEARCH ON EARLY EXPERIENCE

Several conceptual models underlie research on early experiences. Three broad classes of models that have attracted the most attention and have generated considerable research in the animal and human literatures are considered here: sensitive period models, developmental programming models, and life-course models; modified alternatives, adevelopmental and defunct models are then briefly mentioned, partly for historical purposes. Inevitably, given space limitations and the broader aims of this chapter, it is necessary to simplify the definition and description of these models. Many reviews of these models have been provided, along with references. This chapter seeks to cover what is often missing from prior discussions, such as a comparative approach that examines multiple different kinds of developmental models and their distinguishing features, and application to intervention and broader developmental constructs such as resilience.

Sensitive Period Models

The sensitive period model for development has a long history in biology and has been applied across species on phenotypes as complex as bird song and biological processes as basic as cell differentiation (Bornstein, 1989; Knudsen, 2004; MacDonald, 1985). A sensitive period model proposes that there exists an ontogenetic period in the organism's development in which certain specified essential input is needed for normal development to proceed. This is conceptually similar to the experience–expectant model (Greenough, Black, & Wallace, 1987). A *sensitive* period model differs from the related *critical* period model more in terms of degree than in kind. That is, whereas a critical period is generally understood to imply rigid boundaries defining the period with major and uniform effects, a sensitive period model generally implies less rigid periods of ontogenetic vulnerability and possibly less severe consequences and effects. Sensitive period models are often allied with early development, but they need not be. There is, for example, evidence that adolescence and parenthood may also provide a sensitive period for certain exposures and outcomes (Barrett & Fleming, 2011; Dahl & Gunnar, 2009). Importantly, studies of sensitive periods provide links to developmental mechanisms by charting the effects according to timing of exposure, and

cross-tabulating the results with what is known about ontogenetic development. So, for example, if there were a sensitive period of stress exposure on affiliative behavior, then these findings would imply a value in further study of those brain circuits undergoing rapid development during the identified sensitive period.

A distinguishing feature of sensitive period models is their focus on species-typical development rather than more subtle individual differences within normal range of adaptation. That is, sensitive period models are most typically applied when predicting gross pathology that could undermine species survival and reproduction. That is evident in the classic examples of sensitive periods, such as applied to birdsong (Doupe & Kuhl, 1999; Mooney, 1999); aspects of vision (Hubel & Wiesel, 1970); imprinting (Lorenz, 1935); and social attachments and social behavior (Harlow & Suomi, 1970; Martin, Spicer, Lewis, Gluck, & Cork, 1991; O'Connor & Cameron, 2006; Sackett, 1969). The outcome in these studies is not normative variation but rather unambiguous deviation and disorder that could undermine such basic functions as reproduction (e.g., attracting a mate in the case of birdsong). A thematic concern in this line of study is with core principles about the nature of the organism. For example, sensitive period models would consider comparatively extreme nativist hypotheses, or distinguish the dose of exposure that might contrast instinctual behavior from a behavior that required particular environmental input.

A further defining feature of sensitive period models, with particular application to intervention, is the notion that the sensitive period window marks a special period of susceptibility or opportunity in the organism's development. For example, the likelihood of neural tube defects from exposure (e.g., underexposure to folate or overexposure to environmental toxins) is not equally likely at any point in the prenatal period, but only during neural tube formation (e.g., Rice & Barone, 2000). In other words, interventions for neural tube development must occur within a limited time frame defined by the neural tube ontogeny. More broadly, if there were a sensitive period for a particular outcome, then interventions would need to be delivered during that sensitive period; interventions delivered outside the sensitive period would have no effect or, alternatively, would have a different effect. Sensitive period models are therefore distinguished from alternative models in proposing that there is a point in development—outside the period of sensitivity—after which an intervention would not have the intended effect. Moreover, there is little room for recovery or resilience if the necessary and sufficient exposure did not occur within the window of sensitivity.

It may be helpful to elucidate the sensitive period model by contrasting it with contrary concepts, notably plasticity and, particularly for human psychological development, neuroplasticity. Neuroplasticity is the notion that there are ongoing changes in the structure, organization, and function of neurons according to (ongoing) changes in experience (e.g., Licznerski & Duman, 2013). Sensitive period models presume limited or bounded plasticity.

The degree to which there are sensitive periods for human psychological development has generated considerable debate. To be sure, there are examples of sensitive periods not just for classic physical development such as neural tube defects but also for several aspects of brain development affecting language (Flege, Munro, & MacKay, 1995; Johnson & Newport, 1989), hearing (Sharma, Dorman, & Spahr, 2002), or vision (Maurer, Lewis, Brent, & Levin, 1999). Whether or not the clarity of a sensitive period effect can be mimicked in all types of psychological development—behavior in intimate relationships, cognitive problem solving, extraversion, depression—is what stirs debate. Extensions of a sensitive period model to human psychological development have been proposed. Some studies are based on observational designs, as in the case of maternal depression and child behavioral and emotional problems (e.g., Bagner, Pettit, Lewinsohn, & Seeley, 2010); others are based on natural experiments or have other leverage for evaluating sensitive period hypotheses, as in the case of maternal prenatal rubella infection in the first trimester and child autistic-like behaviors (Chess, 1977) or prenatal maternal famine and major mental illness in those offspring in adulthood (Hulshoff Pol et al., 2000). As reviewed in a subsequent section, many purported examples of sensitive periods for human psychological development lack necessary controls and experimental leverage. That does not rule out the possibility of a sensitive period, but it does weaken the strength of the claim. There are also clear instances of misapplying the notion of sensitive periods to human psychological development. These misapplications and their rebuttals have a long history, particularly in the area of attachment and bonding (e.g., Herbert, Sluckin, & Sluckin, 1982) and have generated a disposition toward scepticism (Bruer, 1999).

Importantly, the hypothesis that there may be a sensitive period for certain exposures for specified developmental outcomes is different from proposing that there exists key periods for the emergence of social and cognitive functions. Thus, it is clear that there is a specified period

in development for the emergence of stranger anxiety or self-concept (e.g., Kagan, 1982). A sensitive period hypothesis would take this observation one step further in positing that, for example, the child's self-concept would be especially susceptible to the adverse effects of insensitive caregiving during this period of self-concept emergence.

Most of the empirically demonstrated examples of sensitive (and critical) periods for brain and behavioral development are derived from experimental animal studies. Minimally, that is attributable to the greater experimental leverage and assessment opportunities available in animal compared with human research. And it might also be that sensitive periods are more easily found in rodent and nonhuman models compared with humans. This possibility was illustrated by Berardi and colleagues (Berardi, Pizzorusso, & Maffei, 2000), who plotted the association between life span and sensitive period width across several species from monocular deprivation studies. They found a strong positive relationship between life span of the species and width of the sensitive period; that is, humans have a much wider (and thus possibly harder to detect) sensitive period window than rodents, for example. It is not known if a comparable association between life span length and sensitive period window holds for other kinds of exposures and for psychological outcomes, but that possibility presents a major challenge for research seeking to translate animal (perhaps especially rodent) findings on early exposures to human psychological development, especially where developmental timing may be concerned.

Developmental Programming

Developmental or adaptive programming is an alternative model for understanding how early exposures and experiences may have lasting effects on health and development. Probably the most well-research example of developmental programming is fetal programming, which proposed that in utero exposures instigate an adaptive response in the organism that is carried forward in development with persisting effects on behavior and biology (Amiel-Tison et al., 2004; Barker, 2007; Gluckman & Hanson, 2005; Gluckman et al., 2009). There may be programming effects of postnatal experiences as well, so the broader term developmental programming is used in this chapter.

A key feature of this model is that the biology of the fetus and child adapts to specific features of its environment; these adaptations are referred to as programming because they are thought to set some aspect of the biological system of the organism, with persisting effects that are carried forward into adulthood. The notion that the fetus or child *adapts* to the early exposure is critical in underscoring the importance of organism–environment transactions (e.g., from the fetal period) and for highlighting the explicit evolutionary influence in the model. Furthermore, the concept of adaptation distinguishes the model's focus not so much on normal versus deviant development (as with a sensitive period model) but rather on normative individual differences and the fit between the organism and its environment, that is, the organism's preparedness for its (later) environment. For example, mothers who experience increase stress in pregnancy may be signaling to the offspring and preparing it (i.e., its physiology) for the stressful environment it will encounter (Glover, 2011). Similarly, the thrifty phenotype hypothesis, which derives from the fetal programming model, proposes that poor prenatal nutrition in early life will influence glucose-insulin metabolism of the fetus in preparation for a poor postnatal nutritional environment (Hales & Barker, 2001; Silveira, Portella, Goldani, & Barbieri, 2007). There may be costs associated with certain kinds of adaptations or programming, but it is context dependent and can be judged only in relation to the organism's subsequent fit to its environment. A specific example is the case of the thrifty phenotype. This phenotype is thought to be programmed for a nutritionally poor environment and, if the individual remains in that environment, then the programming may be thought to have provided an adaptive response. In contrast, a programmed thrifty phenotype is ill-suited for a rich western diet and, when exposed to such a context—following migration, for example—may lead to higher rates of metabolic syndrome, type II diabetes, and cardiovascular disease. Accordingly, it is necessary to consider the subsequent environmental context for judging the fit of the programmed response. This component of the programming model clearly distinguishes it from a sensitive period model.

Adaptations or programming that does occur will take place in a particular period in development, that is, during a window of susceptibility or programmability. Much of the research focus to date is on birth weight and early physical growth, which are seen as indicators of early environments that may have programming effects on later somatic health (Barker, 1999; Painter, Roseboom, & Bleker, 2005; Phillips et al., 2000; Roseboom et al., 2000, 2003). Programming has been applied as a model to explain many other outcomes and phenotypes, including stress reactivity and other psychological outcomes. The implication is that there may be programmable effects on several biological

function and mechanisms, including glucose metabolism and stress physiology.

In contrast to the research base on the sensitive period model, which is heavily influenced by animal research, the research base on developmental programming has been substantially shaped by human research. Although much of the attention is on somatic health rather than psychological development, instances of possible programmed psychological outcomes have been suggested (O'Donnell, Glover, Barker, & O'Connor, 2014; Rutter & O'Connor, 2004; Sandman, Davis, & Glynn, 2012; Van den Bergh et al., 2005). One potential limitation to these studies is that the follow-up period rarely extends into or beyond adolescence, so the persistence of a programmed effect is not yet certain.

The application of programmability for intervention has not yet attracted considerable attention. Nonetheless, the clear expectation is that the degree of recovery or change of any sort would be very limited if an exposure such as an intervention occurred outside the period of programmability. This assumes, however, that the window of programming is known, and it may not be. In this context, experimental animal studies of the programmability of the Hypothalamic-Pituitary-Adrenal (HPA) axis from prenatal stress do show that the adverse effects of prenatal stress may be eliminated by postnatal manipulation (Maccari et al., 1995). Interestingly, a human study also showed that the adverse effects of prenatal stress on infant cognitive function could be eliminated if the infant was exposed to sensitive caregiving (Bergman, Sarkar, Glover, & O'Connor, 2010). Furthermore, in a rodent model, some of the effects of postnatal care deprivation could be reduced with an environmental enrichment delivered in the peripubertal period (Francis, Diorio, Plotsky, & Meaney, 2002). These findings leave open key questions about developmental timing and the programming window. For example, results from the Bergman et al. study could be explained if the programming window including both the prenatal period (when the purported risk exposure occurred) and the early postnatal period (when some children experienced a sensitive child–parent relationship). Slightly more challenging are those studies showing that interventions administered much later in development, such puberty, could reverse the presumed programming associated with prenatal stress. Similar to a sensitive period model, the window of programmability is presumed to be limited, although research on the boundaries and limits of the programming window are not always clear and it is rarely itself a target of research. And it may be possible that new periods of programming may open later in development, with implications for earlier programmed effects. That possibility is at least implicit in recent discussions of adolescence as a period during which the effects of early insults might be transformed (Dahl & Gunnar, 2009). Within the developmental programming model, additional research will be needed to examine if there is a point after which the delivery of an intervention would have no effect in resetting or compensating for a programmed response.

Life Span Development or Cumulative Effects Models

Most prominent in developmental studies of psychological development are life span development or life-course models proposing that individual differences in psychological development arise from the individual's particular profile of risk and protective experiences as accumulated through development. Concepts and metaphors such as developmental pathways (e.g., Bowlby, 1988; Sroufe, Egeland, & Kreutzer, 1990) convey the dynamic, unfolding process of development. Life-course models are distinguished from sensitive period and developmental programming models in putting explicit and significant emphasis on both current circumstances and developmental history. Furthermore, any association between early adversity and later outcome would be viewed as probabilistic rather than deterministic; moreover, early experiences would predict longer-term outcomes only insofar as the impact of early exposure is reinforced or maintained by subsequent exposure. So, for example, early adversity would be expected to have little or no—or at a minimum, diminished—effect in the absence of concurrent risk. That is, life-course or cumulative risk models propose that there is a carrying forward in development of early adverse or protective experience or exposure, but the impact is not direct but rather mediated by subsequent exposures. In other words, plasticity may be limited in sensitive period and programming models but is considerable in life span models. A further distinguishing feature of research on life span development models is their emphasis on aging and particularly senescence (Gerstorf et al., 2010; Lovden, Backman, Lindenberger, Schaefer, & Schmiedek, 2010). Reviews and descriptions of the life-course models are widely available (e.g., Baltes, Staudinger, & Lindenberger, 1999; Clarke & Clarke, 2000; Elder, 1998).

Of particular and distinguishing relevance to life span theories are normative and nonnormative transitions, including the transition to adolescence, marriage, retirement, or divorce and remarriage. These are particularly informative points in the developmental pathway; adjustments at these transition points might offer an especially

informative index of future adjustment. In this way, life span models would incorporate well-known psychological developmental stage theories of Erik Erikson, among others. Stage theories are quintessentially life span developmental hypotheses insofar as they propose something specific and distinguishing about the organism at one stage in development that differs from another stage, and that successfully resolving one developmental task increases the likelihood of successfully resolving the next (Sroufe & Rutter, 1984). One stage or developmental task may not necessarily have priority over another, but progressive successes increase the likelihood of continued healthy adaptation. It is not only psychological theorists but also sociological and other social science theorists who emphasis the life-course models for understanding individuals and their fit and adjustment into the family, culture, and economy (Mayer & Schöpflin, 1989).

A still further distinguishing feature of life span models is their focus not on frank pathology but rather on normative variation among individuals. Related to this wide potential for variation are two notions in developmental theory: multifinality, or the idea that a certain risk may lead to diverse outcomes among individuals; and equafinality, which is the notion that individuals may end up at the same (mal)adapted outcome by traversing different pathways or patterns of risk exposure (Cicchetti & Blender, 2006). No such degree of flexibility and focus on individual variation is accommodated within the sensitive period or programming models discussed above.

Whereas animal studies feature centrally in studies of sensitive period and programming hypotheses, they are rarely designed and may not be well-equipped to test life span models; a brief life span in rodents is one obvious reason for this. Alternatively, life span developmental models may be more applicable to behavioral and psychological phenotypes (emphasized in human developmental research) than biological phenotypes (emphasized in animal studies).

It is also in the intervention context that life span developmental models are easily distinguished from sensitive period and programming models. Specifically, life span developmental models emphasize that there is substantial potential for recovery following (early) exposure to adversity. A corollary is that there is not a period in development after which an intervention could not have a salutary effect. (However, to say that there could be an intervention effect is different from proposing that intervention effects will be readily demonstrated.) A life span model proposes that an individual's psychology and by extension biology remains to some important degree malleable and plastic, and this renders current experiences as potentially potent influences on the developmental course and adaptation of the individual. Indeed, empirical examples from naturalistic longitudinal studies that show dramatic life-course changes can be instituted by major transitions occurring in adulthood, including enrolment in the military (Elder, 1986) and marriage (Quinton, Rutter, & Liddle, 1984). Compared with sensitive period and programming models, life-course models place much less emphasis on the timing of the intervention when judging its potential effects.

Alternative Models

There exist other models of development for judging the likely effects of early life experiences and exposures; a few additional examples warrant at least brief discussion. One of these is canalization, which, as discussed by Waddington (1959), described a populations's tendency to produce the same phenotypes despite mild variation in various conditions. That has also been applied to an individual organism, most elaborately by Gottlieb (1991). Put another way, the notion of canalization implies a robustness of the organism's phenotype despite perturbations. The deepness or structural robustness of the canal incorporated in canalization would vary across phenotypes; presumably the more evolutionarily conserved phenotypes may be thought to have a more robust or deeper developmental trajectory in development because they may be more robust to perturbations in the environment. There remains some uncertainty about how well canalization is translated to testable experimental or intervention context, and human research using this model is limited.

In response to findings from studies of children who experienced early institutional deprivation, some authors (Gunnar, 2010; Zeanah, Gunnar, McCall, Kreppner, & Fox, 2011) have suggested that a somewhat modified sensitive period model may be needed. Particularly relevant here is the finding that children who experienced institutional deprivation that was limited to the first six months of life showed no significant differences in many key areas compared with a nondeprived group, and that variation in length of deprivation from six months to more than two years did not reliably predict longer-term outcomes (e.g., Kreppner et al., 2007). Equally important is the observation found in virtually all studies that the experience of institutional care from birth continues to have a persisting mild-moderate effect on several aspects of psychological development long after removal from the institution and placement into a normal-risk family environment. This collection of effects is not easily accommodated by leading

developmental models. There are many limitations to the existing studies, particularly concerning developmental timing effects, and patterns from one sample or design may not extend to another; nonetheless, a stepped function or other nonlinear pattern found in this important collection of studies may require a modified sensitive period model, at least in the case of very extreme deprivation in early development (Zeanah et al., 2011).

A further developmental hypothesis is the so-called sleeper effect. This is the notion that the effects of an exposure may not be apparent immediately or shortly after exposure to the presumed cause, but will become evident later in development. Wallerstein (1985) invoked this notion in suggesting that divorce in childhood may have not only immediate effects, but also effects at a later point in development, such as adolescence, when there is a rekindling of the early developmental struggle or vulnerability. Sleeper effects presume that the (positive or negative) impact caused by the exposure is not readily apparent and measureable because the biological underpinnings of the target behavior were not in place at the time of the exposure, or that the behavior had not yet developed. There are good reasons to expect delayed effects of early exposures, particularly in the context of neurodevelopmental models of psychopathology. That is because the neural circuits associated with stress response and depression may not be developed and integrated at the time of the exposure. On the other hand, one difficulty with the sleeper effect model—and the reason why it is difficult to rule in as a satisfactory explanation—is that the temporal separation of cause and effect could be explained by a cascade of intermediate effects. So, for example, a presumed sleeper effect linking early parental divorce and adolescent sexual behavior could be explained by a chain of indirect effects including increased behavioral disturbance, school difficulties, poor parental monitoring, affiliation with deviant peers, and engagement in high-risk behaviors. This indirect effects model may not only be more accurate, but also more practical for planning interventions. It would be difficult to identify specific intervention options according to a sleeper effect model.

Although influential in studies of risk and psychopathology, the diathesis–stress model is not discussed at length because it is not inherently developmental—although it remains a plausible and valuable null hypothesis for developmental studies. In its basic form diathesis–stress is not fundamentally concerned about how development configures or constitutes a diathesis or vulnerability; rather, the hypothesis is that there is an underlying diathesis is expected to lead to pathology in the context of stress and that this association is essentially invariant across development. This is similar to the experience-dependent model (Greenough et al., 1987).

Finally, it may be worth briefly highlighting, at least for historical purposes, developmental hypotheses that no longer command serious attention. So, for example, the claim that maternal bonding required immediate and extensive post-birth contact was suggested as an evidence-derived human feature some years ago (Kennell, Trause, & Klaus, 1975) but has now been essentially dismissed. It may be that that conclusion was an inappropriate extension from rodent findings, for which there is considerable support. A further example of a now discredited model is the notion of developmental arrest. Disturbances in attachment and social adjustment reported in ex-institutionalized children garnered particular attention because of the strikingly abnormal behavior, including seeking comfort from apparent strangers when distressed, which in some children persisted years after placement in a normal caring environment. The suggestion that the child's psychological development was arrested or frozen in an immature state because of the experience of profound deprivation gained popularity, which persisted for some time. The concept of developmental arrest has been around for some time, viewed by some as an innovation of psychoanalytic theory (e.g., B. Rank, 1949) and considered central to such notions as (infantile) narcissism (Kohut, 1971). To be sure, children who experienced institutional deprivation would have experienced a profound lack of mirroring that is proposed as a basis for healthy psychological development—but this is quite a different matter from the notion of arrested or stopped development. Several authors (Keck & Kupecky, 1995) suggested that the deprived child's arrested development required an extreme form of intervention to unfreeze development. That is where a metaphor inspired radical, coercive, and harmful interventions; some of these radical interventions, such as rebirthing therapy, led to child deaths (Crowder & Lowe, 2000; Mercer, 2005). In response, several professional organizations (Boris & Zeanah, 2005; Chaffin et al., 2006) have taken the extraordinary step of explicitly rejecting as unethical and dangerous coercive and holding therapies. The reason for highlighting this now defunct proposal is not because it is a viable model of development but rather because this dubious model had practical hold on how interventions were practiced, at least for some time and for some individuals. This is not the only discredited model to have had influenced thinking about development and psychopathology. Thus, the notion that birth trauma or the psychic separation from mother at birth is a basis for later anxieties (Rank, 1929) now

seems absurd. The lesson is that it is natural to expect and require that models of development remain in a state of change, requiring further empirical evidence and updating (e.g., Gedo, 1980).

Summary

There is growing recognition that many psychological disorders may be best seen as neurodevelopmental in nature and require a developmental focus (Cicchetti & Rogosch, 2002; Insel & Wang, 2010). Evidence of this takes many forms; one valuable observation is the finding that one-half of those with an adult mental disorder exhibited the problems by early adolescence and that the median age of onset of anxiety and impulse-control disorders is 11 years of age (Kessler et al., 2005). Concepts and findings of this kind underscore the value in formulating and differentiating alternative developmental hypotheses. Accordingly, this opening section sought to draw broad distinctions that might differentiate specific theories of how (early) experiences and exposures may shape psychological development. Rather than focus on individual theories of development, the focus was on broad criteria and features, such as the role of developmental timing, the predominance of animal research, and application to intervention. The three types or classes of models reviewed above may not easily accommodate all specific theories of human development, but might provide a basis for contrasting specific theory hypotheses. For example, in the area of parent–child relationships, the types of models and features previously described may help to distinguish competing theories, such as attachment theory and its focus on life span processes (Ainsworth, 1989; Bowlby, 1988) from alternative theories that place special emphasis on the early relationship (Chodorow, 1978; Winnicott, 1965). The next section identifies key mechanisms that may provide the basis for understanding why (early) experiences and exposure may shape health and development.

DEVELOPMENTAL MECHANISMS

Research findings identify several candidate mechanisms to explain the sources of individual differences underlying psychological development and the mechanisms by which psychological experiences may be transduced to biology and behavior. What constitutes a developmental mechanism can be a matter of some debate, particularly where experimental leverage is limited, as in most human studies and especially those using observational/naturalistic study designs. Indeed, it can be very challenging to identify a factor as a risk mechanism, implying causal effect, rather than merely risk factor, a term which carries much less causal certainty and may merely offer an indirect index of a causal effect. This conceptual issue has been widely discussed in the literature on psychopathology in children and adolescents (e.g., Grant et al., 2003). A further cautionary note on mechanisms is that research may show that a particular factor can be a causal mechanism when considered in isolation or in a very particular sample or context, but the impact may be modest or unknown or unknowable in more typical/normative samples or at the population level. For example, a common experimental animal approach is to study animals in which a particular gene has been experimentally and artificially inactivated; experiments with these genetic knockout animals have been used to implicate a variety of genes in many aspects of development and disease. Such a study may demonstrate that a mouse with inactivated gene X shows disturbance in neurogenesis in the hippocampus and so, by implication, gene X has a role in hippocampal neurogenesis. In fact, what the study has shown is that gene X *can* alter neurogenesis in a very particular (and abnormal) biological context; whether or not gene X *does* govern neurogenesis in the typically developing animal does not necessarily follow. Similarly, findings from several studies strongly suggest that early institutional deprivation *can* be a cause of inattention/hyperactivity (Kreppner, O'Connor, & Rutter, 2001), but the relevance for the population (e.g., in terms of population attributable risk) is uncertain given the rarity and declining numbers of children adopted from institutional settings.

Stress Physiology

Stress physiology is perhaps the most widely studied candidate mechanisms to explain the effects of (early) stress exposure on health and development; of the several stress physiology components, the most popular is probably the hypothalamic-pituitary-adrenal (HPA) axis. The prominent role of the HPA axis in developmental studies in humans is attributable to many factors, including (1) a remarkable evidence base in animal models; (2) the interpretability of markers of the HPA from peripheral samples such as saliva and blood; (3) the modest cost of obtaining and analyzing such samples; (4) the widespread relevance of the HPA axis in many areas of development, making it a quintessentially mind–body biomarker; (5) a now substantial human evidence base implicating the HPA axis and its downstream element cortisol in a wide range of

mental and somatic health outcomes; and (6) accumulating understanding of genetics of the HPA axis.

Human evidence that the HPA axis may be modified by early experiences and may underlie short- and long-term psychological health is substantial (Gunnar, 2003). One line of research has shown that the infant's HPA axis can be modified as a function of early exposures; that list of early exposures includes prenatal maternal distress, variation in early caregiving, and indirect measures of stress exposure such as maternal psychopathology, family conflict, and loss (Brennan et al., 2008; Davies, Sturge-Apple, Cicchetti, & Cummings, 2008; Grant et al., 2009; Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Nicolson, 2004; O'Connor, Bergman, Sarkar, & Glover, 2013). An important follow-on finding is that perturbations in the HPA axis associated with early stress may have persisting effects, as is shown in studies of adults exposed to early trauma or loss (Heim, Newport, Miller, & Nemeroff, 2000; Luecken & Appelhans, 2006; Nicolson, 2004) and longitudinal follow-up of adolescents exposed to prenatal maternal anxiety (O'Donnell et al., 2013) or maternal postnatal depression (Halligan, Herbert, Goodyer, & Murray, 2007). It should not be surprising that a stress response system does, in fact, respond to significant stress. Rather, the previous findings are important for understanding early experience in two ways: (1) by demonstrating that associations between stress exposures and physiological changes can be found from early development, as even the infant's HPA axis is responsive to social environments; and (2) demonstrating reported evidence that early exposures can have lasting and persisting effects into and beyond adolescence, which in at least some studies is well beyond the period of exposure to the putative cause. To be sure, the effects sizes may be small in many cases, implying wide variation in response and the involvement of many other factors. Nonetheless, these findings help make the HPA axis a natural focus for developmental studies.

An important further observation of the HPA axis for understanding developmental mechanisms is how it responds to prolonged stress exposure. Both animal (Sheridan, Stark, Avitsur, & Padgett, 2000) and human (Miller et al., 2009) research work shows that prolonged stress exposure may lead to glucocorticoid resistance or decreased glucocorticoid receptor sensitivity. This may account for the down-regulation of the stress response following chronic and severe stress exposure, and explains why there is interest both in hyper- and hypo-response to stress in child and adult samples. This process also hints at a mechanism by which alterations in the HPA axis may influence other biological processes, such as dysregulated immune function (Cohen et al., 2012).

A developmental notion relevant to the HPA axis (as well as other physiological systems) is the allostatic load model, which focuses on the wear and tear of stress on the body over a prolonged period of time (Juster, McEwen, & Lupien, 2010; McEwen & Wingfield, 2003; Seeman, Epel, Gruenewald, Karlamangla, & McEwen, 2010). The notion here is that adaptive neuroendocrine responses to short-term stress exposure will, if activated persistently, have deleterious effects on the body and hasten the onset of disease. What is not clear is how prolonged the exposure needs to be in order to observe effects, but it is notable that the majority of studies focus on adult outcomes (for exceptions, see Evans, 2003; Evans, Kim, Ting, Tesher, & Shannis, 2007; Flaherty et al., 2009). The implication is that it is the accumulation of stress exposure during the life course rather than stress exposure experienced at a particular point in development—a notion central to sensitive period and programming models—that creates the wear and tear and effect on the HPA and allied physiological systems. Studies based on a life span model have been especially active in incorporating HPA axis mechanisms to explain variation in health and aging (Lupien et al., 1998).

HPA axis-related mechanisms are also main features of developmental programming studies, particularly involving prenatal maternal stress and research on the developmental origins of health and disease (DOHaD) (Hanson & Gluckman, 2011; Swanson, Entringer, Buss, & Wadhwa, 2009). The hypothesis, which has been supported in many studies, is that exposures during particularly sensitive periods in ontogeny program or set glucose metabolism or one of many other functions associated with the HPA axis, with the programming carried forward into adulthood (Gluckman, Hanson, Cooper, & Thornburg, 2008). Most DOHaD-related research examines adult health outcomes, but a few have assessed childhood-onset effects (Ibanez, Ong, Dunger, & de Zegher, 2006). Finally, HPA axis mechanisms have been equally implicated in sensitive period models. One recent report suggested that, in the rodent, corticosterone (the equivalent of cortisol in the human) may influence the sensitive period for attachment learning (Upton & Sullivan, 2010). It would seem that HPA axis-related mechanisms are applicable for the range of developmental models identified in the opening section.

Neuroimmunology

One mechanism for developmental studies that has commanded particularly intense recent interest, particularly concerning early experience and neurodevelopment, is neuroimmunology. In the broadest sense, neuroimmunology is the study of the connections between the nervous

system and the immune system. Psychoneuroimmunology (PNI) expands this area one step further to incorporate behavior. The PNI model grew out of the work of Ader and Cohen several decades ago when they demonstrated that an immune function could be behaviorally conditioned using the classical conditioning paradigm (Ader & Cohen, 1975); that work has since been expanded and reinforced in several ways and in several studies across several decades of investigation (e.g., Ader, Kelly, Moynihan, Grota, & Cohen, 1993).

Research in neuroimmunology and PNI have established robust connections between the immune and the nervous system; specific examples include the finding that (1) there is sympathetic innervation of the spleen and other lymphoid organs; (2) central nervous system manipulations (e.g., lesioning the pituitary) may suppress antibody production; (3) changes in hormone or neurotransmitter levels alter immune function, and the reverse is equally so; (4) lymphocytes express receptors for hormones and neurotransmitters; (5) immunological reactivity is influenced by stress exposure and behavioral interventions. It has been appreciated for some time that stress exposure evokes an immune response, and this has likely evolutionary advantages (Ottaviani & Franceschi, 1996). Other research shows the immune system's role in neural plasticity, such as hippocampal neurogenesis and other areas (Schwartz & Kipnis, 2011; Wolf et al., 2009), and illustrates that the immune system shapes the brain by enacting cellular changes that alter synapse formation, modification, and pruning, thereby shaping neural circuits (Luo & O'Leary, 2005). That means it is reasonable and expectable that influences on the nervous system, such as stress, will have immunological effects and that immunological perturbations may be expected to alter the nervous system and brain development (the most well-known example, the maternal immune activation model, is discussed at some length in section d). These observations justify research on neuroimmune mechanisms as plausible candidates for explaining the early and prolonged effects of stress exposure, variation in neurodevelopment, and the development of psychopathology. The relevance of neuroimmune mechanisms for alternative developmental models in the opening section of this chapter will become clearer as this work unfolds.

Applications of neuroimmunology and psychoneuroimmunology in developmental models and in research with children and adolescents are, so far, quite limited (Ader, 1983; Coe, 1996; O'Connor, Moynihan, & Caserta, 2014). There are several reasons for this. One is the complex nature of CNS-immune connections and, within the immune system, the extraordinary difficulty in understanding the effect of one target amidst a very dynamic system. And, even where immune target effects are demonstrated, the nature of the effects is complex, as in the case of interleukin (IL)-1, which may have both facilitating and impairing effects on learning and memory in the animal model (e.g., Yirmiya & Goshen, 2011). Additionally, candidates for mechanistic research in developmental studies may not be practical research targets in humans. An obvious example is microglia, the resident macrophages of the brain which provide surveillance and maintenance functions. Animal studies provide ample evidence for their role in healthy brain development and repair. A case in point is the study by Paolicelli et al. (2011) who used a knock-out mouse model to demonstrate that microglia played a critical role in synaptic pruning, an essential function for normal development; mice with reduced microglia displayed immature brain circuitry. In this way, microglia may play roles in sensitive period modulation, and in developmental programming of the brain associated with early immune activation (Bilbo, 2013). But, in human developmental research, microglia remain delitescent. That is, human research into microglia rely on the use of post-mortem studies or from recent advances in positron emission tomography (PET) scan studies using specific radiotracers that specifically bind to microglia (Suzuki et al., 2013), but these approaches have evident limitations.

An example of immune function on behavior—and by implication brain—in children and adolescents is Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections (PANDAS), a sudden onset of obsessive-compulsive and tic symptoms following streptococcal infection (Garvey, Giedd, & Swedo, 1998; Swedo & Grant, 2005). In addition, there has been considerable interest in describing immune alterations in autism (e.g., Ashwood et al., 2011; Suzuki et al., 2013), although the etiological and treatment significance of the findings so far reported are unclear, and somewhat difficult to summarize. In general, the extent to which altered immune function is evident in children with behavioral or emotional problems is difficult to estimate because of the limited data available (Birmaher et al., 1994; Keller, El-Sheikh, Vaughn, & Granger, 2010) or reliance on medically ill samples (Mackner, Pajer, Glaser, & Crandell, 2010; Sokal et al., 1998).

In any event, it would appear, based on the current data, that associations between immune markers and psychopathology in children and adolescents may not mimic adult patterns, such as in the case of the cytokine hypothesis in depression (e.g., Mills, Scott, Wray, Cohen-Woods, & Baune, 2013). Indeed, although there is substantial basis for investigating immune mechanisms from early

childhood in relation to stress exposure for what impact it may have on brain and behavior, it is far from clear how the developing immune system may respond to early stress exposure. The young immune system, because it is under development, may be especially vulnerable to the effects of stress; alternatively, it may be less susceptible to long-standing adverse effects because of the greater immunological reserves in younger compared with aged individuals. It is similarly unclear if the immune system early in development would be impaired by stress exposure—the effect readily discernible in adults and especially older adults—or accentuated by stress exposure. Evidence for the latter was demonstrated in several studies, such as an ambulatory sample of preadolescents in whom an index of caregiving and family stress predicted enhanced natural killer (NK) cell functioning (Caserta et al., 2008). In early development, early stress may activate the immune system which may appear, after prolonged exposure, to take the form of down-regulation that has been shown in adults. Later in development, the effect of prolonged inflammatory cytokine elevation may hasten the onset of immunosenescence, which has been operationalized in terms of decreased naïve T cell numbers and declining adaptive responses (Franceschi et al., 2007; McElhaney & Effros, 2009; Pawelec, Larbi, & Derhovanessian, 2010); furthermore, these immune response may be linked with other cognitive and health declines in high stress-exposed individuals. That is, early and chronic psychosocial stress may accelerate the typical process of immunosenescence via exaggerated immune responses. Although the mechanisms in development may not yet be clear, what is certain is that neuroimmune mechanisms could explain why there is a remarkably robust association between early stress exposure and a wide range of disorders, including psychopathology but also autoimmune disease, cardiovascular, periodontal, and respiratory diseases, cancer, and other ailments (Almeida et al., 2010; D. W. Brown et al., 2010; Chen, Miller, Kobor, & Cole, 2010; Dube et al., 2009; Jackson, Kubzansky, Cohen, Weiss, & Wright, 2004; Lemieux, Coe, & Carnes, 2008).

Neural Development and Neural Circuitry

Neural mechanisms in development such as neuronal pruning, specification, consolidation and connectivity, and sculpturing of brain circuits and how these principles underlie such central developmental concepts as plasticity have been discussed at length (Horn, 2004; Knudsen, 2004; Luo & O'Leary, 2005; Sirois et al., 2008; Sur & Rubenstein, 2005). There is obviously a brain basis to the kinds of effects prescribed by a sensitive period, programming, or life-course model as described in the opening segment. The perennial challenge for human psychological research is to document these brain changes, establish their links with behavior, and track intraindividual changes across development to differentiate among competing developmental hypotheses.

One set of findings on human brain development that requires particular attention is the emerging evidence on the amount of brain volume change in the course of the first year, and how the amount of change varies across brain region. For instance, one program of study (Gilmore et al., 2012; Knickmeyer et al., 2008) reported that total brain volume may increase as much as 100% in the first year, and much less in the second; that this increase was largely accounted for by increases in grey matter; that volumetric increases in early infancy may be especially pronounced in the cerebellum; and that changes in specific regions of particular interest in neurodevelopment such as the hippocampus change at rates different from other brain regions from birth to 2 years of age. In addition, other studies suggest that synaptogenesis in the visual and auditory cortex peaks in the early months of life but is more protracted in the prefrontal cortex (e.g., Huttenlocher & Dabholkar, 1997). These findings are obviously central to designing studies, interpreting findings, and developmental theorizing. For example, given these findings it may not be surprising how difficult it is to trace and document stability in stress physiology or effects of stress exposure in early infancy. Variable rates of developmental changes across brain region in early infancy also raise important questions about how to track the formation of brain circuits connecting different brain regions (discussed next); a possible corollary is that no single developmental hypothesis is likely to offer a satisfactory account for such as phenotypes as stress physiology, executive functions, reward learning, or social communication. Also, it remains to be seen how the dominant method in early development of using structural MRI can be translated to more specific questions concerning neural mechanisms involving glia, dendrites, axonal arborisation, and other factors and functions.

A second point concerns the move away from focusing on specific brain regions and links with behavior to systems-level approaches, examining neural circuits and brain connectivity. Conceptual and technical findings and principles have been discussed for normal development (Tau & Peterson, 2010), and examples have been reported for many conditions, including language processing (Gozzo et al., 2009), and in relation to many exposures, such as prenatal maternal anxiety (S. Sarkar et al., 2014).

Movement away from analysis of specific brain regions to the development and change in neural circuits reflects the growing interest in systems neuroscience.

Genetics

There is now no doubt that genetic factors influence a wide array of psychological processes and outcomes across the life span (e.g., Plomin & Rende, 1991). Accordingly, genetic mechanisms are a natural focus for research on how and under what circumstances early exposures may have lasting effects on psychological development. One important line of study has focused on how genetic factors shape behavior that increases exposure to environmental risk, and how genetically influenced biologically factors moderate the effects of exposure. Several findings—insofar as they hint at general principles—are especially relevant to developmental models of psychological development. One is the early emerging genetic influences on behavior, with effects evident for a wide range of behavioral phenotypes from early childhood (Eley et al., 1999; Saudino & Eaton, 1991). A second is the evidence that genetic influences appear to strengthen over time as indexed, for example, by increasing heritability estimates from twin studies or, in an impressive longitudinal analysis, increasing resemblance of adopted-away children to their biological parents (Plomin, Fulker, Corley, & DeFries, 1997).

Molecular genetics research seeks to identify specific genes with putatively direct influence on brain and biology via a cascade of biological processes from brain cells to circuits, e.g., see (Plomin, 2005) and how these allied biological effects modify environmental exposures. Findings from this area of study reinforce the view that there are early-emerging genetically-mediated effects of the environment on behavior apparently associated with specific genes; and, by focusing on specific gene systems, this line of research may also point to biological mechanisms. Many examples with application to developmental models have been reported. For example, in the specific area of child–parent attachment, research findings suggest that children possessing the short variant of the 5-HTTLPR gene were more likely to exhibit an insecure attachment in infancy if they also were exposed to insensitive caregiving (Barry, Kochanska, & Philibert, 2008). The role of dopamine-related genes is also notable in this line of study (e.g., Bakermans-Kranenburg & van Ijzendoorn, 2006; Propper, Willoughby, Halpern, Carbone, & Cox, 2007). Another example with particular relevance to early risk exposure and alcoholism was reported by Barr and colleagues (Barr et al., 2004), who found that the effects of early deprivation on alcohol risk were limited to those female animals at genetic risk according to serotonin transporter gene.

A broader hypothesis with potentially significant impact on development theory proposes that there are genetic influences on susceptibility to the environment; that is, the *same* gene (or more likely, genes) may be associated with better outcomes in the context of positive environmental conditions *and* more negative outcomes in the context of adversity (Bakermans-Kranenburg & van Ijzendoorn, 2007; van Ijzendoorn, Belsky, & Bakermans-Kranenburg, 2012). A recent meta-analysis (van Ijzendoorn et al., 2012) suggested that the serotonin transporter gene may show this susceptibility pattern rather than a vulnerability pattern. Particularly interesting supportive evidence for this model was suggested in a study of children who experienced early institutional deprivation, some of whom also experienced a major early intervention to improve caregiving quality; analyses suggested that the serotonin transporter and brain-derived neurotrophic factor (BDNF) genes may act as susceptibility genes with respect to indiscriminate social behavior (Drury et al., 2012).

Specific genetic influences on the sensitive period phenotype have also been reported, although the evidence is limited to animal models (Hensch, 2004). For example, Huang and colleagues (Huang et al., 1999) demonstrated mice genetically manipulated to overexpress brain-derived neurotrophic factor (BDNF) showed accelerated development and early closure of the critical period in the visual cortex. A complementary proposal that environmental exposure in a sensitive period in development may alter gene expression relevant to NMDA has also been reported (Kinnunen, Koenig, & Bilbe, 2003). Additionally, evidence of ontogenetic changes in glucocorticoid receptor (GR) gene expression in brain development suggests sensitive period of glucocorticoid sensitivity, with application to sensitive period and programming models (Speirs, Seckl, & Brown, 2004). Thus, a picture is emerging that several different gene systems may be relevant for modulating the effects of early exposures on development and perhaps on the sensitivity or susceptibility window. Further work of this kind, insofar as it can be translated to human development, may prove to be especially influential in shaping developmental hypotheses.

More recent research on epigenetic mechanisms offers a powerful method of understanding and redefining genetic influences for shaping developmental models (Meaney, 2010). DNA methylation is one specific epigenetic mechanism that has attracted research attention because the biological processes of methylation and gene silencing

are reasonably well understood (Reik, Dean, & Walter, 2001; Seisenberger et al., 2013), and disrupted patterns of DNA methylation have been associated with specific diseases such as cancer and neurodevelopmental disorders (Urdinguio, Sanchez-Mut, & Esteller, 2009). DNA methylation patterns undergo dramatic developmental change from embryogenesis, suggesting that these systems may be malleable in development (Y. Bergman & Cedar, 2013; Seisenberger et al., 2013). Furthermore, animal models are beginning to demonstrate that exposures in the (early) social environment may induce epigenetic alterations (Champagne et al., 2006; Szyf, Weaver, & Meaney, 2007; Weaver et al., 2004, 2005).

Moving to human research, published reports suggest that childhood maltreatment and traumatic stress are associated with DNA methylation patterns in adulthood (e.g., Mehta et al., 2013); few reports show effects as early as mid- and late adolescence (e.g., Essex et al., 2013). There are important limitations to many of the studies in the area, however. A key question for translating these findings and assessing their reliability derives from the tissue-specific nature of the epigenetic effects, which have been identified in the animal studies but not yet certified in human studies—aside from the limited research on cadavers (e.g., Labonte et al., 2013). There is also limited research including multiple occasions of measurement. That concern is particularly relevant for developmental studies given that normative changes in DNA methylation are particularly notable in pediatric samples (Alisch et al., 2012). What has not yet been reliably documented and replicated is that an hypothesized measure of stress in the social environment is associated with stable methylation patterns. Nonetheless, research has begun to document some of the early predictors of DNA methylation in very young children, including prenatal factors (Herbstman et al., 2013).

A range of plausible candidate gene systems have attracted attention in methylation studies, including the glucocorticoid receptor gene (NR3C1), which has emerged in the animal literature as a leading candidate (Weaver et al., 2004) and is one of the very few replicated human findings across multiple *different* sample types using a range of samples and approaches (Hompes et al., 2013; McGowan et al., 2009; Oberlander et al., 2008). In recognition of evidence for associations between PTSD and immune function, and in support for the review of neuroimmune mechanisms above, immune-related genes are also good candidates for focused gene approaches (Guffanti et al., 2013; Rusiecki et al., 2013). Alternatively, the switch to genome-wide methylation studies will likely gain greater influence in subsequent research (Lam et al., 2012).

A key theme in research on genetic mechanisms, from the earlier work on behavioral genetics to the more recent work on molecular genetics and epigenetics, is on genetic influences modulating development and change. Accordingly, genetic mechanisms will remain an essential component for forming, supporting, and disconfirming models of psychological development.

Psychological Mechanisms

Quite what constitutes a psychological mechanism will likely generate some debate (Bechtel, 2008). But, there should be little debate that attachment theory and its internal working model is an often-referenced candidate for understanding how and if early experience shapes long-term psychological development (Bowlby, 1982; Bretherton, 2005; Steele, Steele, & Johansson, 2002). In infancy, secure internal working models are thought to develop from sensitive and responsive caregiving, from which the child develops a model of the attachment figure as available, protective and caring, and of the self as worthy of love and protection. Children who experience unresponsive and insensitive care form a contrary insecure internal working model. Caregiving behaviors in the early months of life predict security of attachment at one year, as shown in the elaborate and elegant work of Beebe and colleagues (e.g., Beebe et al., 2010). A meta-analysis of some years ago demonstrated that sensitive and responsive care does predict a secure internal working model, at least to a moderate degree (De Wolff & van Ijzendoorn, 1997). Furthermore, the secure versus insecure quality of the internal working model, as derived from several different kinds of attachment measures from infancy through adolescence, is associated with many measures of socio-emotional and behavioral well-being (Allen, Moore, Kuperminc, & Bell, 1998; Arend, Gove, & Sroufe, 1979; Bureau & Moss, 2010; Futh, O'Connor, Matias, Green, & Scott, 2008; Groh et al., 2014; Schneider-Rosen & Cicchetti, 1984; Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009). The above findings underscore two valuable and interlinked lessons for developmental models of early experience: the internal working model mechanism/hypothesis is early emerging and psychologically and behaviorally relevant for current and future clinical outcomes.

Attachment theory and its internal working model mechanism hypothesis, as it is most often expressed, fits squarely within the life-course developmental model, that is, rather than the sensitive period or programming models. That is implicit given the description of the developmental changes in the organization of the child–parent

attachment and explicit in the use of the concept and metaphor of developmental pathway. For example, developmental change is found in the move toward a goal-corrected partnership in preschool-aged and older children (Bowlby, 1982; Marvin & Britner, 2008), reflecting that the child and parent are increasingly able to operate toward a shared set of negotiated goals. Studies of attachment in adolescence have also described important ontogenetic changes and alterations in how attachment qualities and the internal working model in particular may be best assessed (Allen & Miga, 2010; Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993; Obsuth, Hennighausen, Brumariu, & Lyons-Ruth, 2013; Scott, Briskman, Woolgar, Humayun, & O'Connor, 2011). The life-course model underlying attachment theory and the internal working model mechanism is more explicitly described by and expanded by Bowlby (1988) and Ainsworth (1989). And, in fact, empirical research shows that internal working models of security versus insecurity do, in fact, change in the course of development and (presumably) in response to changes in care arrangements. Although both long-term stability (Waters, Merrick, Treboux, Crowell, & Albersheim, 2000) and instability (Weinfield, Sroufe, & Egeland, 2000) have been reported, the core conceptual feature of the internal working model for this chapter is that it is open to changes in the caregiving arrangement. That is central to the concept of lawful discontinuity and the focus on the developmental history and current state of intimate relationships in attachment theory.

Many other psychological mechanisms implicated in the broad class of activity of information processing (e.g., memory) would also need to be cited here insofar as they too can have own to have carry-forward effects from prior experience. Both the content of memory and the integrity of the brain in the processing and storing of memories are now active areas of study in the early experience literature, particularly in the context of trauma and child maltreatment. Thus, imaging studies suggest that retrospectively reported maltreatment and trauma was associated with a reduction in hippocampal volume (Teicher, Anderson, & Polcari, 2012); other studies suggest that the experience of maltreatment may sensitize, impair and distort memory for specific subsequent experiences, especially where negative affect, trauma, and threat may be salient (Goodman et al., 2011; Goodman, Quas, & Ogle, 2010; cf. Howe, Toth, & Cicchetti, 2011). Quite how these dynamics of memory aid in constructing psychological processes such as attributions and related social learning theory constructs requires is yet unclear and requires further investigation.

The history of psychological theory is richly adorned with theories that placed particular and special attention on the child's experiences in the early years and their ability to predict long-term outcomes. Nonetheless, it is notable that there are few, if any, examples of psychological mechanisms that have been developed and empirically demonstrated to account for a sensitive period or programming effects of early experience on psychological development. Psychological theorizing has adopted life-course model, whether the focus originates in early attachment, resilience, or specific stages in the life course (Erikson, 1968).

Additional Mechanisms

Other candidate mechanisms have been proposed to explain sensitive period, developmental programming, or life span development effects. For example, evolutionary pressures may help explain or provide a context for interpreting the impact of early stress exposures on psychological development. If, for instance, a particular function were so important to the normal development of the organism (e.g., for reproductive fitness), then it might make little evolutionary sense for this function to hinge on very specialized demands from the environment in terms of quality or quantity or timing. That, then, would imply that one may want to be cautious about presuming that windows of sensitivity or programming are narrow and demanding. Somewhat related to this notion is the proposal there are evolutionary advantages to the relatively protracted period of prefrontal cortex development in humans (and nonhuman primates) (Thompson-Schill, Ramscar, & Chrysikou, 2009). Countering this view is the modifier that it might not be adaptive for the organism to be equally and endlessly mutable because of the presumed cost that that would carry, although operationalizing and then testing this hypothesis at the psychological or biological level would be a distinct challenge. An alternative expression of evolutionary pressures is the concept of adaptation, and the corollary that there are evolutionary advantages of adapting, that is, responding to early environmental exposures. Along these lines, a remarkable example of prenatal exposure, specifically population density, triggering growth rates in offspring via glucocorticoids was recently reported in free-ranging red squirrels (Dantzer et al., 2013). The findings underscore how maternal experiences may instigate basic biological changes that can be viewed in the context of survival fitness and evolutionary adaptation. More broadly, integrated neuroendocrine response to stress has likely evolutionary advantages from pregnancy and can at least be traced in evolutionary terms, and

Crespi & Denver (2005) discussed how the ability to alter development and growth, one definition of plasticity, may be seen in evolutionary terms. Specific hypotheses derived from an evolutionary perspective in this area have been proposed, such as the infection–defense hypothesis (Anders, Tanaka, & Kinney, 2013), which offers one example of how connections between immune function and mental disorders may have evolutionary significance. Translating these findings for human health and development and clinical application may not be practical, however.

Specific neurotransmitters have also attracted attention in research on early development. Serotonin is one example. A mouse study reported that inhibiting serotonin transporter expression in early development with fluoxetine was associated with behavior consistent with animal models of anxiety and depression; the pharmacological effect was evident only in animals with a genetic variant of the serotonin transporter associated with reduced activity (Ansorge, Zhou, Lira, Hen, & Gingrich, 2004). Implications of these findings for use of SSRIs in pregnancy (for the fetus) and with young children may be substantial, and require follow-up, and that is now underway (Oberlander, Gingrich, & Ansorge, 2009). In addition, catecholamines such as norepinephrine may be plausible mechanisms mediating the effects of early life exposures because they are stress-responsive from early development and because they have neuromodulating effects in the central nervous system and the peripheral sympathetic nervous system (Rifkin-Graboi, Borelli, & Enlow, 2009; Taylor, Way, & Seeman, 2011). Dopamine-mediated roles in brain development have been equally widely discussed and reviewed in relation to specific early exposures such as prenatal substance use and in more general terms of neurodevelopment (Money & Stanwood, 2013; Ross, Graham, Money, & Stanwood, 2014). As in the case of specific genes, there are good examples in the animal work implying that many specific neurotransmitters may mediate the effects of early stress exposure on brain development and their long-term effects; the task now is not so much to isolate one or the other in developmental studies but rather to attempt to characterize their compiling and conjoint effects.

A more recent area of study is the role of the gut microbiome and its influence on brain development (e.g., Forsythe, Sudo, Dinan, Taylor, & Bienenstock, 2010). Some of the early animal work in this area focused on gut permeability and the consequent potential role that microbiota may play in neurodevelopmental disorders (Hsiao, McBride, Chow, Mazmanian, & Patterson, 2012; Hsiao et al., 2013). Application to human development is not yet clear, but this work has helped to generate interest and synthesize preliminary human findings implying gut microbiome connections with the brain from early development. Somewhat related and much better developed in human research are studies focusing on the micronutrient environment in prenatal or early postnatal period and its potential long-term effects (Brown & Susser, 2008; Coe, Lubach, Bianco, & Beard, 2009; Grantham-McGregor & Ani, 2001; Jacka et al., 2013); the advantage in this area is that many studies are on humans rather than relying on animal models.

Summary

Evidently, many different forms of mechanisms may explain how and to what extend early experiences—both good and bad—may have persisting effects on psychological development. One of the key lessons from research, which is not always evident in any one particular study, is the overlap and interdependence of mechanisms of early stress exposure and psychological development; that has scientific, clinical, and training implications (e.g., Garner & Shonkoff, 2012). Specific examples of the interdependence of developmental mechanisms are numerous. For example, prolonged stress exposure may be associated with glucocorticoid receptor insensitivity, which may lead to excessive innate immune responses and increased inflammation, with implications for neuropsychological and psychological development. Links between stress physiology and neuroimmune mechanisms are abundant and compose just one of many different kinds of coordinated responses in mechanisms of stress and health. The interdependence of these risk mechanisms may make it difficult to determine the particular effect of any risk mechanism in a human in vivo context and to differentiate among competing developmental models of early experience. Perhaps the key point here is that there are now many candidate mechanisms for understanding how early experiences and exposures might have lasting effects on psychological development.

CONCEPTUAL AND METHODOLOGICAL CONSIDERATIONS FOR INVESTIGATING DEVELOPMENTAL MODELS AND MECHANISMS

This section highlights some key conceptual and methodological lessons and challenges for research on developmental models and mechanisms with reference to applications in human psychological development.

Limited Experimental Leverage to Assess Timing, Duration, and Intensity of Exposures

Research efforts to test and differentiate alternative hypotheses about the role of (especially) early risk exposures and experiences on human psychological development are hampered by a general lack of experimental leverage for discerning the particular impact of timing, during of exposure, and dose. In fact, even where experimental leverage is optimized, as in the case of a randomized control trial, there are practical complexities that undermine the experimental control: research subjects do not attend the full complement of purportedly necessary sessions; research subjects may engage in other exposures or experiences that are not part of the intervention but nevertheless influence the targeted outcomes; treatment exposure may vary across interventionist or site; and subjects present with a diverse set of possibly confounding or moderating factors, from age and sex to developmental history and genetics. This situation contrasts sharply with typical experimental animal studies in which the type, start and end points, and intensity of dose of exposure are tightly controlled; furthermore, the developmental and genetic background of the animals is often also tightly controlled, for example, through the use of inbred strains. These widespread differences in experimental control highlight one major the challenge in translating findings in this area from animal to humans.

Of course, most studies in the human literature on early experience and psychological development are not controlled intervention trials but observational studies, leading to still further problems because of the lack of experimental and causal leverage. One of the most intransigent problems in observational studies is stability in risk exposure, which confounds research into timing effects. In fact, the most widely researched exposures of early significant stress such as poverty, maltreatment and other indicators of early caregiving, violence exposure, and parental mental illness are very stable. In response to the wealth of data linking early experience of maltreatment with a range of biological and behavioral disturbances (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Cicchetti, Rogosch, Howe, & Toth, 2010; Heim & Nemeroff, 2002; Newport et al., 2003; Pollak, Cicchetti, Hornung, & Reed, 2000), several groups have sought to examine if these adverse outcomes can be linked specifically to early maltreatment or to exposure at other sensitive periods such as adolescence (Andersen et al., 2008; Bolger & Patterson, 2001). The problem is that, in principle, firm conclusions about timing are essentially impossible to discern using observational designs because of the confounding of exposure at one time point, exposure at other time points, and cumulative exposure. And, although studies which assessed individuals who were exposed to, for example, maltreatment only during a very particular and limited period may have leverage for testing timing hypotheses, these studies would not likely yield clinically importable findings because of the unusual nature of the sample. Importantly, the stability in exposure and consequent difficulty in demonstrating a timing effect is likely also to be the case for other nonpsychosocial contributors to psychological development, such as pathogens in the environment, diet and nutrition.

Intervention study designs could provide greater leverage for assessing causal effects and have been instrumental in contributing to the conceptual models of early experience for later psychological development. Notable examples are the Bucharest Early Intervention Project, discussed in the next section (Nelson et al., 2007), and the set of well-known intervention trials using nurse home visitors or the early school setting, discussed in the final section.

One way of circumventing the limits of observational studies to assess developmental timing is to capitalize on experiments in nature (Bronfenbrenner, 1979) to provide experimental leverage. Natural experiments are conditions that naturally arise in some particular context in which there is a possibility of separating otherwise confounded processes or investigating effects that could not be designed for ethical or practical reasons. The next section of this chapter, which considers several research paradigms, incorporates many examples of natural experiments. Natural experiments have been proposed as something of an antidote to the problems of confounded causes and effects in observational (nonexperimental) studies; they do have advantages and offer purchase on causal hypotheses not provided in a typical observational study. However, the leverage provided is still limited, and there may be features of the natural experiment that may limit the generalizability of the findings. The ability of natural experiments to provide generalizable lessons for clinical practice is a particular matter of debate.

Phenotypic and Measurement Stability

Presumptions in developmental studies include (1) the construct of interest can be stable; (2) change in the level or expression of the phenotype is predictable (i.e., nonrandom responsiveness); and (3) some measurements of the phenotype are suitable across an age span (i.e., there are equally valid indicators of the underlying construct across age).

The first point—that there can be stability of the phenotype across a period of interest—is obviously quite

fundamental. An equally fundamental question concerns the age on onset of phenotypic stability; that is, from what age can a construct (e.g., intelligence, social competence, stress sensitivity) be reliably assessed and expected to predict subsequent measurement? It is important to note that some candidate developmental mechanisms do not show stability from early infancy. One poignant example is the HPA axis, which, as already noted, is a leading candidate mechanism for understanding how psychological stress may influence brain and behavior. The HPA axis undergoes rapid developmental change during infancy, as illustrated by the lack of diurnal rhythm in early infancy; some infants fail to show diurnal rhythm until further along in infancy (de Weerth, Zijl, & Buitelaar, 2003). Regardless of the mechanisms that underlie these changes, an important observation from developmental studies is a lack of stability of individual difference in cortisol reactivity even over comparatively short periods in early infancy (Gunnar, Hertsgaard, Larson, & Rigatuso, 1991; Lewis & Ramsay, 1995; Tollenaar, Jansen, Beijers, Riksen-Walraven, & de Weerth, 2010). When in development there is stability is not yet clear, although one study reported stability of individual differences in reactivity between 12 and 18 months of age (Goldberg et al., 2003). The implication is that studies predicting HPA axis function in early infancy may have identified only a transient effect. Other putative mechanisms in development and psychopathology show no/minimal stability from early to late infancy, including indicators of immune function (O'Connor, Winter, et al., 2013), which, as noted, has gained popularity as an early influence on brain development. A lack of stability from early infancy may not be too surprising and is certainly explicable in terms of rapid brain changes, which vary across brain region (Gilmore et al., 2012). A lack of stability from early infancy is important for hypotheses that place particular emphasis on the role of experiences and exposures in early development: predicting biological or behavioral phenotypes in early infancy may be a valuable observation, but could be transient and may not offer clear direction for later development.

Another version of this challenge is linked with the notion of heterotypic continuity, or the notion that a developmental construct may take on somewhat different forms at different stages of development and so require different measures. One well-known example may be intelligence, as long-term studies show stability of individual differences from quite different seeming measures in infancy, childhood, and adulthood (Fagan, Holland, & Wheeler, 2007; Thompson, Fagan, & Fulker, 1991). Other instances of hypothesized heterotypic continuity exist, such as the shift from behavioral to narrative assessments of attachment; alternatively, the limited stability in some studies (Bar-Haim, Sutton, Fox, & Marvin, 2000) might also raise questions about the extent to which different measures are actually indexing the same underlying construct.

Scientists studying human psychological development are not alone in struggling with phenotypes that may not be stable from childhood or carry the same meaning at different points in development. The US Preventive Services Task Force (USPSTF) recently declared that there is not a sufficient basis to justify screening for primary hypertension in asymptomatic children and adolescents because it had unproven prognostic and clinical value (Moyer, 2013).

Few would expect or require stability in a phenotype or putative causal mechanisms from birth; on the other hand, there is far more uncertainty about whether a presumed key developmental mechanism such as HPA axis function should show stability from infancy or what it would mean if robust stability could not be demonstrated until middle childhood or later.

A related concern about measurement is not so much the stability or instability of a phenotype but how detectable it is and at what age. For example, it may be that early insecure attachment or early institutional deprivation to which a child is exposed in infancy may have major effect on the nuances of social interactions that compose peer relationships (Hodges & Tizard, 1989; J. M. Kreppner et al., 2007), but such impairments would not likely be evident until middle childhood when peer relationships take on particular developmental significance and can be rigorously. Similarly, early deprivation may undermine the ability to provide sensitive care for one's own offspring or predict accelerated cognitive decline associated with aging, but these effects will not be evident if the assessment in limited to childhood and adolescence. (It is an open question if the prodromes or intermediate phenotypes of these later-onset outcomes would be). The implication is that the presumed effects of an early exposure need to be put in the context of the age and developmental stage of the assessment, which will inevitably be limited.

Individual Differences

Strikingly, all of the many human studies of children who experience profound early deprivation amply illustrate that even the most severe form of environmental and caregiving deprivation is followed by wide variation in major psychological outcomes, including attachment relationship quality, cognitive competence, and behavior

and emotional problems (Gunnar & van Dulmen, 2007; Merz & McCall, 2010; Nelson et al., 2007; O'Connor, Marvin, Rutter, Olrick, & Britner, 2003). The magnitude of individual differences in response to even very major stresses—and the presumed resilience that that implies—is one of the more important lessons from human research and presents significant challenges for explanatory models. As outlined in detail in a following section, the consistent finding is that only a minority of children who experienced early institutional deprivation show severe attachment disturbance (although the percentage is obviously higher than what is observed in a typical population) and that the range in cognitive abilities in these children is substantial and includes normal and even above average scores (although the overall average is lower than what would be expected in a typical sample). The observed degree of individual variation and resilience would be inconsistent with a simple sensitive period model of the early years, which would predict substantially higher rates of severe disturbance no matter the (generally high) quality of the adoptive environment into which children were placed following institutionalization. Furthermore, the persistence of effects of early institutional rearing long after removal from the institution and despite adoption into generally low/normal risk and well-resourced families is a challenge to the pattern anticipated by life span hypotheses, which would predicting a diminishing effect. A further imprint of individual differences is that deficits associated with early institutional rearing seem particular to certain outcomes, but whereas some children show deficits in cognitive functioning, others may have deficits in social and attachment behavior (Kreppner et al., 2007). Of course, findings and lessons from this unusual paradigm may not generalize to the kinds of exposures that dominate clinical and developmental research. Nonetheless, any model of human development will need to consider the wide variation in individual differences, including a likely domain-specific pattern of results.

There seems to be an exceptionally long list of possible sources for the individual differences that may confound studies of early exposures and subsequent health and development. Perhaps the most is genetics. Indeed, recent work has considered if genetic factors may account for the variation in social and cognitive outcomes following environments as severe as institutional deprivation. Some positive findings have been reported (e.g., Drury et al., 2010). This will likely play increasingly important roles in studies of early exposures and interventions. Many studies have been and are likely to continue to be underpowered and focused on a very limited number of genes and Single Nucleotide Polymorphisms (SNPs), so replication of findings will be an essential step for extending this form of research to conceptual models and clinical settings.

Several modifications or suggestions for interpreting individual differences have been offered that may prove helpful. Some authors (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van Ijzendoorn, 2011) have suggested that susceptibility to environmental exposures may itself be an individual differences variable; the key point is that there are individual differences in susceptibility rather than only in vulnerability. More specifically, the hypothesis is that some individuals would be more likely affected by, for example, early caregiving neglect as well as early sensitive care; others would be less susceptible to both early neglect and early sensitivity. Tests of this hypothesis continue and have infiltrated observational developmental studies (Pitzer, Jennen-Steinmetz, Esser, Schmidt, & Laucht, 2011); genetic analyses (Belsky & Beaver, 2011); and intervention research (Scott & O'Connor, 2012). Another consideration for individual differences in (early) exposure is the possible role of genetic influences on sensitive periods in development, a topic mentioned already. It is not yet widely supposed that genetic factors such as BDNF may alter sensitive periods in human development but, like the differential susceptibility hypothesis, that could also account for some of the findings obtained. Quite how human research could gain adequate experimental leverage for formally testing this possibility remains to be determined.

Sex Differences

Sex differences in response to stress, which may be further compounded by age, are found at multiple levels of analysis, from stress reactivity (Gallucci et al., 1993; Kirschbaum, Wust, Hallhammer, 1992) to response to early adversity and potentially genetically mediated responses (Barr, Newman, Schwandt, et al., 2004) to behavioral symptoms and disorder (Kessler, 2003). Sex differences do not lead directly or clearly to a mechanism. That is because, at least in humans, sex and gender are proxies for a range of hormonal and social and psychological differences that covary and are therefore difficult to disentangle. Nonetheless, it is significant that many of the mechanisms reviewed above have strong biological bases for sex differences. For example, the HPA and hypothalamic-pituitary-gonadal (HPG) axes show considerable overlap and interaction (Lovejoy & Barsyte-Lovejoy, 2013). Furthermore, progesterone provides many examples of communication with the stress response, including that progesterone is released by the brain and adrenal gland; progesterone

is an indirect precursor to cortisol; both progesterone and cortisol are released in response to adrenocorticotropic hormone (ACTH) and stress; progesterone administration may dampen cortisol response to stress (e.g., Wirth, Meier, Fredrickson, & Schultheiss, 2007). As a result, exposures that affect or program the stress response system could be expected to influence and be influenced by sex steroid hormone production.

Biological evidence for sex steroid involvement in the immune response is also strong. A starting point is the pronounced sex difference in infectious and autoimmune diseases (Guerra-Silveira & Abad-Franch, 2013; Lang, 2004). Mechanistic research makes a comparable point. For example, estrogen enhances humoral (B cell) responses and may enhance the T cell response (Lang, 2004); estrogen regulation of the innate immune response has also been demonstrated, including effects on dendritic cells and the production of TNF-alpha (Carruba et al., 2003; Ito et al., 2001; Kramer, Kramer, & Guan, 2004; Wang, Wang, Zhao, & Qiao, 2005; Wilder & Elenkov, 1999); moreover, a different sex steroid 17-beta estradiol enhances innate responses to challenge (van Eijk et al., 2007).

Animal studies of early stress exposure provide ample evidence of sex moderation of effects. For instance, males and female offspring show different patterns of developmental programming (Bale, 2011); in some cases, only one sex appears to be affected by prenatal stress (Howerton, Morgan, Fischer, & Bale, 2013). Sexually dimorphic effects are also found, as in the case of a rodent study showing that prenatal restraint stress was associated with increased anxiety in males but decreased anxiety in females compared with controls (Zuena et al., 2008). It might be presumed that sex differences would also be readily observed in human studies, but that is not always the case. Notably, studies of children adopted following institutional deprivation do not regularly find marked sex differences (Kreppner et al., 2001), and very large-scale studies of prenatal maternal anxiety or stress often fail to detect sex differences (O'Donnell et al., 2014).

Translation of Animal Findings to Human Health and Development

Given the dominance of experimental animal studies in this area, a major obstacle for constructing models of early experience is to estimate the degree to which findings generalize across species. Many authors have pointed out that demonstrations of sensitive periods are not as clear in primates as they are in birds and other species (Berardi et al., 2000), and that may be especially so for socialization outcomes (Ramey & Sackett, 2000).

Translating findings on early exposures from animal studies to the human context is complicated by specific challenges that likely vary according to risk paradigm. More specifically, there are several areas where there may be poor generalization across species, including the varying maturity of the offspring (e.g., brain size) at birth in species considered in studies of prenatal stress, such as rodents, sheep, nonhuman primates, and humans (Coe et al., 2003; Matthews, 2000); variation in the ease with which glucocorticoids (corticosterone/cortisol) cross the placenta (e.g., Challis, Matthews, Van Meir, & Ramirez, 1995); differential distribution and likely differential functional significance of receptors involved in regulating stress in rodents and primates (Sanchez, Ladd, & Plotsky, 2001); different functions and processes relevant for steroidogenesis (Malassine, Frendo, & Evain-Brion, 2003); and incompatibility in linking immune genes, such as between the mouse and the human (Seok et al., 2013). Compounding this problem is the explicit demonstration of nongeneralizability within species. A well-known example is the striking contrast between the monogamous prairie voles and nonmonogamous montane voles, for whom mating and caregiving behaviors differ dramatically (Young, Wang, & Insel, 1998). Research into within species behavioral differences was instrumental in documenting the role of oxytocin. The key point here is that such remarkable within-species differences in fundamental behaviors should caution against extrapolating behavior and perhaps also biology across species.

Finally, whereas experimental animal research relies on generally precisely timed manipulations to investigate early stress effects, no such control is plausible in human studies, and the comparability of severity of stress is equally uncertain when species and effects are compared or used as a guide. Efforts to develop stress paradigms that might have more application to humans, such as the variable forging demand paradigm (Coplan et al., 1998), may offer greater potential for translation. Another approach is to examine naturally occurring variation in behavior. One example is the work on maltreatment in nonhuman primates (Maestripieri, Tomaszycki, & Carroll, 1999).

The concept of translation has commanded significant attention because of uncertainty about how well research findings may generalize across species given inevitable biological differences, wide variation in research paradigms used with different species, and substantial difficulties in operationalizing compatible outcomes across species.

Some findings in the animal literature are certain to have no application to human health; other findings may have application but could be impossible to investigate in humans because of ethical or practical limitations. Inevitably, this means that conceptual models for early experience and human psychological development, and certainly those that shape prevention and treatment must be informed principally by human studies.

Summary

It is no longer seriously questioned if early experiences have particular and lasting effects on behavioral and biology in the animal. The challenge for human health is to document how well, and if, lessons from experimental animal studies generalize to human development. A presumption of some degree of translation from animal to human is typically assumed, and there are clearly some key biological processes that are conserved across species. On the other hand, as reviewed in this section, there are specific reasons why generalization may not occur. Furthermore, difficulties in developing research designs to differentiate alternative developmental hypotheses are matched by data analytic challenges. So, for example, data analytic strategies, however sophisticated, cannot overcome in-built confounds: demonstrating that there may be an independent effect of one particular risk or exposure period from another may not carry much practical application if the nature of the risks is to covary in development. Accordingly, it may not be too surprising that a range of ideas in the clinical and research settings persist about the role of early experience on psychological development in humans.

MODEL SYSTEMS AND PARADIGMS FOR STUDYING DEVELOPMENTAL MODELS AND MECHANISMS

A question continually framing discussions of developmental theory and developmental mechanisms is whether or not there are persisting effects of early (stress) exposures on behavioral disturbance and psychopathology. The early effects hypotheses are scientifically important and have potentially substantial practical application. Influential paradigms for understanding the relevance and distinctiveness of developmental models are reviewed in this section. Paradigms reviewed below were chosen because they have generated considerable experimental animal and preclinical and clinical human research, suggest important areas of convergence among studies of several varieties, demonstrate that there can be persisting effects of early experiences on psychological development, and offer general lessons for research into developmental mechanisms.

Prenatal Stress/Anxiety and Child Development

Research findings on prenatal maternal anxiety/stress are considered in detail because it has emerged from the experimental animal and human literatures as one of the leading examples of developmental programming. As such, it offers an extensive set of findings relevant for developmental theories of early experience; more recently, this research paradigm has begun to shape clinical decision-making. Importantly, because of its recognized scientific and public health significance, the maternal prenatal anxiety/stress paradigm is being pursued by many research groups in several countries.

The notion that the mother's mental state in pregnancy may influence the health of the baby has a rich cultural history. Scientific interest in this topic is also long-standing (Sontag, 1941). Experimental animal studies using the prenatal stress paradigm date back decades (Ader & Plaut, 1968; Hockman, 1961; Joffe, 1965; Keeley, 1962), and this paradigm continues to shape experimental animal research (Henry, Kabbaj, Simon, Le Moal, & Maccari, 1994; Matthews, Owen, Banjanin, & Andrews, 2002; Schneider et al., 1998; Wilson, Schade, & Terry, 2012). The current human model proposes that prenatal maternal anxiety or, in some studies, stress is associated with altered maternal physiology; most attention focuses on cortisol, a downstream product of the HPA axis, but many physiological candidates effects might be identified (Evans, Myers, & Monk, 2008; Kivlighan, DiPietro, Costigan, & Laudenslager, 2008; O'Connor, Tang, et al., 2014; Sarkar, Bergman, Fisk, O'Connor, & Glover, 2007b). Furthermore, this altered physiology is communicated to the fetus to shape fetal brain development directly by maternal transfer or indirectly by altering placental function (Monk et al., 2011; O'Donnell et al., 2012; Sarkar, Bergman, Fisk, O'Connor, & Glover, 2007a). Consistent with the developmental programming model there is an additional premise that increased exposure to cortisol by the fetus may program biological systems with effects observable on physiology, metabolism, immune function, brain and behavior. The intensity of findings in this area suggests that maternal mental health in pregnancy may be, like diet and health behaviors, a factor that requires routine attention in prenatal care.

Many reviews of the empirical evidence supporting links between prenatal anxiety of stress and child outcomes are available (Glover, O'Connor, & O'Donnell, 2010; Huizink, Mulder, & Buitelaar, 2004; Sandman, Davis, Buss, & Glynn, 2011b; Talge, Neal, & Glover, 2007), and new evidence suggesting prediction to behavioral and emotional symptoms, stress physiology, neurodevelopment, and many other outcomes appears regularly from many different studies and sites (Buss et al., 2012; King et al., 2009; Laplante, Brunet, Schmitz, Ciampi, & King, 2008; O'Donnell et al., 2014; Robinson et al., 2011; Sandman, Davis, Buss, & Glynn, 2011a). The breadth of effects in human research is quite striking, and also includes some of the developmental mechanisms cited above, including immune competence and altered cytokines expression (Entringer et al., 2008; O'Connor, Winter, et al., 2013). Particularly impressive are studies suggesting that maternal prenatal anxiety, depression, or stress may extend to more severe mental illness and neurodevelopmental outcomes such as schizophrenia (Khashan et al., 2008; King et al., 2009; Kinney, Miller, Crowley, Huang, & Gerber, 2008). That is in addition to several obstetric and birth outcomes and complications, such as preterm delivery (Hedegaard, Henriksen, Sabroe, & Secher, 1993), which may also contribute to long-term psychological development.

Investigation into the possible mechanisms accounting for the apparent widespread programming effects on psychological and biological development from prenatal maternal anxiety/stress emphasizes stress physiology, and the HPA axis in particular. Much the strongest evidence derives from animal studies because of the substantially greater leverage to test mechanisms that is available. So, for example, nonhuman primate research has shown that injection of ACTH, a precursor of cortisol, in nonstressed pregnant animals has comparable effects on offspring outcomes as uncontrollable environmental stress (Schneider, Coe, & Lubach, 1992).

What particularly distinguishes the findings in this area is not so much the extent of replication across sites or the range of biobehavioral outcomes so far predicted from prenatal maternal anxiety—although that is impressive—but rather the persistence of effects long after removal from exposure to risk (i.e., prenatal anxiety/stress). Data from the Avon Longitudinal Study of Parents and Children (ALSPAC) provide some of the strongest evidence that prenatal anxiety may have bona fide programming effects on behavioral and emotional problems in children and adolescents (O'Connor, Heron, Golding, & Glover, 2003; O'Donnell et al., 2014). Particularly striking was that growth curve analyses indicated no growth or change in the magnitude of prediction across a decade of developmental data, offering a formidable operationalization of a programmed effect. Also, follow-up to age 15 years indicated that prenatal maternal anxiety continued to influence diurnal HPA axis function, leading to flatter slope that has been found in other samples of chronic risk-exposed individuals (O'Donnell et al., 2013); the effect size in this case was very small, however, so the degree of persisting or programming on the HPA axis must be seen as limited and unable to account for observed effects on psychological symptoms.

Findings from other cohort studies provide additionally important results. Data from the Danish Civil Registration System indicated that the death of the father during the pregnancy was associated with a notable 6.5 point reduction in standard IQ points compared with children whose mothers did not experience the death of a spouse/partner (Virk, Obel, Li, & Olsen, 2014). That study has helped to expand the range of outcomes and the developmental mechanisms of interest, given that bereavement also predicted type-1diabetes (Virk et al., 2010) and cranial-neural-crest malformation (Hansen, Lou, & Olsen, 2000). Epidemiological and large-scale cohort studies are beginning to have particular influence in this area of study because they reliably document small to modest links between prenatal maternal stress and many disease states and symptoms in the child long after birth (Tegethoff, Greene, Olsen, Schaffner, & Meinlschmidt, 2011).

Attempts to establish a causal effect in human studies is naturally limited by the constraints of observational or naturalistic study designs that compose virtually all of the reports so far, but a few instances in this area have capitalized on natural experiments. One potentially powerful example was an in vitro fertilization (IVF) study, which was able to dismiss passive genetic transmission as a confound. The findings indicated that prenatal maternal stress significantly predicted conduct problems but not attention or emotional problems in their genetically unrelated children. The design is a potentially valuable one (Rice, Jones, & Thapar, 2007), although findings from women undergoing assisted reproduction may not generalize to other populations, and the measures of stress were from a single item using retrospective report. An important but less compelling sort of natural experiment in the literature contrasts prenatal maternal with prenatal paternal anxiety. Evidence of an in utero programming effect is suggested because the effects on child behavioral and emotional symptoms were far stronger and more robust for maternal prenatal anxiety than for paternal prenatal anxiety (O'Donnell et al., 2014).

A different kind of natural experiment capitalized on a natural disaster that occurred in Quebec. Project Ice Storm has followed mothers and their children and categorized women according to their state of pregnancy at the time of the disaster (King & Laplante, 2005). The study has the advantage that the stress—a dramatic ice storm with widespread and catastrophic effects in the region—was a random occurrence and not obviously confounded with maternal characteristics (although timing, that is, in early pregnancy, is still confounded with duration). Findings from that program support other research in linking stress exposure in pregnancy with behavioral and neurodevelopmental outcomes in the child (King et al., 2009; Laplante et al., 2008). Other research on natural experiments and prenatal anxiety/stress concerning earthquakes (Glynn, Wadhwa, Dunkel-Schetter, Chicz-Demet, & Sandman, 2001) and the events of September 11 (Yehuda et al., 2005) attest to the influence that the prenatal maternal anxiety/stress paradigm is gaining in developmental studies of risk mechanisms. Indeed, there are many very powerful examples of natural experiments that have ruled in the prenatal exposure period as having lasting effects on psychiatric, metabolic, and neurodevelopmental outcomes (Hines, 2003; Stein, Pierik, Verrips, Susser, & Lumey, 2009; Thurner et al., 2013).

Results from several studies imply that there may be important individual differences in the programming effects associated with prenatal maternal anxiety. If replicated, these results would mark an important shift, from a process that describes a general mechanism operating across species to a process that is better conceptualized as varying among individuals. In the case of the ALSPAC cohort, the moderation is from BDNF polymorphisms on internalizing symptoms (O'Donnell et al., in press); in the case of a smaller German cohort, the moderation derives from the 7-repeat allele of a variable number tandem repeat polymorphism in exon III of dopamine receptor DRD4 on conduct problems (Zohsel et al., 2014); in the Dutch Generation R study, a moderation of prenatal anxiety in predicting emotional problems in young children is associated with the serotonin transporter gene (5-HTTLPR) (Tiemeier et al., 2012). To date, the list of examples provided is too short to know if there are robust effects, and few studies consider a broad network of genes rather than a small number of candidates. Nonetheless, the important point is that genetics work in humans may have a sizable impact on the concept of developmental programming and programmability and may suggest that this mechanisms may be something on which individuals may differ from one another according to genetic makeup.

Maternal Immune Activation Paradigm

A second research paradigm, also involving the prenatal period, that has substantially contributed to developmental models of psychological outcomes is the maternal immune activation (MIA) model. Numerous findings on the MIA paradigm have been reported in animal and human studies. Results from this line of study have been important in demonstrating that an immune insult may have long-term neurodevelopmental effects; that immune mechanisms can play major roles in psychological development; and that prenatal immunization strategies offer a sizable public health approach to mental disorders.

Experimental animal studies provide ample evidence that prenatal (or early postnatal) immune activation is associated with brain volume and neurogenesis (Bilbo et al., 2005; Kohman & Rhodes, 2013; Monje, Toda, & Palmer, 2003); this cross-talk is an essential starting point for this avenue of study. Nonhuman primate studies confirmed that infecting pregnant rhesus monkeys with influenza reduced grey and white matter in the offspring in magnetic resonance imaging analyses (Short et al., 2010). Evidence of the MIA hypothesis is not reliant on animal studies, however. A long program of study of Brown, Susser, and colleagues links neurodevelopmental disorders such as schizophrenia to influenza infection during pregnancy; some of these results imply that MIA may account for a sizable percentage of schizophrenia cases (Brown et al., 2004; Brown et al., 2004; Brown, Susser, Lin, & Gorman, 1995).

The MIA model has also been applied to autism. A recent population-based Danish study of over 96,000 individuals indicated that the likelihood of a child being diagnosed with autism spectrum disorder in middle childhood and adolescence was associated with prolonged fever in the mother in pregnancy and with maternal prenatal influenza; effect sizes that have clinical and public health significance (Atladottir, Henriksen, Schendel, & Parner, 2012). Just as interesting was the additional prediction from antibiotics in pregnancy.

Although the MIA model is so far mostly limited to more severe neurodevelopmental outcomes and the precise mechanisms are not yet clear in human research, it is likely that, as neuroimmune mechanisms become more familiar in research on development and psychopathology, this paradigm will be applied to a broader array of developmental and clinical outcomes and yield valuable and practical results.

Early and Severe Caregiving Neglect and Deprivation

A third paradigm singled out for particular attention has the most detailed and complex history in developmental psychopathology, the effects of early caregiving adversity for later psychological adjustment. Research on this topic was central to some early theorizing about sensitive and perhaps even critical periods of caregiving experience for psychological health (Bowlby, 1950, 1951; Spitz, 1945). Experimental animal work of Harlow and colleagues was instrumental in developing some of the early principles for psychological development (Harlow & Suomi, 1970; Suomi, Harlow, & McKinney, 1972; Young, Suomi, Harlow, & McKinney, 1973). These have been taken on board and expanded upon in a series of studies of children who experienced early institutional care. The value of these studies may not be so much in terms of clinical application; given the unusual nature of institutional deprivation, findings from these studies may not generalize to other clinical contexts. Instead, the value of the many studies of children who experienced institutional rearing is what they have to say about the principles of early deprivation, sensitive periods, and the capacity to recover following very severe early care. Indeed, recent years have seen no fewer than three Society for Research in Child Development (SRCD) monographs devoted to studies of children who experienced institutional deprivation.

Probably the most notable set of findings in this area for many years derive from the Bucharest Early Intervention Project (BEIP), a long-term follow-up of an ambitious intervention to improve the caregiving arrangements of a randomly selected sample of children who had been reared in institutions. The study has been instrumental in providing detailed descriptions of biology and behavior that respond to changes in caregiving structures in young children, and in offering a model for improving caregiving arrangements for children without stable caregivers. One report from the study indicated that the intervention—moving children from the institutional setting to a foster care setting—was associated with significant improvements in cognitive outcomes, and that this was especially so for children under two years of age (Nelson et al., 2007). Documented intra-individual improvements in other areas of functioning, such as attachment relationships and social functioning, provide strong causal evidence for the role of caregiving manipulations and, to some extent, hint at potentially sensitive periods for these interventions to occur (Smyke, Zeanah, Fox, Nelson, & Guthrie, 2010).

The finding that early institutional care is associated with significant and lasting impact on several aspects of psychological development has been well described (Bruce, Tarullo, & Gunnar, 2009; Chisholm, 1998; Kreppner et al., 2010; Rutter, Kreppner, & O'Connor, 2001; Vorria et al., 2006; Zeanah, Smyke, Koga, & Carlson, 2005). Detailed analyses have sought to document duration of exposure to deprivation as a measure of developmental timing. Although the effects have varied slightly across studies, there is little doubt that, for some, the effects of early deprivation are strong and persistent (Zeanah et al., 2011). As Zeanah and colleagues note, whether or not a sensitive period model explains the diversity of results so far reported partly depends on how widely the sensitive period is defined. Thus, some studies and some outcomes may imply a sensitive period of less than six months, whereas others may imply a wider period of sensitivity up to two years. It may be unreasonable to expect considerable convergence on a construct as complex as a sensitive period, particularly where data are derived from very divergent research designs such as observational follow-up and randomized controlled trial. In any event, it is reasonably clear that a sensitive period is intrinsically limited because of the wide variation in outcomes that have been reported in all studies at practically all degrees of deprivation, from a few months to several years. That is, mean scores on a scale of symptoms or impairment or overall percentages of affected individuals may show a nonlinear/sensitive period or other type of stepped function pattern; nevertheless, a strict sensitive period model does not easily accommodate the diversity of adjustments among those who experienced brief or prolonged deprivation. Comparable concerns could be expressed in relation to a programming model that could be applied to these data (Rutter & O'Connor, 2004). The individual variation in outcome is every bit as important as the evidence suggesting that prolonged early deprivation can have lasting effects on biobehavioral outcomes. On the other hand, the findings do not fit into a life-course model, given that evidence of persisting and significant impairment has been consistently described in a sizable subset of children long after removal from the depriving environment and in the apparent absence of very significant stress exposure in the adoptive environment.

One limitation in most studies that have followed children who experienced institutional rearing is that the children were placed at birth. As a result it is not possible to know if the effects of institutional care are found only when deprivation is experienced in the early weeks or months of life. In this context, two studies of children who experienced institutional care postinfancy require particular attention (Vorria, Rutter, Pickles, Wolkind, & Hobsbaum, 1998; Wolkind, 1974). For example, some years ago Wolkind

(1974) reported that disinhibition toward strangers, a key behavioral marker of children who experienced institutional care, was associated with early institutional care but not institutional care that was initiated post infancy. That sort of finding and this sort of research design is especially valuable for testing timing effects, a theme that will re-emerge in the following section on intervention.

As noted, the corpus of data on children who experienced early institutional care do not easily conform to a sensitive period, programming, or life-course model. Research into the underlying mechanisms underlying these associations might help to resolve some of this uncertainty. Several candidate mechanisms have been investigated. Stress physiology has attracted considerable attention, and there is some evidence (Gunnar & Vazquez, 2001) that children who experienced prolonged deprivation show the kind of dampened response that other high stress populations display. The involvement of other candidates, such as the neuropeptide oxytocin, may be seen as a natural target (Wismer Fries, Ziegler, Kurian, Jacoris, & Pollak, 2005), although its links with the HPA axis and other biological processes means that it would not operate in isolation. Similarly, involvement of dopaminergic pathways might be relevant here, to explain not only disturbances in attachment behavior but also problems in attention that frequently get reported in children who experienced deprivation. And, a separate line of investigation on a genetic knock-out mice model demonstrated that animals lacking the μ-opioid receptors exhibited disturbances in social behaviors (Moles, Kieffer, & D'Amato, 2004), offering a further biological focus for further study.

Imaging studies also offer some clues about brain regions and functions that may be driving the observed behavioral effects associated with institutional deprivation. One of the earliest reports was from Chugani and colleagues (2001) who described reduced glucose metabolism in children adopted into the United States from institutions in Romania compared with adult and child epileptic comparisons. Affected brain regions included the orbital frontal cortex, prefrontal cortex, and medial temporal structures that include the amygdala and hippocampus. In one of the larger imaging studies of children who experienced institutional rearing, Tottenham and colleagues (2010) found an association between prolonged deprivation and larger amygdala volume, an effect that might accommodate some of the behavioral and symptom pattern expression found in this population. Imaging data from the BEIP suggested that institutional rearing was associated with smaller cortical gray matter volume compared with children who did not experience institutionalization (Sheridan, Fox, Zeanah, McLaughlin, & Nelson, 2012). Furthermore, other brain-based assessment techniques, such as electroencephalogram (EEG; McLaughlin et al., 2010), have similarly identified deficits that may be linked with duration of deprivation.

Collectively, the findings so far reported suggested a predictably wide range of biological mechanisms that might help to locate an effect of institutional deprivation underlying the range of behavioral and health effects. It seems implausible that the effects from deprivation would not have wide-ranging biological effects, so it remains for further study to develop integrative models to synthesize complementary and overlapping biological effects, and to track intra-individual biological changes in response to behavioral changes (Vanderwert, Marshall, Nelson, Zeanah, & Fox, 2010).

Studies of children who experienced institutional rearing and were then placed into normal risk adoptive homes provide a natural experiment to examine the effects of early caregiving deprivation because exposure to deprivation was relatively precisely timed and restricted to the first months or years of life; completing these natural experiments are more formal intervention experiments, such as the BEIP. These studies have had a major impact in pushing forward the notion that, in some circumstances and for some children, there are persisting effects of early severe deprivation. The challenge—which is not yet resolved—is to decide if the lessons from these extraordinary studies can generalize to other settings and samples sufficiently well to inform theories of normal and (less severely) abnormal development, and clinical application.

Summary

Available data from human studies of prenatal maternal anxiety/stress, maternal immune activation, and postnatal deprivation are consistent with some of the key findings from animal studies and offer some of the strongest human evidence that there can be lasting effects of early exposures on psychological development. Results from studies in these areas are less clear about the kinds of mechanisms that may carry these effects. How these findings and uncertainties may be applied to intervention and prevention is the focus of the final section of the chapter.

DEVELOPMENTAL MODELS ARE SHAPING CLINICAL AND PUBLIC HEALTH STRATEGIES

The final section provides applications for research on early experience, and considers how prevention and intervention

studies have informed core conceptual issues. The major themes are (1) many intervention studies starting from early childhood have demonstrated long-term effects on psychological development, although very few have been specifically designed to contrast differing views about developmental timing; (2) prevention and intervention studies, as well as natural experiments, have importantly contributed to the early experiences debate; (3) intervention and prevention studies are increasingly targeted as mediators and outcomes those biological mechanisms that may have particular significance in understanding early stress exposure; and (4) integration of the early experience concepts and findings and its neuroscience basis are beginning to be applied to public and policy debate and treatment rationales, usually with mixed success.

Early Interventions Can Have Lasting Effects

A starting point for this section is that there are several intervention programs that have been administered to young children that show lasting effects on psychological development. School-based interventions are among the best known and widely researched (Barnett, 1995; Yoshikawa, 1995). The Abecedarian project is a longitudinal study of the effectiveness of a school-based intervention with high-risk children randomly assigned to treatment or control conditions (Campbell et al., 2012; Campbell, Pungello, Miller-Johnson, Burchinal, & Ramey, 2001; Campbell & Ramey, 1994; Ramey & Campbell, 1984). One group of children were given the intervention from infancy through to 3 years of schooling; a second group received the preschool treatment only; a third group received only the school-based treatment; the third group constituted the control condition, that is, the comparison/control condition. Analyses of the age 12 data (Campbell & Ramey, 1994) indicated that the children who received the continuous intervention from infancy attained the highest scores on intellectual and achievement tests; children who received only the preschool intervention performed lower, and lower still were children who received the intervention only from school age. Although, on average, children in each intervention group performed better than the control children, their scores were still lower than children from a nonrisk comparison sample. Extending the follow-up period to age 21 years, the investigators found that children in the early intervention group continued to have long-term benefits on cognitive and academic measures. Analyses of the cognitive and achievement data are instrumental in showing that early interventions can have lasting effects, long after the exposure period (i.e., the intervention) was ended.

One of the recent trends in intervention and prevention work is a focus on outcomes extending beyond cognitive, social, and emotional development; that model has been adopted in the Abecedarian project (Campbell et al., 2014). Analyses of select biological data in adulthood, when this component of the study started, indicated that males who received the cognitive and social stimulation intervention in early childhood had, in their mid-30s, fewer signs of prehypertention based on systolic and diastolic blood pressure readings; they were also less likely to show multiple health risk factors. No significant effects were found for females, however. Importantly, the treatment effect differences for males were not explained by the better health care experienced by those who had received the early treatment (e.g., greater health insurance coverage). The follow-up study was of a comparatively small sample and the range of physical health outcomes was limited, but the report is important because it offers one of the few experimental studies assessing early psychological environment and later somatic health, which was not targeted in the intervention. The experimental leverage provided by the intervention trial is far greater than the large number of naturalistic long-term follow-up studies showing associations between psychological risk and exposures with adult health outcomes.

A second very well-known example of an early school-oriented intervention having lasting effects is the Chicago Child-Parent Center (CPC), which provided a comprehensive educational, family and health service intervention to children living in dense areas of poverty (Reynolds, Temple, Robertson, & Mann, 2001). The CPC contrasted an index group of 989 children who received preschool and school-age services with a comparison group of 550 children who received alternative early intervention programs. Effects 15 years after intervention delivery were retained and impressive. Specifically, children in the preschool program had higher rates of high-school completion by age 20 years than comparison children (49.7% versus 38.5%); were less likely to drop out than comparison children (46.7% versus 55%); and were less likely to have been arrested by age 18 years (16.9% versus 25.1%). Additionally, whereas 14.4% of the index children required special education placement, the rate in the comparison group was 24.6%.

A further valuable feature of the study is that not all children received the intervention from preschool through school age. Accordingly, as with the Abecedarian project, it is possible to contrast the outcomes of children who received only early intervention (through preschool) with those children who received a more protracted intervention

(into third grade). Findings showed that school-age participation did not predict additional gain over the preschool intervention for educational attainment or delinquency outcomes, but was associated with additional benefit on the measure of use of remedial services: participation in the school program (for at least one additional year) predicted modestly lower rates of special education, grade retention, and years of special education services compared with children whose receipt of the intervention stopped after preschool (Reynolds et al., 2001). Collectively, the CPC and the Abecedarian project offer some of the strongest evidence for a persisting effect of an early school-based project on cognitive, social, and perhaps even somatic health outcomes and have rightly played a major role in advocating for more widespread use of intensive school-based interventions for high-need children.

The nurse home visiting program (Eckenrode et al., 2000; Kitzman et al., 1997, 2000, 2010; Olds, Henderson, & Kitzman, 1994) is a very different kind of early intervention that has also attracted considerable attention for what it may say about the persisting effects of a fairly mild manipulation to the child's early environment on broadband effects indexed by achievement, behavioral outcomes, and health. Academic achievement, behavioral and emotional problems including more severe disturbances, and domestic violence and other forms of risk exposure are just some of the areas in which the intervention has had replicated and significant effects; to a considerable extent, many of the outcomes associated with intervention were not formally targeted in the intervention. As a result of these persuasive findings, the nurse home visiting program has been extended to many settings.

Other kinds of early interventions have been aggressively pursued in studies of child psychological development; parenting interventions among the most commonly assessed. Whether or not early parenting interventions have long-standing effects on child psychological development is perhaps less clear. That is partly because of the limited number of long-term follow-up studies and the typically modest (one–three-year) follow-up period, although there are exceptions. The Incredible Years' intervention program, which generally targets preschool or early school-age children and seeks to promote parental support and decrease harsh parenting practices, has likely attracted the most widespread interest because it has wide dissemination across many countries and settings (Jones, Daley, Hutchings, Bywater, & Eames, 2008; Webster-Stratton, Rinaldi, & Jamila, 2011). One recently reported follow-up study is of interest because it assessed both an indicated clinic-attending sample and a selective high-risk community sample, and because the follow-up was comparatively long, at approximately 6–7 years (Scott, Briskman, & O'Connor, 2014). Findings indicated long-term retained gains in the treated children relative to the comparison children in behavioral problems, psychopathy, and reading outcomes as well as some measures of parenting in the indicated sample into adolescence. Nonetheless, the overlap levels of disturbance in this clinical sample still exceeded those found in the community sample. In contrast, gains initially observed in the selective group from the parenting intervention were entirely absent at the long-term follow-up assessment. The finding that the intervention effects were most persistent among the more behavioral disturbed children is consistent with other studies, including the large-scale fast track program (CPPRG, 2011). The lesson here is that somewhat early and targeted interventions can alter the longer-term developmental course of high-risk children, but there are likely strong determinants of individual variation in treatment response. It is too soon to know if parenting interventions research can inform questions about early exposures and developmental timing, however, because timing is not itself a core feature of the research design in these studies.

Other changes in caregiving arrangements have been linked with positive outcomes for young children; effects may be found even where the overall environment is extremely poor and the change in arrangement would appear more structural than psychological—at least in terms of the childcare arrangement and intervention focus. For example, Zeanah and colleagues (Smyke, Dumitrescu, & Zeanah, 2002; Zeanah, Smyke, & Dumitrescu, 2002) found that improving the child:staff ratio and increasing staff availability and consistency predicted decreases in severely disturbed attachment behavior, a common and significant disturbance in children reared in institutions.

Even more radical caregiving arrangement interventions have been investigated and may inform discussions of early experience and developmental timing. The most obvious are those of children who were adopted into normal risk families following early institutional deprivation; some of these results were reviewed previously. The BEIP was a formal intervention and moved some children from institutional to foster family care, and assessed the effects. More broadly, though, all of the studies that followed children who were removed from institutional placement provide a powerful assessment of early intervention—although not based on formal randomization. Indeed, there are few interventions as radical as changing the caregiving environment. The beneficial effects of this radical form of intervention were reviewed previously; virtually all studies

identify substantial developmental catch-up and clinical improvement with home placement, and that this occurs at least to some degree for all children. As noted, the implication is that adoption even at a later age (preschool in most of these cases) had salutary effects on child health and behavior. Given these findings, establishing a distinct sensitive period hypothesis for developmental catch-up effects associated with removal from institution and placement in an adoptive family has been difficult, as it may vary across study, age at assessment, and domain of interest; in addition, there are sizable individual differences that confound these efforts (Nelson et al., 2007; Zeanah et al., 2011).

One study that capitalized on a change in placement from a maltreating family to foster placement is noteworthy for suggesting that a sensitive period in the formation of new attachment relationships may extend well into middle childhood or later. Joseph and colleagues (Joseph, O'Connor, Briskman, Maughan, & Scott, 2014) found that nearly half of children who were placed with a foster carer in late childhood exhibited a secure attachment based on a semi-structured attachment interview when the children were early adolescents; evidence of observed parent–adolescent quality and its association with attachment security helped substantiate this finding. This rate of secure attachment is potentially remarkable given that the adolescents had histories of early maltreatment so severe as to require removal from the home, and that their discussions of their biological parents during the attachment interview indicated marked insecurity. Another study investigated late-placed caregiving changes and also found notable gains in children's psychological development, in this case for IQ. Duyme, Dumaret, and Tomkiewicz (1999) found that children with history of neglect and maltreatment and low IQ who were adopted between 4 and 6 years of age showed sizable gains in IQ by early adolescence; gains of eight points in the low and 20 points in the high socioeconomic status (SES) demonstrate that improvements can be particularly large and dependent on the new caregiving situation.

The Joseph et al. and the Duyme et al. (1999) studies are unusual in assessing late placement changes and, more significantly, in demonstrating that sensitive periods for attachment and IQ extend well beyond the period implied by findings from children reared in institutions. It may be that early institutional rearing may limit the extent and duration and degree that developmental catch-up is possible; it may also be that findings implying a sensitive period window from severe deprivation may not extend to less severe forms of stress and trauma. And, it may be that windows of sensitivity or programming may be too particular to exposure type, sample, and outcome to derive general lessons.

An interesting example of how the effects of early school- or cognitive-based intervention may be moderated health status factors was recently reported by Tofail and colleagues (2013). They found that a fairly standard psychosocial stimulation program in Bangladesh to children aged 6–24 months was associated with gains in the Bayley Scales of Infant Development approximately 9 months later; moreover, there was a suggestion—a statistical trend—that the gains were weaker among those children who were iron deficient. That is notable, given that iron (and other biological context variables) are rarely accounted for in studies of psychological interventions and outcomes. The lesson from this study, and an emerging theme throughout this chapter, is that studies of early experience will be limited and may misspecify effects if they adopt a narrow, unidisciplinary conceptual and biological framework. Tofail and colleagues identified one health risk that might alter intervention effectiveness in young children. Incorporating more than a single targeted factor does impose demands and costs and complexities on the research design, which may exceed practical limits. And, it is significant that the iron deficient/anemia condition which had a modest moderating effect on the stimulation intervention in the Tofail et al. study was engineered as part of the research design. That is, it was likely necessary to design iron deficiency into the sampling framework to detect its effect on treatment outcomes. That contrasts with the more typical situation in which biological measures of risk, such as genetics, diet, or physiology, are collected post hoc rather than as part of the sampling frame, which may result in reduced power because of insufficient numbers or ranges of biological risk.

Factors external to the treatment or clinical condition may also moderate treatment effects. Initial severity of disturbance is frequently considered as a moderator of treatment. An example in the early intervention literature was reported as part of an eight-year follow-up of a large sample of children who received an early intervention to compensate for low birth weight. There were no lasting overall effects, but where effects were detected they were limited to the heavier low birth weight premature children (McCarton et al., 1997). It is significant that there are sizable individual differences in treatment effects even when the treatment was delivered so early in development—as early as delivery.

A small but important number of studies in the early effects literature have begun to target specific biological mechanisms alongside key behavioral outcomes. Predictably, the list of biological targets overlaps with the

candidate mechanisms of risk reviewed in the second section of the chapter. Although it is not yet clear that there are robust findings, several sets of results stand out at this early stage. One line of study seeks to examine if disrupted HPA axis function that may result from early adverse care responds to psychological treatment and may mediate treatment effects on behavior. In one instance, Dozier and colleagues (Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008) found that children in an early intervention group exhibited lower initial values at a lab visit than children in the treatment control group. In a separate study, researchers found that children involved in child protective services but remained at home showed flatter cortisol patterns—similar to what has been reported in chronically stressed samples—compared with children who were placed into a foster care setting (Bernard, Butzin-Dozier, Rittenhouse, & Dozier, 2010). Other reports targeting HPA axis and other mechanism that may be especially sensitive to early caregiving adversity are available (Fisher, Gunnar, Dozier, Bruce, & Pears, 2006). It would be premature to make firm conclusions at this stage of the research, and it may even be premature to distinguish the specific optimal physiological outcome that would be targeted in a successful treatment for some of these biological candidates. Further studies with a range of samples and conditions are needed, and this will likely constitute a major topic of further study.

Results from even the small number of selected studies of early interventions reviewed above are challenging to summarize for what they may imply about the role of early experience on psychological development and what they can say about developmental timing. The broadest conclusion is that early interventions can have persisting effects on multiple areas of psychological function, and long after the intervention exposure ceased. Some additional specifics are worth noting, including the finding that at least some of the school-based interventions did not start especially early (although it is not always clear what is meant by early); other interventions with dramatic effects were instituted in middle childhood. Clearly, interventions need not start in early infancy if they are to have lasting effects on the trajectories of psychological development into adulthood, but it is not yet clear how important age (as a short-hand proxy for many aspects of development) is for deciding when the intervention needs to be administered. However, to say that early interventions can have lasting effects is not to imply that it is expectable that all well-constructed interventions would have salutary impact (unsuccessful early interventions are not reviewed at length in this chapter). What the findings reviewed above do imply is that many factors determine the long-term effectiveness of an intervention program, from nutritional factors, to initial severity, to a host of largely untapped sources of individual differences such as genetics. Movement toward research strategies to link interventions to specific biological mechanisms that may carry presumed beneficial effects of the intervention are under way and should provide some clarity for shaping future intervention strategies.

Developmental Hypotheses and Early Intervention

Several authors (Bruer, 1999; Clarke & Clarke, 2000) have summarized some of the main features of the early intervention literature and some of its limitations, and others have put forward a case for greater emphasis on early intervention (Kirp, 2007). Bruer's book of some years ago generated considerable controversy for the intervention field; some of his concerns remain, including an uncertain connection between claims about the critical need for early intervention and the neuroscience that might substantiate that claim. It is fair to say that research designs in the early intervention literature are not, by and large, designed to tackle specific questions of developmental timing. That is, children have not typically been assigned to an intervention according to age with, say, some children getting 12 months of intervention in infancy and others getting 12 months of intervention in middle childhood. As a result, evidence of specific timing effects—whether that is early infancy or any period—is limited.

On the other hand, there are, to be sure, interesting research examples implying timing effects that capitalize on natural experiments. Some of these have very direct practical application. The age at which children enter kindergarten, because of arbitrary age or calendar cutoff or parental choice, is one such example. Data from the NICHD (2007) day care study indicated that children who entered kindergarten at younger ages scored higher on word recognition but lower on other scales, including mathematics, than children who entered later; by follow-up in third grade, children who entered kindergarten (comparatively) later performed better than earlier-entering children on applied problems and picture vocabulary. Although this is a popular kind of natural experiment to assess timing effects, the role of parental choice and planning—and how it has changed over time—mean that the experimental leverage to assess timing effects in this type of study has substantially diminished.

Intervention timing may be examined in other contexts. A further very practical clinical example is treatment for psychological disorders. Interventions using

cognitive-behavioral therapy are especially interesting in this regard because it may be that earlier is not always better if the treatment requires some degree of matured cognitive sophistication. There is, in fact, some evidence that older children respond more positively to CBT, possibly as result of differences in cognitive ability and executive functioning that are evident later in development and mediate treatment response but that has not yet been formally demonstrated (Durlak, Fuhrman, & Lampman, 1991). Another practical application for intervention concerns the question of when preventive interventions for substance abuse might be most effective in engaging and reducing use, either in terms of age or in terms of drug use experimentation (Dishion, Kavanagh, Schneiger, Nelson, & Kaufman, 2002). A still further example for developmental timing studies focuses on the course of the disorder. In this regard, Post and colleagues (Post, 1992; Post, Leverich, Xing, & Weiss, 2001; Weiss & Post, 1994) suggested that first episodes of depressive illness may be linked with psychosocial factors but that subsequent episodes may be more autonomous from psychosocial risk, perhaps because of the neurobiological changes brought on by the illness. In this case, the early treatment imperative links to stage of illness rather than to age. As these examples document, the concept of timing as it relates to intervention may take many forms, and is not always equated with age or maturation. And, as previously noted, there is considerable interest in adolescence as a period during which stress exposures and interventions may have particular effect, perhaps because there is a reopening of sensitive periods.

An application of the developmental timing question is to ask if there is an age after which the intervention would not be effective, or would be substantially less so (i.e., compared with earlier exposures). More entrenched developmental problems will pose additional and significant challenge for interventions delivered late in development and thus may require more intensive effort. In other words, age of the child may predict the intensity required for an intervention to work rather than the ultimate likelihood of success as such (Ramey & Ramey, 1998) because of a bona fide timing effect than can be traced to individual psychology or biology. Clearly, plasticity is a key concept underlying these questions and debates, but it has proven difficult to operationalize in empirical research.

Intervention studies have, for some time, focused on the question, For whom are interventions effective? Another question now also needs to be posed: When in development is the intervention likely to have the strongest effect (and why)? The form of developmental translational research requiring additional attention is what links brain, biology, and behavior in intervention designs that could be positioned to address questions of developmental timing. The needs of such an approach are clear enough: we need to understand not only that the intervention effects a behavioral change, but also what the underlying and sustaining mechanisms are, and if there is particular value in when it may be delivered. Early intervention and prevention studies may be especially well-suited to this sort of translational research, and candidates for biological investigation and the techniques to capture the relevant data are being improved and added to regularly. The conceptual case for multivariate, multilevel, biopsychosocial models of applied research is compelling and will necessitate creative scientific and financial approaches.

Clinical and Public Health Application

There is growing recognition that understanding the effects of early experience on later development and general questions of developmental timing have sizable clinical and public health significance. Identifying the age at kindergarten entry, deciding when and if to remove a child from an abusive caregiving setting, formulating an intervention for early symptom expression versus waiting for diagnostic threshold, and considering prenatal screening and intervention for significant maternal prenatal anxiety are all practical clinical issues that have a core developmental timing component.

One essential element to these discussions that infrequently appears in developmental studies is cost-effectiveness. Cost effectiveness estimates will depend on numerous assumptions, and may well vary across site, and will be limited by the duration of follow-up period. Nonetheless, such analyses have now been calculated for many programs, with generally positive and impressive effects for many model programs (Barnett & Masse, 2007; Olds et al., 2010). That is the sort of outcome that may require greater attention in developmental studies, so that clinical and public health impact—operationalized in monetary terms—are seen as part of the study design. Equally important, there is the matter of research approaches that attend to other areas equally neglected in developmental science, such as implementation science (Smits & Denis, 2014).

National organizations are active in emphasizing the impact and importance of early experiences for health psychological and somatic development, including the National Center for Infants, Toddlers, and Families, and others (e.g., National Scientific Council on the Developing Child, 2012; Sawhill, Thomas, & Monea, 2010), and many reviews and policy-oriented discussions are now available

(Kirp, 2007). Efforts to continue to inform policy makers about early experience and brain development, and the importance of (early) socioemotional development for general health have been informed by a wide range of studies, and the relevant empirical base is clearly growing steadily and quickly, as implied by research covered earlier in the chapter. How it is that scientific concerns of developmental timing and early experience seep into and shape policy debate is complex and hardly linear. As Kirp (2007) suggested, allowing for scientific study to shape so private an enterprise as caregiving, a common focus in studies of early exposure and early intervention, would present a major cultural paradigm shift that may be resisted. The strength of scientific research is only one factor influencing policy and cultural perceptions, and that is so even where the research evidence is undeniably watertight. (We are not yet there in many regards in this field of study.)

Difficult and practical questions will continue to arise and shape clinically oriented research into early exposures and developmental models of health and disease. So, for example, attempts to identify biological risk for later illness, in the absence of frank pathology, pose questions about when in the course of the illness intervention might be warranted, clinically effective, and socially acceptable. Recent findings for cognitive decline and dementia provide one good example (Mapstone et al., 2014), but research findings may soon nominate other illnesses and conditions for these debates.

Summary

A theme of this section is that intervention studies have and will continue to play a key role in differentiating alternative hypotheses concerning the impact of early experience on long-term adjustment. However, there are limits of existing designs, the role of developmental timing is not often formally tested, and the focus on mediating mechanisms is still somewhat limited. Developmental timing, as it relates to intervention and prevention, may take many forms and may be operationalized according to maturation, disease state, or other factors. Research along these lines would provide practical cues about when in development interventions may be most effectively delivered, and these observations could further efforts in monetizing, (de-)politicizing, and disseminating effective practice.

CONCLUSIONS AND FUTURE DIRECTIONS

Advances in research techniques make possible and reports of research findings make plausible multiple active programs of mechanistic studies to identify how and under what conditions exposures to both stress and protective elements early in development may have lasting effects on psychological development. To that end, this chapter provided illustrations of some intriguing findings from research paradigms that have been particularly influential in supporting the hypothesis that early exposures may have lasting effects on psychological and biological development. Furthermore, the chapter identified some of the more prevalent candidate mechanisms that might explain a carrying-forward of effects on longer-term health and development. Countering this scientific enthusiasm and optimism was a section detailing the inherent difficulties of gaining causal leverage to resolve questions about which conceptual models may offer the strongest fit to the available data.

Opportunities for future research were distributed throughout discussions in each section and can be summarized as follows. One is to make more explicit in the research plan both the developmental model being tested and its specific operationalization in measurement and analysis. In this regard, studies seeking to test for the effects of early exposures without accounting for recent and cumulative exposures (i.e., to the same or relevant sources of stress) are especially unhelpful but can nonetheless be found in published reports. Placing competing and plausibly tested developmental models and expectations in competition to account for obtained data may help to differentiate research models and point to further avenues of inquiry, and offer practical applications. In addition, as emphasized throughout the chapter, much more research is needed to document the limits of generalizing or translating findings from one context (e.g., species, sample, research design, scientific paradigm) to another. Human studies to test early experience hypotheses for clinical import clearly do have important scientific limitations but, as noted, influential models and programs have developed significantly, and can provide a basis for clinical research. Making relevant the neuroscience of early experience work will require greater use of plausible clinical phenotypes and mechanisms that are accessible in a clinic context; reciprocally, engaging clinical and public health settings may well be required for leveraging causal evidence. Finally, future research is needed that builds up from research in which a specific and (sometimes artificially) isolated—or just presumably isolated—candidate mechanism is considered and offered undue explanatory power. Many candidate genes, nutrients, brain regions, cytokines, hormones, and psychological processes have currency in research on early experience. It is now necessary to design into investigations their interplay in development.

As a cornerstone of the family, relationship dynamics between parents are highly significant in the lives of children (Amato, 2000). Although some forms of interparental conflict and discord (e.g., resolution) may have benign or salubrious consequences for children, destructive ways of managing conflict pose a substantial public health concern by virtue of their prevalence and risk for child bystanders. Dissolution of interparental relationships is a common occurrence, with over 30% of children experiencing disruption in their parents' relationships by nine years of age (Kennedy & Bumpass, 2008). Moreover, conflict and turmoil between parents often accompanies the family transition (Birditt, Brown, Orbuch, & McIlvane, 2010). Even among parents who remain together, rates of discord and violence are relatively high. Between 20% and 40% of parents in intact dyads experience clinically significant levels of relationship distress (Cummings & Davies, 1994). The proportion of parents who report experiencing physical aggression from a romantic partner within the last year is estimated to be as high as 49% (Slep & O'Leary, 2005). Exposure to high levels of discord and conflict, in turn, has been repeatedly documented to increase children's risk for a wide array of psychological problems including internalizing symptoms (e.g., depression, anxiety), externalizing problems (e.g., aggression, conduct problems), social impairments (e.g., poor peer relations), and academic difficulties (Dunn & Davies, 2001; Harold & Leve, 2012). Moreover, the magnitude of vulnerability experienced by children increases considerably in contexts of interparental aggression and violence (Evans, Davies, & DiLillo, 2008; Kitzmann, Gaylord, Holt, & Kenny 2003).

In drawing on developmental psychopathology as a guide toward better understanding the risk faced by children from high conflict homes, emotional security theory was initially developed to address precisely how, when,

In preparing the chapter, Patrick Davies was supported by the James McKeen Cattell Fund Sabbatical Fellowship.

[1]Color versions of Figure 6.5 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

and why interparental discord is associated with children's trajectories of mental health (Davies & Cummings, 1994). Because witnessing hostile and unresolved conflicts are emotionally arousing and threatening events for children, mounting and regulating emotional responses are regarded as central processes in understanding how children adapt to interparental conflict. In these contexts, preserving emotional security is an important goal that organizes children's emotional experiences (e.g., fear), action tendencies (e.g., withdrawal, intervention), and appraisals of themselves and their families. Thus, a primary thesis of the theory is that witnessing destructive interparental conflict increases children's vulnerability to psychological problems by undermining their ability to preserve emotional security within various family relationships.

In this chapter, our overarching objective is to provide a review and analysis of emotional security theory. Within the developmental psychopathology perspective (Cicchetti & Toth, 2009), the risk posed by interparental conflict is specifically conceptualized as a manifestation of a vibrant undercurrent of evolving exchanges between the dynamic child in a shifting, multilayered constellation of biopsychosocial liabilities and resources in the family. Thus, the developmental course of each child is to some degree unique due to the specific transactions between their prior and current experiences in family contexts and their own attributes, resources, and histories of adaptation. The derivative assumption, then, is that changes in child adjustment can be lawfully predicted and explained by elucidating the nature of transactions between the child and environment.

To organize and represent the inherent complexity of a developmental psychopathology approach, Figure 6.1 offers a framework for the primary substantive themes and pathways that we will cover in the chapter. Throughout the chapter, the main principles of developmental psychopathology will serve as a template for addressing important theoretical and research directions in characterizing associations between interparental conflict and child functioning. Consistent with Path #1 in the figure, the first part of the paper reviews the conceptualization of emotional security within a historical perspective, with a focus on highlighting the components of the system that distinguish it from other prevailing family process models. Next, as a core theoretical assumption of EST, we examine the hypothesis that interparental conflict, in certain forms, increases children's risk for psychopathology by magnifying their concerns about security interparental

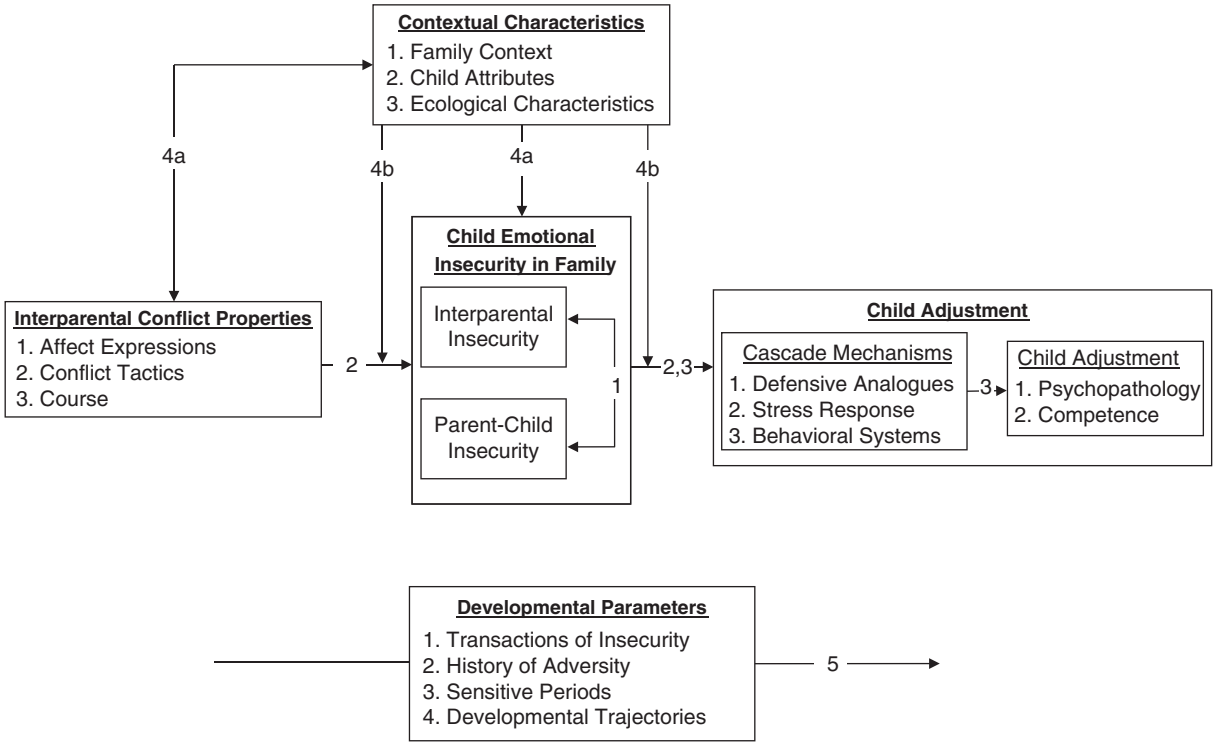

Figure 6.1 Key pathways and processes in emotional security theory that are proposed to inform an understanding of children's heightened vulnerability to interparental conflict.

relationship (see #2 Paths in Figure 6.1). Delving deeper into understanding the multitude of adjustment trajectories of children from high conflict homes, we then explore the developmental processes that are proposed to explain why emotional insecurity increases the likelihood of psychopathology (see #3 Paths in Figure 6.1). The fourth part of the paper illustrates how embedding the study of emotional security in the interparental relationship within the broader contextual landscape can further account for the diverse pathways experienced by children from high conflict homes (see #4 Paths in Figure 6.1). As the final component of our conceptual model illustrated by Path 5 in Figure 6.1, we examine how a fuller appreciation of developmental concepts in developmental psychopathology offers a more nuanced view of the conditions and processes underlying children's adaptation to interparental conflict. Finally, our concluding section of the paper selectively describes the translational implications and future directions of EST.

Throughout the chapter, we distinguish between two primary versions of emotional security theory to adequately characterize the significant conceptual developments in the history of the theory. The original emotional security theory, which we designate with the acronym EST, was first developed by Davies and Cummings (1994) and subsequently refined in several papers (e.g., Cummings & Davies, 1996; 2010; Davies, Harold, Goeke-Morey, & Cummings, 2002). In response to several barriers to advancing EST, we then developed a reformulation of emotional security theory (EST-R; Davies & Martin, 2013; Davies & Sturge-Apple, 2007; Davies, Sturge-Apple, & Martin, 2013). Although EST-R accepts many of the principles of EST, it is designed to provide greater theoretical depth, precision, and novelty by utilizing evolutionary and ethological frameworks as guides. Thus, whenever applicable in the chapter, we will highlight the primary distinctions between the EST and EST-R and any resulting differences in hypotheses and approaches. As a first step in this endeavor, we now turn to providing a historical account of the conceptual developments in EST over the last two decades.

THE SUBSTANCE OF EMOTIONAL SECURITY IN HISTORICAL PERSPECTIVE

Emotional security theory is built, in part, on an enduring conceptual foundation of earlier models of security in the parent–child relationship. As described by Ainsworth and Bowlby (1991), decades of laborious theoretical and empirical work culminated in groundbreaking advances in understanding the significance of relationship security in models of typical and atypical child development during the 1960s and 1970s (e.g., Ainsworth, Blehar, Waters, & Wall, 1978; Blatz, 1966; Bowlby, 1969; 1973). As a primary conceptual product of this progress, attachment theory has continued to be highly influential in understanding the developmental precursors, composition, and implications of individual differences in parent–child relationship security. Consistent with attachment theory, EST shares the assumption that histories of family interactions have a long-term impact on children's development by setting the stage for differences in children's ability to achieve safety and security in close family relationships. Accordingly, EST accepts the hypothesis that security in parent–child relationships serve as key explanatory mechanisms between child-rearing practices of socialization agents (e.g., sensitivity, responsiveness) and children's developmental outcomes (Bretherton, Ridgeway, & Cassidy, 1990; Thompson, 2000).

However, commonality between the theories begs the question of what differentiates EST from attachment security. A fundamental source of distinction between the theories lies in the novel EST hypothesis that a broader array of family characteristics may shape developmental trajectories by altering children's security in multiple family relationships. Because EST was originally developed to explain the developmental sequelae of interparental relationship dynamics, conflict between parents assumed center stage as a contextual factor that may enhance or undermine children's emotional security in family relationships. Although this premise generates several hypotheses regarding the interplay between interparental conflict and children's attachment security in parent–child relationships (see the "Parent–child relationship processes" section for more details), originality in EST is rooted in its proposition that children also develop a relatively distinct sense of emotional security in the interparental relationship. Thus, as shown by Path #1 of Figure 6.1, EST maintains that the unique composition of emotional security cannot simply be reduced into attachment security. Of particular relevance to developmental psychopathology, the distinctive operation of emotional security is theorized to provide incremental leverage in predicting children's trajectories of psychological adjustment in models of parent–child relationship processes.

The Goal-Corrected System of Emotional Security in EST

Toward the goal of delineating similarities and differences between the theories, early conceptual efforts in EST

focused on characterizing how the emotional security system operates in the context of interparental conflict (e.g., Cummings & Davies, 1996; Davies & Cummings, 1994; Davies, Harold, et al., 2002). According to EST, emotional security is a latent goal that is inferred from three observable classes of response processes that are commonly referred to as component processes. As illustrated in Figure 6.2, difficulties preserving security are reflected in the component processes of (1) emotional reactivity, characterized by intense, prolonged, and dysregulated distress (e.g., fear, vigilance) reactions to interparental conflict; (2) regulation of exposure to parent affect, as evidenced by protracted, rigid attempts to become involved in or avoid parental conflicts; and (3) internal representations of interparental relations, as indexed by children's evaluations of the potential consequences parental conflicts have for their well-being. Although each of these responses is hypothesized to serve as a measurable sign of insecurity in the interparental relationship, EST follows the principles of the organizational perspective in developmental psychopathology by proposing that each response process is part of a complex constellation of responses (e.g., Cicchetti & Rogosch, 2002). Thus, deciphering the meaning of any one domain of responding is advanced by examining it within the broader organization of insecure signs of reactivity to conflict.

Guided by developmental psychopathology, the integration of an organizational perspective within EST is instantiated in the model of emotional security as a goal-corrected system. In this behavioral system, preserving emotional security in the interparental relationship is specifically conceptualized as a latent goal that regulates and is regulated by the three component processes (Cummings & Davies, 1996; Davies & Cummings, 1994). Reflecting one part of this transactional feedback process, threats to the goal of emotional security triggered by hostility and conflict between parents organizes children's heightened emotional reactivity, forms of reducing exposure to parent affect, and negative representations of the consequences conflict has for their welfare. Likewise, in illustrating the other component of the reciprocal interplay, the three classes of response processes are designed to regulate children's sense of security. First, the fearful, vigilant forms of emotional reactivity are theorized to serve several protective functions of the goal system, including (1) priming children to rapidly identify and process potential threats, (2) increasing accessibility to psychophysiological resources necessary to mount an effective response to threatening stimuli, and (3) facilitating acquisition and prompt recall of aversive interparental cues in scanning subsequent interparental conflicts (Davies, Forman, Rasi, & Stevens, 2002; Davies, Harold, et al., 2002). Second, as

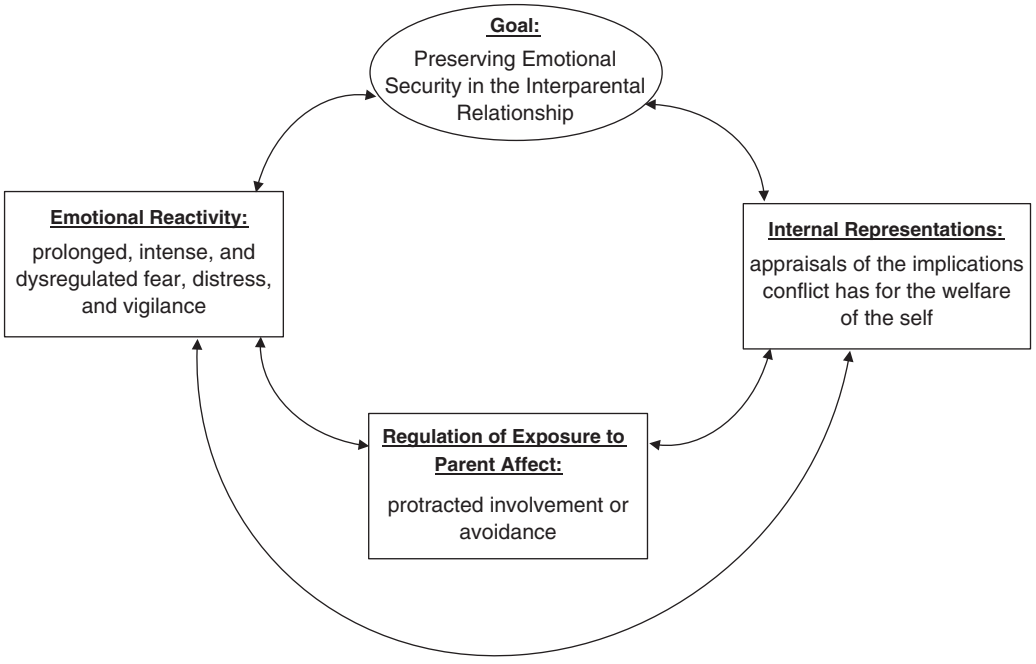

Figure 6.2 A graphical depiction of the bidirectional associations between the latent goal of preserving emotional security and the three component processes of emotional reactivity, regulation of exposure to parent affect, and internal representations.

ways of regulating parent affect, intervention and avoidance are theorized to serve direct protective functions of attenuating children's exposure to the threatening characteristics of interparental conflict. For example, although involvement in conflicts may run the risk of increasing children's initial exposure to interparental difficulties, the underlying attempts to regulate the course of conflict may provide them with a means to modulate parental emotionality and behaviors before they escalate and result in more serious consequences for the family (Cummings & Davies, 1996). Third, in reflecting ways children process the interpersonal meaning and consequences of the ways parents manage conflicts, internal representations may prepare children for potential danger by providing them with templates for scanning, understanding, and responding quickly to imminent interparental threats (Davies, Harold, et al., 2002).

As illustrated by the bidirectional arrows linking each of the three component processes together in Figure 6.2, the original formulation of EST hypothesizes that indicators within and across the three component processes are interdependent in reflecting the superordinate goal of preserving emotional security. Based on the assumptions of interdependency in the security system, a central hypothesis is that the magnitude of associations among the multiple signs of insecurity will generally fall in the moderate range. In accord with this prediction, research has generally reported moderate empirical overlap. For example, in a review of fifteen studies, Davies and Martin (2013) concluded that the mean overlap of response processes proposed to serve the goal of emotional security was approximately 17% ($r = .41$).

Conceptual Pitfalls and Barriers in the EST Conceptualization of Emotional Security

Although EST provided initial guidance in describing the composition and operation of the emotional security system (Davies, Harold, et al., 2002), it still lacks the clarity and richness necessary to fully characterize how the security system operates. Signs of nagging imprecision in conceptual and operational definitions are specifically manifested in considerable inconsistency between studies in the measurement of emotional insecurity in the interparental relationship. At the extreme, problems grasping the conceptual definition of emotional insecurity in the literature are evident in assessments of general behavioral or response styles across multiple contexts that more closely resemble personality and temperament traits (e.g., neuroticism, mood). For example, a prior study utilized self-report measures of "poor regulation of affect (e.g., 'I lose my temper at the slightest offense'); behavior indicating insecurity in a broad array of close relationships (e.g., 'I find myself clinging to people I'm close to because I'm afraid they'll leave me'); and negative expectances about the stability of relationships (e.g., 'I don't feel that important relationships will last. I expect them to end.')" (Mann & Gilliom, 2004, pp. 258–259). Likewise, Su, Simons, and Simons (2011) purported to provide a test of emotional security theory by examining the mediational role of children's generalized anxiety disorder symptomatology as a mediator in the link between interparental aggression and their antisocial behavior problems. In both examples, the use of trait-like assessments is tapping constructs that expand well beyond the circumscribed focus in EST on children's response patterns in the specific relational context of the interparental subsystem. Thus, using inhibited temperament or neurotic personality indices as proxies of emotional security is akin to empirically disconfirmed notions that patterns of parent–child attachment security are reducible to child temperamental attributes (see Sroufe, 1985).

Other scholars view emotional security as a relational construct rather than a trait-like attribute, but experience difficulties in conveying how emotional security differs from parent–child attachment. For example, Crockenberg and Langrock's (2001) description of emotional security as "the belief that one is loved and cared for" (p. 139) closely resembles a dimension of parent–child relationship quality. Likewise, Rothbaum, Rosen, Ujie, and Uchida (2002) described EST as postulating that "child wellbeing is fostered when children have a secure model of the parents' relationship. That is, children's security may depend in part on parents' attachment to one another" (p. 338). In fact, a need for greater clarity in disentangling the two constructs is even apparent in the descriptions of emotional security offered by the original developers of EST. For example, emotional security in the interparental relationship has been portrayed as serving as a "secure base" for children and a metaphorical "bridge between the child and the world" (Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006, p. 134; see also El-Sheikh, Cummings, Kouros, Elmore-Staton, & Buckhalt, 2008). Thus, it is not uncommon for emotional security to be characterized as closely related to, if not synonymous with, attachment security.

Even when empirical efforts have focused more precisely on children's responses to interparental conflict, the relatively vague characterization in EST of children's emotional security in the interparental relationship has generated considerable inconsistencies in the identification of signs of

insecurity. At the one extreme, emotional reactivity has been defined in very broad terms as an aggregation of multiple forms of negative affect and diminished positive affect (e.g., Cummings, Goeke-Morey, Papp, & Dukewich, 2002; Du Rocher Schudlich & Cummings, 2007; Goeke-Morey, Cummings, Harold, & Shelton, 2003). At another extreme, other research has utilized narrower definitions of emotional reactivity as consisting specifically of fearful distress reactions to conflict (e.g., Davies, Cicchetti, & Martin, 2012). In falling between the two poles of this wide continuum of emotional reactivity definitions, other studies have targeted emotional reactivity constructs through indices of relatively global emotional distress in which fear, sadness, and anger were each given relatively equal weight as signs of insecurity (Crockenberg & Langrock, 2001; Davies & Cummings, 1998). To resolve the multiple problems in understanding and assessing emotional security in EST, EST-R was introduced to provide a deeper portrayal of the properties of the security system (Davies & Martin, 2013; Davies & Sturge-Apple, 2007; Davies & Woitach, 2008). Thus, as part of our historical account, the next section provides a synopsis of how the recent reformulation of the theory offers a novel characterization of how the goal-corrected system of security operates.

Advances in the Characterization of the Emotional Security System in EST-R

Consistent with the interdisciplinary nature of developmental psychopathology (Cicchetti & Toth, 2009), EST-R was designed to provide a richer characterization of the properties of the emotional security system based on a growing corpus of psychobiological and animal research in ethological and evolutionary frameworks (Davies & Sturge-Apple, 2007; Davies, Sturge-Apple, & Martin, 2013). According to ethological and evolutionary frameworks, distinct control systems or ethological modules of responding to environmental cues are postulated to have emerged and persisted throughout phylogeny based on their success in promoting survival and reproduction within developmental and ecological niches in our evolutionary past. Therefore, the behavioral and mental processes of all, or virtually all, individuals within a species should be organized in relation to these modules. Each module or system is characterized by an integrated set of processing algorithms, neurobiological processes, and psychological and behavioral repertoires that increase in salience as organizers of functioning when contemporaneous environmental input corresponds with the selective pressures and conditions of ancestral environments (Konner, 2010).

Ethological Differentiation of Emotional Security and Parent–Child Security

Building on this conceptual foundation in ethology, a fundamental premise of EST-R is that children's security in the interparental and parent–child relationships is largely regulated by two different ethological modules: the social defense (SDS) and attachment systems. Table 6.1 provides a comparison of the two types of security based on the characteristics of each of these ethological modules. As depicted in the table, the two systems share the broad adaptive function of protection from harm. However, the security systems organized by SDS and attachment are

TABLE 6.1 Comparison of Security in the Interparental and Parent-Child Relationships Along Ethological Parameters

	Security in the interparental relationship	Parent–child relationship security
Control system	Social defense system	Attachment system
Broad adaptive function	Protection from harm	Protection from harm
External/observed goal	Defuse or avoid threats by conspecifics	Maximize sensitivity and protection of caregiver
Action tendencies	Vigilance, heightened perceptual-cognitive sensitivity to environmental signs of danger, fear, distress, freezing, flight strategies, cut off behaviors (e.g., covering eyes), camouflaging behaviors (e.g., inhibiting verbal and overt emotional expressions; concealing face), long-term demobilization (i.e., dysphoria, vegetative state, fatigue, inferiority, hopelessness, and helplessness), social de-escalation strategies (e.g., appeasing, submissive disengagement, coy or ingratiating behavior), affected behavior (e.g., demonstrative display of distress)	Distress; bids for comfort and support; proximity-seeking; clinging behavior; monitor whereabouts of caregiver
Conditions and environmental cues	Frightening (e.g., hostility, yelling, aggression) and frightened behavior by parents or attachment figures in the family	Internal (e.g., fatigue, sickness) or external (e.g., aloneness, darkness, strangers, novel objects or settings) cues to danger that do not originate with the parental or attachment figure

postulated to be fundamentally different from each other based on (1) distinct external goals, (2) unique conditions that increase their saliency as organizers of behavior, and (3) action tendencies that regulate their external goals. In accord with broader evolutionary frameworks, a primary assumption guiding the delineation of each system is that its external goal is defined by its original, specific function in regulating the ongoing relationship between organism and environment in ways that ultimately contributed to survival and reproduction within ancestral environments (Hilburn-Cobb, 2004). As the primary organizer of security in the interparental relationship, EST-R proposes that the external goal of the SDS system is avoiding or defusing threat from hostile conspecifics. Underlying this proposal is the assumption that the high cost of conflict between members of social groups throughout our phylogenetic history put selective pressure on the development of a behavioral system (i.e., SDS) capable of efficiently identifying social signals indicative of the potential threat (e.g., yelling, dominant posturing) and responding by organizing behavioral strategies to defend against threat (Davies & Sturge-Apple, 2007). Despite obvious differences between the family structures of today and those of our evolutionary past (e.g., extended family units, clans), most, if not all contemporary families are headed by dominant adults who carry disproportionate power in shaping the structure, stability, and safety of the family unit. Because relationship difficulties between these adults can have threatening implications for children and the family as a whole, the SDS and its goal of protecting oneself from interpersonal harm is posited to be a central source of children's response patterns to interparental conflict. Thus, the environmental cues and conditions that increase the salience of the social defense system are mainly composed of displays of frightened or frightening behavior by caregivers.

Conversely, efforts to preserve security in the parent–child relationship are largely regulated by the attachment system and its behavioral goal of maximizing the sensitivity and protection of caregivers in times of distress of threat (Bowlby, 1969). Ethological perspectives on attachment theory within the developmental literature propose that the attachment system evolved out of an evolutionary history in which ecological conditions were characterized by a high risk of infant mortality (e.g., fatal injury in perilous living conditions, predation, infanticide). In these contexts, inclusive fitness increased for those individuals who successfully adopted a strategy of maintaining proximity to and garnering protection from a primary caregiver (Bowlby, 1969; Chisholm, 1996). Consequently, circumstances that activate the attachment system are largely proposed to be different from those that trigger the SDS. In particular, attachment system is viewed as increasing in salience under conditions of internal (e.g., fatigue, sickness) or external (e.g., aloneness, darkness, interpersonal discord, novel people, stimuli, and settings) cues to potential danger or threat. Although interpersonal discord is regarded as a cue that increases the salience of the attachment system, it is only likely to be the primary organizer of children's behavior when attachment figures are physically and psychologically accessible. Thus, increasing proximity to caregivers is unlikely to be the primary external goal underlying children's behavior when the attachment figures are otherwise unavailable by virtue of their engagement in conflict. In most cases, the displays of frightened and frightening behaviors by combatant parents during conflicts will likely inhibit children's motivation to approach and seek support. Under these conditions, EST-R posits that protecting oneself from harm should be prioritized as a predominating goal, manifested in the relatively high salience of SDS as an organizer of children's responses to interparental conflict.

Due to the latent and unobservable nature of the external goals, evaluation of the degree to which the SDS is prioritized in stimulating reaction patterns requires an analysis of the action tendencies that serve each ethological module. For the attachment system, clinging, seeking comfort, verbal bids for support, behavioral signals of distress, and regular monitoring of the whereabouts of the parent are all potential means toward increasing accessibility to a supportive caregiver (Bowlby, 1969; Hilburn-Cobb, 2004). Conversely, minimizing threat accompanying interparental conflict requires that information-processing capacities be predominantly geared toward monitoring the aversive stimuli rather than divided between danger and attachment figure cues. Thus, SDS, at its core, is manifested in increased vigilance or, more specifically, heightened perceptual-cognitive sensitivity to the interparental conflict. Moreover, consistent with the organizational perspective in developmental psychopathology (Davies & Cicchetti, 2004), regulating exposure to the diverse properties and changing course of interparental conflicts can be flexibly achieved through the enlistment of a number of action tendencies and behavioral strategies. Efforts to safeguard against interpersonal harm may be expressed through freezing, cutoff behaviors (e.g., covering eyes), or camouflaging tendencies (e.g., inhibiting verbal and overt emotional expressions; concealing face) in some developmental contexts. Under other conditions, the goal may be achieved through response tendencies that include social de-escalation strategies (e.g., submissive disengagement,

coy behavior, ingratiation), long-term demobilization (e.g., dysphoria, inferiority, hopelessness, helplessness), or affected responses characterized by demonstrative displays of vulnerability. In illustrating the other side of the feedback loop in the goal system, the enlistment of specific configurations of these action tendencies are designed to facilitate the goal of defusing threat.

At this early stage of theoretical development, research has yet to systematically distinguish between the predominant action tendencies of the two ethological systems in order to definitively test whether the SDS is prioritized over attachment system in contexts of interparental conflict. However, trained coders of maternal narratives of toddler responses as bystanders to angry expressions by family members revealed that concerned facial expressions were one of the most consistent ways of responding to both naturally occurring (19%) and simulated anger (20%) incidents, far exceeding the incidence of attachment behaviors such as pick up bids (3% to 6%) (Cummings, Zahn-Waxler, & Radke-Yarrow, 1981). Likewise, maternal and paternal diary reports of preadolescent and early adolescent reactions to interparental conflict in the home revealed a high incidence of frightened or sad responses (18–28%) and avoidance (25–29%). Limited assessments of distinctive attachment behaviors do not allow for a thorough comparison of the relative propensity of interparental conflict to activate SDS and attachment systems. However, in support of EST-R, the distress and avoidance behaviors proposed to serve the SDS increased exponentially for children with histories of exposure to more threatening forms of interparental conflict characterized by violence. For example, children who witnessed violence between parents were two to four times more likely to exhibit fearful, sad, or avoidant reactions than were their counterparts from nonviolent homes (Garcia O'Hearn, Margolin, & John, 1997).

Differences in the Conceptualization of Emotional Security Across EST-R and EST

EST and EST-R differ in how they conceptualize emotional security in the interparental relationship. Without any clearly articulated external goal beyond the colloquial term of *security*, the definition of insecurity in EST has remained underdeveloped. As a case in point, Crockenberg and Langrock (2001) noted that emotional insecurity in EST is largely defined by "general emotional distress . . . [and] the nature of the negative emotion is of no significance to the model" (p. 140). Due the lack of a more precise characterization of the affective underpinnings of emotional security in EST, assessments of security have also been stretched into broad affective constructs reflecting that the degree to which an array of negative (i.e., angry, scared, sad) emotional responses outweigh positive (i.e., happy) emotional responses (e.g., Cummings et al., 2002; Du Rocher Schudlich & Cummings, 2007; Goeke-Morey et al., 2003).

In contrast, the external goal of defending against interpersonal threat in EST-R translates to a more circumscribed definition of insecurity that is organized around the defensive, inhibitory system. Thus, the presence of positive affect in EST-R is not viewed as an unconditional sign of greater security. Rather, the locus of evaluation is centered on the intensity and salience of heightened vigilance and perceptual sensitivity to signs of threat in the interparerntal relationship. Notably, narrower definitions of security as reflecting the absence of efforts to defend against social threat are more consistent with earlier security and attachment theories from which EST and EST-R are derived (Ainsworth et al., 1978; Blatz, 1966; Bowlby, 1969). For example, the Latin root of security translates to "without anxiety" or "without care" (Ainsworth & Bolwby, 1991), and the opposite of fear, alarm, or apprehension underlying insecurity is a calm state that does not require the presence of happiness or joy (Goldberg, Grusec, & Jenkins, 1999). In fact, within the organizational perspective in developmental psychopathology (Cicchetti & Rogosch, 2002), happiness cannot be conceptualized as an intrinsically positive or secure response without deciphering its deeper meaning or function within the broader organization of children's patterns of reactivity to conflict. For example, in EST-R, responses that appear to be positive based on their form or morphology (e.g., praising or entertaining the parents, comforting the parent) are commonly interpreted as signs of insecurity rather than security when they occur in a broader context of fear or vigilance to interparental conflict (Davies & Martin, 2013; Davies & Sturge-Apple, 2007).

Differences between the definitions are not simply minor and semantic in nature. Rather, the distinction provides a fundamental foundation for identifying the nature and substance of emotional insecurity in the face of interparental conflict. From an evolutionary perspective, the inclusion of positive affect in the definition of security adulterates any analysis of the protective function of the SDS and its organization around vigilance and fear. Building a broad construct of emotional security that houses an amalgamation of positive and negative affect blights the ability to distinguish differences in how children defend against interparental threat from the functioning of other distinct behavioral systems that improve fitness through the regulation of positive emotionality and approach (e.g.,

affiliation, exploration). From the perspective of EST-R, winnowing positive affect and diffuse forms of negative affect from the definition of emotional security is essential to understanding the specific operation of the SDS, its coordination with other ethological systems, and its specific place in ontogenesis. Thus, rather than accepting the metaphor of security as a "bridge between the child and the world," EST-R proposes that security (i.e., the absence of anxiety or fear) is the figurative road that paves the way for other approach-oriented systems of exploration and affiliation to serve as the symbolic bridge connecting the child to the broader world.

Due to the early stages of theoretical development in EST-R, research has yet to definitively determine whether this more circumscribed definition provides a better characterization of the emotional security system. Although authoritative tests of the viability of the security conceptualization in EST-R will require collection of close observations and assessments of children's responses to interparental conflict, there is some initial evidence to suggest that positive responses and perceptual sensitivity to threat are not simply gradations of security and insecurity nested on the same continuum. For example, behavioral signs of children's vigilance to interparental conflict in a simulated phone argument task involving the mother and father were unrelated to their reports of happiness at either kindergarten ($r = -.05$) or first grade ($r = -.03$) assessments of a longitudinal study (Davies, Sturge-Apple, Winter, Cummings, & Farrell, 2006). Moreover, factor analyses of children's self-reported reactivity to interparental conflict on the Security in the Interparental Subsystem (SIS) scale over a year revealed that positive behavioral and emotional responses either loaded positively onto higher order insecurity construct (e.g., "When my parents have an argument, I try to be on my best behavior . . . ") or failed to cohere with any dimension of emotional insecurity (e.g., "When my parents have an argument, I laugh or smile") (Davies, Forman, et al., 2002). Likewise, daily diary reports of preadolescent responses to interparental conflict over a six-week period indicated that children's fear and sadness were positively associated with becoming unusually well behaved (Garcia O'Hearn et al., 1997). Finally, Davies and Martin (2013) provided some preliminary evidence for the confluence of vigilance to threat and ingratiating, well-behaved, appeasing, and overbright behaviors within higher order patterns of insecure responding to interparental conflict (see the Person-Based Taxonomy section in Future Directions).

If the data continue to support the more precise definition of security in EST-R, then what are the implications for the whole generation of research that was predicated on the old conceptualization of security in EST? Although it is premature to make any definitive conclusions until more research is conducted, we would like to caution against the practice of throwing the baby out with the bathwater. Even if research consistently supports the characterization of security in EST-R, the methodological and analytic approaches adopted by many past studies may still yield sufficiently valid measures of security. In contrast to the questionable discriminant validity of creating broad manifest composites of negativity and diminished positivity, existing latent approaches that more heavily utilize manifest indicators of fear and vigilance may offer a psychometrically sound approach to assessing insecurity (e.g., Davies, Cicchetti, & Martin, 2012; Davies, Sturge-Apple, & Martin, 2013). By capturing common variance between fearful responses and other action tendencies (e.g., hostility, involvement, behavioral dysregulation) that serve both the SDS and other goal systems, these latent approaches increase construct validity by maximizing the likelihood that fear and defense represent a common underlying source of children's reaction patterns to interparental conflict.

Distinctions Between Emotional Security and Child Temperament and Personality

Defining emotional security as the operation of the social defense system within the bounded relationship context of the interparental subsystem also provides a clear set of conceptual bases for differentiating it from temperament, personality, and psychopathology. As a relational construct housed within the setting of the interparental dyad, children's security in the interparental relationship is theorized to serve as a precursor of subsequent trajectories of personality and adjustment over time. Consistent with transactional models of developmental psychopathology (Sameroff & MacKenzie, 2003), EST-R postulates that temperament and personality can, in turn, affect the calibration of the goal-corrected system of emotional security (e.g., Davies & Sturge-Apple, 2007). However, according to theory, emotional security is not synonymous with dimensions of personality or temperament. That is, children's security in the interparental relationship cannot be regarded as simply a by-product of higher order temperamental (e.g., inhibition or shyness), personality (e.g., neuroticism), or psychopathology (e.g., anxiety) constructs.

Research has consistently supported the distinctive nature of emotional security measures in relation to indices of temperament, personality, and psychopathology measures. During early childhood, various indices

of difficult temperament have evidenced negligible to modest associations with children's emotional insecurity in the interparental relationship. For example, toddlers' temperamental distress derived from maternal surveys was unrelated to coder ratings of their concurrent emotional insecurity based on maternal narratives from a semistructured interview (Davies, Manning, & Cicchetti, 2013). Likewise, as indices of emotional insecurity, measures of fearful reactivity to interparental conflict were not associated with observations of toddler inhibited temperament and were modestly related to lower, rather than higher, levels of observed temperamental irritability (Davies, Cicchetti, & Martin, 2012). As children progress through childhood and adolescence, empirical evidence continues to support the hypothesis that emotional security is distinct from personality or psychopathology constructs. For example, associations among emotional security and indices of personality (e.g., trait negative affect) and psychopathology have typically been in the moderate range during middle childhood (e.g., Davies & Cummings, 1998; El-Sheikh et al., 2008) and adolescence (e.g., Cummings, George, McCoy, & Davies, 2012; Davies, Harold, et al., 2002).

Additional distinctions can be drawn between emotional security and attributes of temperament and personality in the degree of stability of individual differences in the constructs (i.e., differential stability) over time. Whereas personality and adjustment constructs are defined by relatively high temporal consistency, the relational and coping properties of emotional security are proposed to evidence lower developmental stability that typically will fall in the modest to moderate range depending on the length of the developmental span. From a developmental psychopathology perspective, the emergence and intensification of adjustment trajectories are, under many conditions, gradual products of sustained and persistent developmental processes (Sroufe & Rutter, 1984). Thus, in translating these assumptions to our theory, differences between children in their responses to conflict must evidence some coherence over time if they increase the likelihood of intensification and proliferation into patterns of psychopathology (Cummings & Davies, 2010). Continuity in children's experiences of security is specifically theorized to result from (1) some degree of temporal stability in their exposure to properties of interparental conflict that activate the social defense system, and (2) their own tendencies utilize previously developed patterns as guides for interpreting and reacting to subsequent threatening events in the interparental subsystem (Davies, Winter, & Cicchetti, 2006; Davies et al., 2013). However, against this backdrop of stability, adaptation to interparental conflict is assumed to be the product of the dynamic interplay between actively changing children and family contexts. Thus, consistent with the documented plasticity of similar relational constructs (e.g., parent–child attachment; Belsky, Campbell, Cohn, & Moore, 1996), the emotional security system remains at least somewhat open to alteration across time.

Although more research on the temporal consistency of emotional security is needed to make authoritative comparisons with the differential stability of temperament and personality constructs, the emerging empirical evidence is consistent with our hypotheses. For example, with an average developmental span for calculating developmental stability of seven years, a meta-analysis indicated that continuity fell within the moderate to high range for temperamental and personality traits from preschool through late adolescence (e.g., mean $r = .49$; range = .45 to .52; Roberts & Del Vecchio, 2000; also see Nepple et al., 2010). Conversely, correlations between signs of insecurity over a comparable six to seven year span in childhood to adolescence were in the modest to moderate range (mean $r = .23$, range = .17–.30; Davies, Sturge-Apple, Bascoe, & Cummings, 2014). Analyses of differential stability within smaller developmental spans of one or two years commonly yield higher coefficients (e.g., *r*s largely in the .30s to .40s) that fall more squarely in the moderate range (e.g., Davies, Martin, & Cicchetti, 2012; Davies, Sturge-Apple, Bascoe, & Cummings, 2014). However, the stability is still significantly lower than the continuity indices reported for personality and temperament constructs (*r*s =.60s and .70s) of personality and temperament constructs over comparable time periods (e.g., McCrae et al., 2000).

Summary

In sum, the first decade following the inception of EST in 1994 advanced an understanding of the behavioral and psychological processes that regulate children's goal of preserving emotional security in the interparental relationship (e.g., Cummings & Davies, 1996; Davies & Cummings, 1994). Although emotional reactivity, regulation of exposure to parent affect, and internal representations were identified as classes of response processes serving the goal of emotional security, the original formulation did not provide sufficient conceptual precision or depth in characterizing the architecture or operation of the emotional security system. Against a diverse landscape of other social and emotional constructs (e.g., personality and temperamental attributes, parent–child attachment security, broader forms of responding to interparental

conflict), EST offered little theoretical justification for why emotional security should be considered a distinct process in its own right. Guided by evolutionary models, EST-R was developed, in part, to distinguish emotional security from related constructs by precisely describing the ethological underpinnings (i.e., operation of the SDS), primary properties (e.g., vigilance to interpersonal threat as a central process), and developmental characteristics (e.g., differential stability and change) of the emotional security system (Davies & Martin, 2013; Davies & Sturge-Apple, 2007; Davies, Sturge-Apple, & Martin, 2013; Davies & Woitach, 2008). Although definitive empirical tests of all EST-R hypotheses have yet to be conducted at this early scientific stage, the existing research findings have produced consistent support for characterizing the goal of preserving emotional security in the interparental relationship as a distinct relational construct that is regulated by a different ethological module than the parent–child attachment system.

EMOTIONAL SECURITY AS A MEDIATOR OF CHILDREN'S ADJUSTMENT TO INTERPARENTAL CONFLICT

Establishing emotional security in the interparental relationship as a distinct construct is only a beginning step in the scientific process. From a developmental psychopathology perspective, determining the value of a theory also hinges on its utility in elucidating the mechanisms by which risk factors increase children's vulnerability for maladjustment (Cicchetti & Toth, 1998; Sroufe & Rutter, 1984). By enlisting the concept of developmental cascades (Cicchetti, 2002; Masten & Cicchetti, 2010), developmental psychopathology has specifically characterized children's mental health as a product of an unfolding series of processes that proliferate across multiple developmental systems. Drawing on this important conceptual tool, EST proposes that emotional insecurity is part of a mediational chain that ultimately shapes children's trajectories of adjustment (see #2 paths in Figure 6.1). In the first part of the mediational chain, witnessing destructive forms of interparental conflict characterized by hostility, aggression, and conflict escalation is proposed to progressively increase children's concerns about their security and safety over time and in the context of the interparental subsystem. In the second part of the unfolding series of processes, difficulties preserving emotional security are proposed to intensify and proliferate to increase children's vulnerability to poor adjustment and psychopathology (Cummings & Davies, 1996; Davies & Cummings, 1994). Thus, evaluating the developmental significance of EST requires examining whether emotional security serves as a consistent explanatory process in developmental pathways between interparental conflict and child adjustment even after taking into account alternative, viable mechanisms. In the following sections, we describe the progress in testing these pathways, including delineation of (1) the mediational role of emotional security, (2) interparental sources of emotional insecurity, (3) the potency of specific signs of emotional insecurity in the developmental cascade, and (4) the multitude of sequelae of insecurity.

Research on the Mediational Role of Emotional Security

Children have several sound reasons for being concerned about their safety in the context of interparental relationship difficulties. First, conflict between parents may undermine children's security by increasing the likelihood that the unresolved hostility stemming from the conflicts may proliferate into parenting practices, interactions with children, and the broader family unit. Second, disagreements between parents are commonly manifestations of underlying power struggles between adult dominants in the family and, as a result, may signify chaotic collapses and perturbations in the social hierarchy. Third, parental expressions of hostility and distress may reflect a loved one's unhappiness and emotional instability and raise the possibility of family dissolution (e.g., parental break up) and its accompanying hardships (Johnston, Roseby, & Kuehnle, 2009). Accordingly, children's emotional insecurity in the interparental relationship is proposed to develop out of protracted histories of their exposure to destructive properties of interparental conflict, including high levels of anger, verbal aggression, violence, gridlock, and escalation of hostility (Davies & Cummings, 1994). In turn, children's recurrent needs to prioritize the goal of regaining and preserving security in the interparental relationship, set the stage for increased vulnerability to psychopathology through multiple processes that collectively reduce the opportunities for children to successfully engage in other prominent developmental challenges and life goals.

Table 6.2 provides a synopsis of the results from empirical tests of emotional insecurity as a mediator of associations between destructive interparental conflict and children's psychological and physical difficulties. To maximize the construct validity of emotional insecurity in our literature review, studies were only included in the table if they explicitly measured and tested signs of emotional security in the interparental relationship in

TABLE 6.2 Synopsis of Findings from Studies Examining Multiple Signs of Emotional Insecurity as Mediators of Associations Between Interparental Conflict and Child Adjustment

Study	Sample	Approach	Relevant findings
Buehler, Lange, & Franck (2007)	416 11- to 14-year-old children	SEM analyses using multiple methods (i.e., observation, survey) and informants (i.e., child, parent, teacher) within a longitudinal design	Marital hostility predicted adolescent insecurity in the interparental relationship one year later ($\beta = .34$). Insecurity, in turn, predicted greater externalizing ($\beta = .27$) and internalizing ($\beta = .38$) symptoms one year later after controlling for prior symptoms. Due to multicollinearity between emotional security and cognitive appraisals from the cognitive-contextual framework, SEM analyses with both constructs as simultaneous mediators did not produce an admissible solution.
Cummings, George, McCoy, & Davies (2012)	235 5- to 7-year-old children	Multiple methods (i.e., observation, survey) and informants (i.e., mothers, fathers, children) nested within three time points using SEM	Children's exposure to interparental conflict during kindergarten predicted greater emotional insecurity two years later after controlling for prior insecurity, $\beta = .30$. Insecurity in second grade was associated with increases in children's internalizing ($\beta = .25$) and externalizing ($\beta = .21$) symptoms in seventh grade after specifying the autoregressive path involving prior symptoms.
Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings (2006), Study 1	226 8- to17-year-old children	SEM analyses using multiple informants (i.e., mother, father, children) nested within a longitudinal design	Interparental conflict predicted greater emotional insecurity in the interparental relationship ($\beta = .36$) one year later. Emotional insecurity, in turn, was concurrently associated with greater internalizing ($\beta = .35$) and externalizing ($\beta = .20$) symptoms after controlling for children's initial symptomatology and age.
Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings (2006), Study 2	232 5- to 7-year-old children	SEM analyses using multiple methods (i.e., observation, survey) and informants (i.e., mother, father) within a prospective design	Interparental conflict predicted children's emotional insecurity across a one-year period ($\beta = .23$). Insecurity, in turn, predicted greater internalizing ($\beta = .14$) and externalizing ($\beta = .12$) symptoms one year later after controlling for initial levels of symptoms.
Davies, Cicchetti, & Martin (2012)	201 2-year-old children	SEM analyses conducted with multiple methods (i.e., observation, semistructured interview, survey) and informants (i.e., mothers, observers) within a longitudinal design with two annual time points	Interparental aggression predicted concurrent signs of child insecurity as reflected in fearful reactivity to conflict, $\beta = .27$. Insecurity, in turn, significantly predicted: mother reports of internalizing, $\beta = .17$, and, $\beta = .16$, and externalizing symptoms; and observer ratings of internalizing, $\beta = .23$, and externalizing, $\beta = .19$, symptoms. Results were significant even after controlling for initial levels of internalizing and externalizing symptoms in the model, including child inhibited and irritable temperamental characteristics as covariates, and specifying angry and sad reactivity to conflict as alternative mediators in the model.
Davies & Cummings (1998)	56 6- to 9-year-old children	Latent variable path analysis with partial least squares estimation of cross sectional data derived from multiple informants (mothers, children) and methods (observation, semistructured interview, surveys)	Interparental discord was associated with greater emotional reactivity to a simulated conflict involving the mother ($\beta = .34$) and more negative representations of interparental relationships ($\beta = .29$). Emotional reactivity, in turn, was associated with greater internalizing ($\beta = .29$) and externalizing symptoms ($\beta = .26$) whereas internal representations related only to internalizing symptoms ($\beta = .27$). Regulation of exposure to parent affect failed to mediate associations between interparental discord and child problems.
Davies, Harold, Goeke-Morey, & Cummings (2002), Study 2	285 11- to 13-year-olds	SEM analyses of multiple informant (i.e., mothers, fathers, children, teachers) survey data across two measurement occasions spaced two years apart	In separate models conducted for internalizing and externalizing symptoms, discord between parents significantly predicted greater emotional insecurity as indexed by emotional reactivity, behavioral dysregulation, and negative representations of interparental relationships two years later (βs= .16 and .17) Greater insecurity, in turn, was significantly associated with concurrent assessments of child internalizing, $\beta = .47$, and externalizing, $\beta = .25$, symptoms. Results were obtained after controlling for initial child symptoms and specifying cognitive-contextual framework processes of child self-blame and perceived threat as alternative mediators.

TABLE 6.2 (*Continued*)

Study	Sample	Approach	Relevant findings
Davies, Harold, Goeke-Morey, & Cummings (2002), Study 3	173 10 to 15-year-olds	Cross sectional design with multiple informants (i.e., parents, children) using SEM analyses	Destructive interparental conflict was significantly associated with a latent composite of emotional insecurity, $\beta = .25$. Emotional insecurity also predicted child internalizing, $\beta = .54$, and externalizing, $\beta = .23$, symptoms. Findings were part of a larger model that also specified parenting difficulties and parent–child attachment security as predictors.
Davies, Martin, & Cicchetti (2012), Study 1	250 10- to 15-year-olds graders (M age = 13)	SEM analyses of survey data collected from multiple informants (i.e., parents, children) at a single time point	Destructive interparental conflict (i.e. frequency, verbal aggression, child-related conflict) was associated with a multi-indicator latent construct of children's insecurity, $\beta = .32$. Insecurity, in turn, was associated with greater child problems, $\beta = .61$. These results remained significant even after specifying the negligible effects of exposure to constructive interparental conflict and including child negative affectivity, parent–child relationship quality, holistic family functioning, and SES as covariates.
Davies, Martin, & Cicchetti (2012), Study 2	201 2-year-old children	SEM analyses of multimethod (i.e., surveys, observations, semistructured interviews) of three annual waves of data in a longitudinal design	Destructive interparental conflict (i.e., frequency, verbal aggression, violence) predicted increases in children's emotional insecurity over a one year period, $\beta = .37$. Increasing insecurity, in turn, was associated with less steep declines in the latent growth curve slope of child adjustment problems over the three measurement occasions. Findings were consistent after estimating the minimal effects of constructive interparental conflict and covariates of child negative affectivity, parent–child relationship quality, and SES.
Davies, Sturge-Apple, Bascoe, & Cummings (2014)	230 children (M age = 13)	SEM analyses of multimethod (i.e., surveys, observations) and multi-informant (i.e., mother, father, child, teacher) data derived from three annual waves	Destructive interparental conflict predicted increases in children's insecurity over a one year period ($\beta = .31$) which, in turn, predicted greater psychological adjustment problems over the next year, $\beta = .34$. Results were robust after taking into account prior levels of insecurity and psychological adjustment problems, family SES, and child sex.
Du Rocher Schudlich & Cummings (2007)	262 8- to 16-year-old children	SEM analyses conducted with a cross sectional design with multiple methods (i.e., surveys, interviews, observations) and informants (i.e., mother, father, child)	Depressive interparental conflict tactics characterized by parental vulnerability were concurrently associated with emotional insecurity ($\beta = .31$), which in turn predicted children's psychological maladjustment ($\beta = .27$). Results were significant in a broader model of predictor involving maternal and paternal parenting and depressive symptoms, constructive and destructive (i.e., hostile) marital conflict tactics, and child age.
El-Sheikh, Cummings, Kouros, Elmore-Staton, & Buckhalt (2008)	251 children with a M age of 8 years	Multiple informants (i.e., mother, father, child) within a cross sectional design that employed SEM analyses	Six analyses were conducted examining the mediational role of insecurity in models of child internalizing difficulties, PTSD symptoms, externalizing problems, aggression directed toward mother and father, and physical health. Emotional insecurity in the interparental relationship was predicted by both maternal directed aggression toward the father (*Mean* $\beta = .26$) and paternal directed aggression toward the mother (*mean* $\beta = .54$). In the second link in the mediational chain, emotional insecurity was concurrently associated with three of the six outcomes, including child internalizing ($\beta = .45$), PTSD ($\beta = .51$), and externalizing ($\beta = .63$) symptoms. These results were produced in analyses that also included family SES and child age, gender, and race as covariates.
El-Sheikh, Buckhalt, Cummings, & Keller (2007)	166 children with a M age of 9 years	SEM analyses of cross sectional data derived from multiple informants (i.e., mother, father, child, teacher) and methods (i.e., survey, actigraphy)	Children's perceptions of conflict were associated with a multi-indicator construct of emotional insecurity ($\beta = .45$) which, in turn, was associated with diminished sleep quality in models of parent ($\beta = -.33$) and teacher ($\beta = -.32$) adjustment problems. In the final part of the multichain cascade, lower levels of sleep quality were associated with parent reports of emotional ($\beta = -.59$) and behavioral ($\beta = -.54$) problems and teacher reports of emotional problems ($\beta = -.40$) and academic functioning ($\beta = .30$), but not child behavior problems.

TABLE 6.2 (*Continued*)

Study	Sample	Approach	Relevant findings
Harold, Shelton, Goeke-Morey, & Cummings (2004)	181 11- to 12-year-old children	SEM analyses using multiple methods (i.e., surveys, analog methods) over two measurement occasions	Interparental conflict was significantly associated with concurrent insecurity indices of children's emotional reactivity, $\beta = .29$, and cognitive representations, $\beta = .30$, but was unrelated to children's regulation of exposure to parent affect. However, associations involving insecurity and subsequent child internalizing and externalizing symptoms one year later were all nonsignificant in a broader model that incorporated autoregressive pathways of child symptoms and children's emotional security about parenting at Time 2.
Kelly & El-Sheikh (2013)	176 children with *M* age of 9 years	SEM analyses of three waves of longitudinal data over a five-year span with use of multiple informants (i.e., mother, father, child) and methods (i.e., survey, actigraphy)	Interparental aggression predicted greater a multiindicator latent construct of children's emotional insecurity two years later, $\beta = .20$. Child insecurity, in turn, predicted sleeping problems three years later, βs = .20. Results were significant with autoregressive paths included for emotional insecurity and child reports of sleeping problems. Emotional insecurity did not mediate actigraphy assessments of sleep duration or efficiency.
McCoy, Cummings, & Davies (2009)	235 5- to 7-year-old children	Multiple informant (i.e., mothers, fathers, teachers) measures over three time points analyzed through SEM	In separate analytic models, constructive (e.g., resolution) and destructive (e.g., hostility) interparental conflict were each associated with children's emotional security one year later, βs = .32 and -.34, respectively. Children's emotional security was associated with their prosocial behavior in each model, βs = .26 and .30. These findings were generated in the context of larger analytic models testing parental warmth as another possible mediator and including autoregressive paths for prosocial behavior.

mediational models of interparental conflict. Sixteen of the seventeen studies in the table support the hypothesis that interparental conflict increases children's vulnerability to psychological problems by undermining their emotional security in the interparental relationship. That is, 94% of the studies in the table reported at least one significant mediational pathway whereby interparental conflict was associated with at least one sign of insecurity, with insecurity, in turn, evidencing a significant relationship with at least one measure of child psychological functioning. In some of the papers, multiple mediational pathways were specified within single studies due to the inclusion of multiple forms of conflict, signs of insecurity, forms of developmental outcomes, or some combination thereof. Evaluation of all the various pathways in these studies continued to yield consistent support for each link in the mediational cascade. Of relevance to the first link, 81% (i.e., 21 of 26) of the pathways between interparental conflict and children's signs of emotional insecurity were reported to be significant in the studies in Table 6.1. Likewise, pathways tested among children's signs of emotional insecurity and their forms of psychological difficulties were also significant in the majority of cases (59%; 29 of 49).

Confidence in the findings is bolstered by an evaluation of the methodological characteristics of the studies. In highlighting the scientific rigor in the empirical approaches, all the studies included in our review employed, at a minimum, sophisticated latent variable approaches (i.e., most were SEM) with designs that capitalized on multiple informants, multiple methods, or both. Nevertheless, the common observation of an inverse association between methodological rigor and the strength of substantive findings in literature reviews in the developmental sciences (e.g., Kitzmann, Gaylord, Holt, & Kenny, 2003; Rhoades, 2008) raises questions about whether the significant findings may be an artifact of shared method or informant variance. Our analysis, however, does not suggest that this conclusion applies to tests of the mediational role of emotional security. First, if the findings were an artifact of shared method or informant variance, systematic variability in the strength of the findings would be evident across different measurement approaches, with the results favoring less rigorous designs. However, in the studies in Table 6.2, the proportion of significant mediational findings did not differ as a function of whether the design incorporated (1) either multiple informants or multiple methods (16/30; 53%) or (2) both multiple informants and methods (17/29; 59%).

Second, documentation of mediational pathways using temporally ordered lagged analyses of interparental conflict, emotional security, and child developmental outcomes would further strengthen conclusions about the

usefulness of our theory. Consistent with this criterion, the proportion of significant mediational pathways identified in studies utilizing prospective lagged analyses of change in children's health outcomes or their insecurity were actually higher (i.e., 19/28; 68%) than the results from cross sectional designs (i.e., 14/31; 45%). Moreover, the findings from the prospective analyses did not differ considerably as a function of whether the lagged models utilized changes in child outcomes only (i.e., 14/20; 70%) or a more rigorous approach that quantified latent change in both their emotional insecurity and outcomes (i.e., 5/8; 63%).

Third, from a general methodological perspective, the two studies in Table 6.2 that utilized simulations of adult anger as proxies for assessing children's insecurity in the interparental relationship should evidence lower levels of validity than assessments of children's reactivity to actual interparental conflict (i.e., Davies & Cummings, 1998; Harold, Shelton, Goeke-Morey, & Cummings, 2004). Although anger simulations may achieve some degree of psychological realism by activating many of the same processes (e.g., defending against interpersonal threat) that occur in actual interparental conflicts (Aronson, Wilson, & Brewer, 1998; Cummings, 1995), they are unlikely to evidence a one-to-one correspondence with how children respond to conflict between their parents. Consistent with this thesis, assessments of insecurity derived from contexts of interparental conflict produced considerably more support for the mediational pathways (i.e., 31/49; 63%) than did the analog measures of insecurity (i.e., 2/10; 20%). In addition, the power of analog designs to evoke processes approximating insecurity in the interparental relationship is likely to increase when simulations are more affectively charged and personally involving. Thus, empirical bases for EST would be strengthened if support for emotional security is stronger with increases in the psychological realism of the analog design. Consistent with these conditions, the more engaging and involving simulation of live anger involving a mother and experimenter in the Davies and Cummings (1998) yielded evidence for half (i.e., 2 of 4) of the mediational pathways tested. Conversely, the videotaped presentation of conflicts between adult strangers in the study by Harold and colleagues (2004), which was likely to evidence lower psychological realism, provided no support for any of the six mediational pathways examined.

Fourth, evidence for the primary hypothesis in EST would be further garnered if it can be demonstrated that mediational pathways involving interparental conflict, emotional insecurity, and child maladjustment are not simply byproducts of third variables and their more proximal explanatory power. In further supporting the validity of EST, the comparison of studies in Table 6.2 revealed that the proportion of significant mediational pathways involving emotional security did not differ appreciably as a function of the inclusion (i.e., 22/38, 58%) or exclusion (i.e., 11/21; 52%) of covariates in the analytic models. Thus, the robustness of emotional security as a mediator remained even after specifying of a wide array of demographic (e.g., parent education, income, occupational prestige); family-level (e.g., cohesion, instability); parent–child (e.g., warmth, attachment security, relationship quality, role reversal); and child characteristics (e.g., sex, age, temperament) (e.g., Cummings et al., 2006; Davies, Cicchetti, & Martin, 2012; Davies, Martin, & Cicchetti, 2012; Davies, Cicchetti, Hentges, & Sturge-Apple, 2013; El-Sheikh et al., 2008; McCoy, Cummings, & Davies, 2009). Moreover, the results from studies in Table 6.2 (e.g., Davies, Cicchetti, & Martin, 2012; Davies, Harold, et al., 2002) indicated that emotional security remained a significant mediator of interparental conflict while simultaneously specifying the mediating roles of alternative forms of conflict reactivity outlined within the cognitive-contextual framework (e.g., perceived threat, self-blame; Grych & Fincham, 1990), specific emotions theory (e.g., dysphoric conflict responses, Crockenberg & Langrock, 2001), and social learning theory (e.g., angry, hostile responding to conflict; Cox, Paley, & Harter, 2001; Margolin, Oliver, & Medina, 2001; Zimet & Jacob, 2001). Therefore, in accord with our premise that emotional security is a distinctive psychological construct in its own right, the empirical evidence indicates that emotional security was a unique and consistent mediator of associations between interparental conflict and children's psychological functioning even in the context of other alternative contextual and psychological processes.

In conclusion, our systematic review of the literature indicates that there is a clear pattern of empirical support for the role of emotional security as a mediator of associations between interparental conflict and children's psychological adjustment. Support for emotional security as an explanatory mechanism was garnered under the most methodologically rigorous conditions that employed multiple informants and methods, assessments of child reactivity in naturalistic contexts of interparental conflict, designs that carefully examined prospective changes in children's adaptation over time, and statistical approaches that incorporated multiple third variables as covariates. Building on the strength of the findings, the next sections in our analysis are devoted to describing the specific interparental sources of children's emotional insecurity, tracing the implications of insecurity, and outlining the developmental significance of more deeply characterizing the responses underlying emotional insecurity.

Interparental Sources of Children's Emotional Insecurity

Research on the mediational role of emotional security has consistently identified exposure to heightened interparental conflict as a predictor of insecurity. However, common empirical treatment of interparental conflict as a broad homogenous construct in the literature has hindered the identification of specific expressions of interparental conflict that pose a sustained threat to children's emotional security in the interparental relationship. Although this approach is advantageous in maximizing parsimony and retaining a practical (rather than dispersive) scope of inquiry, it is not sensitive to the extensive scientific and clinical acknowledgment that couples vary widely in how they approach and manage conflicts. For example, some parents are able to marshal efforts to work in a collaborative way toward reaching a compromise or resolution to their problems. For other partners, conflicts are marked by tendencies to resort to escalation of hostility and aggression, and, still other couples respond to disagreements by disengaging and withdrawing. From a developmental psychopathology perspective (Cicchetti & Rogosch, 1996), the diversity of interparental conflict expressions highlights the potential operation of equifinality and the underlying notion that a single outcome (i.e., emotional insecurity) may result from multiple factors (i.e., conflict characteristics). Accordingly, a critical step in advancing process-oriented models is to better understand the scope of equifinality in associations among interparental conflict characteristics and children's emotional insecurity.

In attempting to define the boundaries of equifinality, EST and EST-R offer different predictions regarding the range of interparental conflict characteristics that are proposed to affect children's emotional insecurity. According to EST, children's emotional insecurity in the interparental relationship is a product of a wide array of conflict expressions. A primary proposal is that parental conflict tactics can be distinguished in terms of their constructive and destructive properties based on the degree to which they increase or reduce insecurity (Goeke-Morey et al., 2003). Interparental conflict characterized by escalating hostility, aggression, fear, dysphoria, and detachment is defined as destructive because it is posited to increase signs of insecurity. In contrast, parental displays of cooperation, collaboration, and resolution during conflicts are postulated to enhance children's security, in part, by reducing their signs of distress (McCoy et al., 2009). Taken together, EST assigns relatively equal empirical weight to constructive and destructive types of conflict as independent contributors to children's emotional insecurity (Cummings & Davies, 1996; Davies & Cummings, 1994). Thus, equifinality is ubiquitous in the assumption that virtually any form of interparental conflict may impact children's concerns for safety and security for better or for worse.

Although EST-R proposes that there is some degree of equifinality, it was designed in part to more precisely identify the specific characteristics of interparental stimuli that are particularly potent in engendering insecurity. Evolutionary models conceptualize the social defense system as an encapsulated module that responds selectively to a delimited set of contextual stimuli that are comparable in form to recurring cues presaging significant threats to survival throughout human evolution (e.g., angry expressions, loud noises, aggression, dominant posturing) (Davies & Sturge-Apple, 2007; Öhman & Mineka, 2001). As the function of the social defense system is to defuse conspecific threat, children's emotional insecurity in the context of interparental conflict should selectively reflect their sensitivity to histories of exposure to these same interpersonal threat cues displayed by parents in their disagreements (Davies & Sturge-Apple, 2007; Hofmann, Moscovitch, & Heinrichs, 2002). Because diminished displays of mutual happiness, support, and cohesiveness are far less reliable as signals of danger if they are not accompanied by hostile threat cues, these parameters of constructive conflict are hypothesized to carry minimal weight in signifying threat and organizing children's social defense strategies (Öhman & Mineka, 2001). Therefore, EST-R places significantly greater weight on destructive forms of conflict as etiological agents versus constructive or benign conflict tactics (Davies & Sturge-Apple, 2007; Davies & Woitach, 2008).

In further highlighting the importance of more fine-grained differentiations of destructive conflict, EST-R also proposes that other forms of destructive conflict assume varying degrees of salience in undermining children's insecurity. Sensitivity to danger cues is unlikely to simply be limited to the identification of angry, hostile displays by conspecifics. Rather, the ability to decipher fearful expressions holds similar adaptive significance to anger processing capabilities as a mechanism for detecting imminent danger in the social group (Davies & Sturge-Apple, 2007; LoBue, 2009). Thus, exposure to parental fearful and frightened behaviors during interparental conflict is posited to evoke children's concerns about their safety and security that approximate the potent effects of angry, hostile conflicts. In contrast, the strength of interparental dsyphoria and disengagement as predictors of children's emotional insecurity should fall in the intermediate range between the minimal impact of constructive conflict and the potent effects of conflicts containing heightened anger or fear. On the one hand, dysphoria and disengagement

signify abandonment, rejection, and interpersonal struggle within the social hierarchy (Gilbert, 2001). Therefore, repeated exposure to these conflict properties is more likely to undermine children's security in the interparental relationship than variations in constructive conflict by signalling the potential for threat (Dixon, 1998). On the other hand, bouts of disengagement and dysphoria are less reliable prognosticators of imminent interpersonal threat. Thus, it follows that exposure to parental hostile and fearful displays during conflict represent more immediate threat risk than disengaged or dysphoric conflict tactics.

Although studies have examined children's responding to different forms of interparental conflict, direct empirical tests of the comparative utility of predictions derived from EST and EST-R are still relatively rare. Scientific approaches to addressing this gap specifically require the simultaneous examination of the joint interplay among destructive and constructive properties of interparental conflict in the prediction of children's insecurity. However, most studies exploring multiple dimensions of interparental conflict have isolated the predictive power of each class of conflict tactics (e.g., constructive, hostile-destructive) in separate analytic models of emotional insecurity (e.g., McCoy et al., 2009; Cummings et al., 2002; Cummings, Goeke-Morey, & Papp, 2004; Goeke-Morey et al., 2003; Goeke-Morey, Cummings, & Papp, 2007). For example, a recent investigation reported that the association between constructive interparental conflict tactics and children's prosocial behavior was mediated by signs of diminished child insecurity in the interparental relationship (McCoy et al., 2009). However, documentation of heightened insecurity as a mediator of the relation between destructive interparental conflict and prosocial behavior in a separate analysis does not address the question of whether both forms of conflict operate uniquely as predictors (i.e., EST) or whether one class of tactics (i.e., constructive) is a spurious predictor by virtue of its association with a more operative class of conflict expressions (i.e., destructive) in undermining children's security.

Despite the need for more systematic analysis of the interplay between multiple dimensions of interparental conflict in the prediction of child insecurity, the sparse existing studies provide some initial support for the added precision of EST-R in identifying interparental sources of insecurity. For example, Fosco and Grych (2007) reported that children's exposure to destructive interparental conflict was the only significant predictor of their appraisals of threat within a multivariate model that also examined parental positive emotional expressiveness as a predictor. As a more direct test, a multistudy investigation revealed that children's emotional insecurity mediated associations between destructive interparental conflict and children's psychological problems even after specifying the negligible role of constructive interparental conflict and a wide array of family, parenting, and child covariates (Davies, Martin, & Cicchetti, 2012; also see Table 6.2). Replication of emotional security as a unique explanatory process underlying exposure to destructive conflict was especially striking in light of the variation in measures (i.e., multiple informants; multiple methods), methodological designs (i.e., cross sectional; longitudinal), and the risk (i.e., high risk; community sample) and SES (i.e., economically disadvantaged; working and middle class) characteristics of the samples across studies. Thus, these results are consistent with the evolutionary reformulation of emotional security theory and the resulting primacy ascribed to destructive interparental conflict in accounting for individual differences in children's emotional insecurity and its pathogenic implications (Davies & Sturge-Apple, 2007).

More fine-grained differentiation of the relative primacy of frightened (e.g., hostility, aggression) and vulnerable (e.g., worry, dysphoria, disengagement) forms of destructive conflict in studies has produced more complex results. Findings have shown that interparental hostility and disengagement were both uniquely associated with domains of children's insecure responding to interparental conflict (e.g., behavioral indices of distress, negative internal representations) in concurrent and prospective analyses (Davies, Sturge-Apple, et al., 2006). Although this study supports the value of distinguishing between the two types of destructive conflict, it does not provide a strong test of the comparative utility of EST and EST-R because both theories propose that equifinality is operating within the bounds of disengaged and hostile forms of interparental conflict. Likewise, in another study, multivariate analyses indicated that depressive conflict tactics (e.g., sadness, distress) were significantly related to children's insecurity while destructive (e.g., hostility) and constructive (e.g., problem solving) conflict tactics failed to explain any unique variance in child concerns about security (Du Rocher Schudlich & Cummings, 2007; see Table 6.2). Whereas the primacy of depressive conflict expressions over constructive tactics in the prediction of insecurity is more consistent with EST-R than EST, the negligible associations between hostile parental conflict and child insecurity run counter to predictions from both theories.

Complexity in interpretation is further compounded by the use of insecurity measures that fall outside the circumscribed definitional boundaries of the conceptual

construct in EST-R. In contrast to the characterization of emotional security as consisting of defensive, inhibitory behaviors, the two aforementioned studies utilized amorphous assessments of insecurity that included indices of anger and diminished positive affect. Therefore, due to concerns about the fidelity between the conceptualization of security in EST-R and its measurement in existing studies, definitive tests of the salience of different forms of destructive interparental conflict in EST-R (e.g., fear, dysphoria, hostility) will require more fine-grained approaches in future research. Likewise, similar refinements will also be necessary in distinguishing between the forms of destructive conflict that are proposed in EST-R to vary in their threat value for children. For example, in the Du Rocher Schudlich and Cummings (2007) study, the aggregation of both dysphoric (e.g., sadness, withdrawal) and frightened (i.e., fear) parental displays into the assessment of depressive conflict tactics did not permit sharp discrimination of the evolutionary hypothesis that fearful parental expressions would pose a greater threat to children's security than dysphoric expressions. In spite of the complexity of findings, there are compelling bases for expecting that hypotheses offered by EST-R will be supported in future research. Results from experimental research on emotion processing support the notion that there is a potent biological proneness to respond defensively to conspecific anger and fear (e.g., LoBue, 2009; Öhman & Mineka, 2001). For example, LoBue (2009) found consistent evidence for a bias in both young children and adults to more quickly process negative facial cues than positive facial stimuli. Moreover, processing of negative emotion stimuli varied in the same hypothesized way as outlined in EST-R, with more rapid identification of threat relevant emotions of anger and fear than sad stimuli.

The Potency of Signs of Emotional Insecurity in the Mediational Pathways

If emotion is a central organizer of children's efforts to preserve emotional security as emotional security theory proposes, then it should assume primacy in measurement models that utilize multiple indicators of children's insecurity. Given that the majority of papers in Table 6.2 employ latent approaches to assessing children's insecurity and report on their loadings (Cummings et al., 2006; 2012; Davies, Harold, et al., 2002; Davies, Martin, & Cicchetti, 2012; Davies, Sturge-Apple, Bascoe, & Cummings, 2014; El-Sheikh, Buckhalt, Cummings, & Keller, 2007; El-Sheikh et al., 2008; McCoy et al., 2009), they provide a means of examining the viability of this thesis. Consistent with predictions, calculations of the mean standardized loading for each of the dimensions of reactivity onto the latent construct of insecurity across the 10 studies was highest for emotional reactivity (.73) relative to negative representations of interparental relations (.69), ways of regulating (i.e., involvement, avoidance) exposure to parent affect (.66), and behavioral dysregulation (.58). As a further testament to the central role of emotional reactivity, all ten studies utilized an emotional reactivity variable as an indicator of emotional insecurity. In contrast, the studies evidenced greater inconsistency in the inclusion of the other indicators: negative representations (60%), regulation of exposure to parent affect (80%), and behavioral dysregulation (60%). Thus, the consistent support for emotional security as a mediator from the results of these studies can be attributed to a significant degree by the focus on emotionality as a core underlying experience of insecurity in the interparental relationship.

Methodological approaches that examine the relative roles of multiple signs of insecurity in models of interparental conflict and child adjustment offer additional evidence for the centrality of children's affective experiences in the face of interparental difficulties. For example, Davies and Cummings (1998) found that children's emotional reactivity was the most consistent mediator of associations between interparental conflict and child internalizing and externalizing symptoms in a model that also specified children's regulation of exposure to parent affect and internal representations as mediating mechanisms. In a more elaborate model containing nine dimensions of child reactivity as explanatory mechanisms, findings indicated that emotion dysregulation and internalization of distress in contexts of interparental conflict both uniquely mediated the prospective pathway between interparental conflict and children's internalizing symptoms (Buehler, Lange, & Franck, 2007). Meta-analytic results further revealed that negative affective reactions to conflict involving parents was a more consistent predictor of child problems relative to patterns of regulating exposure to parent affect (e.g., avoidance) (Rhoades, 2008).

By the same token, designation of emotional reactivity as a principal organizer of efforts to regulate the goal of preserving security may require additional refinement. Many of the earlier studies have focused on relatively broad assessments of emotional reactivity that contain indices of fear in conjunction with sadness, general emotional upset, anger, and even diminished happiness (Du Rocher Schudlich & Cummings, 2007; Rhoades, 2008). Although EST-R proposes that difficulties preserving emotional security may be manifested in a variety of responses

(e.g., anger, general distress), fear and vigilance are postulated to represent a common underlying source of defending against threat in the reformulated theory (Davies & Sturge-Apple, 2007; Davies & Woitach, 2008). Stimulated by refinements in the theory, some scientific attention has turned to developing more precise measurement strategies for capturing fearful and vigilant reactions than existing measures (e.g., parallel child and parent report assessments of Security in the Interparental Subsystem and Security in the Marital Subsystem–Parent Report; Cummings & Davies, 2010; Davies, Forman, et al., 2002). For example, with the development of the Interparental Disagreement Interview, systems for coding parent narratives derived from the semistructured interview discriminate between multiple forms of children's emotional expressions, including fearful, angry, and dysphoric reactivity to interparental conflict (IDI; Davies, Cicchetti, & Martin, 2012; Davies, Martin, & Cicchetti, 2012). These studies have shown that fearful forms of emotional and behavioral reactivity to conflict mediate prospective associations between destructive interparental conflict and children's psychological problems even after controlling for sad and angry forms of emotional reactivity, indices of temperamental emotionality, and a wide array of contextual variables (e.g., parenting, family functioning, socioeconomic risk). Thus, although it is too early in the research process to draw firm conclusions, these new measurement developments may offer greater flexibility and precision in capturing key emotional processes underlying insecurity.

The Multitude of Sequelae of Children's Insecurity

According to the principle of *multifinality* in developmental psychopathology (Cicchetti & Rogosch, 1996; Cicchetti & Toth, 2009), a diverse set of outcomes can be assumed to result from a common factor or pathway. In research on emotional security, the utility of this concept is illustrated in associations between children's concerns about security and a wide array of mental and physical health outcomes. Inspection of the findings from the studies in Table 6.2 reveals that emotional insecurity in the interparental relationship is specifically associated with internalizing symptoms, externalizing problems, and physical health and somatic (e.g., sleep) difficulties. Beyond domains of psychopathology, insecurity has also predicted a number of poor adjustment outcomes in the form of school difficulties, social and peer problems, attention impairments, and emotion dysregulation and interpersonal dependency (e.g., Bascoe, Davies, Sturge-Apple, & Cummings, 2009; Davies, Manning, & Cicchetti, 2013; Davies, Sturge-Apple, Bascoe, & Cummings, 2014; Davies, Woitach, Winter, & Cummings, 2008; McCoy et al., 2009; Sturge-Apple, Davies, Winter, Cummings, & Schermerhorn, 2008).

Although the list of outcomes associated with insecurity may be impressive in its scope, it begs the question of whether the prognostic value of insecurity varies across domains of functioning. Understanding the relative magnitude of risk for a wide array of outcomes is a critical part of the translational initiatives not only in developmental psychopathology (Cicchetti & Toth, 2006) but also in attempts to understand the unfolding cascade of processes that eventuate in distinctive adjustment patterns for children (Davies, Sturge-Apple, & Martin, 2013). The meta-analysis by Rhoades (2008) provides some of the strongest clues to date regarding potentially differential pathways that are moderated by form of adjustment. Although the system for characterizing dimensions of responding in her study was not specifically defined by dimensions of insecurity, forms of conflict reactivity characterized by negative affect, avoidance, and involvement can be regarded as close approximations of insecurity signs. Notably, when findings from multiple studies were pooled together, each of these parameters of reactivity more strongly predicted children's internalizing symptoms than externalizing symptoms. Analyses of results from studies specifically assessing insecurity in Table 6.2 provide additional, albeit modest, evidence to support this conclusion, with insecurity evidencing somewhat greater consistency in predicting internalizing (12/18, 67%) than externalizing (10/19, 53%) symptoms.

If future research more definitively confirms that insecurity is an especially robust precursor of internalizing symptoms, then it may provide clues in identifying the pathogenic mechanisms of effect. However, complexity is likely to be the rule rather than the exception in light of the plurality of outcomes emerging from the mediational pathways (Cicchetti & Toth, 2009). Regardless of whether insecurity evidences differences in the ability to predict subsequent forms of adjustment, the question still remains as to how and why multifinality prevails. Accordingly, in the next section, we describe the latest theory and research initiatives for identifying the explanatory mechanisms underlying the diversity of outcomes exhibited by children with high levels of insecurity.

Developmental Cascade Mechanisms

In keeping with the concept of developmental cascades in developmental psychopathology (Cox, Mills-Koonce, Propper, & Ganepy, 2010; Masten, 2005; Masten & Cicchetti, 2010), EST posits that the cumulative stress of coping with prolonged insecurity in the interparental

relationship sets in motion an array of cognitive, affective, and biological responses that have a snow-balling impact on adjustment across multiple contexts (e.g., school, peers, romantic partners). Over time, transactions between interparental conflict, emotional insecurity, and child adjustment problems may solidify their interrelationships and in the process spiral and proliferate into widespread child difficulties (Cummings et al., 2012; Kouros, Cummings, & Davies, 2010). Although the exploration of these cascading paths is still in its early stages, theoretical and empirical evidence point to several related processes as likely candidate mechanisms, including (1) the proliferation of defensive analogs to novel social situations beyond the family, (2) the sensitization of the stress response systems, and (3) disruption to other ethological systems that promote survival.

Proliferation of Defensive Analogs

Defensive analogs refer to models children utilize to filter, interpret, and affectively respond to threat and stress in challenging settings (Davies, Sturge-Apple, & Martin, 2013; Johnston et al., 2009). Thus, analogs encompass not only internal representations or working models of the meaning of close relationships but also sensorimotor schemes and action tendencies for coping with difficulties (e.g., submissiveness) that are often implicit and reflexive in nature. A central proposal of EST-R is that the children who experience insecurity in the interparental relationship are likely to become increasingly proficient in processing threat and recruiting resources necessary to guard against threat (e.g., Davies, Sturge-Apple, & Martin, 2013). As part of this process, children tend to utilize this defensive orientation as a guide to coping with novel or challenging social contexts (Bascoe et al., 2009; Cassidy, Kirsch, Scolton, & Parke, 1996; Davies et al., 2006; Johnston et al., 2009). Thus, more stable negative representations of family relationships may engender increasingly greater inflexibility and intractability in approaching subsequent interpersonal contexts (Cassidy et al., 1996; Johnston et al., 2009; Sturge-Apple et al., 2008). For example, psychobiological conceptualizations propose that greater proficiencies in processing and interpreting conflict in the family may, over time, sensitize children to perceiving and identifying threatening interpersonal stimuli (e.g., hostility) while restricting or blunting their recognition of benign or harmonious features (e.g., smiling, friendly approach) of their social environment (e.g., Pollak & Tolley-Schell, 2004).

In support of this hypothesis, research has shown that hostile social information processing of peer transgressions served as a mediator of the prospective link between insecurity in the interparental relationship and children's difficulties adjusting to school one year later (Bascoe et al., 2009). As a testament to the distinctive nature of this pathway, the mediational findings remained robust even after taking into consideration other potential contextual factors, including trait dispositions to experience negative affect, insecure representations of parent–child relationships, and socioeconomic characteristics. Interpreted within our cascade model, the results suggest that negative representations of the interparental relationship may increasingly generalize to other interpersonal relationships with time. From a process-oriented objective, addressing the question of why this generalization process occurs is a critical research direction. For example, based on the clinical work of Johnston and colleagues (2009), EST-R proposes that children's representations develop from scripts that consist of highly rapid and automatic rules for filtering, amplifying, and interpreting characteristics of conflicts between parents. Whereas benign or secure scripts of interparental relationships are likely to pave the way for more approach-oriented goals that engender greater diversity, flexibility, and openness to adapting to new social contexts, insecure scripts of the family are proposed to engender a defensive perceptual processing style that is significantly weighted toward filtering out benign stimuli and selectively identifying and amplifying the threatening stimuli. Through this process, children with insecure representations are proposed to reflexively and intransigently applied to interpersonal contexts, as they continue to scan new settings for old dangers (Davies, Sturge-Apple, & Martin, 2013).

Consistent with the organizational perspective in developmental psychopathology, negative internal representations are theorized to be an inextricable part of broader affective analog that is applied to an increasingly wider array of contexts. As negative processing biases proliferate across interpersonal contexts, children may evidence increasingly malevolent attributions of others, difficulties regulating negative affect, and self-protective behavioral strategies characterized by submissiveness or aggression (e.g., Dodge, 2006; Granot & Mayseless, 2012; Luebbe, Bell, Allwood, Swenson, & Early 2010). In reflecting the amplification of a negative transactional process, these extreme or atypical response styles in social contexts may evoke aversive responses from peers and adults and, in the process, become the only viable strategy for coping with pervasive social threats (e.g., teasing, bullying, rejection; Bierman, 2004;

Eggum et al., 2012; Lansford, Malone, Dodge, Pettit, & Bates, 2010). Through this canalization process (Cicchetti & Cohen, 1995; Gottlieb, 1991), plasticity and change may become progressively more limited as children become ensnared in an aversive transactional web and experience protracted forms of psychological problems characterized by internalizing and externalizing symptoms (Dodge, 2006; Granot & Mayseless, 2011, 2012; Luebbe et al, 2010; Prinstein, Cheah, & Guyer, 2005).

Alterations in Stress Response Systems

Applying a multiple-levels-of-analysis conceptualization to developmental cascades highlights the potential for physiological processes to operate as explanatory mechanisms in linkages between children's emotional insecurity and child psychopathology (Davies, Winter, & Cicchetti, 2006). As a framework for exploring the role of physiological mechanisms in developmental cascades, EST-R draws on evolutionary conceptualizations of the stress response system (SRS) as fulfilling an evolved neurobiological function of coordinating responses to environmental challenges in ways that promoted fitness in ancestral environments (Davies, Sturge-Apple, & Martin, 2013; Del Giudice, Ellis, & Shirtcliffe, 2011; Korte, Koolhaas, Wingfield, & McEwen, 2005). Physiological models highlight three modules that subserve the SRS: the sympathetic nervous system, the parasympathetic nervous system, and the hypothalamic-pituitary-adrenocortical axis (e.g., Repetti, Robles, & Reynolds, 2011). Although the parasympathetic nervous system serves to shift physiological resources toward restorative, homeostatic functioning and reduce physiological arousal (Porges, 1995), it also allows for the other physiological systems to more easily mount responses to threat by dampening its operation in stressful contexts. As the parasympathetic stress system adjusts to the stressful event, the sympathetic nervous system is charged with the task of priming the body to respond to the stressor over relatively short temporal spans (e.g., seconds) by increasing the availability of resources (e.g., cardiac output, oxygen flow, blood glucose levels) (Porges, 2006). Finally, the hypothalamic-pituitary-adrenocortical axis and its end product of cortisol constitutes a third wave of responding to stressful events that mobilizes energy (e.g., glocuose, oxygen) and modulates processing, encoding, and memory consolidation of emotionally significant events over relatively longer periods of time (e.g., minutes; Gunnar & Quevedo, 2007; Juster et al., 2011).

Allostasis and allostatic load are primary concepts in developmental psychopathology that help to inform an understanding of the role of the SRS in typical and atypical development (Cicchetti, 2011). Allostasis refers to the process by which biological set points in homeostasis are temporarily altered to meet the challenging dynamics of the environment and preserve the internal integrity of the organism. However, in highlighting the operation of allostatic load, successive cycles of allostasis engendered by repeated exposure to environmental adversity are theorized to result in wear and tear on the body that undermine the integrity of multiple domains of functioning. Thus, in socialization environments characterized by low levels of interpersonal threat, models of allostasis (e.g., Evans, 2004; McEwen, 2002) propose that healthy activation of SRS components consist of (1) mounting psychophysiological responses that are commensurate with the challenge posed by the stressor, and (2) facilitating the return to homeostatic functioning following the termination of the stressor through disengagement of stress-responsive physiological processes. Conversely, shifts in the operation of the SRS beyond of the homeostatic zones of functioning carry the advantage of increasing children's capacity to adapt to the formidable physiological demands of coping with family adversity. Although these alterations in SRS may take the form of either dampened or heightened physiological arousal, both types of allostatic load are posited to compromise physical and mental health by undermining immune, metabolic, cardiovascular, and central nervous system functions (Ganzel & Morris, 2011; Juster et al., 2011; McEwen, 2006; Turnbull & Rivier, 1999).

Building on allostatic load models, EST-R proposes two primary pathways through which children's prolonged concerns about insecurity may eventuate in psychopathology (Davies, Sturge-Apple, & Martin, 2013). As the first component of the multifinality process (Cicchetti & Rogosch, 1996), insecurity in the interparental relationship may increase children's vulnerability to psychopathology by amplifying their physiological arousal in one or more components of the SRS. The bases for this hypothesis are rooted in earlier behavioral conceptualizations of sensitization and its prediction that experiential histories of adversity in the interparental relationship pose a risk to children's adjustment by progressively intensifying their emotional and behavioral distress in the face of subsequent interparental conflicts (Cummings, 1998; Davies, Meyers, Cummings, & Heindel, 1999; Goeke-Morey, Papp, & Cummings, 2013). As a second component for the multifinality process, translation of the attenuation hypothesis to EST-R generates the prediction that insecurity may adversely impact

children's mental health by inhibiting the operation of physiological responses to threat (Susman, 2006). The dampening of neurobiological systems (e.g., sympathetic nervous system, hypothalamic-pituitary-adrenal axis) may specifically reflect the activation of processes designed to thwart the toxic effects of chronic physiological arousal to threat (Susman, 2006).

Despite the formulation of theoretically guided predictions, studies have yet to directly delineate SRS reactivity and activity as mediating mechanisms in associations between insecurity and children's developmental outcomes. Rather, most of the work has focused on understanding how children's physiological reactivity to interparental events may inform an understanding of the link between interparental conflict and child adjustment without consideration of children's signs of insecurity (e.g., Davies, Sturge-Apple, & Cicchetti, 2011; Davies, Sturge-Apple, Cicchetti, & Cummings, 2007; El-Sheikh, 2005; Hinnant, El-Sheikh, Keiley, & Buckhalt, 2013). Moreover, the rare empirical efforts to delineate the developmental implications of the multivariate interplay between signs of insecurity and physiological functioning have generated a complex, inconsistent pattern of results. For example, as a central indicator of children's insecurity, toddler fearful reactivity to conflict predicted attenuated sympathetic nervous system activity but evinced no associations with cortisol or parasympathetic nervous system functioning (Davies, Sturge-Apple, Cicchetti, Manning, & Zale, 2009). In contrast, observer and maternal ratings of children's fearful distress reactivity to interparental conflict during the early elementary school years were both associated with higher, current levels of cortisol reactivity to conflict even after taking into account other forms of responding (i.e., hostility, involvement) and demographic characteristics (Davies, Sturge-Apple, Cicchetti, & Cummings, 2008; also see Koss et al., 2013).

Solving the inherent complexity generated by the multilevel cascade models of insecurity will likely require careful attention to multiple parameters in the proposed pathways. First, physiological activity and stress reactivity are likely to play distinct roles in elucidating the sequelae of insecurity. Thus, part of the inconsistency in the aforementioned findings may be attributable to differences in whether the study focused on baseline physiological activity (Davies, Sturge-Apple, Woitach, & Cummings, 2009) or physiological reactivity (Davies et al., 2008). Second, if atypically low or high patterns of physiological functioning may be pathogenic as EST-R postulates, then the conventional approach of utilizing linear conceptualizations of physiological functioning may not sensitively discriminate between normal and abnormal neurobiological processes. As the work of Koss and colleagues (2013) illustrated, pattern-based methodological approaches such as growth mixture modeling offer powerful new tools for identifying qualitatively different types of psychophysiological responses that are more amenable to capturing multifinality in models of security. Third, although there is extensive regulation among the three components of the stress response system via a central control center located in higher order limbic structures (e.g., Gold & Chrousos, 2002), different systems can assume dominance within the response hierarchy. Accordingly, one implication of the distinctive nature of the physiological systems is that uniformity in the mediational pathways should not be expected across the modules of the SRS. Moreover, this also suggests that consideration of individual differences in the higher order interrelationships among the SRS modules may offer further insight into the specific physiological patterns of responding that may mediate insecurity (Davies, Sturge-Apple, & Martin, 2013; El-Sheikh et al., 2009). Fourth, sensitizing and attenuating pathways may be part of differing strategies children use to defend against interparental threat. For example, insecurity manifested in high levels of vigilance, freezing, and masking forms of distress may be accompanied by different patterns of physiological reactivity than tendencies to express insecurity by directly engaging the threatening stimuli through aggression and hostility (Davies & Martin, 2013; Davies, Sturge-Apple, & Martin, 2013).

Open systems conceptualizations of developmental psychopathology further highlight the significance of identifying characterological, developmental, and contextual sources of multiplicity in physiological pathways (Davies & Cicchetti, 2004; Richters, 1997). At the characterological level, different psychophysiological cascades of insecurity may be foreshadowed by individual differences in children's earlier temperamental dispositions. In support of this hypothesis, interparental conflict was associated with greater cortisol reactivity to interparental conflict over time, which in turn was associated with concurrent increases in internalizing symptoms only for children with inhibited temperament. Conversely, for children with bold temperaments, exposure to interparental conflict predicted dampened cortisol reactivity to conflict and, in turn, greater attention difficulties and hyperactivity (Davies, Sturge-Apple, & Cicchetti, 2011). At a developmental level, allostatic load models in developmental psychopathology emphasize the possibility of sensitive periods of plasticity and susceptibility in the context of adverse environments (e.g., Curtis & Cicchetti, 2007; Ganzel & Morris, 2011; Mead, Beauchaine, & Shannon, 2010). For example, it is possible that the confluence of neural,

hormonal, and brain changes may bias physiological systems toward attenuating or sensitizing patterns of reactivity at different developmental periods (Ganzel & Morris, 2011). At the level of contextual conditions, prevailing neurodevelopmental conceptualizations posit that calibration of physiological systems may vary as a function of the chronicity of the adversity (Ganzel & Morris, 2011; Susman, 2006). For example, sensitization of the hypothalamic-pituitary-adrenocortical axis may be natural response in the early stages of defending against threat in the interparental relationship. However, as insecurity persists over a longer developmental span, inhibition of the axis may occur to prevent chronic overarousal of the stress system in response to danger (Susman, 2006).

Cascading Effects on Ethological Systems of Approach

Prolonged wear and tear on the stress systems is not the only psychobiological consequence of emotional insecurity. Resource depletion models in human behavioral ecology and developmental neuroscience underscore the importance of efficiently and equitably distributing a limited reservoir of psychobiological resources to multiple developmental and cognitive tasks necessary to support survival and reproductive success across the lifespan (Baumeister, Vohs, & Tice, 2007; Borgerhoff Mulder & Schacht, 2012; Kaplan & Berman, 2010; Posner, 2012; Van Der Meer et al., 2010). Thus, biases toward pursuing selective goals will necessarily limit the resources that can be devoted to other significant domains of functioning (Ford, 2009). In integrating resource depletion conceptualizations, a central thesis in our theory is that prolonged experiences with insecurity in the interparental relationship will tip the balanced allocation of psychobiological resources toward investing in immediate personal safety at the cost of equal investment of resources towards mastery of other important goal pursuits (Davies, Winter, & Cicchetti, 2006).

Although enlisting resource depletion models provided a general foundation for understanding how and why insecurity may be associated with a multitude of negative sequelae, it offers little direction in identifying specific cascade processes. To address this significant conceptual gap, EST-R offers a novel framework that considers the interplay between the operation of the SDS and other ethological modules that play a significant role in organizing approach behaviors necessary to promote fitness (Figure 6.3). These evolved modules represent discrete neurophysiological systems, each organizing specific patterns of affect, information processing, and behavior in service of a unique adaptive function. This broader evolutionary view supports several assumptions, including (1) the common phylogenetic heritage of nonhuman animals and humans produced similarly functioning ethological systems that allow for cross-species comparisons; (2) each behavioral system will be responsive to particular environmental contexts and perceptual cues providing information relevant to their function; and (3) individual differences in psychological adjustment are likely due to differences in the functioning within specific behavioral systems (e.g., prototypic phenotypes) and the relationships between behavioral systems (Buss, 2008; Davies & Sturge-Apple, 2007; MacDonald, 2012; MacDonald & Leary, 2005).

In further elaborating on the last principle, the interplay between behavioral systems with incompatible functions reflect mutually inhibiting relationships with one another that require organisms to negotiate competing motivational demands (Buss, 2008; Davies & Sturge-Apple, 2007; MacDonald, 2012; MacDonald & Leary, 2005). Translated to EST-R, SDS and its behavioral goal of defusing threat are fundamentally at odds with the functions of approach systems or ethological modules. Given that protecting oneself from threat is prioritized in the hierarchy of goal systems, activation of the SDS system is theorized to supersede the salience of approach systems as organizers of behavior. During childhood, the protracted operation of the SDS in the interparental relationship may specifically increase the likelihood of psychopathology by undermining the operation of three approach systems: exploration, affiliation, and caregiving. In the following sections, we offer a synopsis of how these systems may serve as mediators of insecurity in the developmental cascade.

The Exploratory System. As depicted in Figure 6.3, the broad adaptive function of the exploratory system of accessing basic survival materials is achieved through the more specific behavioral or external goal of gaining familiarity and mastering of the physical world (Davies & Sturge-Apple, 2007). Efficient functioning of the exploratory system and increased likelihood of success in achieving the external goal is reflected in action tendencies characterized by intrinsic motivation and behavioral efforts to approach, manipulate, and understand the workings of the physical world. From the multilevel lens of developmental psychopathology (Cicchetti & Curtis, 2007), the exploratory system is catalyzed by neurobiological substrates (e.g., dopaminergic reward mechanisms) that incentivize and reinforce curiosity, approach to novelty, and other exploratory behaviors (Depue & Fu, 2012; Panskepp, 1998; Panskepp & Moskal, 2008).

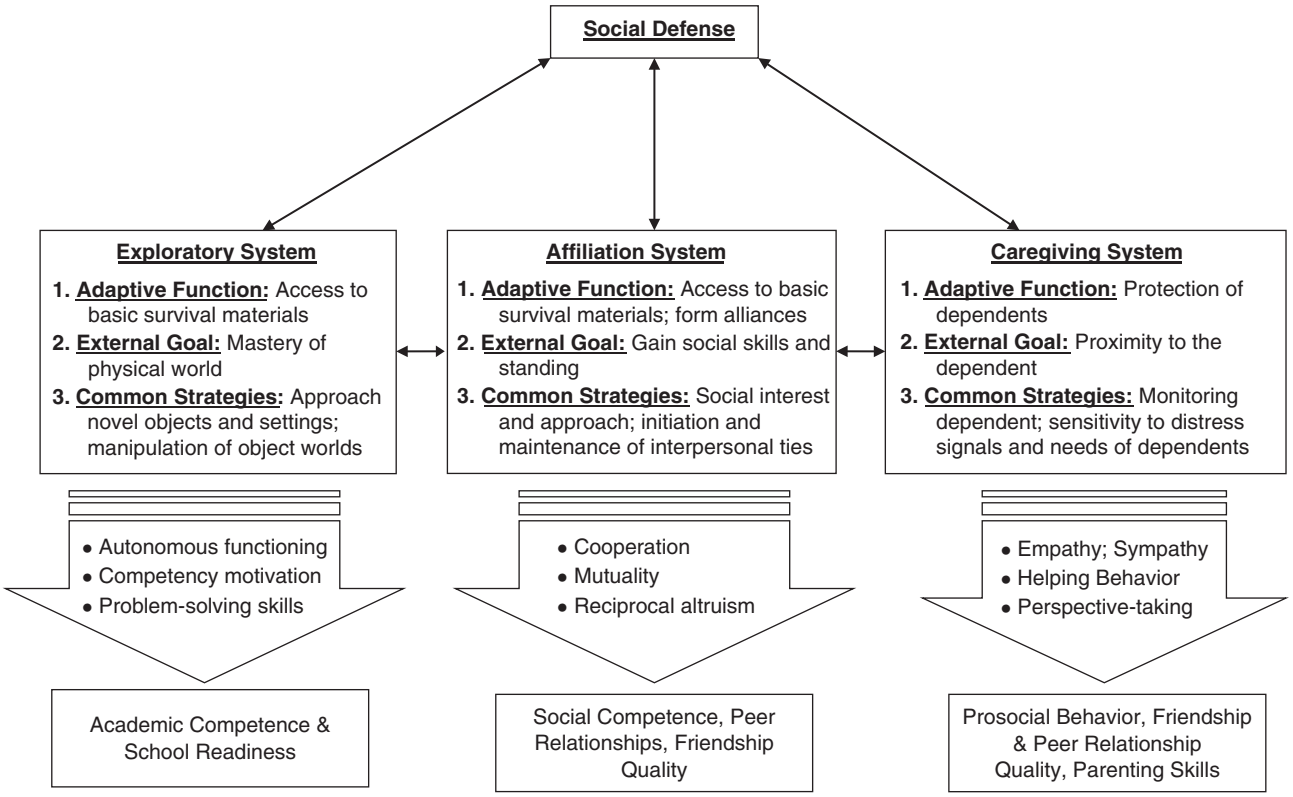

Figure 6.3 A model illustrating how the SDS impacts children's competence in multiple domains by altering the operation of ethological systems that organize approach motives and behaviors.

Given the dialectical opposition of the SDS and exploratory systems, EST-R proposes that recurrent experiences with insecurity in the interparental relationship substantially undermine children's capacities to explore the environment. As part of this process, defensive, reflexive, and automatic reactivity to threat in the interparental relationship may compromise executive functioning and regulatory abilities by reducing neural activity in the brain regions (e.g., prefrontal cortex) organizing reflective engagement with environmental stimuli (Blair & Raver, 2012). Thus, over time, diminished engagement in the physical environment is specifically proposed to compromise resourceful and flexible problem-solving (e.g., set shifting, planning), perceived academic efficacy, and ultimately intellectual performance (Blair & Diamond, 2008; Davies, Woitach, Winter, & Cummings, 2008; Quinkert et al., 2011). Although research has yet to systematically test these hypotheses, initial empirical tests are promising. For example, children's insecure representations of the interparental relationship were associated with increasing attention problems over a one-year period. In the second part of the cascade, attention problems, in turn, predicted broader school adjustment problems (Davies et al., 2008).

The Affiliative System. Figure 6.3 also illustrates that the SDS may limit the opportunities of insecure children to pursue affiliative goals of achieving access to survival materials and social standing through formation and maintenance of cooperative alliances (Irons & Gilbert, 2005; Markiewicz, Doyle, & Brendgen, 2001). The affiliative system is specifically designed to lubricate and sustain cooperative social interactions through the organization of affect expressions (e.g., warmth, affection, trust) and behavioral displays of affiliation and play (e.g., smiling, cooperative play, humor) (Davies & Sturge-Apple, 2007; Furman, 1999; Gordon, Martin, Feldman, & Leckman, 2011). Dopaminergic and opiate systems and hormones such as oxytocin subserve the affiliative system as the foundation for social behavior by stimulating and regulating social bonding, shared attention, eye gaze, behavioral synchrony, and trust (Depue & Collins, 1999; Depue & Morrone-Strupinsky, 2005; Feldman, 2012; Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005). The antithetical nature of the relationship between the inhibitory function of SDS and the approach goals of the affiliative system is supported by research demonstrating that anxiety and hypervigilance interfere with the processing of positive

social cues (Clark, 2001; Frewen, Dozois, Joanizze, & Neufeld, 2008; Hofmann, 2007; Taylor, Bomyea, & Amir, 2010). Difficulties in the processing of social information (e.g., hostile attribution biases, threat perceptions), in turn, increase children's vulnerability to victimization, peer rejection, and poor social competence (e.g., Bascoe et al., 2009; Crick & Dodge, 1994; Taylor, Sullivan, & Kliewer, 2013). Thus, the primacy of the SDS for insecure children is likely to contribute to deficits in social competence by directly interfering with the affective, information processing, and behavioral functioning of the affiliative system.

Recurring activation of the SDS in the interparental relationship is also theorized to indirectly undermine children's social competence by limiting the contextual experiences that might promote the elaboration and efficient functioning of the affiliative system. Experiences with family adversity in conjunction with tendencies to employ fight, flight, or avoidance behaviors as defense strategies are theorized to constrain insecure children's opportunities to elaborate and practice behavioral strategies for forming and maintaining cooperative alliances (Irons & Gilbert, 2005; Markiewicz, Doyle, & Brendgen, 2001). Early acquisition and refinement of social skills for establishing companionship, cooperation, mutualism, and reciprocal altruism are the key building blocks for social competence and harmonious, mutually beneficial peer relationships (Deater-Deckard & Petrill, 2004; Lindsey, Cremeens, Colwell, & Caldera, 2009). Poor social competence, externalizing and internalizing problems, and impulsive or anxious behaviors, in turn, reduce the child's value as a potential play partner and contribute to peer experiences (e.g., rejection, victimization) that serve to sustain insecurity in the long run (Beirman, 2004; Cook, Williams, Guerra, Kim, & Sadek, 2010; Hanish & Guerra, 2000; 2004).

The Caregiving System. The caregiving system functions to organize feelings of empathy, attunement to dependents, and behavior that serves the adaptive function to protect dependents and reduce their distress (Brown, Brown, & Preston, 2011; Davies & Sturge-Apple, 2007; Swain et al., 2012). Although the caregiving system is largely considered in relation to its role in parenting and likely remains relatively underdeveloped during childhood and early adolescence, its adaptive role in organizing the care of offspring requires the development of sensitivity and responsiveness to others' needs early in the lifespan. Due to their common phylogenetic history, the affiliative and caregiving systems share some physiological, affective, and behavioral strategies (e.g., the neuropeptides oxytocin and vasopressin) in motivating and rewarding behaviors that assist others. However, other underlying biological agents (e.g., estrogen) are distinct in serving the caregiving system (Depue & Morrone-Strupinsky, 2005; Galbally, Lewis, van IJzendoorn, & Permezel, 2011; Panskepp, 1998). Thus, relative to the affiliative system and its regulation of mutualism, reciprocity, and shared identity in social relationships, the caregiving system is sensitive to contextual cues that indicate others' vulnerability (e.g., sadness, fear, illness, child-like features) and organizes cognitions and affect (e.g., compassion, sense of efficacy, protectiveness, empathy, sympathy) that bolster the individual's ability to provide protection and care (Goetz, Keltner, & Simon-Thomas, 2010; Swain et al., 2012). The neurophysiological components of the caregiving system work to both motivate approach to those in distress, while simultaneously inhibiting competing stress responses that might interfere with caregiving ability (Brown et al., 2011; Numan, 2006).

When personal distress and SDS responding overwhelm the individual's capacity to regulate or inhibit self-concern, the likelihood that children will exhibit helping behavior is drastically reduced (Batson, 1991; Eisenberg, Fabes, & Spinrad, 2006). Thus, a highly sensitive SDS system may disrupt the normative development of the caregiving system through emotional distress, egoistic concern with safety, and difficulties regulating one's behavior (Collins, Guichard, Ford, & Feeney, 2004; Shaver, Mikulincer, & Shemesh-Iron, 2010; Shields, Cicchetti, & Ryan, 1994). Reductions in the capacity for empathic responding and prosocial behavior may, in turn, contribute to poor social competence, peer rejection, and poor quality friendships (Eisenberg, Huerta, & Edwards, 2012; Eisenberg et al., 2006). Difficulties forming and maintaining positive close relationships (e.g., best friendships, romantic affiliations) during adolescence and early adulthood may further limit opportunities to practice and refine the caregiving strategies that are ultimately critical to developing competent parenting skills (Davies, Sturge-Apple, Woitach, & Cummings, 2009).

CONTEXTUAL CHARACTERISTICS

Although our literature review documents the empirical support for the mediational role of emotional security in pathways between interparental conflict and child adjustment, the research also indicates that there is substantial heterogeneity in children's reactivity to conflict. Thus, a

key question remains: Why is there considerable diversity in these mediational pathways? From a developmental psychopathology perspective, individual development is regarded as part of an ongoing interplay between the child and a constellation of family and extrafamilial processes (Cicchetti, 1993; Davies & Cicchetti, 2004). In applying this notion to emotional security models, a derivative hypothesis is that individual differences in the strength of mediation will lawfully vary as a function of the broader multilevel matrix of contextual characteristics. In the following sections, we describe the theoretical and empirical progress made in contextualizing the study of emotional security across several units of analysis, including: family processes, child attributes, and ecological characteristics.

Family Processes

The significance of understanding the developmental implications of broader family processes in EST is evidenced by the core assumption that children derive emotional security from multiple relationships in the family. Consistent with family systems theory (Cox & Paley, 1997; Davies & Cicchetti, 2004), EST further posits that comprehensively understanding the dynamics of children's emotional security within any specific family relationship (i.e., interparental dyad) is contingent on embedding the study of security within the broader family unit (Cummings & Davies, 1996; Davies, Harold, et al., 2002). To illustrate the utility of this approach, the following sections describe the theory and research on three classes of family processes that may help to account for individual differences in children's pathways of security: parent–child relationship properties, parent psychopathology, and family-level characteristics.

Parent–Child Relationship Properties

Consistent with the emphasis on the interplay between family relationships in family systems theory (Cox & Paley, 1997), EST conceptualizes the interparental subsystem as the cornerstone of the family unit. A derivative assumption is that parental frustration, distress, and relationship preoccupation in the wake of interparental conflicts negatively influence parental interactions with their children (Easterbrooks & Emde, 1988; Grych, 2002). Consistent with these predictions, interparental conflict has been associated with parenting difficulties across both short-term experimental and diary (e.g., minutes, days) designs (Almeida, Wethington, & Chandler, 1999; Jouriles & Farris, 1992) and longitudinal methodologies spanning longer time (e.g., years) periods (Sturge-Apple, Davies, & Cummings, 2006a; 2006b). Moreover, numerous parenting difficulties have been linked with high levels of interparental conflict, including emotional unavailability, diminished warmth, inconsistent discipline, psychological control, disengagement, and harsh discipline (e.g., Benson, Buehler, & Gerard, 2008; Levendosky, Leahy, Bogat, Davidson, & von Eye, 2006; Margolin & John, 1997; Owen, Thompson, & Kaslow, 2006; Sturge-Apple, Davies, & Cummings, 2006b). These parenting difficulties, in turn, have been shown to serve as partial mediators of the link between interparental conflict and children's psychological adjustment (Cummings & Davies, 2010). EST is designed to build on the mediational pathways involving interparental conflict, parenting difficulties, and child adjustment by advancing an understanding of why parenting serves as an explanatory mechanism for interparental conflict. In moving beyond our previous documentation of emotional insecurity in the interparental relationship as a mediator of the link between interparental conflict and child maladjustment, Figure 6.3 depicts three additional pathways that are generated by the integration of parent–child processes into models of emotional security.

Drawing on attachment theory (Bowlby, 1969; Goldberg et al., 1999; McElwain & Booth-LaForce, 2006), Path 1 illustrates the hypothesis that the mediational role of parenting impairments in links between interparental conflict and parenting difficulties is further explained by children's attachment insecurity in parent–child relationships. That is, destructive interparental conflict may undermine children's confidence in parents as sources of protection and support by increasing parental displays of harsh, unavailable, frightening, and frightened caregiving behaviors in interactions with their children. Resulting declines in attachment security, in turn, are proposed to increase children's risk for psychological problems (Davies, Harold, et al. 2002; Davies, Sturge-Apple, & Martin 2013). In support of this hypothesis, findings from a multiple informant study indicated that parenting difficulties characterized by low levels of warmth, emotional rejection, and poor monitoring of children's activities mediated the link between interparental conflict and child-parent attachment insecurity. Attachment insecurity, in turn, was associated with adolescent internalizing and externalizing symptoms even after specifying child insecurity in the interparental relationship as a predictor (Davies, Harold, et al., 2002). In a subsequent multimethod study, observations of diminished responsiveness by parents in interactions with their children served as an intervening mechanism in the link between destructive interparental

conflict and children's insecure representations of parents as supportive figures. In turn, insecure representations of parent–child relationships mediated associations between diminished parental responsiveness and teacher reports of poor academic engagement (Sturge-Apple et al., 2007).

As shown in Path 2, EST postulates that interparental conflict may also increase children's vulnerability to psychopathology by increasing children's attachment insecurity with parents. Thus, even after taking into account the mediational role of caregiving difficulties in parent–child interactions, exposure to interparental conflict is proposed to undermine children's confidence in parents as protective and supportive figures and, in the process, increase their risk for experiencing mental health problems. The few studies examining this pathway have yielded inconsistent results. In accord with the hypothesis, destructive interparental conflict has been shown to be indirectly related to child adjustment through its association with indices of parent–child attachment insecurity (Lindsey, Caldera, & Tankersley, 2009; Sturge-Apple et al., 2008). Conversely, other studies have found that interparental conflict is unrelated to parent–child attachment security in broader multivariate models including parenting variables as predictors (e.g., Davies, Harold, et al., 2002). Resolving the empirical inconsistencies in testing attachment security as a mediator of interparental conflict is a central part of the future agenda for emotional security theory. As a potential conceptual approach to overcoming this barrier, we argue that the complexity in the findings may be attributable, in large part, to the need for greater specificity in conceptualizing and testing the mediational pathways.

In increasing the specificity of hypotheses, EST-R specifically proposes that disorganized and disoriented (D) attachment may be the most potent explanatory mechanism among the various forms of attachment insecurity (Davies, Sturge-Apple, & Martin, 2013). In EST-R, D attachment behaviors are products of the conjoint operation of both the attachment and social defense systems. For example, children's contradictory D behaviors characterized by simultaneous or successive approach and avoidance displays can be interpreted as reflecting an impasse between attachment and defense systems. Likewise, freezing and inhibition of overt distress expressions may specifically reflect self-protective camouflaging efforts that may serve the organized SDS function of reducing children's salience as targets of oppressive adult dominants (Davies & Sturge-Apple, 2007). Thus, although children have a hard-wired, phylogenetic tendency to approach the attachment figure, the D strategy signifies that the attachment relationship is simultaneously a source of threat worthy of activation of social defense strategies. It follows, then, that the high threat value associated with witnessing frightening (e.g., hostile, aggressive), vulnerable (e.g., distressing, fearful), and volatile (e.g., emotionally labile) parental behaviors during intense bouts of interparental conflict may amplify children's social defense responses to caregivers in subsequent parent–child interactions. Consistent with this hypothesis, several studies have identified associations between high levels of interparental conflict and signs of D attachments (Johnston & Campbell, 1988; Leon, 2003; Moss, St-Laurent, Dubois-Comtois, & Cyr, 2005; Zeanah, Boris, & Larrieu, 1997). Moreover, research distinguishing between levels of disorganized and insecure patterns of attachment has shown that interparental conflict is a more consistent predictor of D attachment for mothers and fathers than general forms of attachment insecurity (Owen & Cox, 1997).

Path 3 of Figure 6.4 further illustrates the hypothesis that some parenting behaviors may play a distinct role in increasing children's worries about security in the interparental relationship. Although dimensions of interparental discord are proposed to be among the most robust risk factors of children's insecurity in interparental contexts, parental interactions with children may also increase children's vulnerability by uniquely predicting child concerns about their security in the interparental relationship. Expressions of parental disengagement, unresponsiveness, and rejection directed toward children in high conflict homes are specifically theorized to undercut the establishment of fundamental mechanisms for preserving a sense of security in the interparental relationship, including the development of emotion regulation skills, self-confidence, and coping efficacy. Although parenting practices are theorized to be modest predictors of insecurity in the interparental relationship, tests of this hypothesis have yielded variable results. For example, Sturge-Apple and colleagues (2008) reported that low levels of parental warmth were uniquely associated with children's insecure representations of the interparental relationships even after taking into account interparental conflict. Children's insecure representations of the interparental relationship, in turn, predicted higher levels of their adjustment problems. However, other studies have failed to identify significant pathways between parenting difficulties and children's insecurity in the interparental relationship (e.g. Davies, Harold, et al., 2002; Davies, Sturge-Apple, Cicchetti, Manning, & Vonhold, 2012).

Toward the goal of addressing these empirical discrepancies, tests of the mediational linkages in Path 3 could benefit from the greater conceptual depth afforded by

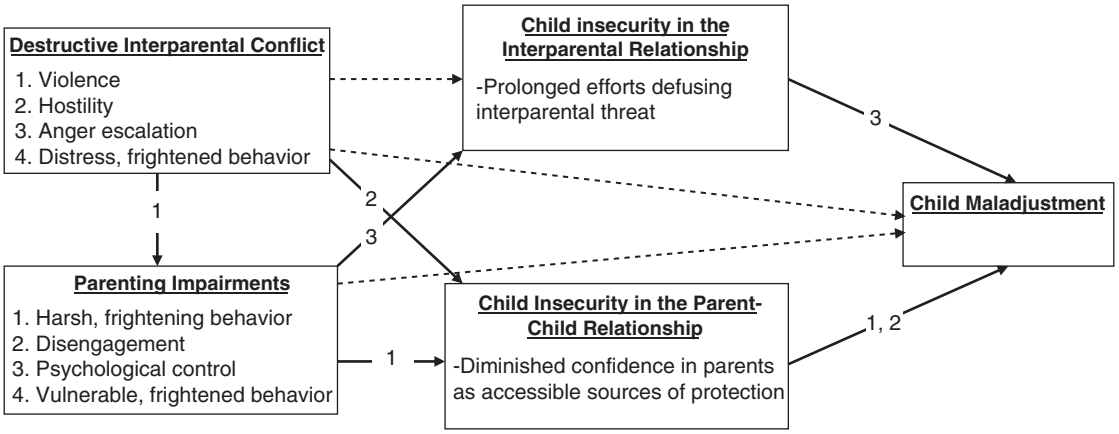

Figure 6.4 A model illustrating how parent–child relationship processes may inform how interparental conflict increases children's risk for psychopathology though their experiences with insecurity in the interparental and parent–child relationships.

EST-R. If child concerns about insecurity in the interparental relationship are underpinned by the goal of defusing parental threat, then it is plausible that children's exposure to frightening or frightened caregiver behaviors in parent–child interactions may be the central etiological agent that increases children's sensitivity to the interpersonal dangers of subsequent bouts of interparental conflict. Evaluated in this context, assessments of parental availability, warmth, and sensitivity in previous studies may be less relevant than parental behaviors that more closely signify imminent interpersonal danger. Thus, EST-R proposes that volatile (e.g., high emotional lability), highly vulnerable (e.g., intense anxiety or dysphoria), or oppressive (e.g., violent, overtly rejecting) parenting behaviors may not only increase psychopathology by undermining attachment security in the parent–child relationship but also by increasing the salience of the SDS as an organizer of behavior in interparental contexts (Davies & Martin, 2013; Davies & Sturge-Apple, 2007). In spite of the strong theoretical basis for this hypothesis, the comparative utility of different forms of parenting behavior as predictors of insecurity in the interparental relationship has yet to be systematically examined in studies. Therefore, comprehensively testing these pathways is a critical direction in future research.

Parental Psychopathology

Developmental psychopathology models of the intergenerational transmission of psychological problems from parent to offspring testify to the importance of parent psychopathology in understanding children's experiences with emotional insecurity (Cicchetti & Toth, 1998; Goodman & Gotlib, 1999). In fact, the high threat value ascribed to atypical and extreme parental behaviors in EST-R suggests that parental symptomatology may impact the mediational role of insecurity in the interparental relationship in several ways (Davies & Martin, 2013). First, parental psychological problems may serve as distal predictors of children's insecurity in the interparental relationship through its association with high levels of family adversity in the form of children's exposure to interparental conflict and frightening and vulnerable caregiving behaviors (Goodman & Gotlib, 1999; Davies, Sturge-Apple, Cicchetti, Manning, & Vonhold, 2012). For example, interparental aggression and hostility has been identified as a consistent correlate of parental depressive symptoms (Cummings, Keller, & Davies, 2005; Du Rocher Schudlich & Cummings, 2003; Shelton & Harold, 2008), antisocial personality traits (e.g., Davies et al., 2012; Jaffee, Belsky, Harrington, Caspi, & Moffitt, 2006), alcohol problems (e.g., Keller, El-Sheikh, Keiley, & Liao, 2009), and general psychological distress (Papp, Goeke-Morey, & Cummings, 2007). In further advancing an understanding of the developmental cascades of parent psychopathology, research is also beginning to identify the unfolding security processes underlying the interplay between interparental conflict and child psychopathology. For example, studies have shown that interparental conflict mediates associations between various forms of parental symptomatology and children's insecurity. Insecurity, in turn, was a robust predictor of children's psychological problems (e.g., Davies et al., 2012; Du Rocher Schudlich & Cummings, 2007).

Second, interaction models propose that parent psychopathology serves as a potentiating factor in family process models of child adjustment (Cummings, Davies, & Campbell, 2000; Goodman & Gotlib, 1999; Leve et al., 2007). Parent psychopathology may specifically create a

double whammy in magnifying the pathogenic mediational pathways involving interparental conflict, children's emotional security, and their adjustment. By virtue of the heritability of parental psychological difficulties, children of parents with psychopathology may possess genetic vulnerabilities that increase their susceptibility to adverse family experiences and processes (Leve et al., 2010; Reiss & Leve, 2007). Likewise, because higher levels of parental psychological difficulties are associated with children's exposure to maladaptive caregiving behaviors, the toxic nature of the family environment may compound the threat children experience in the interparental relationship (Davies & Sturge-Apple, 2013; Goodman & Gotlib, 1999). Against this conceptual backdrop and the extensive research on associations between parent and offspring psychopathology (e.g., Frick et al., 1992; Goodman et al., 2011), it is surprising that very little research has examined parental psychological symptoms as possible moderators in mediational pathways involving family conflict and child coping and adjustment. Notably, only one study to our knowledge has tested whether the strength of children's emotional security as a mediator of interparental conflict varies as a function of parental psychopathology. In supporting this research direction, Kouros, Merriliees, and Cummings (2008) found that paternal depression selectively moderated the first link in the mediational chain of emotional insecurity. Moderated-mediation analyses revealed that interparental conflict was a stronger predictor of emotional insecurity for children whose fathers evidenced clinical levels of depression than for children whose fathers had lower levels of depressive symptoms. In addition, maternal depression failed to moderate emotional security, but was associated with emotional insecurity in the interparental relationship, which in turn increased children's risk for experiencing psychological problems.

Toward the goal of advancing this line of research in the future, greater precision may be achieved by identifying the specific forms of parental psychopathology that serve as contextual factors in models of insecurity. For example, parent antisocial personality disorder, which is characterized by a stable pattern of intentionally violating the basic rights of others in a callous, impulsive, manipulative, and aggressive manner, may be a particularly robust risk factor in organizing children's emotional insecurity. Relative to other forms of psychopathology, parental antisocial personality symptomatology is a robust predictor of interparental aggression (Humbad, Donnellan, Iacono, & Burt, 2010; Jaffee et al., 2006; Magdol et al., 1998). In tracing its implications for children's emotional insecurity, research has also shown that maternal antisocial personality symptomatology was the only predictor of interparental aggression in a model that contained other forms of maternal psychopathology including depressive, anxiety, and substance use problems. Moreover, interparental aggression, in turn, was associated with greater signs of child emotional insecurity (Davies et al., 2012). In contrast, low self-worth, hopelessness, loss of interest, and depressed affect underlying depressive syndromes may engender more disengaged and dysphoric expressions of interparental conflict. For example, Du Rocher Schudlich and Cummings (2007) revealed that both paternal and maternal depressive symptoms were indirectly associated with children's emotional insecurity through the mediational role of depressive (e.g., sadness, withdrawal, distress) styles of interparental conflict. Although studies have not examined the impact of parent psychopathology on emotional security within the parameters of EST-R, it is plausible that specific features of parental psychopathology may result in children enlisting different insecure strategies to defend against interparental threats (see Person-Based Taxonomy section). Taken together, the conceptual and empirical progress provides foundations for future research to consider how the unique features and facets of psychopathology in parents may differentially operate in the process models of interparental discord and children's emotional insecurity.

Family-Level Characteristics

Family systems theory offers a useful heuristic for integrating the study of children's emotional security and developmental psychopathology in a broader family context (Davies & Cicchetti, 2004). According to the theory, broader stressors and perturbations in the family unit may provoke reorganizations that change the nature of interdependencies among family relationships and the functioning of individuals (Cox & Paley, 1997; Grych, 2002). Family-level characteristics are theorized to be central agents in regulating transactions between family members because they reflect higher order operations in the family that transcend individual and dyadic relationships (Davies & Sturge-Apple, 2014). Thus, in keeping with the potentiating and protective frameworks in developmental psychopathology, interrelationships among the interparental subsystem, children's emotional security, and child development may vary depending on properties of the larger family system (Erel & Burman, 1995; Grych, 2002).

Family instability and cohesion constitute two central family-level factors that may assist in deciphering how children cope and adjust to interparental conflict. Characterized by the accumulation of disruptive family events

(e.g., caregiver changes, job/income loss, family deaths, caregiver romantic relationship changes), family instability functionally reflects breakdowns in the ability of the family unit to serve as a source of stability, continuity, and predictability in the lives of children (Ackerman, Kogos, Youngstrom, Schoff, & Izard, 1999; Forman & Davies, 2003). Conversely, family cohesion is conceptualized as the degree of emotional closeness, warmth, and harmony in the family unit (Olson, Russell, & Sprenkle, 1983; Minuchin, 1974). Given their designation as processes at the whole family unit, family instability and cohesion are theorized to regulate the strength of mediational pathways involving emotional insecurity. Consistent with this thesis, family instability has been empirically identified as a moderator in the first link in the mediational chain through its effect on potentiating or amplifying associations between interparental conflict and children's emotional insecurity. Family cohesion, in contrast, moderated the second stage of the unfolding mediational pathway as a protective factor. More specifically, children's insecurity in the interparental relationship was more weakly associated with their psychological problems when they experienced higher levels of family cohesion (Davies, Harold, et al., 2002). Although additional analyses indicated that associations between interparental conflict and child insecurity did not vary depending on the level of cohesion (Davies, Harold, et al., 2002), other research has shown that arguments between parents more weakly predict children's perceptions of threat in the interparental relationship when there is higher warmth and cohesion in the family unit (Lindahl & Malik, 2011). Thus, it is premature to settle on any definitive conclusions without additional research.

Family systems frameworks also underscore the usefulness of analyzing interpersonal boundaries to more firmly contextualize interparental conflict and child emotional security in the whole family system (Davies, Cummings, & Winter, 2004). Boundaries in family relationships are defined by characteristic ways of exchanging resources, information, and materials in the family unit. Although theory and research on family systems has identified a number of different configurations of emotional and relational functioning in the family, cohesive, disengaged, triangulated, and enmeshed patterns of communication have been most consistently delineated in empirical work (Davies et al., 2004; Johnson, 2010; Kerig, 1995; Kretchmar & Jacobvitz, 2002; Minuchin, 1974). Flexible, well-defined boundaries characteristic of cohesive families provide children with ready access to resources (e.g., warmth, support, guidance) while respecting their autonomy and individuality. Conflict and distress among family members tend to be mild, well managed, and encapsulated within interparental, parent–child, and sibling relationships and are substantially outweighed by warmth, affection, and autonomy support. Thus, children in these families are theorized to be more likely to experience trajectories of security and healthy psychological functioning.

Children growing up in families with the other types of boundaries are proposed to fare significantly worse than children in cohesive families. Overly rigid, thick, and inflexible boundaries in disengaged families block access to support, protection, and other resources across family subsystems. Consequently, high levels of emotional detachment, apathy, and alienation are commonly accompanied by bouts of hostility that collectively serve to increase or maintain psychological distance between family members. In contrast, enmeshed families are characterized by weak metaphorical boundaries in which children's access to resources commonly comes at a price of a loss of autonomy and undue exposure to discord. Thus, any displays of warmth and support commonly occur in a larger context of family expressions of psychological control, intrusiveness, and hostility that tend to proliferate seamlessly across individuals and relationships (Davies et al., 2004; Jacobvitz, Hazen, Curran, & Hitchens, 2004; Kerig, 1995). Likewise, triangulation in families reflects various blends of enmeshment and disengagement across family subsystems and individuals in which family members form defensive alliances (i.e., enmeshed component) against another individual or subsystem (i.e., disengaged component). For example, in detouring families, children's difficulties intensify as they serve to increase closeness between parents who are in an otherwise unhappy relationship. Conversely, the psychological burdens of serving as caretaker, confidante, or guardian in parent–child coalitions pose its own set of risks for children (Buehler & Welsh, 2009; Johnson, 2010; Kerig, 1995).

As a first test of the utility of family boundary conceptualizations for understanding children's emotional security, Davies et al. (2004) utilized pattern-based analyses to identify both enmeshed and disengaged family typologies. Whereas each type of boundary disturbance experienced elevated levels of interparental conflict and distress, enmeshed families exhibited greater coparenting disagreements and higher levels of parent acceptance, inconsistent discipline, and psychological control than did disengaged families. Although children in enmeshed and disengaged families exhibited higher levels of child insecurity in the interparental relationship relative to cohesive families, the family enmeshment profile was associated with the most widespread signs of emotional insecurity.

Moreover, emotional insecurity was a more consistent mediator of psychological problems experienced by children in enmeshed families than it was for their counterparts in disengaged families. Thus, one possibility is that diffuse boundaries evident in enmeshed families fuel concerns about insecurity by "breaking down any affective distance between the children and the parents' distress" (Coyne, Downey, & Boergers, 1992, pp. 222). Future progress depends on more comprehensively capturing family level processes and their implications for security pathways. For example, research has yet to examine whether the mediational role of emotional security may vary depending on the occurrence and type of triangulating relationships in the family (e.g., detouring, parent–child coalitions). Likewise, the earlier findings by Davies et al. (2004) raised the possibility that enmeshed and disengaged family dynamics may engender different expressions of children's insecurity in the interparental relationship. Thus, as we outline in the Future Directions section, EST-R may be used as a guide in examining whether qualitatively distinct SDS profiles of insecurity evolve from different constellations of interparental and family-level functioning (Davies & Sturge-Apple, 2007).

Child Characteristics

Although it is important to note that a variety of child attributes may figure prominently in the variability of children's adaptation to interparental conflict, we selectively focus on two primary dimensions for the sake of illustration: gender and temperament.

Gender

Although child gender has garnered considerable scientific attention in models of interparental conflict (e.g., Davies & Lindsay, 2001; Emery, 1982; Rutter, 1970; Snyder, 1998), its significance in advancing an understanding of emotional security has yet to be compellingly demonstrated. Part of this knowledge gap can be attributed to the tendency in the literature to ignore child gender in reporting findings (Cummings & Davies, 2010). In spite of calls to move the study of gender from its background or nuisance variable designation to a more central role in models of interparental conflict (Davies & Lindsay, 2001; Snyder, 1998), gender has not been systematically incorporated in empirical tests of emotional security. For example, a small subset of studies in Table 6.2 reports on findings from analyses of child gender as a covariate (29%) or moderator (35%) in mediational tests of emotional security. Tendencies to relegate gender to a peripheral variable in emotional security research are understandable to some degree. Research over the past two decades has largely focused on testing emotional security as an explanatory mechanism within increasingly sophisticated models of family relationship processes. Thus, advancing to the use of complex blends of mediation and moderation required to incorporate gender in analyses hinges first on the compellingly documenting that emotional security mediates interparental conflict. Moreover, the small sample sizes of many of the earlier studies were ill equipped to sensitively examine the role of gender in models of emotional security.

The recent accumulation of evidence of emotional security as a mediator of interparental conflict now raises a critical question: What role, if any, might gender play in elucidating child emotional insecurity as a mediator? Our tentative answer is that child gender, in itself, is unlikely to assume center stage in the objective of identifying the multiple pathways between family processes, emotional insecurity, and child adjustment. Our conceptualization of security does not regard gender as a primary source of variability in children's vulnerability to interparental conflict. Within EST-R, the survival value of guarding against social threat and competition is theorized to be comparable for males and females (Davies & Sturge-Apple, 2007). As a result, the function, developmental origins, and implications of the SDS are not expected to vary widely across child gender, particularly in comparison to other potential contextual factors. Rather, gender is conceptualized as a proxy for a set of more operative mechanisms that more directly shape children's vulnerability to interparental conflict (Davies & Lindsay, 2001).

It may still be tempting to posit that gender plays a significant role in altering the power of emotional security as an explanatory mechanism. After all, early studies underscored the possibility that boys and girls may express their insecurity in different ways. For example, prior to adolescence, some studies have reported that girls respond to conflict between adults through subtle channels of distress, worry, and fear, whereas boys react with greater anger and aggression (Davies & Lindsay, 2001; Snyder, 1998). Research during adolescence further indicated that girls exhibited higher levels of emotional and behavioral involvement in conflicts between their parents (e.g., Buchanan, Maccoby, & Dornbusch, 1991; Davies & Lindsay, 2001; Gore, Aseltine, & Colten, 1993). Consistent with this work, gender comparisons in the psychometric analyses of the first survey of emotional insecurity indicated that adolescent girls reported higher levels of emotional reactivity, avoidance, involvement, and destructive internal representations than boys did (Davies, Forman, et al., 2002).

However, in the context of the broader literature on gender effects, these findings have not been replicated with enough regularity to make any firm conclusions. For example, in the five studies in Table 6.2 that explicitly examined associations between gender and signs of emotional insecurity, gender failed to predict emotional security or alter its power as a mediator (Davies, Cicchetti, & Martin, 2012; Davies, Sturge-Apple, Bascoe, & Cummings, 2014; Du Rocher Schudlich & Cummings, 2007; El-Sheikh et al., 2008; Kelly & El-Sheikh, 2013).

Even if future research identifies gender as a unique predictor of signs of insecurity, it does not address the qualitatively different question of whether mediational pathways involving interparental conflict and children's emotional insecurity and psychological problems differ significantly for boys and girls. That is, identifying gender differences in absolute levels of children's reactivity to conflict is orthogonal to understanding whether the developmental precursors and implications of children's concerns about emotional security vary as a function of their gender. In more directly addressing this question, the six studies in Table 6.2 that explored child gender as a moderator of insecurity failed to find any evidence that the mediational paths involving emotional security varied by gender (Cummings et al., 2006, 2012; Davies, Cicchetti, & Martin, 2012; El-Sheikh et al., 2008; Kelly & El-Sheikh, 2013). Moreover, the null findings do not appear to be attributable to statistical power issues, as the average sample size in these studies was 220. Thus, consistent with EST-R, the most parsimonious interpretation of the findings is that child gender offers little in the way of uniquely explaining children's security-related vulnerability to interparental conflict.

However, at this juncture, it may be premature to completely discard child gender from models of emotional security. Null, inconsistent, and weak findings on gender may still simply be the result of a failure to fully consider gender processes within conceptualizations of insecurity (Snyder, 1998). Interpreted within a developmental psychopathology framework, gender-linked characteristics may confer both potentiating and protective factors that may offset each other. First, tendencies for girls (particularly in adolescence) to experience higher levels of communion or interpersonal connectedness may signify that they have stronger emotional stakes in monitoring family relationship dynamics (Davies & Lindsay, 2004). Thus, when they are repeatedly exposed to destructive interparental conflict, they may be more vulnerable than boys to experiencing emotional insecurity. Yet high levels of interpersonal connectedness may also signify greater acuity in identifying and processing family adversity. Thus, in counteracting their greater sensitivity to interparental anger, the resulting advantage of more sophisticated social information processing abilities may be manifested in the ability to respond to interparental conflict with more effective strategies of coping (Cummings & Davies, 2010). Second, the predominant assessment of broad composites of interparental conflict and emotional insecurity may be masking important gender differences in pathways involving distinct parameters of conflict, specific signs of emotional insecurity, and child maladjustment. For example, the moderating role of child gender in associations between interparental conflict and children's reactivity to conflict may actually vary depending on the gender of the parent, the form of the conflict (e.g., physical aggression), and the specific way insecurity is expressed (e.g., mediation, avoidance) (e.g., Crockenberg & Forgays, 1996; Davies & Lindsay, 2001; Shelton, Harold, Goeke-Morey, & Cummings, 2006). Thus, identifying gender-differentiated pathways of emotional security in future research may benefit from more fine-grained models that are specifically designed to capture gender processes.

Temperament

In capturing individual differences in characteristic ways of behaving that are largely constitutional in origin and stable across time and context (McCrae et al., 2000; Rothbart & Posner, 2006), temperament has been consistently regarded as source of heterogeneity in the adjustment of children from high-conflict homes (Crockenberg & Langrock, 2001; Davies & Cummings, 1994; Grych & Fincham, 1990). However, research on the role of temperament as a moderator of interparental conflict has produced inconsistent, complex results. For example, whereas some studies find support for the role of negative emotionality as a vulnerability factor that exacerbates the risk posed by interparental conflict (e.g., Pauli-Pott & Beckmann, 2007), other findings indicate that negative temperament is not a significant moderator of interparental conflict (e.g., Crockenberg, Leerkes, & Lekka, 2007). Still other studies report that associations between interparental conflict and infant affect dysregulation are more pronounced for children with low negative emotionality (Du Rocher Schudlich, White, Fleischhauer, & Kitzgerald, 2011).

Why might empirical inconsistencies exist in the literature? According to EST-R, the scientific complexity can be attributed, in large part, to the predominant focus on assessing children's distal outcomes that are temporally removed from the original threatening experiences of witnessing destructive interparental conflict. Repeated

exposure to interparental conflict is conceptualized as slowly setting in motion the dynamic emergence of risk processes characterized by regularity in child response patterns in specific contexts that, over time, intensify, broaden, and crystallize into the development of children's negative outcomes. Thus, temperamental attributes may play a more powerful role in altering the cascade of insecurity processes that underlie links between exposure to interparental conflict with more distal mental and physical health outcomes (Masten & Cicchetti, 2010).

Although little is known empirically about how temperament operates within models of security, EST-R proposes that temperamental attributes play a significant role in shaping the multiple mediational pathways involving interparental conflict, child insecurity, and child developmental outcomes (Davies & Sturge-Apple, 2007). As a particularly informative taxonomy of temperament for EST-R, Rothbart and colleagues parsimoniously classify child attributes into three higher order classes of behavior: (1) negative affectivity; (2) surgency; and (3) effortful control (Rothbart, Ellis, Rueda, & Posner, 2003). Whereas negative affectivity consists of intense, prolonged experiences of fear, frustration, or sadness, surgency is composed of approach behaviors that are generally manifested in high activity level, impulsivity, and intense pleasure. As forms of reactivity, negative affectivity and surgency are each defined as hard-wired, early emerging, and reflexive responses to environmental cues (Garstein & Rothbart, 2003; Putnam, Ellis, & Rothbart, 2001). In contrast, effortful control dimensions of temperament reflect voluntary, deliberate efforts to suppress and regulate forms of reactivity. According to EST-R, consideration of each of these classes of attributes may provide insight into the multiple ways temperament may alter security pathways (Davies & Martin, 2013; Davies & Sturge-Apple, 2007).

Dimensions of negative affectivity are specifically posited to calibrate the SDS to be highly sensitive to the threat cues accompanying recurrent interparental conflict (Davies & Windle, 2001). Therefore, indices of negative emotional reactivity may alter the first link in the proposed mediational cascade of insecurity by serving as both: (a) additive precursors that catalyze the SDS system in organizing insecure responses to interparental conflict, and (b) moderators that specifically increase their sensitivity to exposure to interparental conflict (Davies & Sturge-Apple 2007). However, greater precision may be necessary to discriminate between dimensions of negative emotionality. In drawing on evolutionary perspectives, Marshall and Stevenson-Hinde (2005) conceptualized fearful inhibition as a manifestation of a highly sensitive fear behavior or defense system. Thus, fearful inhibition may play a particularly strong role in increasing the saliency of the SDS as an organizer of behavior in contexts of interparental conflict (Davies & Martin, 2013). Another critical task will involve identifying whether the multiplicative interplay between temperament and interparental conflict corresponds more closely with the operation of a vulnerability or susceptibility factor. Whereas diathesis–stress models postulate that temperamental negativity is a vulnerability factor that compounds the risk associated with interparental conflict (Rothbart, 2011; Zuckerman, 1999), the differential susceptibility hypothesis proffers that children who are high in negative emotionality exhibit *susceptibility* or plasticity to both negative and supportive interparental contexts (Belsky & Pluess, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011).

Several temperamental attributes may also serve to amplify or dilute the sequelae of children's emotional insecurity. For example, difficulties preserving security may be particularly likely to proliferate and broaden across contexts for children who are predisposed to respond to challenges and stressors with intense, lengthy bouts of negative affect. Studies have provided support for associations between inhibited, reactive temperament and greater vigilance to threat and novelty, broader generalization of conditioned fear responses to other stimuli, and slower extinction of acquired fear responses (Barker, Reeb-Sutherland, & Fox, 2014; Helfinstein, Fox, & Pine, 2012; Schwartz, Stutz, & Lederman, 2012). Thus, from a developmental cascade framework, inhibited temperamental characteristics may potentiate pathways between insecurity in the interparental relationship and children's mental health difficulties by catalyzing the development of extensive negative representations of familial and extrafamilial relationships. As another example, effortful control and surgency dimensions (e.g., extraversion) may protect insecure children from developing psychopathology by bolstering the operation of approach-oriented ethological systems. For example, children who are more sociable and extraverted may be better able to weather the prolonged operation of the SDS and its pernicious impact on the social competence and peer relationships because they naturally devote greater efforts toward the affiliative system and its external goal of acquiring social skills and standing. Likewise, children with higher levels of effortful control may provide the constitutional tools (e.g., attention shifting and focusing, inhibitory control) to sufficiently manipulate and acquire knowledge about objects and establish intellectual and academic competencies even in the context of diminished resources resulting from a highly

active SDS. Consequently, the exploratory system and its goal of mastering the physical world may be relatively intact among insecure children with high effortful control.

Ecological Characteristics

Consistent with the transactional, ecological systems approach of developmental psychopathology (e.g., Cicchetti & Lynch, 1993; Cicchetti & Toth, 1997), a contextual understanding of emotional security in the interparental relationship requires consideration of the child's broader social ecology beyond the family. In highlighting the urgency of this goal, numerous calls across multiple disciplines have been made to further contextualize the study of family and developmental processes within community and cultural settings (e.g., Garcia Coll, 2005; Kazak, 2004; Parke, 1998). Because the theoretical and empirical agenda for emotional security theory over the past two decades has largely been organized around explicating the composition, family correlates, and developmental implications of emotional security as a goal-corrected system, little progress has been made in integrating the study of emotional security within an ecological framework. As a first step toward advancing this research direction, the next sections offer a preliminary conceptual heuristic for developing more formal theoretical assumptions and hypotheses by selectively focusing on three representative ecological characteristics: (1) socioeconomic, neighborhood, and community contexts; (2) race, ethnicity, and culture; and (3) peer relations.

Socioeconomic, Neighborhood, and Community Contexts

The interplay between family processes and community and socioeconomic factors are theorized to play a significant role in children's concerns about security and ultimately their adjustment (Cummings & Davies, 2010). With respect to socioeconomic difficulties, the family stress model proposes that economic upheaval and impoverishment may indirectly increase children's risk for psychopathology by undermining family dynamics (Conger & Conger, 2002; Conger et al., 2002). Empirical tests of the family stress model have shown that low income, financial instability, or economic problems are associated with lower levels of marital quality (e.g., Amato, Booth, Johnson, & Rogers, 2007; Dakin & Wampler, 2008; Falke & Larson, 2007) and child adjustment (e.g., Ackerman et al., 1999; Conger & Conger, 2002; Conger, Conger, Matthews, & Elder, 1999). Process-oriented research has also demonstrated that socioeconomic strain may undermine child coping with stress through its association with family conflict (e.g., Conger & Donnellan, 2007; Wadsworth & Compas, 2002). In signifying a complementary set of processes, other socio-ecological models have theorized that neighborhood and community characteristics play a critical role in shaping family processes that are relevant to children's concerns about safety and security (Cummings, Goeke-Morey, Schermerhorn, Merrilees, & Cairns, 2009; Margolin & Gordis, 2000; Martinez & Richters, 1993). Experiences with community violence and chaos are relatively common in the lives of families both in the U.S. and the broader world (Barber, 2008; Feerick & Prinz, 2003; Margolin & Gordis, 2000). Exposure to high levels of community and political violence place families at greater risk for high levels of conflict and a lack of cohesion (Cooley, Turner, & Beidel, 1995) and heightened risk for children's maladaptive functioning (Bradley & Corwyn, 2002; Lynch & Cicchetti, 1998).

Although research has documented the prevalence and negative family repercussions of community violence and socioeconomic difficulties, little is known about how family and economic factors operate jointly to alter child coping and adjustment. Process-oriented accounts delineating the role of children's emotional security within ecological models may be useful in advancing an understanding of precisely how and why the confluence community and family adversity may undermine child adjustment (Cummings & Davies, 2010; Cummings et al., 2009). As a primary hypothesized pathway, these frameworks postulate that community violence and socioeconomic problems may increase insecurity in the interparental relationship and ultimately its effects on child psychopathology by taxing interparental resources in ways that increase destructive interparental conflict and discord. Research by Cummings and colleagues has demonstrated that children's emotional security in various family relationships served as unique mediators between community violence exposure and their adjustment problems (e.g., Cummings et al., 2009, 2010a, 2010b). In testifying to the value of distinguishing between different forms of community violence and their implications for family violence, this programmatic work has shown that sectarian violence (i.e., between ethnic, religious, or cultural groups) is a more robust predictor of family and child functioning than other forms of violence. Consistent with the multiple pathways outlined in their socioecological model, their findings indicated that sectarian violence was related to children's emotional insecurity indirectly through its association with the greater interparental conflict. Insecurity, in turn, was associated with children's increased risk for internalizing symptoms (e.g., Cummings et al., 2010b).

Socioeconomic and community factors may not only leave indelible imprints on children by altering the very family dynamics that impact child security, but also by serving as conditions that regulate or modify mediational pathways of security (Cummings & Davies, 2010). For example, exposure to socioeconomic difficulties or community discord may prime the social defense system, resulting in high sensitivity to the subsequent deleterious effects of exposure to interparental conflict. Consistent with this premise, research has documented associations between ecological sources of stress (e.g., socioeconomic difficulties, community violence) and children's concerns about their security in family and extrafamilial contexts (e.g., Cummings et al., 2010b, 2011). However, a necessary condition for supporting this hypothesis involves demonstrating that the exposure to adversity in ecological settings is a moderator that magnifies the role of interparental conflict as a predictor of children's insecurity. Thus, future research is required to fully test this hypothesis. In providing a complementary perspective that emphasizes the operation of resilience in the face of risk conditions, it is also plausible that support and cohesion in the neighborhood (e.g., caring, reliable adult) or community (e.g., school) settings may interrupt the pathogenic processes set in motion by insecurity. For example, connection with caring adults in the community may provide the structure necessary for insecure children to accomplish goals organized by the other ethological systems (e.g., exploratory, affiliative, caregiving) and thereby may promote desirable outcomes.

Cultural Contexts

Investigations on children's emotional security have primarily focused on White populations within the United States. In the rare cases in which research samples evidenced appreciable diversity in race and ethnicity, studies typically ignore these characteristics in their conceptual and analytic approaches to testing processes models. Overcoming the dominance of Eurocentric theory and research has been highlighted as a primary goal for the field of developmental psychopathology (Garcia Coll, Akerman, & Cicchetti, 2000) and continues to be raised as a significant issue in the literature on emotional security theory (Cummings & Davies, 2002; 2010). In spite of these recommendations, limited progress has been made in integrating the study of race, ethnicity, or culture in tests of emotional security theory. Substantiating the urgency of this issue, growing Latino and African American populations in the United States are proposed to continue increase substantially for the next half century (Flores et al., 2002; U.S. Census Bureau, 2012). Moreover, ethnic and racial minority children continue to face significant challenges and risks (Kerr, Beck, Downs Shattuck, Kattar, & Uriburu, 2003; McLoyd, Harper, & Copeland, 2001). For example, African-American families are at increased risk for interparental discord and dissolution compared with European American families (McLoyd, Harper, & Copeland, 2001).

Integrating emotional security theory into a broader framework that systematically considers race, ethnicity, and culture as key processes requires consideration of the potential value of two different models: (1) ethnic equivalence and (2) cultural values (Lamborn & Felbab, 2003). Whereas an ethnic equivalence orientation yields predictions that the mediational process associations involving children's insecurity will be comparable across ethnic, racial, and cultural groups, cultural value models theorize that culture may alter the mediational pathways of emotional security. The few studies comparing the relative viability of these models have yielded inconsistent findings. In support of cultural value approaches, Parke and colleagues (2004) reported that interparental conflict was a significantly stronger predictor of psychological problems for Mexican-American children compared to White samples. Similarly, Cummings, Wilson, and Shamir (2003) reported that interparental hostility was more strongly associated with adjustment problems in Chilean children than in American children. However, American children exposed to interparental violence were significantly more vulnerable to psychopathology than were Chilean children. In adding to the inconsistencies, other studies have reported no significant differences between non-Latino and Latino samples in associations between interparental conflict and negative child outcomes (Buehler & Gerard, 2002; Stutzman et al., 2011). Examinations of racial differences in the risk posed by interparental conflict have also yielded comparable sets of complex results. For example, Nievar and Luster (2006) found that associations between interparental conflict and child adjustment problems were significant for non-Latino White families but not for African American families. Conversely, other findings have indicated that associations between interparental conflict and child psychopathology were comparable for married White and African American families (Krishnakumar, Buehler, & Barber, 2003). Thus, the small corpus of inconsistent findings does not provide evidence that substantially favors either the ethnic equivalence or cultural values models.

Even less is known about whether the mediational role of emotional security varies significantly as a function of race or ethnicity. Empirical tests of emotional security as

a mediator have yet to be directly conducted with Latino families. However, at this early juncture, the scant findings suggest that the mediational pathways involving family conflict, emotional security, and child adjustment evidence more similarities than differences across racial and ethnic groups. For example, the predictive role of interparental conflict in models of perceived threat appears to be similar in Mexican American and European American families (Tschann Flores, Pasch, & Marin, 1999). Similarly, in the only direct analysis conducted on race as a moderator of children's emotional security, El-Sheikh and colleagues (2008) reported that mediational pathways between interparental conflict, children's emotional security, and their adjustment problems did not vary for African American and White families. Further highlighting the generalizability of the findings across different races, research with predominantly Black, impoverished families have demonstrated that emotional security mediates associations between destructive interparental conflict and children's psychological difficulties (e.g., Davies, Cicchetti, & Martin, 2012; Davies, Martin, & Cichetti, 2012; Davies, Sturge-Apple, Cicchetti, Manning, & Vonhold, 2012). Thus, although it is premature to draw any definitive conclusions about the role of race and ethnicity in models of emotional security, the sparse research findings have documented the generalizability of emotional security as a mediator for families with different racial and ethnic backgrounds.

Predictions regarding race and ethnicity as moderators are commonly predicated on the assumption that they reflect fundamental differences in cultural processes. However, wide and meaningful individual differences exist within racial and ethnic groups in the adoption of cultural beliefs and practices. For example, in a sample of Mexican American families, individual differences in maternal and paternal endorsement of familism each uniquely predicted lower levels of interparental conflict (Taylor, Larsen-Rife, Conger, & Widaman, 2012). Moreover, race and ethnicity co-occur with other ecological characteristics (e.g., economic factors, community processes, family structure, racial discrimination), which may, themselves, serve as unique regulatory conditions in models of emotional security. Thus, although race and ethnicity may offer expedient starting points for the study of culture, they are, at best, unrefined markers of more significant psychocultural processes. To address this significant barrier, a critical step in advancing culturally sensitive models of emotional security is to understand how specific cultural beliefs and practices may shape the meaning of family adversity and introduce distinctive constellations of protective and patenting factors (Garcia Coll et al., 2000; McLoyd et al., 2001; Tschann et al., 2009).

In facilitating this research direction, McLoyd et al. (2001) proposed that the tendency for ethnic and racial minority families to place greater value on extended family and extrafamilial networks of support may actually serve to attenuate the risk trajectories of children from high conflict homes (Nievar & Luster, 2006). Extended kinship networks may not only be an adaptive strategy for minority families to cope with considerable social and economic disparities (Hatchet & Jackson, 1993; McAdoo, 1978; Wilson, 1989), but they may also help to minimize the repercussions of interparental conflict for children. From an emotional security perspective, interparental conflict may engender fewer child concerns about security when it occurs within a larger unit of family members. Moreover, the larger number of adult and older sibling caregivers in these families may provide children who do experience insecurity with the emotional support and guidance necessary to promote resilient developmental outcomes. In support of this hypothesis, research has demonstrated that kinship emotional support, advice, and counseling had positive effects on family relationships, parental psychological wellbeing and adolescent adjustment (Taylor, Seaton, & Dominguez, 2008).

Capturing the traditional cultural values and practices of Latino families may also advance tests of the cultural specificity and generalizability of emotional security as a mediator of interparental conflict. Greater emphasis on the importance of the family over individual differences (i.e., familism) and child dutifulness and deference to parents (i.e., respeto) may specifically change the meaning of interparental conflict for children and families who follow conventional Latino traditions (Halgunseth, Ipsa, & Rudy, 2006; Lindahl, Malik, Kaczynski, & Simons, 2004). Due to the high value placed on the family and the maintenance of order and harmony, exposure to high levels of interparental conflict may potentiate children's concerns about their security and safety in families endorsing higher levels of familism and respeto. In supporting the plausibility of this prediction, Cummings and colleagues (2003) found that Chilean children responded to videotaped simulations of unresolved conflict between adults with greater distress and more negative expectations about interadult relationship quality than did American children. However, the high value placed on the family may predispose family members to provide support and protection to children who experience insecurity, thereby counteracting any vulnerability to psychopathology. As an alternative hypothesis, differences between families in the adoption of

Latino cultural traditions may shape how children express their insecurity rather than directly amplify or dilute emotional security as an explanatory mechanism. For example, proper respect to parents and broader devotion to the family may prompt children to suppress any overt, blatant expressions of distress and insecurity in favor of more veiled displays of fear and wariness.

Peer Relations

Peer relationships represent increasingly important sources of both opportunity and challenge as children age and attempt to navigate their complex social world (Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006; Rubin, Bukowski, & Parker, 2006). In highlighting the interplay between multiple interpersonal contexts, research has linked interparental conflict with poor peer relationships and maladaptive social behavior (e.g., more aggression, less prosocial behavior) (Gottman & Katz, 1989; Kouros, Cummings, & Davies, 2010; Lindsey et al., 2009; Lindsey, Colwell, Frabutt, & MacKinnon-Lewis, 2006; McCoy et al., 2009; Stocker & Youngblade, 1999). Consistent with this research, the ethological analysis of developmental cascades highlights how the SDS can undermine peer relationships processes through the proliferation of defensive analogs into extrafamilial settings and reductions in the salience of the affiliative system as an organizer of behavior (see Developmental Cascade Mechanisms section). Nevertheless, it is plausible that some dimensions of peer and friendship quality may serve as moderators of the mediational role of emotional security. Although some studies have failed to identify peer relationship characteristics as moderators of interparental conflict (e.g., Jenkins & Smith, 1990), research has shown that children's perceptions of peer availability and active solicitation of friendship support reduced their likelihood of exhibiting adjustment problems in the context of heightened interparental conflict (Rogers & Holmbeck, 1997). Moreover, this protective function has been documented across a range of peer relationship experiences including friendship quality, sociometric popularity, and peer support (Wasserstein & LaGreca, 1996; Xin, Chi, & Yu, 2009). In highlighting the potentiating role of friendship problems, there is also some evidence to indicate that the magnitude of the linkage between interparental conflict and psychopathology was increased for adolescents with low quality friendships (Larsen, Branje, van der Valk, & Meeus, 2007).

However, challenges and barriers remain in identifying how peer and friendship characteristics may inform an understanding of children's coping with interparental conflict. Empirical inconsistencies are evidenced by null findings on the moderational role of peer relationship qualities in models of interparental conflict (e.g., Jenkins & Smith, 1990). A large part of this gap in knowledge may be due to the failure to examine how peer and friendship experiences alter the unfolding cascade of processes in the pathways between interparental conflict and children's health outcomes. Many peer relationship and friendship experiences may buffer children from the negative consequences of exposure to interparental conflict by offering an alternative source of support and warmth. Yet, without theory, there is an insufficient base to identify the precise point in the cascade at which friendships and peer relationships serve to interrupt the unfolding pathogenic processes experienced by children from high conflict homes. In offering some conceptual direction toward this goal, EST-R proposes that the moderating roles of friendship and peer relationships are most pronounced in the second link in the mediational pathways involving interparental conflict, emotional security, and child functioning. A primary hypothesis is that supportive friendship and peer relationships may protect children who have concerns about security from developing psychopathology. From a process-oriented perspective, supportive, prosocial peer networks may counter the tendency of the SDS system to undermine the functioning of the affiliative system and propagate defensive analogs and representations across multiple social contexts. Conversely, histories of peer rejection or involvement with antisocial peers may catalyze the processes by which children's insecurity increase their psychopathology by magnifying their experiences with threatening social contexts and synergistically undermining the approach (e.g., affiliative, caregiving) systems. Consistent with many of the other dimensions of contextual characteristics in emotional security theory, efforts to understand how peer relationship processes may inform an understanding of the antecedents and consequences of emotional insecurity are still in their scientific infancy. Therefore, future research is critical for testing key predictions derived from EST-R.

DEVELOPMENTAL PARAMETERS

Integrating the psychopathology component and its accompanying consideration of risk and protective processes within the "developmental" element of developmental psychopathology requires understanding of security as a dynamic process over broad spans of time. Consistent with this theme in developmental psychopathology, an ultimate goal of EST is to characterize how children's concerns

about emotional security operate within a broader model of the shifting constellation of risk and protective processes across specific developmental periods. Although achieving this complex objective requires multiple approaches and steps, it can be concisely divided into four primary scientific directions. As outlined in Path 5 of Figure 6.1, these directions include (1) delineation of transactions of children's insecurity in broader developmental contexts; (2) characterization of the history and duration of experiences in understanding pathways of insecurity; (3) the significance of sensitive periods in understanding emotional insecurity; and (4) identification the developmental trajectories of insecurity.

Transactions of Insecurity

Developmental psychopathology strongly emphasizes that child adaptation is an evolving product of the interactions between an active, changing child within a dynamic, multilayered ecological context (Sameroff & MacKenzie, 2003). The active role of children specifically translates to the assumption that the interplay between family and child characteristics is reciprocal in nature over time. In support of this premise, there is growing evidence that children's functioning is both a precursor and product of interparental conflict. For example, Jenkins, Simpson, Dunn, Rasbash, and O'Connor (2005) found that child externalizing problems subsequently increased arguments between parents two years later, particularly in families facing additional challenges (e.g., children with high externalizing symptoms, stepfamilies). Likewise, Cui, Donnellan, and Conger (2007) examined the reciprocal interplay among interparental conflict over child-rearing and adolescent symptomatology in a series of cross-lagged autoregressive analyses over three time periods each spaced one year apart. Consistent with transactional models, adolescent depressive and delinquency symptoms were identified as both outcomes and predictors of interparental conflict.

These initial findings point to the plausibility of viewing child functioning as an antecedent and consequence of interparental relationship dynamics within a spiraling bidirectional cycle. However, little is known about how children's concerns about security may operate in shaping the course of interparental conflicts. Toward further advancing precision in the domain of children's responses, EST specifically proposes that the different forms of reactivity assume distinct roles in the unfolding bidirectional influences between interparental conflict and children's emotional insecurity (Davies & Cummings, 1994; Schermerhorn, Cummings, DeCarlo, & Davies, 2007). In the early stages of the transactional process, EST proposes that exposure to interparental conflict increases children's concerns about insecurity in the form of negative emotional reactivity. Negative emotional reactivity, in turn, increases the likelihood that children may increase their efforts to interrupt the course of escalating conflict before it substantially threatens the family system (Davies & Cummings, 1994). Relative to veiled forms of fearful distress (e.g., avoidance, freezing), more demonstrative displays of conflict reactivity manifested in involvement, mediation, or disruptive behavior are more salient to parents who are otherwise occupied with their ongoing conflict and, as a result, may have a particularly potent influence on the course of interparental disagreements. In keeping with this premise, Emery (1989) proposed a transactional cycle of effects between children and the interparental subsystem that designates children's coercive reactions to conflict as primary architects of conflict. In the initial series of unfolding processes, children respond to witnessing violence with higher levels of distress that, in turn, precipitate specific attempts on the part of children to alleviate their distress through disruptive (e.g., temper tantrums) behaviors. At the subsequent phases of this reciprocal cycle, children's misbehavior is posited to broaden and intensify in subsequent conflicts because it serves a function of distracting parents from engagement in the ongoing, aversive conflict (Davis, Hops, Alpert, & Sheeber, 1998).

Questions remain as to whether the effectiveness of children's forms of involvement in reducing conflict is sustained over broader developmental spans of days, months, or years. Rare empirical inquiries into this issue highlight the possibility that it may depend on the specific approach children use to regulate the conflict (Schermerhorn et al., 2005, 2007). Consistent with EST, these studies have shown that interparental conflict increases tendencies to exhibit forms of involvement through its association with children's negative emotional reactivity to conflict. Although forms of involvement, in turn, predicted subsequent changes in the frequency of destructive conflicts over a two-year period, whether conflicts subsided or improved varied as a function of the form of involvement (Schermerhorn et al., 2007). Higher levels of coercive involvement (e.g., yelling, causing trouble) were associated with increases in interparental conflict over a two-year span. Thus, the proposed utility of involvement in reducing contemporaneous bouts of interparental conflict was paradoxically related to greater long-term disruptions in the interparental relationship. Conversely, children's greater use of facilitative intervention behaviors

designed to diminish conflict was associated with decreases in interparental conflict over two years.

Although the mechanisms for these differential associations have yet to be identified, transactional models have posited that disruptive forms of involvement are part of a coercive family process that, while temporarily alleviating conflict, ultimately increase distress, ill-will, and hostility in both the children and parents (Emery, 1989; Patterson, 1982; Schermerhorn et al., 2007). In contrast, when children exhibit more constructive, facilitative forms of involvement, parents may be in a more reflective emotional state that allows them to sensitively respond to their children's burdensome involvement by working together in the long run to reduce their disagreements. Regardless of the explanatory mechanisms underlying the different interparental sequelae of children's forms of reactivity, advancing precision in charting transactional processes will require careful consideration of how the reciprocal interplay between child reactivity to conflict and interparental conflict over time may shift progressively over time (e.g., minutes, days, months, years). In addition, future research would be facilitated by considering the possibility that the impact of signs of child insecurity on interparental conflict may differ in magnitude or even quality across dimensions of interparental conflict. From a family systems perspective, child-related conflicts reflect perturbations in the coparental relationship, a subsystem that is theorized to be more susceptible to variations in child behavior than the more encapsulated marital subsystem (Feinberg, 2003; McHale, 1995; Lindsey, Caldera, & Colwell, 2005). Moreover, frequent disagreements about the children commonly signify extensive proliferation of stress across family subsystems (Davies, Cummings, & Winter, 2004; Kretchmar & Jacobvitz, 2002). Consequently, children's insecure reactions may be more strongly related to parental disagreements over child-related issues than conflicts about marital or adult issues. Although research has yet to systematically test children's insecurity as a predictor of different forms of interparental conflict, children's psychological difficulties have been shown to predict greater conflict parental conflicts only for arguments centered on child-related issues (Cui et al., 2007; Jenkins et al., 2005).

Experiential Histories

Developmental psychopathology is also a useful heuristic for examining how early histories of adversity may inform an understanding of children's later adaptation to interparental conflict (Davies, Sturge-Apple, Bascoe, & Cummings, 2014). According to the definition of hierarchical motility, continuity in functioning may result from the tendency for older psychological patterns to be integrated in subsequent forms of functioning. Even after considering subsequent family experiences between earlier adaptation and subsequent outcomes, hierarchical motility models translate to the assumption that early experience has a unique and persistent impact on developmental sequelae (Fraley, Goisman, & Haltigan, 2013; Roisman, Collins, Sroufe, & Egeland, 2005; Sroufe, Egeland, & Kreutzer, 1990). In the context of emotional security, this assumption raises the plausible hypothesis that earlier histories of insecurity in the interparental relationship will continue to predict subsequent trajectories later in childhood and adolescence even after taking into account contemporaneous experiences with insecurity and family adversity.

Longitudinal studies have shown that emotional insecurity is a persistent predictor of children's maladjustment across developmental periods. For example, Kelly and El-Shiekh (2013) reported that children's insecurity in preadolescence and early adolescence was associated with greater sleep problems three years later in middle adolescence. In another study, children's insecurity in second grade was associated with increases in children's internalizing and externalizing symptoms five years later in seventh grade (Cummings et al., 2012). Although these investigations provide preliminary support, they were not designed to test the enduring effects hypothesis. Because neither study incorporated family and insecurity experiences that were concomitant with the adjustment outcomes, they cannot rule out the possibility that contemporaneous adversity fully mediated links between early insecurity and child adjustment. In addressing this gap in the literature, a recent investigation reported that child interview assessments of their insecurity over a two year span in the early elementary school period uniquely predicted a multi-informant assessment of their adjustment difficulties six years later in adolescence even after controlling for concurrent and prior adolescent emotional insecurity, adolescent exposure to interparental conflict, contemporaneous family socioeconomic background, and children's sex (Davies, Sturge-Apple, Bascoe, & Cummings, 2014).

In building on this small corpus of research, key research questions still remain. What is the unique set of pathogenic processes set in motion by childhood histories of insecurity that were not accounted for by more temporally proximal experiences with interparental adversity during adolescence? As children assume greater social roles and challenges during the early school years, might this be a sensitive period for increasingly utilizing ways of

responding to family adversity (i.e., defensive analogs) as a guide in coping with complex or stressful social contexts (e.g., peer interactions)? If this developmental cascade process is delineated in future research, it may specifically provide clues into how defensive strategies displayed by insecure children may take on a "life of their own" by evolving into intractable patterns of heightened sensitivity to extrafamilial stressors and, in the process, uniquely impact their later adjustment (Bascoe et al., 2009). Likewise, it is possible that the substantial increases in social perspective taking capacities during the early school years precipitated new ways of responding to interparental conflict by sensitizing children to concerns about the safety of their caregivers (Cummings & Davies, 2010). A developmental psychopathology perspective also serves as a heuristic for proposing that insecure histories earlier (e.g., toddler or preschool period) or later (e.g., adolescence) in the life span may engender unique mechanisms that generate enduring effects of insecure experiences at different developmental periods. For example, EST-R proposes that insecurity in early childhood is largely characterized by preverbal, sensory motor patterns of emotional reactivity that are largely inaccessible to conscious processing (Davies & Sturge-Apple, 2007). Thus, the encapsulated, automatic forms of defending against threat may incur psychological burdens on children across subsequent developmental periods by impeding processing, assimilation, and integration into patterns of effortful, regulated engagement with the environment (Johnston et al., 2009).

Our developmental model of security further posits that histories of insecurity and experiences with family discord modify and shape the mediational role of emotional security (Davies, Sturge-Apple, Bascoe, & Cummings, 2014). Insecure histories may potentiate either part of the subsequent mediational cascades involving insecurity, including associations between (a) interparental conflict and emotional insecurity and (b) insecurity and the ensuing probability of developing psychopathology. Prior experiences with family adversity (e.g., interparental conflict earlier in the life span) and psychological problems are also proposed to operate in similar roles as moderators of the mediational role of emotional insecurity. For the sake of illustration, the remainder of this section addresses the legacy of earlier insecure experiences as a moderator of the association between interparental conflict and children's subsequent sense of security. Prevailing models in developmental psychopathology have offered some guidance on three plausible ways early adversity primes children to become increasingly sensitive to subsequent stress. As shown in Figure 6.5a, the stress amplification or dual-risk model proposes that early adversity serves as a risk factor that becomes disproportionately magnified following exposure to subsequent stressful experiences (Rudolph & Flynn, 2007). Support for this model in EST would be evidenced by findings indicating that childhood histories of insecurity amplify the associations between interparental conflict (i.e., the stressful event) and adolescent emotional insecurity (Davies et al., 2006). The ordinal nature of the interaction depicted in Figure 6.5a further illustrates that children with insecure histories will exhibit relatively higher vulnerability to subsequent problems even when interparental conflict is low or benign.

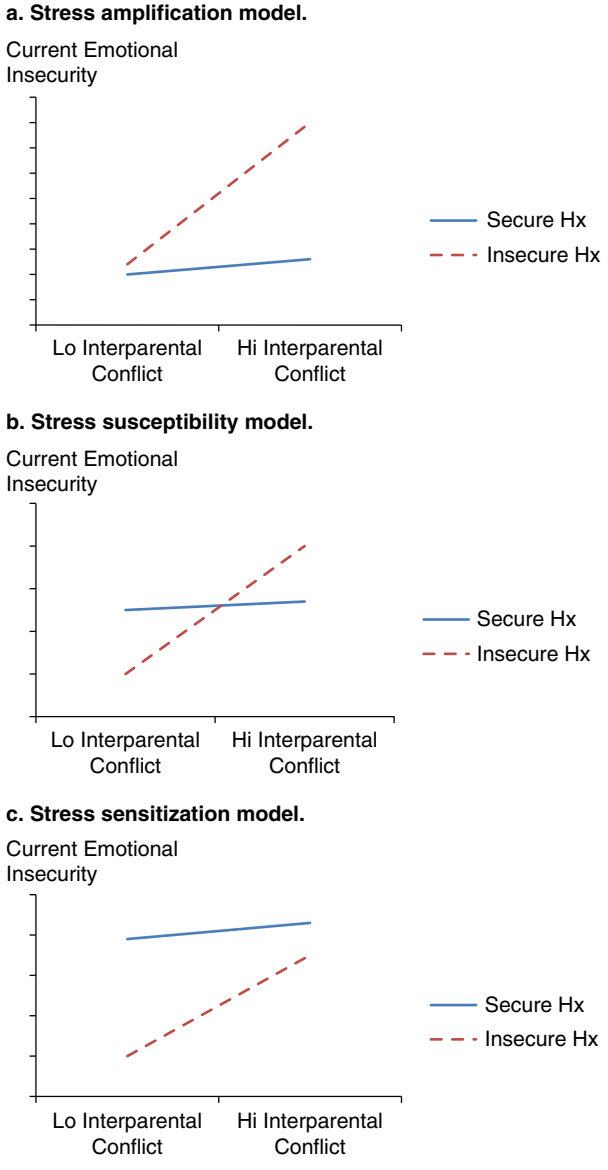

Figure 6.5 Models in developmental psychopathology. See footnote 1.

According to the second conceptualization, a stress susceptibility model postulates that children with histories of insecurity are more reactive to subsequent interparental conflict for better or for worse. Biological sensitivity to context theory and the adaptive calibration model both propose that children's early exposure to stress may amplify their biological and stress sensitivity to challenges in a way that may increase their openness to subsequent environmental input (Del Giudice et al., 2011; Ellis, Essex, & Boyce, 2005). Translated to EST, the dotted line in Figure 6.5b demonstrates that increases in destructive interparental conflict predict progressively higher levels of emotional insecurity for children with prior adverse histories of insecurity. Thus, similar to the stress amplification conceptualization, the stress susceptibility model hypothesizes that children with histories of insecurity suffer disproportionately in the face of high interparental conflict (i.e., dotted line) relative to their counterparts with secure histories (i.e., solid line). However, as the primary locus of distinction between the two models, the stress susceptibility model postulates that the greater sensitivity to environmental cues exhibited by children with insecure histories is manifested in substantially fewer concerns about their security in the context of more benign and constructive conflicts between parents. In sum, synthesis of stress susceptibility models within EST yields the prediction that insecure histories increase children's sensitivity to interparental relationship quality such that they fare substantially better than normal in benign interparental contexts, but suffer disproportionately worse fates in the face of high interparental conflict.

As a third form of moderation, the risk sensitization model proposes that histories of vulnerability lower children's subsequent thresholds of sensitivity to family difficulties (Harkness, Bruce, & Lumley, 2006; Rudolph & Flynn, 2007). Through this kindling process (Monroe & Harkness, 2005), the level of family adversity necessary to evoke children's psychological difficulties becomes progressively more mild. Thus, in models of security, the hypersensitivity of children grappling with earlier vestiges of insecurity is reflected in experiences of greater security concerns than their counterparts with secure histories only at low or mild levels of interparental conflict (Figure 6.5c). Conversely, exposure to frequent, destructive forms of interparental conflict (i.e., high levels) poses such a palpable threat that children have a general tendency to experience insecurity regardless of their prior developmental histories.

At this early stage of research, it is premature to draw firm conclusions about the role of early histories of adversity in altering the mediational pathways of children's emotional insecurity. However, a recent study provides some preliminary support for the fruitfulness of examining histories of insecurity for understanding how children contend with later conflicts (Davies, Sturge-Apple, Bascoe, & Cummings, 2014). Moderator findings specifically indicated that children who experienced high levels of insecurity during the early elementary school years exhibited greater sensitivity to subsequent exposure to interparental conflict in a for-better-or-for-worse manner predicted by the stress susceptibility framework. On the worse side of the plot (Figure 6.5b), adolescents with childhood histories of insecurity evinced greater emotional insecurity in contexts of high interparental conflict than teens with secure histories. Conversely, on the better side of the plot, higher childhood insecurity was actually associated with lower adolescent insecurity when interparental conflict was low. Testing the specificity and generalizability of these results across developmental periods, types of experiential histories, and forms of sequelae will be an important direction for future research.

Sensitive Periods

EST posits that emotional security should be associated with psychological adjustment across the lifespan. However, this moderate stability is also proposed to occur in the context of developmental transformations and burgeoning stage-salient challenges during the course of childhood and adolescence that may serve to attenuate or intensify the pathways among interparental conflict, child emotional insecurity, and adjustment (Cummings & Davies, 2010). Thus, advances in understanding emotional security in developmental context will require examining possible sources of developmental stability and change. The most common approach to addressing this issue is to focus on age as a marker of developmental differences between children. However, the analyses generally indicate that children in any one age group or developmental period do not evince heightened susceptibility to interparental conflict (Buehler, Anthony, Krishnakumar, & Stone, 1997; Buehler et al., 1998; 2007; Gerard & Buehler, 1999).

Difficulties in identifying periods of developmental susceptibility may result from the tendency to focus on associations between interparental conflict and psychopathology without consideration of how children cope in high conflict homes. For example, null findings on age as a moderator in a previous meta-analysis may be an artifact of the selective focus on examining child internalizing and externalizing symptoms as outcomes of interparental

conflict (Buehler et al., 1997). A more nuanced analysis of the unfolding processes in links between interparental conflict and child psychological symptoms raises the possibility that age may play a more significant role as a moderator of the mediational role of emotional security. Simply examining age as a moderator of associations between interparental conflict and child outcomes may miss the possibility that age-linked vulnerabilities shift across the cascade of insecurity. For example, a developmental period evidencing a potentiation in associations between interparental conflict and child insecurity may actually be counteracted by its protective function in the subsequent pathway from insecurity to adjustment problems. For example, meta-analytic results indicated that associations between interparental violence and children's distress reactions to simulated conflict were most pronounced for preschool girls in comparison to older children (Kitzmann et al., 2003). Conversely, in a meta-analysis investigating the second part of the mediational pathway, proxies of insecurity (e.g., negative emotional reactivity, perceived threat) were the weakest predictors of internalizing and externalizing symptoms for younger children in samples ranging in age from five to nineteen (Rhoades, 2008). However, in adding to the complexity, these patterns are not always replicated in studies that specifically utilize assessments of insecurity in the context of actual interparental conflicts. For example, running counter to the meta-analytic results, Cummings and colleagues (2006) found the magnitude of the link between interparental conflict and emotional security was significantly stronger for older children in a sample of 8- to 17-year-olds.

Given the nagging empirical inconsistencies, any comprehensive developmental analysis must drill to a conceptually deeper level than age or developmental period. Age is a proxy for a complex undercurrent of social, cognitive, emotional, and physiological processes that directly alter children's coping and adjustment in the face of interparental conflict. Due to the wide-ranging developmental changes across childhood, emerging psychological or physiological vulnerabilities at any one age may be offset by a comparable set of buffers and competencies. For example, interparental conflict may more easily overwhelm the regulatory capacities of preschool children. In comparison to older children, preschool children respond to conflict between adults with greater fear, distress, and threat, poorer perceived competence, and limited abilities to utilize coping strategies (e.g., Cummings, Vogel, Cummings, & El-Sheikh, 1989; Davies, Dumenci, & Windle, 1999; El-Sheikh & Cummings, 1995; Grych, 1998). Although this evidence suggests that the mediational role of insecurity may be particularly pronounced for younger children, their vulnerabilities may be offset by their lower sensitivity to adult problems and diminished social perspective taking abilities (Davies et al., 1999).

Conversely, adolescent concerns about their security and their pathogenic implications may be amplified by their greater awareness of subtle interparental difficulties, stronger dispositions to mediate conflicts, and their longer histories of exposure to interparental conflict (Cummings, Ballard, El-Sheikh, & Lake, 1991; Davies, Myers, & Cummings, 1996; Davies et al., 1999). Underscoring the salience of another developmental period, evolutionary models highlight the juvenile period (i.e., middle childhood) as a potential sensitive period or "switch point" for the translation of early stress experiences into specific strategies for regulating stress and coping with threat and conflict (Del Giuidice, Angeleri, & Manera, 2009; Del Giudice & Belsky, 2011). However, in the context of interparental conflict, these adrenarche-linked increases in children's susceptibility may be counterbalanced by tendencies to exhibit more effective emotion regulation and coping strategies than younger children and diminished sensitivity to subtle interpersonal problems relative to adolescents. Thus, no one age group or developmental period appears to be uniformly more vulnerable to experiencing insecurity and adjustment problems in the face of interparental conflict. Rather, it is likely that each age ushers in specific vulnerabilities that are counteracted by newly emerging developmental competencies and buffers.

Our analysis collectively begs the question of whether there may be an alternative way of comprehending how insecurity is linked with these age-graded vulnerabilities and competencies. The substantive emphasis on stage-salient or developmental tasks in models of developmental psychopathology offers a fruitful approach to addressing this knowledge gap (Cicchetti, 1991; 1993; Sroufe & Rutter, 1984). Within these models, development is conceptualized as a series of stage salient tasks that emerge as prominent in a particular developmental period and subsequently remain important throughout the lifespan. At each developmental stage, children are faced with resolving a number of significant tasks across multiple domains of functioning (Chase-Lansdale, Wakschlag, & Brooks-Gunn, 1995; Cicchetti, 1991; Sroufe & Rutter, 1984). Table 6.3 provides a listing of examples of major developmental challenges from infancy through adolescence. Given that these tasks are already challenging in themselves, their successful resolution may be particularly sensitive to the risk associated with children's concerns about their security (Davies et al., 2006). Moreover,

TABLE 6.3 Developmental Challenges Faced by Children From Infancy Through Adolescence

Developmental period	Stage-salient challenges
Infancy	Modulation of arousal
	Physiological regulation
	Harmonious, synchronous interactions with caregivers
	Secure attachments with primary caregivers
	Interpersonal trust
Toddler	Awareness of self as distinct
	Exploration of social and object worlds
	Emotion regulation and management
	Awareness and responsivity to standards
	Mastery, persistence, and problem solving
	Autonomy
	Understanding of internal emotion states of others
Preschool	Flexible self-control
	Self-reliance
	Initiative
	Awareness of social roles
	Gender role development
	Establishing effective peer relations
	Empathy and prosocial behavior
Childhood	Social understanding (equity, fairness)
	Gender constancy
	Same-sex friendships
	Peer relations and reputation
	Sense of industry (competence)
	Social agency
	School adjustment
	Internalization of standards of conduct
Adolescence	Flexible perspective taking
	Abstract thinking and moral reasoning
	Reconciling ideal world with real world
	Loyal same-sex friendships
	Establishing romantic relationships
	Balancing emotional autonomy with relatedness to parents
	Identity development
	Interpersonal intimacy
	Sexuality
	Risk management (e.g., substance use, sexual promiscuity)

because mastery of early developmental tasks serves as building blocks for successfully achieving subsequent tasks, difficulties in resolving the predominant challenges at one period in development are theorized to lay the foundation for subsequent problems mastering stage-salient tasks that collectively increase children's risk for mental health problems over time.

In the context of a stage-salient task framework, insecurity may be hypothesized to increase vulnerability to psychopathology by undermining children's progress in resolving distinctive developmental challenges within well-defined sensitive periods. For example, as a first test of stage-salient task functioning in elucidating the sequelae of insecurity, Davies, Manning, and Cicchetti (2013) reported that toddler insecurity predicted their difficulties resolving stage-salient tasks (i.e., emotion regulation, autonomy, problem-solving) one year later after controlling for initial stage-salient task performance. Stage-salient task difficulties, in turn, were associated with increases in children's behavior problems one year later. Table 6.3 may be a useful guide for future empirical efforts to identify stage-salient cascade processes involving insecurity. For example, given the importance of physiological regulation and the rapid changes in cardiac functioning related to the regulation of distress during infancy (Bar-Haim, Marshall, & Fox, 2000; Graham, Ablow, & Measelle, 2010), it is possible that insecurity may ultimately confer risk during the first year of life by disrupting physiological reactivity to stress. Likewise, childhood is characterized by numerous social challenges, including establishing and maintaining harmonious relationships with peers and the development of empathy and prosocial behavior strategies (Eisenberg, Fabes, Schaller, & Miller, 1989). Thus, insecurity may be particularly likely to increase children's adjustment problems by disrupting their ability to resolve these challenges (Bascoe et al., 2009; Sroufe, Egeland, & Carlson, 1999).

Developmental Pathways and Trajectories

In conceptualizing development as a product of transactions between a multifaceted, changing child and the multidimensional, dynamic context, developmental psychopathology frameworks commonly assume that there are multiple, diverse developmental trajectories for both family and child functioning (Sroufe, 1997). Accordingly, at the level of child functioning, a critical task is to identify the multitude of developmental pathways by examining interindividual differences in intraindividual change. At the level of family functioning, a central objective is to understand children's functioning within a developmental-contextual framework that underscores the continuity, variability, and transformation of family processes over time.

Although treatment of interparental conflict as a static, stable trait is common in the literature, a developmental perspective considers risk factors, like interparental conflict, as potentially dynamic processes (Cui, Conger, & Lorenz, 2005; Cummings & Davies, 2010; Fincham, Grych, & Osborne, 1994). Conceptual distinctions between enduring and transient risk factors within developmental psychopathology models provide a useful blueprint in advancing an understanding of how children adapt to family contexts (Cicchetti & Toth, 1995). In signifying

different ends of a temporal risk continuum, enduring factors are defined by their relatively long life span, whereas transient factors refer to temporary conditions. Because different couples face unique arrays of dispositions, challenges, and stressors, it is likely that there is considerable interfamilial variability in the enduring or transient nature of interparental conflict. Thus, one derivative hypothesis in EST is that the degree of risk posed by destructive interparental conflict for children's safety and well-being is a direct function of the chronicity of their exposure to parental problems. By the same token, EST also posits that this general rule of thumb only applies for children who are experiencing comparable forms and levels of interparental conflict. Consequently, under some conditions, the enduring bouts of interparental discord may not be universally more powerful than transient bouts of conflict in predicting child problems, especially if transient conflicts are reflecting severe forms of destructive conflict (e.g., violence) (Cummings & Davies, 2010).

Propositions in EST-R may offer a more nuanced perspective on the interplay between temporal dimensions of interparental conflict and children's insecurity. If human response systems are guided by a complex set of algorithms to cope with the multiplicity of prehistoric environmental niches as evolutionary accounts postulate (Klein, Cosmides, Tooby, & Chance, 2002), then the association between duration of destructive interparental conflict and child reactivity may not be linear in form as earlier sensitization models postulated. Developmental-evolutionary models specifically postulate that variability in environments with high fitness implications (e.g., threat, reproduction) has been associated with greater developmental plasticity and malleability to subsequent environmental input (e.g., Frankenhuis & Del Giudice, 2012). Thus, rather than proposing that prolonged exposure to relatively unchangeable levels of destructive interparental conflict will progressively increase children's fearful reactivity to later conflicts, EST-R draws on evolutionary models in positing that fluctuations in the balance between destructive and benign forms of interparental conflict over extended developmental periods (e.g., years) may engender maximal sensitization to subsequent conflicts.

How, then, do we reconcile this hypothesis with repeated empirical documentation that recurring exposure to destructive interparental conflict is associated with progressively greater signs of insecurity? Our interpretation is that this is likely an artifact of the tendency to only examine interparental conflict within narrow temporal periods in samples of families who are relatively advantaged (e.g., middle class) and, unlikely, on the whole, to experience highly stable forms of aggression and discord. Although empirical tests have yet to examine whether variability rather than stability of destructive conflict is the key parameter underlying children's sensitization, existing research has produced some promising results. For example, in moving beyond narrow snapshots of interparental functioning to more dynamic assessments of change in children's experiences with destructive interparental conflict, Goeke-Morey and colleagues (2013) reported that changes in destructive conflict in annual assessments over a three-year period continued to predict concomitant increases in children's negative emotional reactivity and threat responses to parental conflict even after taking into account children's average exposure to interparental conflict over the duration of the study.

EST-R eschews the tacit assumption that the sensitization process can be sustained in a constant dose-response fashion over periods over several years. Consistent with the attenuation hypothesis in the psychophysiological literature (Gold & Chrousos, 2002; Susman, 2006), there must be an ill-defined upper limit in experiencing fear and distress that is likely to precipitate qualitative differences in how children respond to subsequent threats in the interparental relationship. EST-R proposes that protracted exposure to high levels of aggression, violence, and intimidation between parents with little source of solace, protection, and support in the family may, initially amplify fear and anxiety as they grapple with concerns about their security. However, over longer developmental histories of exposure to this highly adverse context, children are theorized to develop a "demobilizing" pattern characterized by helplessness, dysphoria, anhedonia, lassitude, and pervasive inhibition of exploratory and affiliative behavior (Davies & Sturge-Apple, 2007). This qualitative shift in behavior is specifically proposed to serve the function of reducing harm by lying low and signaling submissiveness to conspecifics (Gilbert, 2006; Sloman, Atkinson, Milligan, & Liotti, 2002). Moreover, because a "demobilizing" profile is an adaptive solution to a highly stable context that, within our evolutionary past (Del Giudice et al., 2011), commonly signified protracted future exposure to interpersonal violence and threat, it is likely to be highly resistant to modification even with significant changes in constellations of family threat. Thus, in accord with stress autonomy and experiential canalization models in developmental psychopathology (Morris, Ciesla, & Garber, 2010; Sroufe, 1997), it is plausible that the highly automatic and intractable nature of some forms of reactivity to conflict may become

canalized and take on a life of their own, which progressively diminishes their sensitivity to subsequent interparental conflicts.

FUTURE DIRECTIONS

Throughout our discussion of emotional security theory and research, we have attempted to address specific substantive gaps in the literature and their implications for future research. However, it is also important to step back and contemplate broader thematic issues in beginning to formulate an integrative agenda for future research. Toward this goal, the remaining part of this chapter is devoted to sketching some rough blueprints for future scientific work on emotional security theory.

Person-Based Taxonomy

The original version of EST places conceptual emphasis on the hypothesis that indicators within and across the three component processes are interdependent (i.e., intercorrelated), reflecting the common goal of preserving emotional security. Consequently, empirical tests of EST have predominantly utilized variable-based measurement approaches that aggregate different dimensions of conflict reactivity (e.g., distress, vigilance, involvement, negative representations) into a single, additive composite of insecurity. However, questions can be raised about the viability of searching for linear correspondence among the three component processes of emotional security. At an empirical level, the average shared variance among signs of insecurity was modest to moderate in magnitude in a review of existing research (Davies & Martin, 2013). At a conceptual level, the additive approach to combining forms of reactivity into a single composite of insecurity does not fully capture the assumption that emotional security is a dynamic, nonlinear control system. By designating inherently negative types of responding as carrying relatively equal weight as signs of greater insecurity, linear quantitative approaches to assessing security are also inconsistent with the organizational assumption that the meaning of morphologically identical responses to conflict cannot be deciphered unless examined in relation to children's larger constellation of responses (Cummings, 1987; Davies & Forman, 2002; Maughan & Cicchetti, 2002). For example, within the context of high levels of overt emotional reactivity and excessive regulation of conflict exposure, children's low levels of self-reported distress may reflect an insecure strategy of suppressing subjective threat. Alternatively, if low subjective distress occurs in the context of well-regulated concern and low levels of involvement and avoidance, it may be regarded as part of a secure pattern of coping with conflict (Davies & Forman, 2002).

To remedy incongruities between theoretical and empirical approaches to characterizing emotional insecurity, EST-R has recently proposed a person-based taxonomy that is designed to identify the qualitatively different profiles. Each profile possesses unique functional utility in defending against threat under specific family and developmental conditions. Thus, although the SDS is universally designed with the external goal of neutralizing interpersonal threat, an ethological approach assumes that humans adopt a limited number of distinctive subroutines or strategies for achieving this overarching goal that were exquisitely designed, over evolutionary history, to manage and defuse specific configurations of recurring interpersonal threat (Crittenden, Kozlowska, & Landini, 2010; Del Guidice et al., 2011). Likewise, adopting specific strategies to defend against threats is proposed to also advance developmental psychopathology initiatives of more precisely charting the sequelae of coping styles in adverse family environments. Thus, in an attempt to move beyond the nondescript, pathogenic meaning of insecurity in EST and its laundry list of proposed negative outcomes, EST-R is designed to offer greater depth and pinpoint precision in identifying how each pattern or profile of insecurity is associated with a distinctive constellation of developmental vulnerabilities and competencies. In the following sections, we provide a synopsis of the hypothesized form and function of four fundamental social defense strategies and their hypothesized developmental antecedents and consequences (also see Davies & Martin, 2013; Davies & Sturge-Apple, 2007).

Secure Patterns

A secure profile of responding to interparental conflict is characterized by minimal or mild displays of distress that largely reflect mitigated, empathetic concern for the parents rather than egoistic worries about safety. Subjective experiences accompanying this behavioral profile are postulated to consist of benign internal representations of parental relationship challenges, relatively low impulses to regulate interparental conflict, and minimal or mild experiences of distress. The pattern of behavior is organized by an SDS system that is designed to appropriate substantial psychobiological resources toward defusing threat only in relatively circumscribed instances of direct, interpersonal danger (Davies & Sturge-Apple, 2007; Gilbert, 2001).

Thus, regulated by children's underlying confidence in their parents to effectively resolve interparental disagreements, the SDS assumes salience as an organizer of behavior only under dire interparental conflicts and, even in these rare occasions, operates efficiently to preserve security.

Confidence in the parents to encapsulate and regulate their conflicts is posited to evolve from witnessing well-managed parental disputes (e.g., minimal anger, resolution) within a family context that is sufficiently resilient to intermittent interparental conflict (Davies & Sturge-Apple, 2007). Accordingly, the broader family system is likely to be characterized by harmony, child trust in parents as sources of support in times of distress (i.e., secure attachment), and parental psychological health (e.g., high well-being; low psychopathology). Likewise, temperamental characteristics of the child reflecting effortful control and a high threshold for negative affect are theorized to bias the operation of the SDS towards developing a secure profile (e.g., Davies & Martin, 2013). In turn, the high threshold of activation and the efficiency of the SDS system in contexts of interparental conflict allows for balanced resource investment of psychobiological resources to other significant goals organized by ethological systems (e.g., affiliative, exploratory) (Davies, Sturge-Apple, & Martin, 2013). In this way, emotional security may lay the foundation for the development of a wide range of social and academic skills, including problem-solving abilities, social skills, cooperation, empathy, and prosocial behavior, and ultimately low risk for psychopathology. However, EST-R proposes that security may not confer uniformly advantageous outcomes. For example, as described in Davies and Martin (2013), the relatively simple and underdeveloped system for identifying and defending against threat may increase children's risk for victimization and bullying in some developmental contexts.

Mobilizing Patterns

Responses to interparental conflict organized around a mobilizing profile consist of overt, blatant, and demonstrative expressions of distress and fear that are commonly accompanied by active de-escalation strategies (e.g., appeasing, overbright behavior), submissiveness, and vulnerable forms of involvement (e.g., caretaking). At a functional level, the considerable stakes in monitoring and managing interparental conflicts reflect the goal of sustaining vigilance to emerging patterns of threat while also remaining prepared to capitalize on sporadic opportunities for gaining resources in the family (Davies & Sturge-Apple, 2007; Trower, Gilbert, & Sherling, 1990). The high emotional entanglement of mobilizing children in the interparental relationship is also reflected in subjective experiences characterized by considerable negative affect, pessimistic appraisals of the impact of interparental conflict on the family and their own welfare, and considerable impulses to regulate interparental difficulties through fight (e.g., intervention) or flight strategies. In light of the proposal that the mobilizing strategy serves to simultaneously reduce threat and garner attention and sympathy from family members, children who exhibit these strategies are theorized to experience heightened destructive interparental conflict and family discord but also periodic, conditional expressions of warmth and support from family members. Blurred family boundaries (e.g., parental psychological control, resistant attachment, family enmeshment) may further fuel mobilizing strategies by emotionally pulling or coaxing children into interparental difficulties (Davies & Sturge-Apple, 2007). High stakes in guarding against threat and cultivating connectedness evident in the mobilizing profile may be further amplified by temperamental dispositions to exhibit high sensitivity to both punishment (e.g., high distress proneness) and reward (e.g., impulsivity, approach) and impairments in effortful control that prevent inhibition of prepotent, reactive responses to conflict (Davies & Martin, 2013).

Consistent with our ethological account of the cascade mechanisms of insecurity (for details, see the Developmental Cascade Mechanisms section), the mobilizing pattern along with the remaining two insecure profiles may broadly increase adjustment problems by depleting resources that could otherwise be devoted to developing skills and behaviors organized by other behavioral systems (Davies & Martin, 2013). However, the incremental utility of the person-based taxonomy of EST-R also lies in the specificity of the hypothesis that each profile is associated with a distinct portfolio of developmental costs and advantages. On the harmful side of the equation for mobilizing children, acute awareness of the threatening implications of interparental conflict, perseveration on their interpersonal standing in the family, and reflexive alternations between emotion dysregulation and vulnerability (e.g., appeasing behaviors) are proposed to increase vulnerability to anxiety problems, attention difficulties, and borderline personality symptoms (e.g., unstable sense of self, interpersonal dependency, emotional lability) (Gilbert, 2001; Gratz et al., 2009; Jensen et al., 2006). On the socially desirable side, persistent motivation to cultivate and maintain interpersonal relationships may set the stage for trajectories characterized by social interest, interpersonal engagement, openness to intimacy, and empathetic orientations in some developmental contexts.

Dominant Patterns

The functional utility of the dominant strategy consists of enlisting strategies designed to directly defeat threat. Because direct engagement of the source of potential harm requires keen identification of aversive stimuli, children adopting dominant strategies evidence prolonged activation of the SDS characterized by high levels of wariness and vigilance. However, unlike the mobilizing pattern, minimizing the experience and expression of vulnerability (e.g., fear, submissiveness, sadness) and downplaying the significance of family relationships permits the enactment of dominance posturing, coercion, callous indifference, and aggression in an effort to directly confront threat and regain power in the family (Davies & Sturge-Apple, 2007; Dixon, 1998; Hilburn-Cobb, 2004). High levels of destructive interparental conflict are likely to engender dominant strategies when significant collapses in family power hierarchies lead to obscured guidelines for accessing family resources and inconsistent consequences for violations of interpersonal conduct (Davies & Sturge-Apple, 2007; Sloman, Farvolden, Gilbert, & Price, 2006). Ill-defined power hierarchies are most commonly reflected in hostile detachment in the interparental relationship, cold, disengaged family contexts, low parental investment in the lives of children (e.g., apathy, passivity), and vulnerable forms of adult psychopathology (e.g., anxiety, depression). Likewise, temperamental characteristics comprised of bold approach to novelty, low sensitivity to punishment, poor effortful control, and impulsivity may further calibrate the SDS system toward a dominant strategy in contexts of threat (Davies & Martin, 2013).

In serving as a guide to more precisely identifying the sequelae of dominant strategies, the taxonomy in EST-R specifically proposes that the blunting of vulnerable emotions and devaluation of family relationships may be especially likely to take a toll on the affiliative and caregiving systems. Over time, the confluence of dampened interpersonal processes (e.g., empathy, communion) required for the operation of caregiving and affiliative systems and the depletion of resources to devote to goals organized by these systems are theorized to engender poor social competency, hostile attribution biases, callousness, and the rigid, reflexive reliance on aggressive behaviors across social contexts. As this hostile, disenfranchised interpersonal orientation continues to proliferate beyond the interparental and family contexts, children adopting dominant strategies may be specifically vulnerable to developing conduct problems, delinquency, and antisocial symptomatology (Davies & Sturge-Apple, 2007). However, in highlighting the developmental tradeoffs, dominant strategies may also increase the likelihood, in some contexts, of adaptive trajectories characterized by self-confidence, agency, and a bold readiness to experience novelty and challenge (Hawley, Little, & Rodkin, 2007; Sih, Bell, & Johnson, 2004).

Demobilizing Patterns

Designated as an involuntary defeat strategy in ethological models, demobilizing profiles are functionally designed to reduce children's salience as targets of hostility and ire from dominant conspecifics in the social group (Gilbert, 2001; Gilbert & Allan, 1998; Marks & Nesse, 1994; Sloman et al., 2006). The lie-low function of demobilizing strategies may be expressed in a wide array of forms, including freezing, vigilance, quiet disengagement, appeasing behavior (e.g., head down, gaze aversion, unexplainable and intense smiling), sadness, anhedonia, helplessness, fatigue, postural slumping, or downtrodden behaviors. High- (e.g., tenseness, freezing, gingerly moving away) and low-arousal behaviors (e.g., postural slumping, fatigue) may each serve the overarching function of limiting children's exposure to concurrent or future threat. Because demobilizing profiles are last resort strategies for diffusing threat in our evolutionary past, EST-R postulates that this profile evolves from exposure to very dire, agonic family niches. Agonic family contexts are typically characterized by recurrent displays of aggression, intimidation, and oppression by adults that can be manifested in interparental aggression and coercion, family hostility, intimidating forms of parental functioning (e.g., antisocial personality disorder, anger dysregulation), and disorganized attachment. Moreover, unlike the mobilizing strategy, children with demobilizing profiles are theorized to grow up in family contexts that offer minimal (if any) opportunities or resources to mitigate threat through the provision of support, protection, or warmth (Davies & Martin, 2013; Davies & Sturge-Apple, 2007; Gilbert, 1993).

Children adopting a demobilizing strategy are predicted to bear the most significant long-term mental and physical health burdens of any of SDS strategy (Gilbert, 2006; Sloman et al., 2006). The collateral damage of utilizing demobilizing strategies to limit exposure to interpersonal threat is likely to be revealed in disproportionate increases in internalizing symptoms (e.g., depression, anxiety). The attenuation of approach motivations may be most pronounced in deficits within the affiliative and exploratory systems. As a result, demobilizing tendencies should be associated with ample impairments in social skills, agency, and problem-solving abilities (Davies & Sturge-Apple, 2007; Gilbert, 2001; Sloman et al., 2002). However, even

though children with demobilizing profiles may experience considerable and widespread susceptibility to adjustment problems, their underlying aversion to risk may protect them from the development of disruptive, risky, and oppositional behavior problems. Moreover, in reflecting a potential bright spot in tracing the development trajectories, evolutionary models have postulated that some of the components of a demobilizing profile persisted across evolution by promoting a reflective orientation toward the environment and greater inhibitory control (Aksan & Kochanska, 2004; Bell, 2007; Davies, Cicchetti, Hentges, & Sturge-Apple, 2013; Sih et al., 2004).

Summary

The person-based taxonomy in EST-R is designed to increase novelty and precision in the identification of the developmental precursors and consequence of different patterns of defending against threat in the interparental relationship. Although our preliminary findings provide support for the prevalence of each of the four profiles, research has yet to systematically test the hypothesized origins and outcomes of the profiles (Davies & Martin, 2013). Thus, empirically testing the utility of the EST-R taxonomy remains an important direction for future research. However, in addressing this gap, it is important to recognize that the hypothesized relations among family and developmental conditions, SDS strategies, and outcomes are probabilistic rather than certain. Consistent with the open systems model in developmental psychopathology (Cicchetti & Rogosch, 1996; Davies & Cicchetti, 2004), EST-R acknowledges child and ecological characteristics are likely to serve as regulatory conditions (i.e., moderators, predictors) that increase heterogeneity in the mediational pathways of the security profiles. Thus, equifinality is evidenced in expectation that different experiences may give rise to any given SDS profile and pattern of adjustment, whereas multifinality is reflected in the hypothesis that comparable family experiences will produce different forms of adjustment.

Expanding Emotional Security Beyond the Interparental Dyad

In underscoring its potential to cultivate multiple growing points in developmental psychopathology, the conceptualization of the SDS in EST-R may have broad translational implications in other family and ecological contexts. In contrast to the circumscribed focus in EST on security within the interparental subsystem, EST-R offers greater flexibility in defining emotional security as a product of the operation of the SDS. By accepting the premise that the SDS organizes strategies that were designed to defuse configurations of threat in social networks, EST-R has the potential to break the conceptual shackles of EST and expand the scope of inquiry to multiple interpersonal contexts. Careful attention to form and function of patterns of defending against threat in EST-R may specifically offer new insights into the developmental course of individual differences in preserving safety in other ecologies (e.g., parent–child and triadic contexts, peer relationships, community violence). To illustrate the potential translational implications for developmental psychopathology (Cicchetti, 2010), we provide a brief and selective overview of how EST-R may advance an understanding of how children cope with both familial and extrafamilial settings (for more details, see Davies & Martin, 2013).

The interparental relationship is not the only source of conflict, anger, and aggression in the family unit. Children are both bystanders and recipients of hostility and conflict by parents and siblings (Bush & Peterson, 2013; Margolin & Gordis, 2000; Straus, 2001). Despite empirical evidence that these family relationships can serve as sources of threat that may organize children's defense strategies (Davies & Martin, 2013), traditional approaches to understanding the processes by which parent–child and sibling discord impact children's mental health and adjustment have predominantly focused on social learning (e.g., modeling) and attachment (e.g., support) theories (e.g., McElhaney, Allen, Stephenson, & Hare, 2009; Gass, Jenkins, & Dunn, 2007; Volling & Blandon, 2005). Thus, EST-R may offer a unique theoretical window into understanding how and why children exhibit specific defense strategies in contending with threat in parent–child, sibling, or broader family relationship contexts. Because the taxonomy in EST-R is guided by evolutionary and ethological work on individual differences in coping with conspecific threat, it has the strong potential to provide a heuristic for identifying the nature, origins, and sequelae of defense strategies in multiple family contexts. In support of this research direction, our preliminary observations have provided solid evidence for the occurrence of the four SDS patterns (i.e., secure, mobilizing, dominant, demobilizing) in triadic conflicts involving children and both of their parents (see Davies & Martin, 2013). Future research is needed to explore whether each defense profile develops from the hypothesized unique constellations of early family threats, supports, and temperamental dispositions. Likewise, predictions regarding the distinctive sequelae of defense strategies in parent–child, sibling, triadic, and family-level contexts remain to be tested.

Exposure to threatening interpersonal contexts is also common outside of the family. Children regularly grapple with a wide array of peer stressful events, including victimization, rejection, conflict, and competition in peer and school settings (Asher & Coie, 1990; Craig & Pepler, 1998; Juvonen & Graham, 2001; Laursen & Pursell, 2009). Despite increased recognition of the significance of peer relationships for children's mental health, research on the nature, precursors, and implications of children's coping with stressful peer interactions remains underdeveloped at multiple levels. At the conceptual level, no formal theories exist to guide the identification of patterns of individual differences in how children organize behavioral responses to threatening peer events (Asher & MacDonald, 2009). Predominant conceptual and empirical focus on the morphological properties (i.e., form, structure) of behavior has resulted in limited attention to the functional utility (i.e., purpose) of behavior within person-based patterns of children's reactivity to peer threat. Thus, little is known about how children cope with and respond to stressful peer interactions beyond broad indices of interpersonal functioning (e.g., rejected status, aggressive/withdrawn behavior). The field continues to grapple with the challenge of generating process-oriented hypotheses about the origins, course, and sequelae of distinct patterns of behavior in response to challenging peer interactions.

Given our account of the contextual versatility of EST-R, our person-based taxonomy and its broader array of hypotheses may be useful in addressing this gap. In supporting the significance of EST-R for peer contexts, pilot research has identified that the four SDS profiles are commonly employed by children in peer settings (Davies & Martin, 2013). The focus on functional utility and its leverage in precisely identifying developmental precursors and implications of SDS profiles in EST-R is also readily applicable to the study of peer relationships. For example, if the mobilizing profile functions to garner support, sympathy, and alliances as a way of defending against peer threat, then it may be most evident when exposure to threat and conflict are intermingled with intermittent access to resources in peer ecologies. Thus, the approach–avoidance dialectic evidenced in mobilizing responses is hypothesized to be cultivated in interpersonal contexts containing moderate levels of peer hostility in conjunction with some relationship dynamics (e.g., friendship, support) that motivate children to maintain or increase social ties (Davies & Martin, 2013; Martin, Davies, & MacNeill, 2014). Consistent with our taxonomy, emotion dysregulation and interpersonal preoccupation resulting from mobilizing tendencies is posited to coalesce into anxiety, attention, and hyperactivity difficulties as the stress response associated with prolonged SDS activity undermines developing regulatory systems (Hilburn-Cobb, 2004; Sloman et al., 2006).

In conclusion, by casting emotional security theory within an ethological framework of social defense, EST-R may serve as a useful guide for increasing precision and novelty in numerous areas of developmental psychopathology that extend well beyond the interparental dyad. At the level of the family, social defense conceptualizations may be usefully adapted to understanding the developmental trajectories that evolve from the common occurrence of conflict in parent–child, sibling, triadic, and family-level interactions. In moving beyond the family, EST-R may also serve as a useful tool for formulating and testing hypotheses on children's adaptation to peer, neighborhood, and community adversity (see Davies & Martin, 2013).

Protection and Resilience in the Face of Insecurity

Emotional security theory has largely been centered on characterizing the vulnerability and maladjustment of children facing histories of adversity (Davies et al., 2006; McCoy et al., 2009). However, identifying maladaptive outcomes without balanced consideration of resilience does not adequately represent the primary tenets of developmental psychopathology. One of the foundational principles of developmental psychopathology consists of the importance of considering, with equal weight, both risk and resilience in development (Cicchetti, 1989; Luthar, Cicchetti, & Becker, 2000; Masten & Tellegen, 2012). Resiliency is specifically defined as the ability of children to adapt fairly well in spite of their exposure to considerable adversity (Luthar et al., 2000).

In integrating resiliency into emotional security theory, conceptualizations and assessments must be able to capture the dynamic, multidimensional nature of resilience, with particular recognition that some children may evidence shifting levels of competence in some areas of functioning and psychopathology in others (Luthar et al., 2000). Evolutionary models of development underscore the significance of conditional adaptation based on the goodness of fit between children's characteristics and their ecological niches. Some seemingly maladaptive behaviors may specifically be sustained within the population because they confer advantages in supporting survival and, in some cases, healthy development under specific social and ecological conditions (Belsky & Pluess, 2009; Ellis et al., 2011). For example, differential susceptibility theory proposes that children who are high in sensitivity

to environmental input fare substantially better than their peers in resource-rich environments but experience disproportionately greater problems under highly adverse developmental conditions (Belsky & Pluess, 2009). In further highlighting the potential costs that may accompany resilience, the person-based taxonomy in EST-R posits that specific patterns of insecurity commonly result in developmental trade-offs in which proficiency or resilience achieved in one domain occurs at the cost of undesirable outcomes in other areas of functioning (Davies & Martin, 2013). For example, whereas mobilizing children are theorized to be at increased risk for experiencing some forms of psychopathology, the risk is balanced to some degree by the potential for these children to follow developmental trajectories characterized by high communion and social attunement.

After sufficiently characterizing resilience in a multidimensional framework, the next challenge is to further delineate the protective factors and mechanisms that explain why some insecure children are able to develop along competent developmental trajectories. Taxonomies that distinguish between various forms of protective effects will be valuable tools in precisely characterizing how a given factor might contribute to the adaptation of children with high levels of insecurity (Luthar, 1993; Luthar et al., 2000). For example, *protective-reactive* factors confer substantially greater competence when insecurity is low, with its buffering potency waning significantly at high levels of insecurity. In contrast, *protective*-stabilizing *factors* produce uniformly high levels of adaptation across increasing levels of insecurity. Alternatively, *protective-enhancing* factors operate in a way that actually promotes better functioning with increasing experiences with insecurity.

Investigations have yet to identify protective factors that mitigate the deleterious effects of insecurity. However, due to its conceptual and empirical links with emotional security, research on interparental conflict may provide a starting point for specifying the form of protective effects. For example, a series of studies identified vagal regulation (i.e., suppression of vagal tone) during adult arguments as a protective factor in associations between interparental aggression and children's adjustment problems (El-Sheikh, Harger, & Whitson, 2001; El-Sheikh & Whitson, 2006). To more precisely identify the form of protection for vagal regulation, additional analyses indicated that vagal suppression was a protective-stabilizing factor, conferring consistently low internalizing symptoms across levels of interparental aggression (El-Sheikh & Whitson, 2006). Even existing findings on moderating factors that do not explicitly pinpoint the forms of protection may be usefully interpreted within these taxonomies. For example, results on the role of maternal communications about conflicts in moderating the risk posed by interparental conflict were not initially framed in a protective factor classification scheme (Gomulak-Cavicchio, Davies, & Cummings, 2006). However, post hoc inspection of the findings indicates that various forms of maternal communication served distinct protective functions in associations between interparental conflict and child externalizing symptoms. Whereas the moderating effects of maternal remorseful apologies to children were expressed in a protective-stabilizing form, communications denying or limiting child exposure to conflicts (i.e., renunciation) were consistent with a protective-reactive effect. Given its documented value in developmental psychopathology research, future identification of protective effects in models of insecurity would benefit from the precision afforded by systems for classifying protection.

The identification of protective factors is commonly regarded as the final scientific objective in research on resilience (Cummings et al., 2000). However, from a process-oriented perspective, simply ending the inquiry at cataloguing protective factors and their specific effects is conceptually unsatisfying. This approach does little to advance an understanding of why individuals with certain characteristics or experiences benefit from the protective factor. Addressing questions of why protective factors buffer insecure children from developing adjustment difficulties will require more sophisticated analytic approaches (e.g., mediated-moderation) than the standard moderator models. For example, in drawing from the broader literature on interparental conflict, Manning, Davies, and Cicchetti (2013) first identified that maternal sensitive parenting served as a protective factor in associations between interparental aggression and preschooler psychological functioning. However, in moving beyond the simply delineating protective factors, the use of mediated-moderation analyses specifically revealed that maternal sensitivity buffered children from violent homes through its association with diminished levels of child angry reactivity to interparental conflict.

In accord with multiple levels of analysis perspectives in developmental psychopathology (Cicchetti & Curtis, 2007), the search for mechanisms underlying protective factors can be facilitated by analyzing the interplay between risk and protective factors across biological, psychological, and interpersonal units of analysis. Returning to our example of vagal regulation as a protective factor (El-Sheikh & Whitson, 2006; El-Sheikh et al., 2001), it is possible that future research might identify vagal

suppression as a protective factor in pathways between children's insecurity and psychological adjustment. A multilevel, process-oriented approach may consist of examining the psychological manifestations of vagal suppression that serve to mediate of its moderating effects. For example, vagal suppression is theorized to function as a physiological substrate for effective emotion regulation strategies and successful adaptations to stressful events threat (Bornstein & Suess, 2000; Graziano & Derefinko, 2013; Porges, 2003). Therefore, testing emotion regulation and coping strategies as potential mechanisms that account for how and why vagal regulation protects insecure children may further an understanding of resilience within a multiple levels of analysis framework. The resulting advances in the interplay among multiple levels of protective factors may, in turn, provide greater strength and versatility in delineating clinical targets and therapeutic tools for treatment initiatives.

Prevention, Intervention, and Public Policy

Our ultimate goal in advancing emotional security theory is to facilitate the translation of theoretically guided empirical knowledge into practice. Consistent with this objective, progress in testing and refining EST and EST-R over the past two decades has provided a base of scientific findings to guide clinical practice and public policy initiatives. Although outlining the translational implications of our theory for clinical and policy programs is a pressing research direction, successfully achieving this goal remains a formidable challenge. Generating policy, legislation, and services for children from high conflict homes is still in its infancy as public health, community, and legal systems continue to grapple with treatment implications of a growing and complex body of data. Given the state of the literature on children's emotional security, it is premature to offer any definitive recommendations for treatment or public policy. Accordingly, we outline, at a broad level, the potential translational implications of emotional security theory for alleviating the burden of child mental illness.

Identifying Children at Greatest Risk for Psychopathology

Identification of children's sense of security as a mediating mechanism of the vulnerability experienced by children who are exposed to interparental conflict has important implications for clinical assessment. The process-oriented approach of EST emphasizes the importance of utilizing clinical assessments designed to carefully observe children's behavior under conditions of conflict and threat in the interparental and broader family unit. Although capturing children's conscious responses to interparental conflict should be a fundamental part of clinical assessment process, EST and EST-R are unique relative to other prevailing theories of interparental conflict (e.g., Crockenberg & Forgays, 2001; Grych & Fincham, 1990) in underscoring that children's experiences with insecurity in the interparental relationship are commonly rooted in affective structures outside the child's conscious awareness or verbal articulation (Davies & Sturge-Apple, 2007). Moreover, the resulting expressions of child behaviors organized by these affective structures commonly exhibit modest correspondence with reports of their subjective emotional experiences and appraisals (Davies & Forman, 2002). Consequently, obtaining a comprehensive profile for identifying children at high risk for psychopathology within an emotional security framework would be facilitated by use of other informants (e.g., parents) or methods (e.g., observations) in the assessment process. In addition to the availability of structured and semistructured methods for obtaining children's self-report measures of their security (Davies, Forman, et al., 2002; Davies, Sturge-Apple, et al., 2006, 2013), clinicians have, at their disposal, a number of other new approaches for implementing a multi-informant, multimethod measurement battery, including caregiver surveys (Davies, Harold, et al., 2002), semistructured interviews with parents (Davies, Manning, & Cicchetti, 2013), and observational systems (Davies et al., 2004).

Scientific progress in characterizing the substance and operation of the goal-corrected system of emotional security also offers clinical blueprints for precisely identifying patterns of reactivity to conflict with high prognostic utility. Advances in articulating how children express their insecurity in EST-R specifically highlight the significance of fear and vigilance as a common underlying sources of children's reactivity to interparental difficulties. By the same token, EST-R also recognizes that the vigilance and fear may organize a diversity of ways of defending against the threat accompanying interparental conflict, including anger, flight, fight, submissive disengagement, appeasing behavior, camouflaging behavior, demobilizing, and demonstrative displays of distress (Davies & Sturge-Apple 2007). Although the myriad of different expressions of insecurity may increase the challenges and complexities in clinical assessments of family process, EST-R offers a parsimonious taxonomy of identifying the profiles of security through the articulation of the four SDS profiles.

Greater precision afforded by EST-R is also balanced by the integration of children's trajectories of coping and adjustment within a broader, complex developmental

system. The schematic in Figure 6.1 embeds children's emotional security within a dynamic constellation of family, ecological, child, and developmental processes. In some parts of the model, the contextualization of emotional security highlights the operation of other complementary processes (e.g., parenting, parent–child attachment) that may help to increase the ability to identify children from high conflict homes who are at risk for experiencing psychopathology. In other parts of the conceptualization, family, ecological, and developmental processes may serve as moderators that may be useful clinical sources of information for determining which children may evidence disproportionately greater or diminished risk for experiencing problems. Finally, our objective of explicating how and why insecurity may increase risk for mental health problems may help clinicians to identify areas of concern that play more proximal roles in developmental cascades to psychopathology. Collectively, the contextualization of emotional security underscores the value (whenever feasible) of obtaining more comprehensive assessments of adversity, strengths, and opportunities of at-risk children within family, developmental, and ecological levels of analysis.

Delineating Clinical Targets and Approaches

Given the central role of children's emotional security in the interparental relationship as a mediating factor contributing to their long-term mental health, it makes intuitive sense that reducing signs of emotional insecurity should be a primary treatment goal in programs aiming to reduce the negative public health consequences of family conflict. However, a singular, myopic focus on reducing specific expressions of insecurity in the interparental relationship may have unintended, negative consequences of stripping children of the very strategies that commonly prove to be successful in defending against threat in high conflict homes (Davies & Martin, 2013; Davies et al., 2006). From this perspective, any therapeutic approach that is designed to reduce risk for psychopathology by altering children's reactivity to conflict must be accompanied by a complementary focus on ameliorating the destructive interparental family processes (e.g., interparental aggression, family disengagement) that foster insecurity. Without the comparable family intervention component, children are likely to revert to their old, insecure strategy as a way of tailoring their response to the threatening environmental input. Moreover, failing to institute more comprehensive family-wide programs may create new sets of risks for children who are ill equipped to cope with the continuing perturbations in the family system.

An alternative approach may consist of programs designed to prevent or reduce destructive family conflict characterized by hostility, aggression, and violence between parents (Cummings & Davies, 2010; Cummings, Faircloth, Mitchell, Cummings, & Schermerhorn, 2008; Cummings & Shatz, 2012; Shifflett & Cummings, 1999). Numerous therapeutic prevention and intervention programs exist to help distressed couples decrease their destructive conflict tactics (Cowan, Cowan, Ablow, Johnson, & Measelle, 2005; Feinberg & Kan, 2008; Halweg & Richter, 2010; Loew et al., 2012; Markman & Rhoades, 2012). However, these programs typically vary in their efficacy, are rarely tested within randomized-control trials, and seldom consider the perspective of the child (Cummings & Schatz, 2012; Markman et al., 2010). Toward addressing these gaps, the Happy Couples, Happy Kids (HCHK) program is a psychoeducational program that translates EST principles into treatment models that are designed to foster child well-being by reducing destructive interparental conflict (Cummings & Schatz, 2012; Faircloth & Cummings, 2008; Faircloth, Schermerhorn, Mitchell, Cummings, & Cummings, 2011). As a brief program delivered to parents in a small group setting, HCHK has three primary objectives: (1) to provide couples with evidenced-based knowledge on distinctions between destructive from constructive conflict strategies; (2) to inform them of the influence interparental conflict on children and on their own ability to successfully parent; and (3) to explain the importance of maintaining a sense of security across multiple family relationships in supporting child mental health (Faircloth & Cummings, 2008). HCHK program has been shown to reduce the destructive conflict tactics, increase marital satisfaction, and enhance child adjustment for up to two years after the program (Cummings & Merilees, 2010; Cummings & Shatz, 2012; Faircloth & Cummings, 2008; Faircloth et al., 2011).

For practitioners who have significant resources available, complementary family-wide approaches may also provide significant clinical leverage in reducing children's insecurity in the interparental relationship. Consistent with developmental psychopathology and family systems approaches (Davies & Cicchetti, 2004), EST proposes that children's insecurity is a product of complex associations between interparental, family, developmental, and ecological factors. For example, EST posits that the nature of the interplay between interparental conflict and parenting difficulties may increase children's vulnerability to psychopathology by undermining insecurity in multiple (e.g., interparental, parent–child) relationships (Sturge-Apple et al., 2008). Thus, EST may provide a useful framework for

integrating couple-centric therapeutic approaches into the broader family system (Coatsworth, 2013). Consistent with this recommendation, a growing number of family-wide programs are designed, in part, to minimize interparental conflict and its deleterious developmental consequences (Kaminiski et al., 2008; Sanders, 2008). In keeping with this clinical direction, adaptations to the HCHK now include additional educational components aimed at improving communication and reducing destructive conflict in both interparental and parent–child subsystems (Cummings & Schatz, 2012). By directing clinical focus to issues of multifinality and equifinality in the emergence of children's concerns about security (Cicchetti & Rogosch, 1996), these types of programs for targeting multiple pathways of risk across family relationships may be particularly effective in reducing child insecurity across different family subsystems (Cowan & Cowan, 2002; Cummings & Davies, 2010; Cummings & Shatz, 2012; Liddle & Schwartz, 2002).

Although the opportunities to improve children's security and adjustment through family interventions are encouraging, implementation of these programs is not always feasible. In addition to not always yielding meaningful, sustainable improvements in child adjustment, family-wide interventions require considerable expenditure of professional resources and, in some cases, are impossible to implement in families who are unwilling or unable to participate in treatment. To increase the flexibility and accessibility of intervention programs informed by emotional security theory, EST and EST-R can also assist in identifying alternative points for intervention that do not require the engagement of parents or family. As knowledge continues to accumulate on the downstream processes set in motion by children's insecurity (Davies & Martin, 2013), we will be in an increasingly stronger position to interrupt the pathogenic processes before they crystallize into broader trait-like patterns of psychopathology. Although still in its early stages, research has delineated several cascade mechanisms that account for why insecurity poses a risk for children, including proliferation of defensive representations and analogs to other interpersonal relationships (e.g., Bascoe, et al., 2009), disruption of biological processes (e.g., sleep activity; Kelly & El-Sheikh, 2013), difficulties focusing and sustaining attention (e.g., Davies et al., 2008), and failure to resolve stage-salient developmental tasks (e.g., Davies, Manning, & Cicchetti, 2013). Thus, specific clinical goals for insecure children may include (1) managing hostile attributions and rigid negative analogs by developing safe, supportive, and trusting interpersonal havens for more openly processing interpersonal problems (Dodge & Godwin, 2013; Johnston et al., 2009); (2) supporting healthy sleep patterns through parental establishment of regular sleep hygiene and bedtime routines (Mindell & Owens, 2009; Mindell et al., 2011); (3) increasing child attention and executive functioning capacities (DuPaul, Helwig, & Slay, 2011); and (4) enhancing mastery of stage-salient tasks across childhood and adolescence (Schulz & Kerig, 2012; Ursache, Blair, & Raver, 2012).

With future empirical testing, EST-R may also deliver a unique lens for refining and tailoring intervention strategies to the individual needs and capacities of insecure children. Although extreme caution should be exercised in translating the largely untested hypotheses to clinical initiatives, the value of EST-R lies in its potential to refine treatment targets by (1) identifying specific developmental and ecological conditions that serve as precursors of each of the four SDS profiles; and (2) offering greater precision in delineating the advantageous and disadvantageous sequelae of each profile (see Davies & Martin, 2013). By selectively adapting therapeutic components to address the distinctive experiences, needs, and strengths of each profile, it may be possible to maximize the efficacy of intervention and prevention efforts. For example, because children with mobilizing tendencies tend to value interpersonal connectedness in the context of exhibiting poor social skills and emotion regulation difficulties, the effectiveness of intervention programs may be enhanced by treatment modules that rely heavily on social skills exercises, emotion regulation training, and pairings with competent peers. Conversely, as part of a dominant profile, efforts to defeat threats in the family through oppositional strategies are likely to be sustained by ambiguity in family power structures and tendencies to downplay the significance of interpersonal relationships. Thus, interventions tailored to this profile may be more successful if they are integrated into a therapeutic context that offers clear communication of guidelines for conduct, consistent disciplinary consequences for transgressions, and material (rather than simply social rewards such as praise) reinforcement for desirable behavior.

CONCLUSIONS

In conclusion, the integration of emotional security theory and principles of developmental psychopathology has advanced our understanding of the implications of children's processing and responding to family conflict in the typical and atypical development of children. As our review of research in this chapter documents, there is now

firm evidence that emotional insecurity is a unique and robust mediator of multiple pathways involving family adversity and children's adjustment problems. Moreover, strides in contextualizing the study of the mediational pathways of insecurity in the interparental relationship are evidenced by the conceptualization of a multilayered framework that highlights the roles of broader family characteristics, developmental processes, child attributes, and ecological parameters. Complementary progress is also being made in characterizing the pathogenic cascade processes underlying the vulnerability experienced by children with high levels of insecurity. Based on preliminary research, we are cautiously optimistic that the EST-R will offer incremental degrees of precision and novelty in characterizing the origins, nature, and sequelae of children's patterns of responding to interparental conflict. Through a balanced approach to testing hypotheses generated by EST and EST-R, it is hoped that the coming decades generate a knowledge base to further guide intervention and public policy initiatives and reduce the burdens experienced by children and families in high-conflict homes.

INTRODUCTION

The capacity to be emotional is the heart of human development. This capacity can be thought of as a rapid radar-and-response system that has evolved to enable continuous appraisal of the fit between a person's circumstances and goals for well-being and readiness to act in particular ways in relation to the circumstances to achieve, preserve or regain well-being. The capacity to be emotional has its evolutionary origins in a primitive function, common to even simple organisms, to detect and respond to conditions to avoid harm and to reproduce (Darwin, 1872; LeDoux, 2012). The capacity evolved in humans to support the development of social groups, developing a communicative function that organizes social interaction. Its essential importance to being human is seen throughout the centuries; philosophies, religions, and science have contemplated and debated the nature of *emotion*, including grappling with the seeming paradox of why an arguably adaptive capacity is so often a salient feature of *maladaptive* psychological functioning.

This chapter addresses the role of the capacity to be emotional in the development of emotional competence and psychopathology. It uses two conceptual models to discuss the role of emotion in healthy development, the vulnerabilities that emerge along the path to competent emotional functioning, and the challenges encountered that compromise the development of emotional competence and contribute to the development of psychopathology. The first conceptual model is the developmental psychopathology framework (Cicchetti & Cohen, 1995). The principles of this framework include the importance of understanding atypical development in the context of typical development (and vice versa). They include the principle that challenges encountered at one point in life may strengthen psychological functioning by fostering and exercising newly emerging skills but that they may also pose risk for healthy development. The framework appreciates the complexity of ontogenetic pathways; early experience that involves significant risk provides a foundation from which development can cascade toward a particular pathological outcome, and yet developing systems begin with malleability that permit resilience despite risk conditions. The framework appreciates that there are multiple pathways to a single outcome (e.g., a symptom of depression or conduct disorder) as well as commonalities in pathways associated with different outcomes (e.g., a history of child sexual abuse is associated with any number of psychiatric disorders as well as healthy adjustment). In focusing on the capacity to be emotional from a developmental psychopathology framework, this chapter examines how emotional competence develops and how, at different points of development, emotional competence is threatened and can be diverted toward psychopathology.

The second framework that organizes the chapter is the functional perspective on *emotional development* (Barrett & Campos, 1987; Witherington, Campos, & Hertenstein, 2001) and its application to the concept of emotional

competence (Denham et al., 2011; Saarni, 1998). This perspective emphasizes the *relational, contextual, dynamic* nature of emotional functioning. Emotional competence, a desired outcome of emotional development, entails successfully navigating a complex interpersonal and intrapersonal world in a flexible, socioculturally appropriate, and effective manner. Emotional dysfunction, a prominent feature of psychopathology, can be conceptualized as compromised development of emotional competence.

To begin, the nature of the capacity to be emotional from the functional perspective is elaborated. Next the chapter summarizes what is known about the development of emotional competence in childhood and adolescence, organized around three interrelated domains of emotional competence—emotional expressiveness, emotion understanding, and emotion regulation. Because of the emphasis on a functionalist view of emotion, priority is given to evidence that furthers our ability to understand emotion in context as a relational, dynamic, process. Finally, the chapter considers how the development of emotional competencies involves skills that not only enable flexible, appropriate, effective emotional functioning but also occasion new ways that an individual is vulnerable to emotional dysfunction and the risks posed for the development of psychopathology.

THE NATURE OF EMOTION

Scholarly inquiry about healthy and unhealthy aspects of the capacity to be emotional has echoed through the centuries in major world religions, in classic philosophies, in many disciplines of modern science, in contemporary emotion research and theory, including in subfields focused on typical and atypical human development. In all of these efforts, scholars have recognized that emotion is essential for survival, for being fully human, for being a member of a social world. Yet, at the same time, emotion is consistently portrayed as irrational, as interfering with human functioning, or as needing control. In contemporary psychological science, the most influential theories all addressed emotion—Freud, of course, in his many volumes, James notably—but it was also addressed by scholars who did not emphasize emotion, notably Piaget (*Intelligence and Affectivity*, 1981) and even Skinner (*Walden Two*, 1948). Yet the scientific investigation of emotion has not always been in vogue. The ascendancy of behaviorism in the early twentieth century with its sole focus on observable behavior and environmental contingencies shifted attention away from cognition and emotion. This was followed by the post–World War II cognitive revolution and its emphasis on information processing and computer modeling. These periods muted scientific progress in the study of emotion for many years. By the 1980s, however, the study of emotion suddenly surged. Behaviorism and cognitive science had not provided complete accounts of human functioning. Since 2000, there has been tremendous growth in the study of emotion, most recently spurred by major advances in our ability to study genetics and neuroscience. What has been learned has deepened interest in emotion but also furthered debates about its fundamental nature, the degree to which emotions are biologically determined or psychologically specified, and about the conceptual boundaries of the concept of emotion and related concepts such as emotion regulation. The functional perspective, which organizes this chapter, emphasizes the continuous, relational, dynamic, and contextual nature of what we refer to as emotion. It is selected as an overarching framework because of its potential to enlighten our understanding of typical and atypical development, guiding a view of atypical emotional development as a problem of the relation between person and environment. This perspective has a lineage in theoretical positions asserting that the capacity to be emotional evolved as critical for adaptation to the environment (e.g., Arnold, 1960; Izard, 1977; Lazarus, 1999; Plutchik, 1980). Its critical value was that it enables very rapid appraisal of the significance of situations for well-being and very rapid organismic preparation to act to achieve, maintain, or regain well-being.

The functionalist view of emotion has roots in the germinal work of Magda Arnold (1960), who took a distinctly neurobiological approach to understanding emotion at a time when behaviorism was at its peak and the cognitive revolution was underway. In her effort to produce a comprehensive emotion theory, Arnold included discussion of the evolution of emotion, the role of learning in emotional functioning, and the contributions of emotion to personality development, linking her work to leading models of the time. Most importantly, Arnold shifted the scientific focus from subjective feelings and unconscious anxiety, which were the prevalent perspectives in psychoanalytic scholarship, to neurophysiological patterns that supported mental processing of environmental information and organized action. Arnold defined emotion in terms of neurophysiological processes that enable (1) implicit (not necessarily conscious) judgments about the environment that motivate action, or appraisal, and (2) organismic changes that prepare the individual to move toward or away from the environment or action readiness. Nico Frijda (1986) extended this perspective, further specifying

appraisal/action readiness patterns that are uniquely associated with different emotions—joy, anger, fear, sadness, shame, and others. For example, fear and sadness both involve physiological changes that ready the individual to withdraw from rather than approach the environment. But fear and sadness nonetheless differ in important ways. Fear is defined by the appraisal that circumstances endanger well-being and preparedness to act in ways that minimize or escape threat; these require the mobilization of resources (energy) for action. Sadness, by contrast, is defined by the appraisal that a goal for well-being cannot be attained and neurophysiological readiness to relinquish effort, which reduces the demand for energy to act and conserves energy.

Arnold's work is a precursor of Lazarus's (1991) appraisal theory of emotion. Lazarus focused on the mental processes: appraisal as determining whether a situation challenged well-being (stress) and assessing possible actions (coping). The emphasis on appraisal tended to focus on explicit, reflective processes more than on the intuitive, automatic processes that Arnold defined. Lazarus' model does not dwell on neurophysiological changes, such as readiness to act, that were part of Arnold's definition of emotion. For a developmental perspective on the role of emotion in psychopathology, appraisal theory presents two limitations. First, the emphasis on the conscious content of thought turns emotions into mental objects—discrete, periodic mental states that result from interpretive processes. Emotion becomes a result of appraisal, rather than appraisal (and action readiness) being active, ongoing processes that define emotion. The functional perspective intends to dispel the view of emotions as discrete objects or events. This definitional shift is challenging to grasp, in part because the lexicon we use to communicate about emotion relies on nouns, which tend to reify emotion. In this chapter, we emphasize the capacity *to be emotional*, because the functional perspective emphasizes conceptualizing emotion as dynamic relating to the world. The second limitation of a strict appraisal theory is that most of its associated research has not been informed by a developmental perspective. As will be discussed, the behavior of infants and very young *children* offers unique views on the nature and role of the capacity to be emotional. It is from infant research that the functional perspective on emotional development emerged (Barrett & Campos, 1987).

As we can see, the functional perspective challenges traditional conceptualizations of emotion. Its main point of divergence is its assertion that emotion is *relational* in nature; that is, it is a process defined by the ongoing relation of the perceiver to the environment. This perspective recognizes that humans have the mental capacity to reflect on this relation process, creating objects of conscious thought. But the functional perspective on emotional development has its origins in infant research and is influenced by the fact that infants, who cannot consciously reflect on how they are relating to the environment, nonetheless have the capacity to be emotional. In the first year of life, infants communicate emotionally to signal their needs, detect and interpret communicative signals of others' emotions, and use this information to guide their own behavior. Thus, the functionalist perspective conceptualizes emotion as situated in the transactional space between individual needs or goals for well-being and the environment. Emotions are not psychological objects residing within a person but are psychological processes that enable individuals to relate to the environment in ways that serve attaining and preserving well-being (Barrett & Campos, 1987; Campos, Dahl, & He, 2010).

Arnold's (1960) neurobiological view was prescient, forecasting contemporary affective neuroscience, which also conceptualizes the neurophysiology of emotion in terms of processes by which organisms perceive and orient to changing environments. Conscious perceptions of emotions, in the self or in others, create the impression of static events because these conscious percepts are *categorical judgments*. The terms we use for the judgments objectify glimpses of a psychological process that depends on a self-organizing nervous system and its connections to and from peripheral sensory and skeletal-muscular systems, systems that enable us to sense, perceive, process, and act on information. But contemporary neuroscience also shifts from an historic view of emotions as discrete and occasional events and to emotional processing as dynamic and relational (Davidson, 2000). At the physical level, neuronal activity is ongoing and reorganizes as circumstances change. At times, changes in brain circuitry specialized for discerning circumstances of significance for well-being, probably in association with associative networks help to construct meaning and classify experience. These processes occasionally achieve a magnitude of such adaptive importance that they reach conscious awareness (feelings). Similarly, when we observe changes in others' nonverbal signals in the context of situational cues, we are likely to make categorical judgments about their emotions. Whether observing self or others, we classify and conceptualize processes as discrete events. Because most of our knowledge has been founded on analysis of subjective feelings and observations of others, we have conceptualized emotions as categories, discrete

events. However, like many processes that are fundamental to human functioning (seeing, digesting, breathing, or walking), appraising and action readying operate largely outside of conscious mentation (Bargh & Morsella, 2008; LeDoux, 1996; Ohman & Soares, 1994; Panskepp, 1998; Pessoa, 2005). In addition to emphasizing the dynamic and relational nature of emotion, the functional perspective also emphasizes the highly context-sensitive nature of emotion. An example is a mother who frowns and says she is angry when viewing a video of her distressed infant; when she explains that she's angry with herself for letting a research assistant frustrate her infant, her anger is different than if she revealed that she was angry at the infant for getting distressed (Killeen, 2010). In sum, the capacity to be emotional is best conceptualized as continuous appraising of changing circumstances in terms of their significance for well-being and associated changes in readiness to act to maintain or regain states of well-being.

The dynamic, contextualized, relational nature of emotion poses a challenge to scientific endeavors, requiring inferences based on changes in sets of tangible, measurable phenomena in specific situational contexts. Emotional changes are inferred on the basis of patterns of physiology, self-reported experience, or observed actions, including nonverbal and verbal behavior, in the circumstances being processed (Cole, Martin, & Dennis, 2004). There are promising new directions in the study of emotion that will base inferences on examination of the dynamic, temporal flow of tangible indices of latent constructs, evaluated in context (e.g., Butner, Diamond, & Hicks, 2007; Chow, Haltigan, & Messinger, 2010; Steele & Ferrer, 2011). A functional perspective on emotion also requires methods that carefully assess environmental conditions and predictions about end-states of goals and how goals can be achieved (Campos et al., 2010; Campos, Frankel, & Camras, 2004). Finally, it requires that we study emotion in contexts that are personally meaningful to participants and that we use methods that help us understand those personal meanings (Campos et al., 2010).

EMOTION AND PSYCHOPATHOLOGY

Despite its clear adaptive advantages, our capacity to be emotional often gets us into trouble. When emotion compromises the development of competent functioning, we refer to emotional dysfunction. Dysfunction connotes that the emotional processes are functioning in the interest of individual goals for well-being but at a cost to healthy development. Emotional dysfunction has been highlighted as a major correlate and potential precursor of many adult and childhood psychological disorders (Aldao, Nolen-Hoeksema, & Schweizer, 2010; Berenbaum, Raghavan, Le, Vernon, & Gomez, 2003; Cicchetti, Ackerman, & Izard, 1995; Cole, Michel, & Teti, 1994; Gross & Muñoz, 1995; Keenan, 2000; Kring & Bachorowski, 1999; Southam-Gerow & Kendall, 2002; Vine & Aldao, 2014). In addition, its broad relevance as a general feature of psychopathology, emotional dysfunction has been conceptualized as a central feature of many specific disorders, including schizophrenia spectrum disorders (Johnson & Fulford, 2009; Kring & Moran, 2008); eating disorders (Greeno, Wing, & Shiffman, 2000; Haynos & Fruzzetti, 2011); mood disorders (Joormann & Gotlib, 2010; Luby, 2009; Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008); anxiety disorders (Behar, DiMarco, Hekler, Mohlman, & Staples, 2009; Mennin & Fresco, 2010); and various impulse control and aggression-related disorders, including conduct disorder (Cole, Hall, & Radzioch, 2009; Frick, Ray, Thornton, & Kahn, 2013) and personality disorders (Cyders & Smith, 2008; Gratz & Gunderson, 2006; Linehan, 1993; Tragesser, Solhan, Schwartz-Mette, & Trull, 2007). This range of work has suggested that emotional difficulties are a core feature of all psychological disturbances (Bradley, 2000).

If being emotional is an essential, ubiquitous process motivating action, then it logically follows that emotional processes are intricately involved in both maladaptive and competent functioning. At first flush, a large and wide-ranging body of research has suggested that the differences in emotional functioning between individuals with and without diagnosed disorders involve differences in three related areas: greater intensity, duration, or frequency of negative emotion; biases in attending to or classifying others' emotions; and a lack of certain emotion regulatory strategies. Added to these common themes are aspects of emotional dysfunction that arise from clinical observations, including emotional numbing and blunted emotional expression, limited self-awareness of emotions (poor emotional clarity), insensitivity or hypersensitivity to emotion, and the ineffective strategies or ineffective use of typically effective strategies for coping with negative emotions or problem situations. In sum, the research literature suggests a range of ways in which the emotional functioning of individuals with psychiatric disorders deviates from typical functioning. This literature often compares one group of individuals with a *DSM*-defined diagnostic condition with healthy controls, but this research has not yielded evidence that any single form of emotional dysfunction is associated with any single disorder. Rather, emotional dysfunction is widely implicated in psychopathology.

The realization that emotional dysfunction is pervasive in psychopathology is consistent with the push for a transdiagnostic approach to clinical problem identification and intervention (Cuthbert & Insel, 2013). The integration of a functional perspective on emotional development with a developmental psychopathology framework is compatible with the contemporary trend toward transdiagnostic approaches to psychopathology and intervention (Harvey, Watkins, Mansell, & Shafran, 2004; Nolen-Hoeksema & Watkins, 2011). The transdiagnostic approach contends that psychological processes that have gone awry can be shared across different disorders and that targeted intervention need not depend on diagnostic classification. As one example from the adult psychopathology literature, blunted affect in schizophrenia and anhedonia in depression potentially share a common core. Adults with schizophrenia process positive emotional stimuli similarly to healthy controls in some respects, but they differ in that they do not anticipate or sustain attention to positively valenced stimuli (Gard, Kring, Gard, Horan, & Green, 2007; Horan, Wynn, Kring, Simons, & Green, 2010). Impairments in anticipating pleasure and maintaining positive emotions are also associated with major depression in both adults (e.g., Sherdell, Waugh, & Gotlib, 2012) and have been investigated as a risk factor for depression in young children (e.g., Durbin, Klein, Hayden, Buckley, & Moerk, 2005; Olino et al., 2012).

From the functional perspective, then, there is a need to understand the developmental processes that foster the ability to anticipate positive outcomes, even in the face of blocked or lost goals, and how this capacity may be compromised. In one of our studies, a typically developing 36-month-old cannot get a locked box open to retrieve a desired gift. As she continues to try she becomes increasingly frustrated and begins to mutter, "I can't do it. I can't do it." But then she shifts from the appraisal/action readiness pattern of persisting with effort to overcome the blocked goal to a pattern of relinquishing the goal. That is, she flops back in her chair, discouraged, and her attention wanders. But in a moment she returns her attention to the locked box and says with a lilting voice, "Maybe this time I can do it. I know I can!" Her capacity to anticipate positive outcomes appears to modulate a very reasonable appraisal that she may have encountered an unsolvable problem. Her negative emotion, of which she had a bit, is not the best way to understand her. Rather it is the changing, unfolding emotional relations she has with the locked box that distinguish her response from the children who give up or tantrum. A developmental perspective on the functional nature of emotion, especially work that places emotional dynamics in situational context, has significant promise for identifying features of emotional competence and early detection of risk for atypical emotional development. Resulting findings can inform interventions that remediate atypical conditions and prevent psychological disorders. The functional perspective on emotional development allows us to conceptualize the nature of emotional competence, how it develops, and how it may go awry. To understand atypical emotional development, we must first understand emotional competence.

EMOTIONAL COMPETENCE

If psychopathology involves maladaptive functioning in a person's relation to the environment, then psychopathology must always involve emotion processing and often involves emotional dysfunction. Therefore we can use the construct of emotional competence as a hallmark of healthy emotional functioning against which to contrast emotional dysfunction. Emotional competence has been identified as a critical component of healthy functioning throughout childhood and adolescence in terms of success in both academic and interpersonal functioning (Cicchetti, Ackerman, & Izard, 1995; Denham, 2006; Raver, 2003; Roeser, Eccles, & Sameroff, 1998). The construct is similar to one used in clinical and personality research with adults, emotional intelligence, which is also associated with well-being and success in relationships, education, and work (Brackett, Rivers, & Salovey, 2011; Nelis et al., 2011). From a developmental psychopathology viewpoint, then, it is important to understand and study the ontogeny of emotional competence and how in its course dysfunction arises such that functioning is impaired to the degree that it is regarded as psychopathology. The functionalist perspective on emotional development has informed conceptualizations of child emotional competence (Denham, 2006; Halberstadt, Denham, & Dunsmore, 2001; Saarni, 1999). Consistent with the central premises of the functionalist perspective, these models of emotional competence assert that emotional functioning cannot be conceptualized apart from context, particularly social meaning. In general, emotional competence entails being responsive to one's circumstances, including access to the full range of emotions, the ability to engage emotionally flexibly such that one is effective in accomplishing goals for well-being while behaving appropriately as defined by situational and sociocultural realities (Saarni, 1999). These models subdivide this complex construct into three domains of competence: (1) emotion expressiveness; (2) emotion awareness and understanding; and (3) emotion regulation.

The capacity to express emotion—both nonverbally and verbally—is the earliest developing emotional competency. It is critical to survival because survival depends on emotional communication and the formation and maintenance of early relationships. It includes the use of emotional expression to initiate, maintain, and coordinate social interaction. Building on this essential communicative function, emotional competence comes to include the ability to read and understand the emotions of others and to understand one's own emotional experiences and associated actions. Accurately interpreting the emotion signals of others in terms of their needs for well-being and coordinating their needs with one's own well-being is an essential aspect of emotional competence. As individuals develop across the life span, their accumulating experience and growing emotion knowledge enables them to make increasingly sophisticated judgments and to find solutions to complex intra- or interpersonal problems. Finally, although the capacity to be emotional equips us to respond instantly, intensely, and persistently in our own best interests, competence reflects learning to balance this capacity with the constraints posed by situations and relationships. Thus the third main component of emotional competence is emotion regulation. This last component involves the ability to anticipate, modulate, and reorient emotional responses for them to serve both self-focused and social goals. These three components, which can be distinguished conceptually and are often studied in isolation, are not mutually exclusive; in fact they are deeply intertwined. Nonetheless, they develop on different time courses. In the next sections, we review knowledge regarding the development of the capacity to be emotional and the constituents of emotional competence, beginning with the origins of the capacity to be emotional. We prioritize evidence that examines emotional functioning in situational context and that considers longitudinal relationships that advance our ability to hypothesize the role of emotion in developmental trajectories toward emotional competence and emotional dysfunction. In the discussion, we consider the ways that the emergence of competence in given domains equips the child for productive, effective behavior but also introduces vulnerabilities that set the stage for the development of emotional dysfunction and psychopathology.

DEVELOPMENT OF EMOTIONAL COMPETENCE

The Prenatal Period: Typical Development

For a long time, it was assumed that the behaviors and abilities observed in neonates were innate and inherited, attributable to genetic factors. This view has been altered by remarkable advances in our understanding of genetics and gene–environment interplay. In addition, changing views of the role of genetics in human functioning are shaped by growing knowledge about the development of physiological systems and behavior during the prenatal period. The basic capacity to be emotional depends to a substantial degree on fetal development.

Advances in the field of genetics have revealed the exquisite complexity of the human genome, the limits of its contributions to psychological development, and its intricate dependency on environmental input. It is no longer the case that we can assume that the genes inherited from each parent are simple replicates that explain complex developmental outcomes such as personality traits or psychiatric disorders. Genetic variations influence the formation of physiological systems, by which psychological processes emerge, and contribute to the capacity of the developing organism to sense, perceive, process, and respond to environmental conditions. Moreover, current knowledge indicates that there are over 20,000 genes in humans, thousands more noncoding RNA genes that regulate DNA genes, (perhaps) 80–100 gene mutations between each generation (some of which affect the individual and others of which affect future generations), epigenetic processes that determine whether a gene is expressed, and, complex multigene interactions that most likely underlie the developmental outcomes we are so eager to explain, such as mental processes, behavioral traits, and psychological disorders. A thorough discussion of the field of genetics is beyond the scope of this chapter, but several general points can be derived from current research on genetics to inform the role of emotion in the development of psychopathology:

1. Characteristics of each individual human genome contribute to the physiological structures and functions that enable the capacity to be emotional and to individual differences in this capacity.
2. Genetic variations influence outcomes such as emotional competence or psychopathology through their influences on components along the pathway from genotype to psychopathology, including the development of physiological structures and processes such as neural structures, neural transmission, and neural networks (Bevilacqua & Goldman, 2011; Gottesman & Gould, 2003). These neurophysiological elements are steps in pathways from the genome to emotional functioning, pathways that involve many steps.

3. Despite considerable research on candidate genes, it is generally assumed that the influence of any single gene depends on both epigenetic factors (Gottlieb, 2007; Harper, 2005; Meaney, 2010) and gene-by-gene interactions (Hariri & Holmes, 2006; Stranger, Stahl, & Raj, 2011). Thus, for a gene like the serotonin transporter gene (5-HTT) to influence any aspect of emotional functioning depends on the expression of other genes and environmental conditions.
4. Genetic influences on neurophysiological processes are rarely inherently pathogenic (Cicchetti & Rogosch, 2012; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011; Homberg & Lesch, 2011). A phenotype such as sensitivity to negative emotion in human faces may be an emotional competency, a risk factor, or both. For example, the well-being of marital partners depends on each partner's sensitivity to the other's emotions; heightened perceptual sensitivity to negative emotions in faces, often regarded as a risk factor for psychiatric conditions such as anxiety disorder or borderline personality disorder, is an asset in the partner of a person suffering Parkinson's disease, a condition that impairs the clarity of emotion expression (Petrican, Moscovitch, & Grady, 2014).
5. Finally, genetics research underscores the critical importance of the environment on which much genetic influence depends. Consider again heightened perceptual sensitivity to negative emotion. In the context of emotionally supportive families, children who are predisposed to react strongly to others' negative emotion may be fussy and unhappy infants but some may become highly sensitive, productive, satisfied adults, such as various types of artists who skillfully depict human emotion in the face or professionals like therapists or other care providers who are highly attuned to the unspoken needs of their clients. If, however, the environment surrounding reactive children is emotionally adverse (e.g., unmitigated harsh parenting and the absence of adult supports for coping with adversity), their sensitivity to others' emotions may contribute to self-doubt, compromised self-esteem, and persistent interpersonal difficulties.

In sum, nature and nurture "mutually constitute each other" (Sameroff, 2010, p. 9). The neurophysiological undergirding of appraisal, action readiness, and emotion-relevant behavioral processes depend on genetic contributions but these account for only part of the variance in any given form of psychopathology, even among the more heritable conditions (Duncan, Pollastri, & Smoller, 2014; Bevilacqua & Goldman, 2011). More sophisticated research incorporating the best genetics methods and detailed understanding of the environment, including the prenatal environment, will contribute significantly to our understanding of the development of the capacity to be emotional. This will advance our knowledge beyond the simplistic view of a candidate gene interacting with an adverse environment to produce a psychiatric disorder, and help us study and document the pathway of endophenotypes that link genetic influences to outcomes of relevance for emotional functioning and dysfunction. Thus, the basic tools that undergird the capacity to be emotional depend on genetic processes, and their expression depends on environmental conditions; to survive, it is critical for these aspects of development to occur before the infant is born. Thus, another important step in the emotional pathway to competence includes the influences of the prenatal environment.

In the prenatal period, the nervous system develops rapidly—neurons develop, proliferate, migrate, and begin to form connections with other neurons, allowing sensory, cardiovascular, and cardiopulmonary systems to begin to organize (Anderson & Thomason, 2013; Glynn & Sandman, 2011). Fetal processing of the environment begins, and by the third trimester activity that presages infant behavior is detectable. By the twenty-fifth gestational week, the fetus is responsive to stimuli, such as stimulus-induced heart rate changes and motor activity including facial activity (Gingras, Mitchell, & Grattan, 2005; Kisilevsky, Muir, & Low, 1992). By the thirty-sixth week, the fetus responds to loud sounds, including the mother's voice, with changes in fetal heart rate, head turning, and eye movement (DeCasper, Lecanuet, Busnel, Granier-Deferre, & Maugeais, 1994), which may account for neonates' apparent recognition of their mothers' voices (DeCasper & Fifer, 1980). Notably, a single case study indicated that fetal temporal region activity (assessed by fetal function magnetic resonance imaging [fMRI]) is specific to the changes in the mother's voice (Jardri et al., 2012). In sum, the development of physiological systems that enable psychological functions occurs in utero and may depend on qualities of the fetal environment. Stimuli that affect the structure or function of fetal neurophysiological systems include acoustic signals, nutrients, hormones, and movement (Glover, 2011; Mayes, 1999; Raznahan, Greenstein, Lee, Clasen, & Giedd, 2012). Development in the prenatal period appears to involve neurophysiological changes that ready the infant for entry into the caregiver–infant relationship, in which emotional communication is critical.

Risk for Emotional Dysfunction Associated with Prenatal Period

Appreciation that the prenatal environment influences fetal development has heightened awareness of potential effects of prenatal risk exposure. Much of this research has had to depend on animal models that permit experimental manipulation of hypothesized mechanisms (for reviews see Boksa, 2010, on prenatal infection; Field, Diego, & Hernandez-Reif, 2006, on maternal prenatal depression; Gräff, Kim, Dobbin, & Tsai, 2011, on multiple risk factors; Meyer & Feldon, 2010 on conditions posing risk for schizophrenia). Due to the complexity of human neurophysiological systems, it is not yet possible to extrapolate findings from animal model research to the emotional development of the human child, and this fact has motivated studies of the human prenatal environment. When the effects of the prenatal environment are studied in humans, the main research design has been to contrast infants of mothers with an identified risk factor during the prenatal period—for example, substance use (antidepressants, smoking, cocaine), emotional problems (stress, depression, anxiety), or malnutrition or disease (anemia, infection)—with infants of mothers without such conditions. This work suggests that certain biochemical and environmental conditions can stress, foster, and compromise fetal development.

Research on stress and the human prenatal environment initially focused on fetal physical development, such as gestational age and birth weight. There is, however, considerable interest in the effects of maternal prenatal stress on the infant or child's later psychological functioning, including emotional functioning (Glover, 2011; O'Donnell, O'Connor, & Glover, 2009). Maternal stress, defined by maternal anxiety about the pregnancy or by clinical symptoms of depression and anxiety, affects blood flow to the placenta and distributes glucocorticoids through the placenta, a mechanism by which maternal stress may influence fetal brain development (often referred to as fetal programming). Much of this work suggests that maternal prenatal stress has deleterious effects on infant emotional functioning. Specifically, effects have been reported for greater infant fear and anger reactivity (Davis et al., 2004; DiPietro, Ghera, & Costigan, 2008), cry reactivity (Werner et al., 2007), and stress reactivity (Glover, 2011) and poorer attention control, which could affect regulation of emotional reactions (Huizink, Robles de Medina, Mulder, Visser, & Buitelaar, 2002).

These findings, however, are often limited by study design. For example, they often focus on only one of various types of stresses a pregnant woman can face (e.g., pregnancy-related anxiety, daily hassles, marital strife, symptoms of psychopathology, physical illness) or on only one of several potential infant outcomes that may be affected. In studies that measured multiple infant outcomes, effects emerge for some but not all outcomes (e.g., attention regulation but not emotion regulation; Glover, 2011). Furthermore, because prenatal stress is typically assessed by maternal self-report, studies are often limited in their ability to parse out the degree to which infant or child outcomes are influenced by maternal trait stability (an anxious pregnant woman may also be a chronically anxious mother), heritable stress responding (shared genetic variance), and prenatal environmental conditions (Federenko et al., 2006; Kendler & Prescott, 2006). In addition, most studies overlook the fact that the fetus *contributes* to the prenatal environment. The fetus generates the placenta, a source of corticotrophin-releasing hormone (CRH), and the fetus also begins to engage in behavior (e.g., motor activity; DiPietro, 2012). A study that attempted to circumvent some of these constraints compared infants who were conceived through in vitro fertilization by related or unrelated parents (Rice et al., 2010). Relying on maternal retrospective reports of stress, the study concluded that lower infant birth weight, earlier gestational age, and childhood misconduct were related to late pregnancy prenatal stress for both related and unrelated parents, suggesting influences of the fetal environment rather than genetic contributions. In contrast, it reported that child attention-deficit/hyperactivity disorder (ADHD) symptoms appeared only for offspring of related parentage and these were thus attributed to genetic factors. Finally, a link between prenatal stress and child anxiety symptoms was mediated by concurrent maternal anxiety and depressive symptoms.

Clearly, critically needed research on the prenatal environment is in its early stages. As limitations of study designs are met with solutions, this line of research is likely to help us understand the conditions that foster or compromise the neurophysiological components that support the capacity to be emotional. It is unknown what will be learned but it is reasonable to anticipate that not all effects of prenatal stress may be deleterious. Pregnancy-specific psychological stress, rather than symptoms of clinical anxiety, was associated with increased fetal motor activity, accelerated neurological maturation as indexed by neonate auditory ERP, and neonate irritability (DiPietro et al., 2010) as well as by higher scores on the Bayley Scales of Mental Development at age 2 years (DiPietro, Novak, Costigan, Atella, & Reusing, 2006). In life, stress exposure creates demands to

adapt and adaptations can facilitate development as well as create risk.

In sum, it is likely that risks associated with prenatal development, both in terms of genetic unfolding and environmental factors, can compromise the capacity to be emotional and the most fundamental building blocks of emotional competence. That is, the consequences of fetal programming of the nervous system and fetal adaptations to the prenatal environment must be considered in the pathway to emotional functioning. Relatively mild stress may facilitate aspects of fetal neurodevelopment in ways that enhance later emotional functioning (e.g., through fostering attention or emotional skills), whereas exposure to more severe stress (e.g., maternal clinical anxiety) may compromise the most basic neurophysiological processes on which the development of emotional competence is founded.

The Development of the Components of Emotional Competence

Emotional Expressiveness, Understanding, and Regulation

The prenatal period equips the infant with the basic neurophysiological systems that enable information processing, including experience–expectant neurophysiological networks that will further develop as the infant interacts with its new environment (Greenough & Black, 1992). The neonate enters an emotionally rich environment, including the critical interpersonal environment. The interactions of infants and caregivers depend on the capacity to be emotional and these interactions influence the development of component skills that will lead to the development of an emotional competent person.

Emotional competence can be analyzed in terms of three main domains of emotional functioning: emotional expressiveness, emotion understanding, and emotion regulation (Denham, 2006; Halberstadt et al., 2001; Saarni, 1999). Each of these domains is discussed separately, with an emphasis on the individual child's development. However, the larger view from the functional perspective is that each domain of emotional competence is inextricably related to the other. Moreover, each domain must be understood in terms of actual situations that are personally relevant to the child, particularly interpersonal contexts. Furthermore, the emotionally competent person draws from each domain to engage the world in an effective way to achieve personal goals for well-being in the context of social interactions, relationships, and rules of conduct. When possible, the review emphasizes studies in which emotional competence has been studied in real or realistic circumstances. Next, each domain of emotional competence and the evidence for its developmental progression described. Each is introduced in terms of how it supports healthy psychological functioning and then considered in terms of how it contributes to vulnerabilities that lead to the development of emotionally dysfunctional appraisal/action readiness patterns and increase the chances of developing psychopathology.

Typical Development of Emotional Expressiveness

Emotional competence involving emotional expressiveness is defined by the ability to respond to circumstances with a full range of emotions and to communicate emotion effectively (in terms of achieving goals, which includes both personal and social goals), appropriately (in terms of sociocultural standards), and flexibly (in terms of situational appropriateness) (Cole, Hall, & Hajal, 2013; Denham, 2006; Halberstadt et al., 2001; Saarni, 1999). The emotionally competent child experiences and conveys emotion in a spontaneous and authentic manner. That is, the child is emotionally responsive to the variety of situations and interactions—familiar and novel—and conveys that emotional responsiveness in age appropriate, situationally relevant, socially acceptable ways. To do so requires the ability to modulate emotional expressiveness in ways that accomplish personal goals but also conform to situational demands and sociocultural values. The importance of emotional expressiveness in early childhood is revealed in detailed observations of preschool-age children at school (Fabes et al., 1999). In this natural setting, children's patterns of emotional expressiveness, both positive and negative, as they interact with peers and teachers are associated with teacher ratings of child social competence, even at such a young age.

The capacity to express emotion begins to develop in utero. In the first year of life, typically developing infants express emotions through nonverbal modes of communication, their facial expressions, the prosody of their vocalizations, and often their whole bodies. Within the first year, children begin to gesture to communicate personal goals (e.g., shaking the head to indicate no) and in the second year, soon after children begin to use words, they begin to refer to simple, basic emotions. By the third birthday, typically developing children show signs that they can engage in spontaneous expressive control. The ability to engage in emotional expressiveness is critical to the development of the other domains of emotional competence—emotion understanding and emotion regulation—and each of these contributes to emotional expressiveness over the course of childhood and adolescence.

Nonverbal Emotional Expressiveness

The neuromuscular systems that will enable emotionally meaningful communicative behavior with caregivers develop in utero for most infants. The motor branch of the facial nerve develops as early as the third week of gestation, and by 12 weeks synapses have begun to form, such that tongue and lip movement are observed (Molina, Reyes, Joshi, Barrios, & Hernandez, 2010). To engage in behavior like smiling, for example, the neural signal takes a somewhat arduous path from the brain through the temporal bone to the facial muscles. Early in the third trimester, fetuses engage in facial activity in which can be discerned behaviors that resemble frowning, smiling, crying, and laughing (Gingras et al., 2005; Kurjak et al., 2003; Reissland, Francis, Mason, & Lincoln, 2011; Yan et al., 2006). Thus, fetal development prepares the infant for interpretable emotional expressiveness, ensuring that the infant will be able to signal information about well-being to caregivers who can read those signals and provide for the child's needs. This process forms the foundation of the deep emotional bonds that will later mature into attachment security.

Interactions between infants and caregivers are emotion-rich exchanges that enable caregivers to interpret and meet the needs of the dependent infant and provide experiences that help infants form expectations about their emotional lives and relationships (Bowlby, 1969; Sroufe, 1997). Infants communicate about their well-being—whether their needs are met or not—through nonverbal behavior, mainly facial and vocal activity, often accompanied by gross motor activity. Initially, infant nonverbal signals are not highly specified in terms of basic categorical emotions. Crying is the earliest emerging signal of distress; even undifferentiated vocal distress conveys information about infant well-being (Izard et al., 1995; Oster, Hegley, & Nagel, 1992). Most caregivers are eager to and intent on interpreting infant nonverbal signals, adjusting their actions in efforts to stimulate and extend infant contentment and to alleviate infant distress. Caregiver reliable, sensitive responsiveness to these signals are the basis of the development of the child's sense of security, internal representations that distress can and will be alleviated. These attachment representations have long-lasting implications for close relationships throughout life (Isabella & Belsky, 1991; Izard, Haynes, Chisholm, & Baak, 1991; Simpson, Collins, Tran, & Haydon, 2007).

There is considerable debate regarding the presence and ontogeny of facial expressions of discrete emotions. In large part, the debate hinges on a conceptual issue regarding the degree to which human infants are biologically prepared to engage in motoric activities, such as facial configurations, that represent discrete emotions, and a methodological issue regarding the degree to which infant facial activity in emotion-relevant situations are discrete and specific. One view contends that infants do not communicate a set of basic, discrete emotions in the first year of life and that emotions are something more than hard-wired programming that unfolds in infancy (Camras et al., 2007; Camras & Shutter, 2010). An alternative view is that there is a core of first-order emotions (e.g., interest, joy, sadness, anger) for which infants are biologically prepared and that as early as the second month infants begin to engage in the first discrete expressions (Izard, 2011; Izard et al., 1995; Malatesta, Culver, Tesman, & Shepard, 1989). One way to integrate the information gleaned from both perspectives is to hypothesize that (1) human infants are biologically prepared for certain forms of appraisal/action-readiness patterns, which include nonverbal communication, that are socially interpreted as basic emotions; (2) that the facial musculature may not be capable of producing discrete expressions in early infancy but that infants may engage in varied and seemingly random facial activities that are a form of facial babbling; (3) that regardless of the clarity and specificity of infant nonverbal communications, most caregivers work diligently to interpret these nonverbal behaviors as signals about the infant's well-being; and (4) that during infant–caregiver interactions psychological meaning is ascribed to these expressions, contributing to the development of discrete expressions (Cole & Moore, 2015). Our understanding of infant expressive development will benefit from a view that includes consideration of both biological preparedness to engage in particular appraisal/action readiness patterns as well as appreciation of the influence of the interpersonal context in which communicative behavior develops and in which meaning is made. In sum, emotional expressiveness develops in the first year of life, contributing to the development of relationships, importantly the attachment relationships.

In the first months of life, infants engage in at least two forms of facial and vocal activity that are interpreted as meaningful by caregivers: crying, which is interpreted as indicating infant distress, and smiling, which is interpreted as indicating infant pleasure. Movements observed in the third trimester through the use of high-resolution sonograms suggest that fetuses engage in cry- and smile-like activities in utero, suggesting biological preparation for communicative signals that will be critical for survival in the first days of life (Gingras et al., 2005; Reissland et al., 2011). Crying and smiling behavior has been observed in neonates (e.g., Barr, Hopkins, & Green, 2000; Bertin

& Striano, 2006; Cecchini, Baroni, Di Vito, & Lai, 2011; Messinger et al., 2002; Zeskind, 2013). Although it is not yet known when infant facial and vocal activity reflects infant social understanding, it is clear that these nonverbal expressive behaviors have meaning for caregivers; typically, caregivers respond both physiologically and behaviorally, organizing to respond contingently, which serves to elicit infant responses, such as infant mirroring of an adult's smile (e.g., Del Vecchio, Walter, & O'Leary, 2009; Lavelli & Fogel, 2005). Moreover, although there are cultural differences in caregiver responsiveness to infant crying and smiling, it appears that all typically developing infants not only cry but also begin to engage in social smiles around age 2 months (Keller, 2013; Wörtmann, Holodysnki, Kärtner, & Keller, 2012).

Risk for Emotional Dysfunction Associated With Nonverbal Emotional Expressiveness. Because of the importance of nonverbal emotional expressiveness for an infant's survival and for the formation of a secure attachment, this capacity is sensitive to conditions that compromise effective emotional expressiveness. First, there are rare conditions that involve paralysis or very poor muscle tone, such as facial palsy, congenital myotonic dystrophy, Willi-Prader syndrome, and Möbius syndrome that interfere with expressiveness, including emotional expressiveness, and introduce significant consequences for social interaction and relationships, including the all-important caregiver–infant relationships on which attachment is founded. Möbius syndrome, for example, causes facial paralysis in infants. Impairments in facially expressive behavior were observed in all 25 children with Möbius syndrome in one of the rare studies of these infants (Sjogreen, Andersson-Norinder, & Jacobsson, 2001). This study, however, did not evaluate infant emotion expressiveness or emotional functioning. A single case study of an infant with Möbius syndrome (Szajnberg, 1994) noted that the child's separation behavior at age 14 months was consistent with an insecure (resistant) attachment, despite apparently normal cognitive development. This was interpreted in terms of the caregiver's difficulty knowing the infant's needs, which affected the ability to respond sensitively, leading to an insecure attachment.

Other neurodevelopmental conditions that are present early in life may also interfere with competent expressive behavior. There is a dearth of research on the emotional expressiveness of infants and young children with these conditions, limiting our ability to trace the contribution of atypical emotional expressiveness to the development of emotional dysfunction (Adams & Oliver, 2011). Down syndrome has varied presentations but children with this condition often present with hypotonia (muscle laxity) and delayed motor coordination, which can affect facial activity. Unlike infants with Möbius syndrome, infants with Down syndrome spontaneously engage in emotional expressions but, relative to typically developing infants, their expressive behavior develops more slowly and can be difficult to interpret (Carvajal & Iglesias, 2006; Cicchetti & Sroufe, 1976), which may contribute to higher rates of insecure attachment in these children by toddler age (Ganiban, Barnett, & Cicchetti, 2000). Due to their difficulties with social communication, there is more research on emotional expressiveness in children with autism than children with other neurodevelopmental disorders, although there is no known neuromuscular cause of expressive impairment. When compared with age-matched (chronological or mental age) children, young children with autism express emotion, both facially and vocally. However, they tend to display more negative and less positive spontaneous emotion, produce less articulated or more awkward expressions both in spontaneous social interaction and when asked to produce or mimic emotional expressions, have more monotonic prosody, and express emotion spontaneously more often during self-absorbed activity than during social interaction (Capps, Kasari, Yirmiya, & Sigman, 1993; Grossman, Edelson, & Tager-Flusberg, 2013; Hubbard & Trauner, 2007; Lord et al., 2000; Loveland et al., 1994; Snow, Hertzig, & Shapiro, 1987). For children with autism, atypical emotional expressiveness may be related to their difficulty engaging in face-to-face social interaction than in an impaired capacity to be expressive (McIntosh, Reichmann-Decker, Winkielman, & Wilbarger, 2006). A tendency to avoid social interaction, including avoiding looking at others' faces, could interfere with the types of affect mirroring and observational learning that is part of the coconstruction of meaning that occurs in typical infant–caregiver interactions. Discomfort or difficulty processing face-to-face communication then could affect how often and how well children will communicate nonverbally, which would then compromise their ability to convey unmet needs, which could increase their frustration, as well as create risk for emotion understanding and emotion regulation.

In sum, early childhood neuroatypical conditions may affect a child's ability to produce clear emotional expressions that others can use to interpret the goals and needs of the child. To the degree that children have such difficulty, their emotional competence in all domains is placed at risk.

There is little work that examines the pathway from neurodevelopmental risk to quality of emotional expression, but this represents one potential explanation for why these children have a higher incidence of mood and behavior problems (Eisenhower, Baker, & Blacher, 2005; Ross & Oliver, 2003). Early infant–caregiver emotional exchanges depend on infant non-verbal emotional expressiveness and compromised infant expressiveness is a risk factor for the development of a secure attachment, which is associated with lifelong challenges to healthy psychological functioning (e.g., Cicchetti & Roisman, 2011; Mikulincer & Shaver, 2012).

Being able to communicate whether needs are met or unmet, however, does not necessarily avoid risk for emotional dysfunction. It is essential that caregivers have the resources to understand those infant expressions and that accurately perceived infant expressions do not overwhelm the capacity of caregivers to attend to infant needs. First, infants who competently convey emotion depend on caregiver responsiveness to further develop their emotional competence. The quality of caregiver responsiveness to infant distress signals appears particularly important for later emotional competence. More than responsiveness to infant contentment and joy, caregivers' emotional responses to infant distress and the promptness and sensitivity of their actions appear to influence infant attachment status at age 16 months and child emotional functioning at 36 months (Leerkes, Blankson, & O'Brien, 2009; Leerkes, Parade, & Gudmundson, 2011). Second, some infants who are able to express emotion do so in ways that interfere with infant–caregiver interaction quality. It has long been understood that there are individual differences in very young infants, which has come to be understood as temperament. That is those individual differences reflect constitutional, neurobiologically based predispositions affecting infant reactivity to the environment and infant readiness and capacity for regulation (Rothbart & Derryberry, 1981). Some infants are characteristically quick and intense in their reactions to changes in the environment and not readily soothed or able to self-soothe (Rothbart & Bates, 2006). Their intense, enduring distress challenges caregiver–infant interactions (Kim & Kochanska, 2012; Leerkes et al., 2011). In this case, emotional expression of distress is not hard for caregivers to perceive, but the source of distress and what will alleviate the distress may be difficult to understand. Thus, the infant's ability to express emotion and the caregiver's ability to read infant emotion expressions are interpersonal microprocesses that are critical to relationship formation and quality, which are in turn critical for healthy development of the components of emotional competence. Atypicalities in infant–caregiver emotional expression interaction pose risk to relationship development, learning about emotion, and developing a repertoire of regulatory strategies. Thus this constitutes a potential path to emotional dysfunction that can consolidate in the form of symptoms of psychopathology, including co-occurring mood and behavior problems in infants with neuroatypical conditions.

Beyond infancy, caregivers continue to address children's needs but they also make more attempts to socialize child emotion expression. Often implicitly, and sometimes explicitly, socialization processes acculturate child emotional expressiveness (Cole & Tan, 2015). That is, in the course of caregiver–child interaction, children's emotions are socialized even caregivers are focused in children's conduct more than their expressiveness. As young children walk and broaden their repertoire for communication, caregivers strive to get toddlers to coordinate their emerging autonomy efforts with the constraints of their settings and to do in terms of caregivers' sociocultural expectations for acceptable, safe behavior. In addition to implicit socialization of emotion, caregivers may also explicitly teach or coach very young children as a response to child emotional expressiveness (Brophy-Herb et al., 2011; Lunkenheimer, Shields, & Cortina, 2007). In the course of these social exchanges, the typically developing child acquires a sense of the categorical, separate self, which matures into a formal theory of mind in the fourth year (Edwards & Liu, 2002; Wellman, 2011). The development of a sense of both self and other then contributes to the expansion of the emotional expressiveness repertoire, seen in toddlers' expressions of pride, embarrassment, guilt, and empathy (Davidov, Zahn-Waxler, Roth-Hanania, & Knafo, 2013; Lewis & Sullivan, 2005; Stipek, 1983).

This discussion of risk for emotional dysfunction has thus far emphasized nonverbal expression in the first years of life. Moreover, it has relied on studies that tend to focus on facial expressions. There is much more limited knowledge about typical and atypical development in other expressive channels, such as the voice, gesture, and body movement, which may have different developmental courses (Malatesta-Magai, Leak, Tesman, & Shepard, 1994). Nonetheless, we can conclude that, by the end of the second year of life, most typically developing children have a sizeable repertoire of nonverbal emotionally communicative behavior. To the degree that children's nonverbal emotional expressiveness is difficult for caregivers to understand, there is risk for the child–caregiver relationship, which is central to all aspects of the development of emotional competence. In the second year, however, an

important developmental milestone in typically developing children is the ability to communicate about goals and needs in a new way, through language. Verbal emotional expressiveness refers to the semantic content of speech rather than nonverbal activity.

Typical Development of Verbal Emotional Expressiveness

Very young children have remarkable growth in expressive language between infancy and school entry (Hart & Risley, 1995). Theoretically, the ability to verbalize needs and desires should reduce reliance on nonverbal communication of emotion and improve the specificity with which needs and goals are communicated in addition to contributing to emotion understanding and emotion regulation (Cole, Armstrong, & Pemberton, 2010). Studies show that children with language delays are more likely than the general population to have behavior problems, and children with behavior problems are more likely than the general population to have language delays. There are however very few studies that explain how and why language development contributes to any aspect of emotional competence (Cole et al., 2010).

Two longitudinal studies build on cross sectional evidence of associations between language development indices and aspects of emotional competence. Each found that toddler language skills contributed significantly to children's self-regulation during the preschool-age years (Roben, Cole, & Armstrong, 2013; Vallotton & Ayoub, 2011). For example, language skill level (relative to others) and the growth of language development (relative to self) in toddlers accelerated the normative decline in anger reactivity (in the context of having to wait to open a gift) between toddlerhood and preschool age (Roben et al., 2013). This effect appeared to involve children's development of putative regulatory strategies, including calmly verbalizing to the mother about the frustrating situation. Yet there is no reason to assume that the relation between expressive language and anger reactivity is unidirectional or that it is always an inverse relation. Intense emotional reactivity during the period of language acquisition may interfere with early language learning. Bloom (1995) contended that intense emotional reactions interfere with first word acquisition and vocabulary growth because the resources required for regulating the intense emotion compete for resources need for language learning. Longitudinal studies provide partial support of this contention, but only in the toddler years (Nozadi et al., 2013; Roben et al., 2012). On the other hand, being better able to verbalize needs appears not to automatically foster self-regulation as in the case of highly verbal, highly argumentative children. It is possible to draw on language skills to further self-determined goals for well-being that conflict with the goals of others. Thus, there is much to learn about the relations among child language development and its many facets and the development of emotional competence. Perhaps the most substantive research relating verbal expression of emotion and competence comes from research on children's ability to use terms for emotions.

Most of the research on children's emotion-related speech involves internal state language and specifically "emotion talk" (Bretherton, Fritz, Zahn-Waxler, & Ridgeway, 1986). As soon as children acquire expressive language, they begin to use terms for basic emotions, such as happy or mad (Bretherton et al., 1986). The methods used to study emotion talk often involve observations of parent and child interaction around hypothetical situations (e.g., talking about storybook characters) or reminiscing about past events involving the child. Parental use of emotion talk fosters young children's use of emotion terms, which in turn contributes to the development of theory of mind and social competence (Brownell, Svetlova, Anderson, Nichols, & Drummond, 2013; Taumoepeau & Ruffman, 2008). From the functionalist perspective, a particular interest is observing how children use language and nonverbal emotion expressiveness in situations that activate personally defined goals and not just contexts in which children are encouraged to talk about others' emotions or their own past emotions. These methods are used, however, because emotion talk occurs less often in naturalistic contexts, such as unconstrained home observations, and then child emotion talk appears to depend on parental use of emotion terms (Dunn, Brown, & Beardsall, 1991; Howe, Rinaldi, & Recchia, 2010). Naturalistic observations in the preschool setting recorded over two months yielded an average of 29 emotion references per child, with large individual differences (Fabes, Eisenberg, Hanish, & Spinrad, 2001). More often, preschoolers' internal state references were largely present tense, first-person references to their own likes and dislikes. Specific emotion terms were significantly less likely to occur: happy (10%), afraid (7%) sad (5%), and angry (3%). An interesting additional finding was that preschoolers' references to anger and sadness, although infrequent, usually entailed explanations about others' emotions rather than references to children's own experiences. Moreover, children who used emotion terms in explaining others' emotions were rated as more likable by their classmates. Thus, children's spontaneous references to emotion are infrequent, must

be taken in context, and are associated with competent social behavior.

Because observations of spontaneous speech are time-consuming and labor-intensive, researchers have used other strategies to place emotion talk in realistic context, such as examining references to emotion when parents and children discuss actual past events (Fivush, Hazzard, Sales, Sarfati, & Brown, 2003). Between ages 9 and 18 years, internal state language increases in narrative accounts of situations children and youth experience (Styers & Baker-Ward, 2013). The relevance of this method for understanding the role of verbal emotion expression may depend on the personal relevance of the recalled events for each partner as well as the timing of the conversations relative to when they happened. Immediately after a devastating tornado, mothers and their children did not refer to internal states any more than they did when discussing non-traumatic situations (Bauer, Stark, Lukowksi, Rademacher, & van Abbema, 2005). However, several months after the tornado, older children (~9 years old) made more references to their internal states than they had at immediately afterward, they did so more than younger children (~3 through 7 years), and their internal state language also increased in its specificity. Moreover, the history of the parent-child interactions may have been a factor. The effects were noted if mothers referred to positive emotions in discussing the tornado immediately afterward, suggesting that reminiscing about actual negative events may have been enhanced by the emotional tone of initial discussions. This work also suggests the value of repeated assessments when observing how children and their parents or peers verbally process the emotions associated with significant experiences.

Despite assumptions that children draw on their verbal abilities to cope with challenges to their goals, few studies have observed children's spontaneous verbalizations in such situations. However, there is research on young children's private speech, which is regarded as indicative of a transition from the sole function of speech for social communication to an internalization of social experience that guides action and problem solving (Berk & Winsler, 1995; Vygotsky, 1986). Day and Smith (2013) recorded preschool-age children's nonverbal emotion expressions and verbalizations in a quasi-naturalistic context: trying to attain a desired toy from a transparent locked box that would not open (mothers were present but asked not to engage in conversation). In this context in which children's expressions appeared authentic and spontaneous, nonverbal sadness was associated with mother-directed verbalizations, which can be interpreted as the use of both modalities to communicate their need for assistance in solving the problem. Their nonverbal anger expressions were associated with speech content that expressed frustration or hopelessness and fewer constructive self-instructions, which can be interpreted in the spirit of increasing effort to overcome the blocked goal. This study's findings raise interesting questions about the temporal dynamics of children's emotion expressiveness, verbalizations about emotion, and strategic efforts. That is, do outcomes depend on what a child verbalizes or the order in which verbalization, emotion expressions, and action occur? If frustration builds, a child verbalizes hopelessness, and then rebounds to try again, as was the case of the little girl described earlier in this chapter, the verbalization of hopelessness has a different context than if the child gives up trying and begins to cry after such a verbalization. There is much to learn about verbal communication related to emotion in typical development.

Risk for Emotional Dysfunction Associated with Verbal Emotional Expressiveness. Problematic verbal interactions are a hallmark of caregiver–child interactions among children or parents with elevated symptoms or diagnosed conditions. Many studies ask participants to discuss family conflicts that allow observations of caregivers and their children (preschoolers through adolescents) talking about situations that are personally relevant. These studies often do not differentiate verbal and nonverbal emotional expressions and if they do code them separately they rarely analyze them separately. Speech content may have a very different meaning depending on the affective prosody and facial expressions with which it is communicated (Cole, Teti, & Zahn-Waxler, 2003; O'Kearney & Dadds, 2005). In general, this research demonstrates that the problem discussions of caregivers and children who are symptomatic involve more negative emotion than asymptomatic control groups. For example, caregiver and adolescent anger during an interaction in which families were asked to resolve conflicts found that adolescents with depression communicated more anger and had higher heart rates (Jackson, Kuppens, Sheeber, & Allen, 2011). In conflictual interactions, partners, including caregivers and children, tend to mirror each other's emotions (e.g., Cole, Teti, & Zahn-Waxler, 2003; Dumas, LaFreniere, & Serketich, 1995). Many of the communications in these studies involve situations in which each partner is blocking the other's goal. However, if a partner expresses sadness, is it reciprocated? Typically, we expect sympathetic responses to sadness. For instance, children report expecting caregiver support when they express sadness in contrast to their

expectations about caregiver responses to anger, which involve sanctions (Zeman & Garber, 1996). Perhaps the more serious risk is caregiver dismissiveness of children's negative emotions, including their sadness and anxiety (Lunkenheimer et al., 2007). Too often however research on verbal emotional expressiveness focuses on general caregiver reactions to child emotion (e.g., encouraging emotion expression) and not responses to different emotion expressions in specific situations (but see Morris et al., 2011; Zeman & Shipman, 1997). We should also be cautious about interpreting the angry conflicts of caregivers and children with symptoms or disorders as indicating that mutual anger necessarily represents risk. Anger, the appraisal/action readiness that a goal is blocked and a person is ready to respond with effort to attain it, is adaptive because it helps personal goal achievement particularly when the partners validate each other's anger and work toward resolution. A person diagnosed with depression who communicates anger is conveying something other than hopelessness or dysphoria. In the context of family interaction, we should consider that a depressed child or youth who is angry is still striving to communicate and achieve personal goals, even if those goals conflict with caregivers' goals. An important clinical question, then, is what distinguishes healthy angry exchanges from those that reflect dysfunctional interaction? Might anger buffer the depressed child or youth against despair and suicidality (Cole, Hall, & Radzioch, 2009)? A functional perspective requires a deeper analysis, which also requires analysis of the temporal, dynamic flow of interaction. Notably, in one prospective study adolescents who had been classified as secure as infants expressed more, rather than less anger, toward their mothers in the context of a frustrating game compared with adolescents who had been classified as insecure as infants (Spangler & Zimmermann, 2014); in other words, anger expression in this context was not associated with risk and may reflect implicit understanding that one can express authentic anger in the safety of a trusted relationship. In sum, how partners verbally communicate about emotions is as central to pathways toward dysfunction as nonverbal expressions. Intense nonverbal expressiveness of negative emotion however is likely to elicit strong reactions from partners that may interfere with the clarity of messages being communicated verbally.

Another clinically relevant issue regarding children's verbal expression of emotion and spontaneous talk in or about personally meaningful circumstances is the fact that many children with clinically elevated symptoms or diagnosed disorders do *not* talk about how they feel. There is little normative research to address why children come to this point, and clinical research dwells more on emotion understanding and regulation than it does on emotional expressiveness, with the exception of work on alexithymia, the condition in which individuals appear unable to label emotions. The ability to talk authentically and spontaneously about actual circumstances is an aim of most therapeutic approaches. There are several hypotheses that can be generated to consider the development of this impairment in an emotional competency. Some children and youth may lack emotional awareness. Others may be acutely aware of their emotions but avoid talking about intense feelings as a method of regulating them. Still others may be aware and willing to talk but expect that others will be punitive, misunderstand, or be indifferent to their needs. Parents and their 8- to 13-year-old children, with and without diagnosed anxiety disorders, were asked to discuss past occasions in which the child had been anxious, angry, and happy (Suveg et al., 2008). Mothers and fathers, particularly those whose children were diagnosed with anxiety disorder, expressed more negative emotion when recalling their children's anger (relative to anxiety and happiness) but this emotion specificity was not observed in the children. How does this pattern of interaction develop and where does it lead? Does parental anger reflect frustration with a challenging child? Is it a cause or a result of clinical levels of child anxiety? A similar reminiscing task was used to observe family interaction with 3- to 9-years-olds who were diagnosed with conduct disorder diagnoses; the children were divided into high and low categories on callous-unemotional (CU) traits (Pasalich et al., 2014); notably, children who were higher in CU traits communicated more negative emotion, but these were accounted for by references to sadness and fear (e.g., "sometimes you shout at me and I get *scared*"; p. 308). These verbalizations, which were contrary to predictions, were independently judged as appropriate and genuine communications, yielding findings that call into question the prevailing view of callous children being emotionally indifferent. They are also interesting in relation to a finding that preschool-age children who were emotionally inexpressive, relative to highly and modulated expressive children, were more likely than either of those other groups of children to report depressive symptoms two years later (Cole, Zahn-Waxler, Fox, Usher, & Welsh, 1996).

Research on verbal communication about emotion in school-age children and youth has not yet documented developmental pathways involving authentic verbal expression of emotion. The available literature suggests that the use of words to communicate about emotion begins as early as the second year of life and that the quality of

parenting influences whether children's verbal expression becomes an aspect of competent emotion expressiveness or an additional aspect of symptomatic behavior, such as being argumentative. From a functional perspective, research is needed that examines children's interactions with others about personally meaningful circumstances and that considers these interactions from multiple temporal perspectives: (1) the immediate temporal dynamics of emotion exchanges that involve personally relevant goals, including conflicting goals, and how each partner relates to the other leading to either effective problem solving or to prolonged or increased interpersonal conflict (see Dagne & Snyder, 2011, for an illustrative approach to time series of emotional exchanges), (2) consideration of whether and in which conditions it may become easier to discuss important topics with the passage of time (Bauer et al., 2005), and (3) prospective analysis of how communication about emotion contributes to stability and change of emotional dysfunction over time (Cole et al., 2003; Denham et al., 2000; Schwartz et al., 2012). In addition to incorporating a dynamic view, the functional perspective advocated for research to appreciate that negative emotions are not inherently problematic (anger reflects an effort to effect change) and that positive emotions are not inherently valuable (enjoying another's distress is callous). Emotional competence is defined by authentic, socially appropriate emotional expression, such that expressive control—being expressive but modulating expressiveness is key. The ability to verbalize about emotion, or at least to label emotions, may serve to dampen or modulate emotional reactivity, a regulatory function of language that has been observed in experimental (nonnaturalistic) studies with adults but which has not yet been studied in children (Lieberman, Inagaki, Tabibnia, & Crockett, 2011; Matejka et al., 2013). Competent emotional expressiveness, nonverbal and verbal, involves effective, appropriate, flexible communication and this entails the ability to modulate expressiveness, an aspect of emotion regulation that we discuss in the section on emotional expressiveness.

Typical Development of Expressive Control

The ability to modulate emotional expressiveness is consistently linked to parent- and teacher-rated child socioemotional competence in the preschool, elementary, and high school years (e.g., Blair, 2002; Eisenberg et al., 2001; Feldman, Tomasian, & Coats, 1999; McDowell & Parke, 2005). The earliest development of expressive control occurs during the third year of life, when young children make autonomous, self-initiated efforts to control their expression of negative emotion and distress in the absence of adult directions to do so (Kopp, 1989). Early work on expressive control entailed conscious masking of emotion and intentional deception with a focus on the face (e.g., Feldman, Jenkins, & Popoola, 1979; Lewis, Sullivan, & Vasen, 1987). Children were instructed to pose or deceive, which informs the development of voluntary expressive control in situations that may not have had little personal relevance for children. An exception was a paradigm in which children were told not to peek at a tempting object and then were asked if they had, a more naturalistic analogue of the circumstances in which children lie (Lewis, Stanger, & Sullivan, 1989). A study of 3- through 7-year-olds found that a substantial majority peeked (70%), that lying about peeking increased between age 3 (50% confessed) and age 6, when more children lied (~60%), and that adults (parents and undergraduates) could determine who lied only on the basis of verbal and not nonverbal expressiveness (Talwar & Lee, 2002). This skill is well established by elementary school age (Halberstadt, Grotjohn, Johnson, Furth, & Greig, 1992). From the functional perspective there is a need for more research on involuntary as well as voluntary expressive control in real-life situations. Indeed, school-age children report feeling and expressing more emotion in contrived or hypothetical situations than they express in actual situations, such as being treated unfairly or experiencing pain (Larochette, Chambers, & Craig, 2006; Parker et al., 2001).

In more naturalistic contexts involving negative emotions, typically developing children as young as age 3 years show spontaneous expressive control, although this depends on social context. That is, typically developing preschool-age children try to control disappointment in their faces when disappointed by an unfamiliar person (a research assistant) but not when alone (Cole, 1986). At this young age, children are not skillful dissemblers, but they spontaneously try to control their nonverbal expressions of anger, sadness, or disgust. For example, a girl who had turned three on the previous day smiled broadly as a matter-of-fact research assistant handed her a broken toy, her least desired prize; however, as soon as the assistant left, the little girl frowned, wrinkled up her nose, raised her upper lip, and pushed the prize away. Why she controlled this expression in the presence of the assistant is not known but her behavior was spontaneous control of emotional expression. The expressive control may have served to regulate her own emotions, to avoid a punitive reaction by the assistant, or internalization of rules of polite emotional behavior. Such expressive control is less likely to occur in interactions with trusted caregivers.

Skill at expressive control improves over the course of middle childhood (Garrett-Peters & Fox, 2007; Saarni, 1979), a result of experience and socialization influences. Parental warmth, sensitivity, positive expressiveness, sensitive control, and use of child emotion as a teaching opportunity have all been correlated with child emotional competence, including expressive control (Eisenberg, Cumberland, & Spinrad, 1998; Garner & Power, 1996; Gottman, Katz, & Hooven, 1997; McDowell & Parke, 2005; Morris, Silk, Steinberg, Myers, & Robinson, 2007). However, to inform the development of *psychopathology*, much more needs to be known. For example, many parents react to inappropriate emotional expression in their children by countering with their own negative emotion while others are dismissive. In typical development, parents' warning tone of voice or frowning faces may help children inhibit undesirable behavior. In the context of warm, supportive relationships typical parental anger may enhance rather than compromise children's ability to inhibit behavior and contribute to children's learning of family and sociocultural rules about the contexts in which one does and does not communicate different appraisal/action readiness patterns (see Morris et al., 2007 for review).

Child characteristics that develop in early childhood are thought to contribute to expressive control. Effortful control, defined by processes that modulate emotional reactivity, and general skill at emotion knowledge have both been associated with children's expressive control (Hudson & Jacques, 2014; Kieras, Tobin, Graziano, & Rothbart, 2005; Kochanska, Murray, & Harlan, 2000; Zeman & Shipman, 1998). The inference that children's abilities to recruit executive processes and to access or to apply emotion knowledge to control emotional expressiveness is based on correlational research. Effortful control may aid expressive control because it involves activation of networks that allow for top-down regulatory influence over action readiness or prepotent response tendencies. Functional near infrared spectroscopy (fNIRS) with 3- to 5-year-olds revealed greater lateral prefrontal cortex in the context of a blocked reward, an ecologically meaningful experimental situation, and that greater activation, which is associated with executive attentional control, was associated with better child frustration tolerance as reported by parents (Perlman, Luna, Hein, & Huppert, 2014). Emotion understanding has also generally been associated with younger children's expressive control (Garner & Power, 1996; Hudson & Jacques, 2014) but findings may not extend to all contexts (Ceschi & Scherer, 2003). Thus, the study of evidence for putative sources of expressive control—child characteristics such as effortful control and emotion understanding and parenting characteristics such as warmth, sensitivity, and control—need to be addressed in terms of specific emotions in specific contexts, particularly when participants are engaging in natural or reasonably simulated natural situations. The inclusion of neurobiological measures may also advance understanding of the development of expressive control. Finally, intervention research that distinguishes among treatment components may help to disentangle relations between expressiveness, expressive control, effortful control, and emotion knowledge (Raver, Garner, & Smith-Donald, 2007).

Risk for Emotional Dysfunction Associated with Expressive Control. When children do not engage in the expressive control typical of children their age, they are often regarded as odd or problematic by others. Naturalistic observations of children's emotional expressions indicate that between ages of 4 through 12 years most children's expressions are brief and moderate, even in challenging situations, and the assumption is that they modulate expressiveness (Buss, Davidson, Kalin, & Goldsmith, 2004; Fabes et al., 1999; Sears, Repetti, Reyonds, & Sperling, 2014). There is a number of ways in which the expressive control of at risk and symptomatic children differs from that of typically developing children. Some express emotions judged to be disproportionate and reactive (quick, rapidly intensifying expressions involving multiple elements in the face, voice and possible other motor behavior such as gestures), some express emotions in situations in which their emotional expressions are unexpected or atypical (context inappropriate or context insensitive), and some are inexpressive when expressiveness is typical and expected (Buss, 2011; Cole et al., 2013; Cole, Zahn-Waxler, & Smith, 1994; Cole et al., 1996; Dix, Meunier, Lusk, & Perfect, 2012; Locke, Davidson, Kalin, & Goldsmith, 2009). There are multiple potential factors leading to atypical expressive control. As noted previously, there are conditions that interfere with neurophysiological control of facial muscles, such as facial palsy, Parkinson's disease, and involuntary emotional expression disorder (Bogart, Tickle-Degnen, & Ambady, 2012; Lauterbach, Cummings, & Kuppuswamy, 2013); with intervention, many individuals with these conditions learn compensatory methods of expressing themselves (Bogart et al., 2012). If they do not, their social interactions are impaired, which can cause a cascade of negative effects on their social interactions, relationships and self-worth.

Among children with the physiological capability to engage in expressive control, impaired expressive control

is usually a consequence of other risk factors and has negative consequences on children's self and social development. Most often, negative emotion that is expressed very quickly and intensely is interpreted as reflecting poor expressive control. For example, there is ample evidence that children and adolescents with externalizing behavior problems express more intense and persistent anger and sadness in frustrating or disappointing situations, with parents or with unfamiliar adults, then asymptomatic children who appear to engage in expressive control (e.g., Cole et al., 1994, 1996; Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; McLaughlin, Hatzenbuehler, Mennin, & Nolen-Hoeksema, 2011). Another concern is the expressive control that underlies some children's reluctance to express emotions that are authentic, reasonable, and acceptable to express. Chaplin (2006) used a quasi-naturalistic procedure, a difficult task that required cooperative behavior between friends, to investigate individual differences in expressive control as a function of depressive symptoms. Older adolescents with depressive symptoms reported more anger but displayed less anger, and reported less happiness but displayed more happiness, than the older adolescents without elevation in depressive symptoms. How might this develop? One cross sectional study of 9-year-old girls found that both inhibited and disinhibited emotion expression during a family interaction was associated with depressive symptoms in children whose symptoms had not yet meet criteria for a diagnosis of a depressive disorder (Keenan, Hipwell, Hinze, & Babinski, 2009). A longitudinal study indicated that 13- to 14-year-olds' depressive symptoms predicted a decline in parental support over the course of a year, which mediated a relation between earlier depressive symptoms and increases in inhibited expressive control over two years (Larsen et al., 2012). Finally, preschool-age girls with symptoms of oppositional defiant disorder engaged in more expressive control than typically developing girls and boys, and boys with symptoms, even in situations in which other children conveyed their anger and sadness (Cole et al., 1994). These studies indicate the highly transactional nature of expressive control and the interpersonal climate in which children and youth develop and suggest that suppression of authentic emotions is as much a clinical concern as intense emotional reactions.

In sum, the capacity for authentic emotional expressiveness develops prenatally and emotional expressions become acculturated and articulated early in life. Early nonverbal expressiveness and caregiver responsiveness, particularly to infant distress, is essential in the development of a secure attachment relationship. Throughout life, the capacity to communicate clear, authentic emotion nonverbally is important for the formation and maintenance of all relationships and for skillful social interaction. With this capacity comes risk for emotional dysfunction related to conditions that compromise nonverbal expressiveness. Risk conditions include atypical development of nonverbal expressiveness as well as poor quality caregiver responsiveness to infant nonverbal expression. In addition to nonverbal behavior, emotional expressiveness develops in two further ways over the course of childhood and adolescence. By the second year of life, children begin to express goals, needs, and emotions with words. By the fourth year, they begin to show the capacity to spontaneously modulate what they communicate—expressive control. Difficulty verbalizing about one's emotions, having difficulty modulating emotional expressions, and inhibition of authentic emotion (verbal or nonverbal) are all associated with being less socially skilled and pose risk for the development of emotional dysfunction. When challenging circumstances arise with which children have limited experience (e.g., loss of a grandparent, exposure to community violence, bullying), the emotionally competent child is able to discuss difficult material with a trusted, sensitive caregiver. When the caregiver is poorly equipped to engage in such communication with the child, when the child does not trust caregivers with difficult emotional material, and when the challenging circumstances are presented by the caregiver, the child's ability to effectively express emotion can be compromised. This can lead to the blunting of expressiveness or to unpredictable, disproportionate, or context-inappropriate expressiveness. Furthermore, inability to communicate emotion authentically and appropriately compromises the interpersonal exchanges from which competence in emotion understanding and emotion regulation develops; these skills further refine an individual's emotional expressiveness.

Emotion Understanding

Competence in *emotion understanding* comprises a variety of component skills all of which involve knowledge about one's own and others' emotions. These skills include being able to accurately recognize and discriminate among different emotions, knowing about potential causes and consequences of different emotions, and knowing how emotions can be regulated. Competence in this domain includes related concepts such as emotional awareness or clarity (being able to experience and recognize one's own emotions clearly), emotion perception (being able to accurately decode facial activity and vocal qualities of different emotions expressed by others), and display rule knowledge

(being aware of cultural rules about how emotion is communicated and being aware that expressive behavior may not reflect subjective feeling). Competent emotion understanding also involves the development of theory of mind (being able to understand that another person may have a different emotional reaction than your own) and empathy (understanding another's emotion and being emotionally responsive on behalf of the other's needs). In total, competent emotion understanding entails effective and flexible application of these different skills to actual situations, particularly those in which this knowledge contributes to coping with problematic situations (Saarni, 1999).

As with other domains of emotional competence, emotion understanding is closely linked to the other components—emotion expression and emotion regulation—and is best understood in the context of social interactions and relationships. The reciprocal, interacting components of emotional competence begin to develop within caregiver–infant interactions and extend through the companionships of elders. For example, just as the infant begins to engage in emotional expressiveness, the infant quickly learns to read emotional expressions, such that competence at expressiveness may contribute to competence in emotion perception. Moreover, intense negative emotion may influence the degree to which emotion understanding can be successfully recruited or effectively applied (Cummings & Rennels, 2014; Fizke, Barthel, Peters, & Rakoczy, 2014; Prigatano, 2013). Much of the research on the development of emotion understanding has relied on methods using schematic or hypothetical stimuli but emotional competence requires understanding emotion in the real-life or realistic simulations of circumstances that infants, children, and youth encounter. Although there is a relative dearth of work derived from naturalistic studies, there is, nonetheless, ample evidence that the ability to recognize, conceptualize, and label emotions is associated with children's social competence (Denham, 1998; Dunn, 2004). Moreover, there is considerable research indicating that children and youth with various forms of psychopathology often show less skill in emotion understanding (e.g., Southam-Gerow & Kendall, 2002).

Typical Development of Emotion Understanding

The most basic component of emotion understanding is the ability to perceive and recognize emotional signals in others' nonverbal behavior, notably facial configurations and vocal prosody. This basic component of emotion understanding is a complex psychological process, involving a number of cognitive components whose successful execution depends on the coordinated effort of different regions of the brain (Adolphs, 2002). The readiness to perceive others' emotionally expressive behavior appears to have a very early origin; the development of perception is known to involve the converting of sensory information into percepts (and eventually concepts) and this process depends on exposure to stimulation. Little is known about prenatal visual development. In utero, infants do not observe faces, although by midterm the suprachiasmatic nuclei, which are responsive to light and implicated in circadian rhythm, have developed (Rivkees, 2003). In the first months infants can only see 8–12 inches before them; the development of the ability to discern facial activity details develops during the first year; experience with visual stimulation fosters the perceptual discrimination of shapes, patterns, and motion, spurred in large part by the visual array of the caregiver's face (Graven & Browne, 2008). Auditory processing, on the other hand, develops earlier. The fetus is exposed to auditory stimulation, particularly the mother's voice. Fetal auditory cortical and heart rate changes are evidenced by at least the third trimester, including selective processing of the mother's voice (Jardri et al., 2012; Kisilevsky & Hains, 2011), which may explain why neonates recognize their mother's voice (DeCasper & Fifer, 1980).

The ability to recognize nonverbal emotional information in faces and voices then depends on experience. It does not appear to depend, however, on the ability to produce facial expressions and affective prosody. For example, a case study of three adults with congenital Möbius syndrome indicated they were able to recognize emotions in facial and vocal stimuli (Calder, Keane, Cole, Campbell, & Young, 2000). Moreover, only some aspects of emotion understanding may depend on experience with sensing stimuli. Severely visually impaired children have difficulty identifying emotion in vocal stimuli, but perform as well as children without any sensory impairment (and better than hearing-impaired children) in understanding the meaning of emotion words and in reasoning about the causes of emotion (Dyck, Farrugia, Shoceht, & Holmes-Brown, 2004). Among typically developing infants, the ability to discriminate among different types of affective prosody is evident by the middle of the first year, as inferred from behavioral and neuroimaging studies (Fernald, 1993; Nelson & de Haan, 1997). Similarly, infants discriminate among basic facial expressions of emotion (Grossmann, Striano, & Friederici, 2006; Kobiella, Grossmann, Reid, & Striano, 2008). By the time they reach their first birthday, before they have acquired emotion labels and concepts,

very young children not only differentiate among nonverbal emotional signals; they use the information they have gleaned from others' nonverbal signals to guide their action as indexed by approach behaviors and attribute emotional signals to the expressive person and not to other stimulus conditions (Klinnert, Emde, Butterfield, & Campos, 1986; Repacholi & Meltzoff, 2007; Repacholi, Meltzoff, & Olsen, 2008).

As children enter toddlerhood, they soon begin to develop an emotion lexicon of simple terms, such as happy, scared, and mad (Bretherton & Beeghly, 1982; Ridgeway, Waters, & Kuczaj, 1985), usually referring to their own experience. Between ages 2 and 3, children can associate these terms with simple schematic representations of basic facial expressions (Borke, 1971; Denham, 1986; Reilly, McIntire, & Bellugi, 1990). Children first identify happiness reliably and over the first years continue to develop skill at differentiating among negative emotions (Camras & Allison, 1985; Widen & Russell, 2003). Emotion vocabulary appears to double in size each year from ages 4 to 11 years and then may plateau during adolescence (Baron-Cohen, Golan, Wheelwright, Granader, & Hill, 2010). By preschool-age children can apply their emotion vocabulary to concepts about the nature of emotion. That is, they not only demonstrate a basic understanding of the causes and consequences of the principal emotions but have also developed an understanding that others' emotions may differ from their own, that others' thoughts about their behaviors influence their emotional reactions in the present and over time, that another person's distress may or may not be justified, that one can pretend to feel emotions, and that certain emotions are more acceptable to display than others (Bassett, Denham, Mincic, & Graling, 2012; Hepach, Vaish, & Tomasello, 2013; Lagattuta, 2007, 2008; Sidera, Amadó, & Serrat, 2013). Hence, preschool-age children understand a considerable amount about emotion, which is a contributing factor to their social competence.

In sum, infants navigate a communicative world in which they perceive and interpret emotional signals that are converted into conceptual representations by the time they reach preschool age. There are, however, significant limitations on their ability to understand the complex emotional events they perceive. Thus, perceptual sensitivity and initial attribution of meaning to those percepts is both an accomplishment and potential vulnerability. For example, typically developing infants and toddlers exposed to very brief angry exchanges between two adults orient toward action as evidenced by cardiovascular changes, appear distressed and often become behaviorally disruptive (Cummings, Zahn-Waxler, & Radke-Yarrow, 1981; Cummings et al., 1987; Moore, 2009). Very young children are therefore sensitive to emotional information but also lack the cognitive skills to reason about emotional information in the more sophisticated ways that develop throughout middle childhood and adolescence.

There is less research, especially longitudinal research, on the development of emotion understanding beyond early childhood (Zeman, Klimes-Dougan, Cassano, & Adrian, 2007). Between ages 6 and 13 years, emotion understanding becomes more complex, more nuanced, and more abstract (Lagattuta, 2014). Over this period of time, children become better able to infer emotions on the basis of situational information without the advantage of nonverbal expressive cues, to generate alternative views about how a person might feel in a given situation, and to appreciate that a person can experience multiple emotions, even if those different appraisal/action readiness patterns appear to be contradict each other (Pons & Harris, 2005; Hoffner & Badzinski, 1989; Harter & Whitesell, 1989). In addition, during the middle childhood years, children become more fluent in describing their own emotions and styles of emotional responding, in describing and reasoning about different strategies for regulating emotion, in appreciating that regulatory strategy effectiveness depends on the specific emotion, its intensity, and the situational context (e.g., who is present), and appreciating that how one thinks about a situation affects emotional valence (Bamford & Lagattuta, 2012; Davis, Levine, Lench, & Quas, 2010: Dennis & Kelemen, 2009; Larsen, To, & Fireman, 2007; Penza-Clyde & Zeman, 2002; Reijntjes et al., 2006; Waters & Thompson, 2014; Zeman & Shipman, 1997). The normative emotion understanding development associated with middle childhood that is absent for most preschool-age children is why clinicians are able to move from activity- and play-based to conversation-based interventions around age 9.

By adolescence, experience and cognitive development continue to permit increasingly sophisticated ways of understanding emotion, including integrating knowledge of emotions into ever more complex understanding of human physiology, social relations, and cultural values (e.g., Fischer, Shaver, & Carnochan, 1990). These ways of understanding include advances in metacognition, that is, reflection on cognitive processes and how one uses them, including appraisal/action readiness patterns, self-monitoring, cognitive flexibility, such as the capacity to evaluate the risks and benefits of acting on one's appraisal/action readiness, and more abstract reasoning about emotion relevant circumstances, such as principles like fairness and justice (Arsenio, Gold, & Adams, 2006;

Crone & Dahl, 2012; Flavell, 2000; Steinberg, 2005). Adolescents' emotion understanding skills broaden the capacity to infer emotions (and emotions are inferred processes), enhance coping with stress, including coping with stressful events that have not been encountered previously and for which one lacks experience (Compas, Malcarne, & Fondacaro, 1988; Eisenberg et al., 1997; Williams & McGillicuddy-De Lisi, 1999).

Research ranging from early childhood through adolescence often assumes that emotion understanding is a prerequisite for emotion regulation. Although the various components of emotion understanding are consistently correlated with parent-, teacher-, or peer-reported social competence or behavior problems, effect sizes are modest. Among the components of emotional competence, emotion regulation has larger effect sizes as a mediator of relations between predictors and outcomes than emotion understanding (Garner & Hinton, 2010; Trentacosta & Fine, 2010). One concern about the status of knowledge on the development of emotion understanding and its relation to emotional competence involves the methods used to assess emotion understanding. With participants in middle childhood, many studies have relied on decontextualized, experimental stimuli and hypothetical situations. Research that is informed by clinical concerns and takes a functional perspective will investigate children's understanding in realistic or actual situations, and yield information that is more pertinent to the unique role of emotion understanding in the development of emotional dysfunction and in pathways to psychopathology.

Risk for Emotional Dysfunction Associated with Emotion Understanding

There is ample evidence that children, youth, and adults with elevated symptoms or clinical disorders are less accurate at recognizing emotion, particularly in faces, and are less mature in their reasoning about emotions (Southam-Gerow & Kendall, 2002; Trentacosta & Fine, 2010). Neuroimaging studies indicate that these differences are reflected in temporal and spatial aspects of neural activity (e.g., Blair, 2003; Herba & Phillips, 2004). In considering risks associated with emotion understanding, it is useful to return to a fundamental principle of the functional perspective on emotion. That is, the capacity to be emotional is designed by evolution to enable adaptation to changes in the environment. Most children are biologically prepared to be sensitive from a very early age to the emotional information in the environment. They perceive changes, appraise their meaning and orient to act in relation to them, and in this way adapt to regular patterns in their emotional environments. In typical development, adaptation to environmental challenges can provide opportunities for psychological growth, including experiential learning that cultivates emotional understanding (and all aspects of emotional competence), and is supported by caregivers who help to relieve child distress, model emotional behavior, help children understand emotions and their circumstances, and teach them how to cope with emotions and situations (Eisenberg, Cumberland, & Spinrad, 1998; Morris et al., 2007). However, early competence in emotion understanding also contributes to children's vulnerability. Historically, popular culture believed that adversities like marital distress did not negatively influence very young children because they could not understand; in other words, the very young were oblivious to distress. We now know that infants and young children not only perceive but are sensitive to emotional information, and that limitations on young children's ability to further understand what they perceive creates vulnerability. When environmental conditions are perceived but stress children who lack the cognitive resources to resolve the distress, and most especially when they also lack the social resources because the stress involves caregivers' behavior, children will adapt. But, in doing so, their long-term emotional development may be compromised.

Because young children perceive emotional information, they can be stressed by it. Moreover, depending on their age and experience, children are prone to misunderstand what they perceive, to misattribute the causes of emotional events, and to even assume they play a central role in these events if they have not developed the ability to decenter, that is, mentally separate themselves from events; Shantz, 1993). Moreover, in early childhood when neurophysiological systems that enable appraisal/action readiness are still forming and are plastic, open systems, emotional understanding means children are not impervious to adverse conditions. The resulting stress can have enduring effects on the biological systems that support appraisal and action readiness.

Early adversity is defined by various circumstances, including potentially traumatic interpersonal situations, such as domestic violence, child abuse and neglect, as well as non-interpersonal situations such as injury, malnutrition, and natural disaster. In children ages 24 to 48 months, it is estimated that exposure to potentially traumatic experiences is as high as 26% (Briggs-Gowan, Ford, Fraleigh, McCarthy, & Carter, 2010; U.S. Department of Health and Human Services, 2009). Early and persistent exposure to adversity influences gene expression (Meaney et al., 1996), stress physiology (McEwen, 2000), and neural connectivity

(Burghy et al., 2012; Fan et al., 2014; Graham, Fisher, & Pfeifer, 2013). In these various ways, early adversity has profound implications for all domains of developing emotional competence, including psychopathology (Green et al., 2010). A substantial majority of research, however, has concentrated on emotion understanding.

One form of early adversity occurs when young children are deprived of adequate social interaction, a condition that has pervasive negative consequences. Child neglect and institutionalization represent this form and are known to have consequences for emotion understanding. Child neglect is associated with a range of problem outcomes affecting both cognitive and emotional functioning (Erickson & Egeland, 1996; Heim, Shugart, Craighead, & Nemeroff, 2010). Preschool- and school-age children who experienced neglect are less skilled in detecting, labeling, and understanding emotion, even when child IQ and harsh parenting are taken into account (Pollak, Cicchetti, Hornung, & Reed, 2000; Shipman, Edwards, Brown, Swisher, & Jennings, 2005; Sullivan, Carmody, & Lewis, 2010). Institutionalized children, compared with those placed in foster care or never institutionalized, also are less skilled at recognizing emotion in faces (Nelson, Westerlund, McDermott, Zeanah, & Fox, 2013; Moulson, Fox, Zeanah, & Nelson, 2009; Slopen, McLaughlin, Fox, Zeanah, & Nelson, 2012). Adults with a documented history of childhood emotional neglect, but not physical or sexual abuse, had reduced resting state connectivity in pathways associated with the social brain, that is, between the right amygdala and (1) the precuneus and lateral occipital cortex; (2) the left orbitofrontal cortex, insula, hippocampus, and putamen; and (3) the dorsal anterior cingulate cortex (all active in socio-emotional information processing and emotion regulation) and they have enhanced amygdala reactivity to emotion faces (van der Werff P et al., 2013; van Harmelen et al., 2010). These findings suggest that insufficient opportunity to interact with others' emotions compromises emotion understanding. Fortunately, the plasticity of early development may make it possible for the introduction of adequate caregiving and social interaction to remediate the early effects of neglect and deprivation, although it may be critical for such intervention to occur before age 2 (Moulson et al., 2009; Tarullo, Bruce, & Gunnar, 2007). That is, the costs to emotion processing of insufficient or unresponsive caregiving, through parental neglect or institutionalization, may be ameliorated by healthy emotional interactions, particularly during the most formative period.

While the deleterious effects of insufficient human interaction have consequences for children's development of emotional competence, many children experience interactions that threaten their well-being, notably child abuse (physical and sexual) and exposure to interadult conflict. Of course, these different forms of early adversity often co-occur. From the viewpoint of emotional development, if what is most salient to children are threatening interactions, these should have somewhat different consequences than those of consistent diminished interactions in terms of children's adaptation to those environments. Abused children provide further evidence that significant adversity attunes and shapes neural processing. Physical abuse is linked to *better* rather than less skillful emotion perception, specifically for angry expressions. Physically abused children are quicker, more prepared to detect anger as an adaptive response to unpredictable threat in their environment, which improves their ability to avoid danger although it also causes them sustained anxiety (Pollak, Messner, Kistler, & Cohn, 2009; Pollak & Sinha, 2002; Shackman & Pollak, 2005; Shackman, Shackman, & Pollak, 2007). It is particularly interesting to note that in the case of abusive mothers, their angry nonverbal expressions may not be as clearcut as those of non-abusive mothers (Shackman et al., 2010). The advantage of such quick perception of potential threat, however, does not extend to other aspects of emotion understanding; physically abused children do more poorly than other children in understanding the causes of emotion (Luke & Banerjee, 2013). Thus, perceptual sensitivity may heighten stress when children are exposed to environmental threats, without the presence of supportive caregiving, altering both autonomic and central nervous systems that process emotional information (e.g., Cicchetti, Rogosch, Gunnar, & Toth, 2010; McCrory et al., 2013). However, these conditions do not foster children's ability to develop other aspects of emotional understanding, in part because uncontrollable stress may require them to turn their attention away from emotional experience.

Another well-researched form of adversity encountered by many children in which emotion understanding plays an important role is interpartner conflict. The way that children interpret interpartner conflict influences their adjustment (Grych & Fincham, 1990). Interparental conflict is a fact of life for a large swath of children in the United States, although precise estimates are difficult given the variations in the structure of modern family life. Most adults marry and most couples have children. After rising rapidly, American divorce rates have begun to level off. According to a Pew Research Foundation report (Krogstad, 2014) about 14% of couples, most with children, are separating or divorcing at any given time. In addition, about 50% of children live with a step-sibling,

and a growing number of children are reared by a single parent. In each of these different situations, children may experience interpartner conflict or violence. Exposure to interpartner conflict, notably unresolved conflicts, is believed to confer risk by threatening the emotional security the child has achieved (Cummings & Davies, 2011). Nearly 16 million children live in households experiencing intimate partner violence (McDonald, Jouriles, Ramisetty-Mikler, Caetano, & Green, 2006).

Appraisal and action readiness in the context of conflicted close relationships is influenced both by children's sensitivity to emotional stimuli and the extent of their emotion understanding skills. Infants and toddlers are sensitive to interadult anger, which elicits stress responses in them, as inferred from changes in their behavior, their cardiovascular activity, and their neural activity (Cummings, Zahn-Waxler, & Radke-Yarrow, 1981; Graham, Fisher, & Pfeifer, 2013; Moore, 2009; O'Hearn, Margolin, & John, 1997). But infants and toddlers are quite limited in being able to understand this source of stress. With prolonged exposure to conflict and without compensatory caregiving, very young children's capacity to be responsive can be altered permanently as it is for young children exposed to other adversities.

Children whose first encounters with interpartner conflict occur after early childhood have more emotional understanding tools to draw on, but still have limits on that understanding depending on their phase of emotional development. Their understanding could make them more acutely aware of the problems they witness and lead them to engage in reasoning that is not a match of the problems. Preschool-age children exposed to parental shouting, yelling, screaming, swearing, and cursing had lower self-esteem and more conduct problems *if* they had better rather than poorer emotion knowledge skill (Berzenski & Yates, 2013). Older children (8- to 12-year-olds) are able to describe their strong emotional reactions to interpartner conflict, describing anger, sadness, fear, and self-blame when they witness interpartner conflict (DeBoard-Lucas, Fosco, Raynor, & Grych, 2010; Davis, Hops, Alpert, & Sheeber, 1998; Shelton & Harold, 2007). Yet they are less inclined to express these negative emotions and more inclined to try to intervene (Cummings, Pellegrini, Notarius, & Cummings, 1989; Cummings, Zahn, Waxler, & Radke-Yarrow, 1984). The way that they interpret and reason about the conflict they perceive mediates the effects of exposure on the child's emotional functioning and psychological adjustment (Fosco & Grych, 2007; Grych & Fincham, 1990). If they feel to blame, this influences their own self-evaluation, diminishing their sense of efficacy and worth. If they feel more fearful in situations involving unresolved conflict between their caregivers, more inclined to act if they feel anger, and more avoidant if they feel sad and helpless (Koss et al., 2011).

By adolescence, the effects of exposure to interpartner conflict are more mixed. Some but not all youth feel personally threatened by the conflict, they feel more devalued in their own eyes, and they also report self-blame (Siffert, Schwarz, & Stutz, 2012). However, older children and youth are better able to accept and adjust to conflict, particularly if the conflict does not spill over into unsupportive caregiver-child relations (O'Donnell, Moreau, Cardemil, & Pollastri, 2010). As noted, there is considerable research linking poorer emotion understanding in adolescents with elevated symptoms or psychiatric diagnoses. The leading view is that these youth have strong emotional reactions that have interfered with their ability to regulate emotion, which then interferes with processing emotion information; their strong emotional reactions could be related to combined influences of adversity exposure, including the new challenges faced in adolescence, as well as dispositional vulnerabilities that may be emerging. The view that these youth have strong reactions that are difficult to regulate that compromise their emotion processing is supported by neuroimaging research that links poor emotion recognition to heightened amygdala activity, diminished prefrontal region activity, or both.

Yet more recent work suggests caution, indicating much more needs to be known about the complex ways the brain functions and changes during adolescence (e.g., Crone & Dahl, 2012; Perlman et al., 2013). For instance, Perlman and colleagues recently found that brain regions in addition to the amygdala may be involved; they showed that youth with bipolar spectrum disorder show less activation in the fusiform gyrus, which is involved in general face processing, when processing facial emotion compared with asymptomatic youth (Perlman et al., 2013). In terms of adolescent development, Crone and Dahl (2012) contend that the view that immature prefrontal activity or connectivity may underlie emotional impulsiveness and risk-taking behavior in adolescents may be simplistic; they propose that there is variability, or flexibility, in the degree to which adolescents *apply* emotion understanding when making decisions and that this depends on their motivational stance. That is, the decisions about behavior depend on which appraisal/action readiness tendencies are active in a particular situation. Thus, the adolescent's gains in cognitive flexibility enable them to switch priorities more readily than younger children, which has advantages (increased creativity) and potential risk (poor, impulsive

choices such as risky behaviors). As Crone and Dahl further note, many studies linking adolescent cognitive development, including importantly emotion understanding, are limited by the fact that they do not assess emotion understanding in realistic, personally meaningful contexts (but see Guyer et al., 2008) and rarely address how differences in adolescence *develop*.

In considering risk for emotional dysfunction in the context of emotion understanding, we must consider one additional aspect: emotional awareness. There is very little normative research on the development of emotional awareness but it is a prominent clinical concern (e.g., Flynn & Rudolph, 2010). Many evidence-based interventions for addressing emotional problems, such as anger and anxiety management protocols, require clients to identify initial activation of those emotions and to engage in remedial actions or thoughts early in the emotion generation process. Yet many children and youth lament or protest that they do not recognize their reactions until they are intense. Recently, a client bemoaned the fact that he had no yellow zone, referring to the aid of a traffic light metaphor for assessing his anger intensity.

Emotional awareness involves recognition of bodily changes, bodily action, and different types and blends of subjective feelings (Lane & Schwartz, 1987). From the functional perspective, this awareness occurs when appraisal/action readiness patterns reach conscious awareness and are experienced as subjective feelings that a person may also be able to describe. Its early origins are thought to be cultivated by social interaction with partners who attend to, mirror, and comment on a young child's emotions as described earlier (Bigelow et al., 2010). Over time, emotional exchanges foster the ability to represent emotions in childhood and increasingly apply emotion understanding in self-reflective fashion as children transition from childhood to adolescence (Fonagy, 2002; Gergely & Watson, 1999; Izard & Harris, 1995).

Only one study assessed emotional awareness in young children (Warren & Stifter, 2008), investigating concordance between preschool-age children's verbal descriptions of their reactions and their nonverbal expressions during a long delay to receive a reward and relating these to mother–child communication about a different problem. Children reported being significantly more angry than they appeared but with concordance for sadness and happiness, consistent with previous normative research. A study of 8-year-olds losing a game used latent profile analysis to create groups based on children's self-reported anger, observed anger, and skin conductance (Smith, Hubbard, & Laurenceau, 2011). Of the five resulting groups, the modal profile was reporting high levels of anger but displaying low levels and modest physiological reactivity. A small group was defined by children who reported little anger but who displayed moderate anger and arousal. Each of these studies provides quasi-naturalistic situations that may be useful in studying the early development of emotion awareness.

More often, emotional awareness is studied in adolescence. Emotional awareness plays a role in adolescent friendship formation and maintenance, in increasing sense of well-being over time, and in better mental health outcomes (Ciarrocchi, Kashdan, Leeson, Heaven, & Jordan, 2011; Hamilton, Hamlat, Stange, Abramson, & Alloy, 2014; Roswell, Ciarrocchi, Heaven, & Deane, 2014). In this approach, however, emotional awareness is largely conceptualized as a stable trait. If emotion is best conceptualized as a dynamic process then it is likely that there is intra-individual variability in emotional awareness as situations vary and unfold. For example, does an individual's emotional awareness fluctuate based on the level of significance of circumstances? An approach that might reveal intraindividual variability as well as take into account the context specificity of appraisal/action readiness patterns in naturally occurring situations is ecological momentary assessment (EMA), which has been used to study children's and adolescents' emotions (Dunton et al., 2014; Silk, Steinberg, & Morris, 2003).

In sum, the development of emotional awareness and increasingly sophisticated emotion understanding emerge from neurological maturation, cognitive development, increasing opportunities and variety of social experiences, and accumulating emotional experiences. At each point in the development of emotion understanding there are attendant vulnerabilities, first in terms of perceptual sensitivities and limited ways to cope with what is perceived. Consider the plight of a 4-year-old experiencing sexual abuse by a parent; the child is likely to be flooded with multiple emotions, not just during sexual acts but also the strain of wondering when the next threat will come. Given the child's lack of options for coping, it may be adaptive for perceptual sensitivity to be keen but for further processing to be truncated, which may be why sexually abused children are more likely to avoid emotional experience (Shenk, Putnam, Rausch, Peugh, & Noll, 2014) and to engage in dissociation (Cole & Putnam, 1992). Clearly, the young child's ability to be sensitive to and begin to understand the meanings of the emotional environment are a competency but also a risk factor (Pechtel & Pizzagalli, 2011; Tronick & Beeghly, 2011).

By middle childhood, children can apply greater emotion understanding to the adversities they face but they may nonetheless feel responsible, experiencing self-blame, as well as feeling unable to resolve problems despite feeling they should. By adolescence, a time when youth experience increases in emotional reactivity, develop more complex, abstract, stable and stylized emotion reasoning, and yet face myriad new challenges, including changing academic and social demands and pubertal changes (Abela & Hankin, 2008; Pons & Harris, 2005; Steinberg, 2005), they are better equipped to deal with adversity. However, the advantages of their cognitive growth are coupled with risks, specifically the emergence and stabilization of thought patterns that can increase and sustain emotional reactions without leading to effective problem solving. These include development of capacities for excessive worry, perfectionism, rumination, and hopelessness, hallmarks of psychopathology, particular clinical anxiety and depression (e.g., Abela & Hankin, 2011; Burwell & Shirk, 2007; Damian, Stoeber, Negru, & Băban, 2013; Fowler & Szabó, 2013). These are regarded as ineffective ways to regulate emotion.

Typical Development of Emotion Regulation

The third and final domain of emotional competence is *emotion regulation*; a large corpus of work implicates emotion regulation in the development of children's social and academic competence and their mental health as well as in a wide range of health problems, ranging from situational noncompliance with medical procedures to obesity and psychopathology. The importance of being able to manage one's emotions for each of the outcomes seems self-evident, yet from a scientific perspective emotion regulation is often studied without being defined, using diverse methods, and inferred solely on the degree to which research participants appear or describe themselves as emotionally negative, without assessment of regulatory processes and their relation to that emotion (Cole et al., 2004). The wide variety of approaches and findings reinforces how important effective emotion regulation is, but the imprecision becomes increasingly problematic, preventing progress from the historical view of emotions as discrete events and toward unifying process models.

From the functional perspective, emotion and emotion regulation are part and parcel of the same fundamental process—appraisal/action readiness tendencies that define emotion are inherently regulatory (Campos et al., 2004). Changes in appraisal/action readiness (i.e., emotions) reflect changes in a person's perception of the environment in terms of the person's well-being and attendant orienting of cognitive and behavioral systems, such as narrowing or broadening attention or motivating action. Moreover, the functional perspective on emotional *development*, which emerged in the context of infancy research, defines emotion as relational, drawing attention to the dynamic, context-defined, interpersonal processes involved in infant emotion. As reviewed previously in the section on emotion expressiveness, infancy research clearly demonstrates that (1) partners influence each other's emotions in communicative exchanges, (2) infants perceive and use emotional information to organize their action, and (3) infants initiate behaviors that have the potential to alter their relation to the environment (i.e., emotion). If emotion comprises change in appraisal/action readiness, then emotion regulation involves anticipation, modification, or terminations of those changes (Cole et al., 2004). The dynamic nature of emotion processing must be conceptualized in terms of change and not static events.

A second source of confusion arises when discussions equate different levels of analysis. As neuroscience has begun to document the functioning of the central nervous system, it becomes evident that the brain is a regulatory system, sets of neural networks that coordinate in different ways to afford emergent psychological capacities (Bullmore & Sporns, 2012). This characterization of the brain is consistent with a dynamic, systemic view of emotional functioning but at the same time neural network functioning should not be equated with behavioral processes. Emotion regulation as an aspect of competence functioning cannot be reduced to physiological activity. The nature of neural circuitry in personally meaningful contexts remains to be discovered. Nonetheless, this level of analysis is distinctly different from inferences drawn on the basis of observations of infant or child interactions, the basis of judgments regarding emotional competence.

In terms of developmental pathways to emotional competence, two dominant views of emotion regulation—self-regulation and coregulation—involve *behavioral* outcomes of emotional processes. The functional perspective helps us to interpret appraisal/action readiness patterns as indicative of a person's relation to circumstances in terms of their goals for well-being and to infer changes in those motivational stances from behaviors. At the behavioral level, competent emotion regulation is defined by self-regulation of emotional reactions, both in interpersonal and solitary situations, and coregulation in interactions, in ways that are effective (achieve goals in the specific context) and appropriate (conform to the immediate situational constraints and to

sociocultural standards) (Denham, 2006; Halberstadt et al., 2001; Saarni, 1999). Furthermore, competent self-regulation of emotion entails self-initiated efforts to anticipate to anticipate appraisal/action readiness patterns, to modify appraisal/action readiness patterns (intrapersonal processes, related to emotion-focused coping), and to modify potentiated action readiness, that is, actions motivated by appraisal/action readiness (Gross & Thompson, 2007; Thompson, 1994). The development of emotional competence requires learning to use either intrapersonal or interpersonal mechanisms to engage in effective, flexible, appropriate (age-, sociocultural- and situational-) emotional behavior that achieves, maintains, or regains goals for well-being. For the purposes of this chapter the focus is on the typical development of intrapersonal and interpersonal strategies for emotion regulation and the conditions under which they are associated with emotional dysfunction.

The role of the prenatal period in the development of emotion regulation is largely unknown. Yet, as noted, the available facts support the assumption that genetically influenced neurophysiological systems that are needed for the capacity to be emotional develop in utero and in the context of interaction with the prenatal environment. These systems are so fundamental that they must play a role in the development of emotion regulation as they do with all aspects of emotional competence. The available data, reviewed earlier, further suggest that risk in the prenatal period may compromise the later development of emotion regulation. Specifically, maternal stress and anxiety, probably via the release of cortisol from maternal hypothalamic-pituitary-adrenal (HPA) axis activity, is related to more intense infant sensitivity to some or all stimuli, often observed as infant fussiness, reactivity, or negativity (Sandman & Davis, 2010). Such sensitivity is not in itself evidence of ineffective emotion regulation, but the view is that this sensitivity may hinder infants' rudimentary abilities to recover from distressed states, such that prenatal stress is also associated with newborns being less likely to regain calmness on their own and being less easily consoled (Davis, Glynn, Waffarn, & Sandman, 2011) and 6-month-olds have fewer periods of self-quieting (Bolten et al., 2013).

These findings can be incorporated into the vertical-integrative neurobiological model offered by Geva and Feldman (2008) to characterize the complex origins of emotion regulation. The ability to self-initiate executive control of appraisal/action readiness changes in effective, appropriate ways requires the child to develop neural networks that connect prefrontal cortical regions, which are assumed to support executive or top-down regulatory processes, to limbic regions that support appraisal/action readiness. Geva and Feldman assert that this neural circuitry is predicated on earlier developing neural networks. During the prenatal period, brainstem circuitry develops and forms the basis for neonatal state regulation, including regulation of capacities like breathing and temperature and then vagal tone and circadian rhythms. With this achieved, the neonate is in a better position to have periods of alertness during which the environment can be engaged. In this way, early in infancy, brainstem-limbic system circuitry develops that supports appraisal/action readiness and attention systems. In this model then, risk posed to fetal development of brainstem-regulated systems can have a cascading effect, compromising later developing systems that evolve from earlier developing circuitry and that underlie self-regulation of emotion. Yet the plasticity of developing neurophysiological systems makes it possible for early risk to be mitigated by responsive caregiving and well-coordinated caregiver–infant interaction. Such interactions can enhance newborns' ability to achieve basic neurophysiological regulation, helping them develop patterns of feeding and sleep–alertness cycles. These early elements of neonate regulation appear to have both genetic and non-shared environmental influences (Wang & Saudino, 2013). Although much remains to be learned about the contributions of the prenatal period to the development of emotion regulation, the prenatal period may contribute to basic elements of both emotion processing and state regulation in neonates.

Individual differences in infants are conceptualized as temperament, that is, constitutional, neurobiologically based predispositions involve reactivity to the environment and self-regulation (Rothbart & Derryberry, 1981). There are many approaches to conceptualizing temperament in terms of its constituent dimensions but all include emotional reactivity (Goldsmith et al., 1987; Shiner et al., 2012). Emotional reactivity, usually referred to as negative emotionality, involves an automatic, prepotent, consistent tendency to react with strong negative responses to stimuli, and can be further distinguished in terms of reactivity to frustration (anger proneness) and reactivity to novelty (fear proneness; Rothbart & Bates, 2006). The prevailing view is that moderate emotional reactivity aids the development of emotion regulation (Calkins, 1994). Microanalyses of infant–caregiver interactions reveal (1) periods in which dyads engage in mutually coordinated emotion exchanges (e.g., cooing and smiling), which elicit and sustain each partner's calm, pleasant demeanor; and (2) periods during which dyads are not coordinated but in which each often

acts to gain the other partner's attention and in which the caregiver acts to repair infant distress (Fogel, 2000; Tronick & Cohn, 1989). Over the first months, typically developing infants and their caregivers become increasingly responsive to each other's specific behaviors, resulting in more effective mutual regulation (Beeghly, Fuertes, Liu, Delonis, & Tronick, 2011; Crockenberg & Smith, 2002; Evans & Porter, 2009; Isabella, Belsky, & von Eye, 1989). These periods provide a basis for developing expectations of sustained, mutually coordinated, emotionally positive exchanges, and expectations of exchanges in which unmet needs can and will be addressed. Establishment of predictable emotional exchanges contributes to the development of the attachment relationship (Beebe et al., 2010; Cohn & Tronick, 1987; deWolff & van IJzendoorn, 1997; Sroufe, 1997).

The development of these effective, patterned exchanges is easier to achieve for dyads in which infants are more readily consolable and caregivers have psychological and social resources that enable them to be reliably attuned to and able to address infant needs. Their establishment is more difficult if infants are highly reactive and harder to soothe or disengaged or unresponsive, or if caregivers lack adequate psychological or social resources for handling caregiving challenges (Costa & Figueirdo, 2012; Lyons-Ruth, Bronfman, & Parsons, 1999; Spangler et al., 1994; van den Boom & Hoeksma, 1994). However, for infants who are reactive or unresponsive, there may be a greater need for predictable, effective caregiver skill, a form of differential susceptibility (Ellis, Boyce, Belsky, Bakermans-Kranenberg, & van IJzendoorn, 2011; Geva & Feldman, 2008). The ability of the infant–caregiver dyad to form a stable, predictable pattern of coregulatory exchanges is widely believed to contribute to the development of children's self-regulation of emotion (Cassidy, 1994; Kim & Kochanska, 2012; Martinez-Torteya et al., 2014).

Although regulation of infant needs is largely achieved through dyadic interactions with caregivers, infants appear to have some limited self-regulatory capacity. That is, they initiate behaviors that briefly interrupt or reduce the intensity of their distress, which may sometimes resolve distress. Specifically, distressed infants engage in behaviors that can have a calming effect, such as sucking on their hands or averting their gaze from the source of distress; they also engage in these behaviors when they are not distressed, and it may be that through conditioning they learn to use them in a self-regulatory manner (Stifter & Braungart, 1995; Rothbart, Ziaie, & O'Boyle, 1992). In addition to these self-directed behaviors, infant emotional expressiveness is regulatory in that it typically captures, sustains, and guides caregiver attention and behavior (Braungart-Rieker, Garwood, Powers, & Notaro, 1998; Cohn & Tronick, 1983; Mangelsdorf et al., 1995; Tronick, 1989). Thus, emotional communication (often referred to as support-seeking), self-soothing, and gaze aversion are the primary self-regulatory behaviors observed in the first, year, with gaze aversion increasing as self-soothing declines (Rothbart et al., 1992).

Infant self-regulation of emotion is often observed using the Still Face Procedure, which capitalizes on established dyadic exchanges (Tronick, Als, Adamson, Wise, & Brazelton, 1978). By age three months, infants perceive changes in caregiver responsiveness and are typically distressed by caregiver unresponsiveness. During the period of the procedure during which caregiver demeanor is unresponsive, infant behaviors are interpreted as regulatory, both those that strive to regain caregiver responsiveness and those that potentially regulate infants' own distress. Between ages 3 through 5 months, during the still period, typically developing infants' behavior changes (Ekas, Lickenbrock, & Braungart-Rieker, 2013). Specifically, although infant distress is stable across this age period, infants' looks at the unresponsive caregiver decrease and their looking away and vigorous movement increases. These short-term longitudinal data suggest that infants have learned to shift attention from a source of distress. Their vigorous movement may reflect appraisal/action readiness to regain the thwarted goal (caregiver responsiveness). During this age period, looking away is usually followed by momentary decreases in distress, suggesting that the frequency of looking away increases but its effectiveness does not. Thus, as they reach the midpoint of the first year, typically developing infants expect caregiver responsiveness, are distressed when it stops, and may learn to use a spontaneous tendency to shift attention from the source of distress in a limited, self-regulatory manner.

More often, in distress circumstances, infant behavior is communicative and coregulatory. Emotion coregulation is observed throughout the life span (Butler & Randall, 2013; Coan, Schaefer, & Davidson, 2006) but unlike adults, infants and very young children have few and limited alternatives for regaining well-being other relying on caregivers. Infant–caregiver interactions not only regulate infant appraisal/action readiness tendencies, but also begin to scaffold infant behaviors that contribute to the later development of child self-regulation of emotion (Kopp & Neufeld, 2003; Sroufe, 1997). The scaffolding of young children's self-regulatory efforts begins in earnest in the toddler years, when children engage in more autonomous behavior and caregivers communicate

standards of behavior. Toddlers have limited ability to modulate their prepotent responses, such as inhibiting approach behavior (happy or angry) or approaching a task they do not wish to do (angry or afraid). Their spontaneous self-regulatory efforts are not regarded as reflecting conscious deliberation and they are of limited effectiveness. For example, gaze aversion is a well-practiced behavior but it still has only temporary immediate effect on anger and no effect on fear during quasi-naturalistic laboratory tasks (Buss & Goldsmith, 1998). Toddlers' self-regulatory attempts are also context-dependent. The degree to which toddlers express anger and engage in regulatory efforts, as well as the relation between emotion and regulatory efforts, depends on the situation, e.g., arm restraint versus snack delay (Calkins & Johnson, 1998; Feldman, Dollberg, & Nadam, 2011).

The spontaneous, brief efforts of very young children to regulate negative emotions are soon strengthened by neurophysiological change and learning from thousands of experiences with emotional events. As Kopp (1989) posited, during the transition from toddlerhood to preschool-age children's self-regulation of distress and negative emotion transforms. Children begin to direct and modulate their behavior in accord with adult standards when adults are present, a form of compliance, with increasing understanding and acceptance of those standards (Feldman & Klein, 2003; Kochanska, Coy, & Murray, 2001). During the third year, they begin to deliberately initiate efforts that alter their distress without adult instruction or even presence, suggesting internalization of rules and self-regulation (Kochanska et al., 2001; Kopp, 1982). Typically developing children as young as three and four years engage in spontaneous expressive control (Cole, 1986; Garner & Power, 1996) in the absence of familiar caregivers. Specifically, when a research assistant gives typically developing preschool-age children an undesirable prize for their work, 3- and 4-year-olds modulate nonverbal expressive indications of disappointment (sadness, anger, disgust). Toddler gaze aversion when reward goals are blocked (e.g., Hill, Degnan, Calkins, & Keane, 2006) appears to develop into preschoolers' deliberate effort to distract themselves in such situations (Rothbart, Sheese, Rueda, & Posner, 2011). It is not clear how aware such young children are of their self-regulatory efforts. Their efforts may be more automatic, unconscious strategies, which would be consistent with evidence that they do not articulate strategies although they recognize effective strategies (Cole, 1986; Cole, Dennis, Smith-Simon, & Cohen, 2009). Spontaneous infant and toddler behaviors that serve regulatory functions may begin as non-deliberate, non-conscious behaviors that may later become available to self-awareness although with repeated practice they may eventually become automatic and non-conscious (Bargh & Williams, 2007).

When trusted caregivers are available, preschool-age children seek support when confronted with blocked or lost goals (e.g., Cole, Tan, Hall, Zhang, Crnic, Blair, & Li, 2011; Eisenberg, Fabes, Bernzweig, Karbon, Poulin, & Hanish, 1993). Initiating support-seeking is a form of self-regulation, aimed at achieving a goal by soliciting another's help. Between toddler and preschool age, angry support-seeking declines and calm support-seeking increases (Cole et al., 2011). Support-seeking reflects the representation that caregivers can be helpful, an interpretation consistent with the fact that children of this age engage in less support seeking when their parents are rated as angry and coercive (Eisenberg et al., 2003). During this age period, when self-regulation is just emerging, caregivers often initiate support and they do so more if they perceive children as more emotionally reactive and less able to employ effective self-regulatory strategies (Perez & Gauvain, 2005).

Most studies of young children's autonomous emotion regulation employ quasi-naturalistic laboratory tasks to evoke anger or fear, and in these contexts the most commonly observed self-regulatory strategy is distraction (Buss & Goldsmith, 1998; Calkins, Gill, Johnson, & Smith, 1999; Calkins & Johnson, 1998; Cole et al., 2011; Day & Smith, 2013; Grolnick, Bridges, & Connell, 1996). As noted, distraction is defined by deliberately shifting attention away from the stimulus to which a child has an emotional response (a threat or a blocked goal) and toward an alternative activity. Individual differences in the use of distraction may reflect individual differences in child dispositional negativity, prior regulatory capacity and parenting practices or style (Hastings & De, 2008; Morris et al., 2011; Perry, Calkins, Nelson, Leerkes, & Marcovitch, 2011; Rothbart, Posner, & Keiras, 2006).

As predicted by Kopp's (1989) developmental framework for self-regulation, and Posner and Rothbart's (2000) developmental framework for executive attention, between 24 and 36 months of age, there is a change in young children's self-initiated distraction. This change appears due to the maturation of an executive attention system, a product of neurological development and experience (Rueda, Rothbart, & Posner, 2005). At 24 months children initiate few distractions, the distractions are brief and, if children had expressed negative emotion, the distraction has a momentary, limited effect on reducing emotion intensity (Buss & Goldsmith, 1998; Cole et al. 2011).

By 36 months, however, children initiate distractions more readily, the distractions are sustained somewhat longer, and they often occur *prior* to anger expression (Cole et al., 2011; Supplee, Skuban, Trentacosta, Shaw, & Stoltz, 2011). By 36 months, children are better able to become absorbed in alternative activities once they distract themselves, which appears to help them tolerate a potential frustration and forestalls getting openly angry (Cole et al., 2011). Although there are still limits on preschool-age children's strategy effectiveness, by age 4 and 5 years, distraction has become a more practiced regulatory strategy and typically developing children use it successfully in contrast to same-aged children with behavior problems (Feng, Shaw, & Moilanen, 2011; Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; Jahromi, Meek, & Ober-Reynolds, 2012; Silk, Shaw, Skuban, Oland, & Kovacs, 2006). Thus, by the time children reach kindergarten age, they can tolerate commonplace experiences with novelty, frustration and disappointment by forestalling and modulating emotionally negative reactions (Blair, 2002; Denham, Bassett, Sirotkin, & Zinsser, 2013; Eisenberg, Valiente, & Eggum, 2010).

There is far less research on the development of emotion regulation in middle childhood (Zeman, Klimes-Dougan, Cassano, & Adrian, 2007). There appear to be two main reasons for this neglect. First, there is considerable interest in adolescence due to its being a period of rapid developmental changes in which youth experience significant new demands in their academic and social lives, emotional intensity increases, and there appears to be significant reorganization at the neural level (Casey, Getz, & Galvan, 2008; Casey, Jones, & Somerville, 2011; Dahl, 2004; Larson, Moneta, Richards, & Wilson, 2002; Peper & Dahl, 2013). Second, research on emotion regulation in school-age children (and adolescents) tends to be dominated by contrasts between individuals with and without symptoms or risk factors, reflecting perhaps the expectations that typically developing children should be fairly well-regulated by school age.

Nonetheless, there is growth in emotion regulation in middle childhood in the form of increased and more varied experiences in which emotion regulation is needed, in their greater autonomy and reduced need for close adult supervision, more opportunities to learn about and use strategies, and an increased repertoire of regulatory strategies. Between 8 to 12 years, children continue to seek support and employ distraction but they are also have more opportunity and are better equipped to engage in direct problem solving, acceptance of problem situations, and altering appraisals (cognitive restructuring), as well as intentionally avoiding or withdrawing from situations (Garber, Braafladt, & Zeman, 1991; Garber, Braafladt, & Weiss, 1995; Tan et al., 2012; Zimmer-Gembeck & Skinner, 2011; Zimmermann & Iwanski, 2014).

During adolescence youth appear to develop more efficient cortical functioning in regions associated with regulatory processes (Lamm & Lewis, 2010; Perlman & Pelphrey, 2010), which may explain their increasing ability to intentionally inhibit prepotent responses such as emotional reactions (Eisenberg et al., 2005). They probably also gain greater flexibility and effectiveness of their strategies and more autonomy and confidence in using them. Cognitive advances in symbolic, abstract reasoning and self-reflection are thought to contribute to the skill with which adolescents select among possible strategies, choosing those that are better suited to situations and switching strategies when one is ineffective (Flynn & Rudolph, 2010; Holodynski & Friedlmeier, 2006; Zimmer-Gembeck, Skinner, Morris, & Thomas, 2012).

These conclusions are tempered by a limitation of research on emotion regulation in middle childhood and adolescence, specifically the heavy reliance on self-report data. Self-report instruments inform us of the regulatory efforts of which participants are aware and which they are willing to endorse. These reports have three important limitations, especially for research guided by a functional perspective on emotion: (1) they tend to treat emotion regulation as a trait; (2) they tend to ignore the varied contexts in which emotions, even the same emotions, occur; and (3) they tend to overlook the dynamic, unfolding nature of emotion and emotion regulation. Moreover, when applied to the development of psychopathology, there will be individual differences in the reliability of self-reports of emotion regulation. The reliance on self-report is due in part because it is difficult to observe older children's and adolescents' emotion regulation in naturalistic contexts; they can generate and use intrapersonal strategies, such as reappraisal, as well as more automatic or potentially problematic strategies, such as denial, rumination, wishful thinking, and emotional numbing (Langrock, Compas, Keller, Merchant, & Copeland, 2002; Wadsworth, Raviv, Compas, & Connor-Smith, 2005; Zeman et al., 2007; Zimmermann & Iwanski, 2014). Clearly, a thorough documentation of the development of emotion regulation in middle childhood and adolescence requires a careful, sophisticated approach. Several studies have employed multiple measures to increase inferences about emotion regulation—including self-report, observations or psychophysiological assessment. Moreover, several of these have been successful at increasing the ecological validity

of the data gathered, assessing children's and adolescents' emotion regulation in actual or quasi-naturalistic relational contexts. These include parents and children discussing actual problems or planning an activity, children and adolescents giving a speech or having actual or computer-based (simulated social media) peer interactions, including some that lend themselves to use in the MRI environment (Guyer, McClure-Tone, Shiffrin, Pine, & Nelson, 2009; Klimes-Dougan & Zeman, 2007; Reijntjes et al., 2006; Yap, Schwartz, Bryne, Simmons, & Allen, 2010; Zalewski, Lengua, Wilson, Trancik, & Bazinet, 2011). Focus groups on important topics and experience sampling methods, such as daily diaries and ecological momentary assessment have also been employed to capture children and adolescents' emotions in real-life situations (Dunton et al., 2014; Larson, Raffaelli, Richards, Ham, & Jewell, 1990; Reeves, Nicholl, & Mackenna, 2011; Silk et al., 2003; Tan et al., 2012; Tenenbaum, Varjas, Meyers, & Parris, 2011). Finally, these types of procedures can generate data that can be used to capture individual differences in emotional dynamics (Dagne & Snyder, 2011; Sheeber, Kuppens, Shortt, Katz, & Davis, 2012).

Risk for Emotional Dysfunction Associated with Emotion Regulation

Many studies have associated deficits in emotion regulation to psychopathology in children, adolescents and adults, including a number showing that emotion regulation mediates relations between risk factors and psychopathology outcomes (e.g., Aldao, Nolen-Hoeksema, & Schweizer, 2010; Boden, et al., 2013, on posttraumatic stress disorder; Cavanagh, Quinn, Duncan, Graham, & Balbuena, 2014, on oppositional defiant disorder; Cisler, Olatunji, Feldner, & Forsyth, 2010, on anxiety disorders; Harrison, Sullivan, Tchanturia, & Treasure, 2010, on eating disorders; Joorman & Gotlib, 2010, on depression; Martel, 2009, on attention-deficit disorder; Beauchaine, Gatzke-Kopp, & Mead, 2007, on conduct disorder; Salsman & Linehan, 2012, on borderline personality disorder). Although these studies are quite limited in informing the dynamic, context specific emotion processing in personally meaningful situations relates to psychopathology. Moreover, few have used longitudinal designs that come closer to addressing the question of whether difficulties with emotion regulation are a correlate, causal factor, or consequence of psychopathology. Another challenge to answering these questions is that emotion regulation changes rapidly in early development but most *DSM*-defined diagnoses require clusters of stable symptoms that are rarely observed before middle childhood.

Early childhood longitudinal studies indicate that infants and toddlers who do not yet engage in age-level emotion regulation tend to have stable or worsening symptoms in the preschool years, particularly in the presence of adversities, such as economic disadvantage or caregiving inadequacies (Calkins & Keane, 2009; Crockenberg, Leerkes, & Bárrig, 2008; Gilliom et al., 2002; Halligan et al., 2013; Kochanska & Knaack, 2003). A small number of additional longitudinal studies extend these findings into middle childhood (Blandon, Calkins, Grimm, Keane, & O'Brien, 2010; Eisenberg et al., 1996; Kim & Cicchetti, 2010; McLaughlin, Hatzenbuehler, Mennin, & Nolen-Hoeksema, 2011; Trentacosta & Shaw, 2009).

Generally, the conditions that pose risk to the development of competent emotion regulation include those already discussed: genetically based influences on the development of physiological systems that support emotion processing and stress responding; atypical patterns in caregiver-child contributions to emotional exchanges, which includes the conditions that lead to insecure attachment; and factors that overly tax the self-regulatory capacities of the child or the capacity of caregivers to foster children's development of effective emotion regulation. Here we organize the discussion into two main categories of risk for emotion regulation: child characteristics, namely temperament and attachment security, and environmental characteristics, including inadequacies in caregiving qualities and exposure to adversity, which often includes inadequate caregiving.

Child temperament is generally shown to be a risk factor for the development of emotion regulation. The research has focused largely on the dimension of negative emotionality, although the degree to which it poses risk depends on the other major dimension of temperament, effortful control. Again, negative emotionality refers to automatic, prepotent, and stable tendencies to react with strong negative responses to stimuli, including to perceived obstacles to well-being (reactivity to frustration) and perceived threats to well-being (reactivity to novelty; Rothbart & Bates, 2006). Such non-conscious, spontaneous and intense reactivity reflects neurobiologically based dispositions that are shaped by prenatal and subsequent experience (Davis et al., 2011; Wang & Saudino, 2013). As noted earlier, emotional reactivity poses a challenge for the development of effective emotion regulation because management of strong negative emotions may outpace children's self-regulatory resources as well as those of caregivers trying to aid and teach them (Calkins, 1994). But negative emotionality may not have longer-term negative consequences if children also have a temperamental

disposition toward effortful control (e.g., Eisenberg et al., 2009). Effortful control involves readiness for attentional flexibility and control that can be deployed to interrupt or inhibit prepotent responses such as emotional reactivity (Rothbart & Bates, 2006). That is, very young reactive children who are readily distracted by caregivers when they are highly distressed, and who later in childhood can more exert cognitive resources to shift attention or inhibit action despite their strong appraisal/action readiness should be less at risk for compromised emotion regulation. Indeed, there is considerable overlap in the literature between the concepts of effortful control and emotion regulation. For the purposes of this chapter, temperament is conceptualized as a largely neurobiological, relatively stable set of predispositions and emotion regulation is largely learned, acquired over time, and influenced by multiple factors, including temperamental dispositions.

Emotionally reactive children are less successful at using regulatory strategies (e.g., Morris & Silk, 2001), but their reactivity does not lead to inappropriate actions if they engage in appropriate regulatory strategies (Calkins, Gill, Johnson, & Smith, 1999; Santucci et al., 2008). However, negative emotionality and effortful control are better understood in the context of interpersonal processes (e.g., Raby et al., 2012). The degree to which young children exert effortful control depends on the situation, including who is interacting with them and the ability of those others to encourage child effortful control (Braungart-Rieker, Garwood, & Stifter, 1997; Spinrad et al, 2012; Volling, McElwain, Notaro, & Herera, 2002). Emotionally reactive infants who are less disposed toward effortful control may be especially dependent on caregiving qualities to develop effective emotion regulation (Ellis et al., 2011; Klein Velderman, Bakermans-Kranenburg, Juffer, & van IJzendoorn, 2006).

One pathway by which high negative emotionality and low effortful control pose risk for the development of effective emotion regulation is through the demands placed on infant–caregiver interactions, including contributions to the establishment of relationship patterns, including the attachment relationship (Lorber & Egeland, 2011; van IJzendoorn & Bakermans-Kranenburg, 2012). If infants and caregivers have difficulty establishing predictable emotion exchanges in which infant distress is reliably addressed by sensitive caregiving, it is more difficult for infants to achieve secure attachment (Beebe et al., 2011; Leerkes et al., 2011). Individual differences in attachment status are defined by different styles of emotional organization when children's need to regain a sense of well-being overtakes their interest in exploring the world, and attachment status establishes a working model of distress relief that contributes to the development of emotion regulation (Cassidy, 1994). Insecure attachment is associated with both reduced spontaneous, authentic support seeking (insecure-avoidant style) and with intense, exaggerated emotional (insecure-resistant style; Cassidy, 1994). It is important to recall that attachment security, which is established in the first year, influences the developing organization of biobehavioral stress systems that affect appraisal/action readiness and regulation (Crockett, Holmes, Granger, & Lyons-Ruth, 2013; Feldman, 2012; Hill-Soderlund et al., 2008; Lujik et al., 2010; Spangler & Grossmann, 1993) and their neural concomitants (DeWall et al., 2012; Eisenberger et al., 2011; Karremans, Heslenfeld, van Dillen, & Van Lange, 2011).

Evidence supports the view that attachment status influences behavioral self-regulation of emotion. In delay and compliance tasks used to assess emotion regulation, insecure-resistant infants communicate more angry distress and engage in fewer self-regulatory attempts than secure infants, and their mothers appear to interfere more with infant self-regulatory attempts (Berlin & Cassidy, 2003; Diener, Mangelsdorf, McHale, & Frosch, 2002; Leerkes & Wong, 2012; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996; Kok et al., 2013; Vondra, Shaw, Swearingen, Cohen, & Owens, 2001). Resistant attachment style also predicts preschool-age behavior problems, many of which involve poorly regulated anger (Crittenden, 1992; Vondra et al., 2001). Insecure-avoidant and secure infants appear less overtly dissimilar. As Cassidy (1994) suggested, avoidant infants can appear emotionally self-contained despite physiological indices of distress, and engage in more self-soothing and toy exploration, which is understandable given their mothers are less engaged (Braungart & Stifter, 1991; Leerkes & Wong, 2012; Nachmias et al., 1996; Spangler & Grossmann, 1993). Whereas resistant and avoidant attachment represent risk, they are nonetheless regarded as organized adaptations to inadequate caregiving; disorganized attachment is not by definition (Hesse & Main, 1999). Disorganized attachment appears to reflect conditions that would lead infants to have difficulty adopting a patterned appraisal/action readiness stance. Their emotional confusion results from starkly mixed presentations by their mothers who can appear both frightening to or frightened by their infants (Hesse & Main, 1999), a pattern that is more emotionally abusive than inadequate. Thus, disorganized infants are not emotionally spontaneous, intense, or self-contained, but appear dazed, anxious, afraid, and confused and without effective regulatory strategies. These patterns may underlie the

tendencies of individuals with abuse histories to dissociate from emotional experience and to act in highly controlling ways (Hertsgaard, Gunnar, Erickson, & Nachmias, 1995; Liotti, 1999; Main & Solomon, 1990; Solomon, George, & De Jong, 1995; Spangler & Grossmann, 1993).

The relative and conjoint contributions of temperament and attachment status to risk for ineffective emotion regulation have not been studied sufficiently (Lickenbrock et al., 2013). Ideally, studies examining these child characteristics would also include other contextual factors that would predict pathways to emotion regulation. One study employed a multiple domain model to predict different types of symptoms in preschool-age children with oppositional defiant disorder (Lavigne, Gouze, Hopkins, Bryant, & LeBailly, 2012). The findings are limited by the fact that all predictors and outcomes were measured concurrently, mainly with questionnaires, for a single age group; nonetheless, the evidence suggested complex pathways in which child effortful control, negative emotionality, and attachment insecurity intersect with contextual factors such as parental psychopathology and stress.

Attachment status appears to be relatively stable from infancy to adulthood, which is attributed to the early establishment of the internal working model (Fraley, 2002; Hamilton, 2000; van IJzendoorn, 1995; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000; Weinfield, Sroufe, & Egeland, 2000; Zimmermann, 1999). Individuals with a history of insecure-resistant attachment are less able to regulate anger in interactions with persons other than their infant caregivers, as seen in studies of preschool-age children interacting with their younger siblings or foster parents and of adolescents and adults interacting with parents, friends and romantic partners (Allen & Miga, 2010; Crowell et al., 2014; Dozier, 2003; Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993; Pietromonaco, Uchino, & Schetter, 2013; Volling, 2010; Zimmerman, Maier, Winter, & Grossmann, 2001). Although insecure attachment is a risk factor for the development of psychopathology, it is not in and of itself psychopathology. The question has been raised why insecure attachment is so common if it is places a person at risk and the question posed whether a diversity of attachment styles in a social group may advantage group survival better than a group composed only of securely attached individuals (Ein-Dor, Mikulincer, Doron, & Shaver, 2010). In other words, insecure attachment, an adaptation to inconsistent, unavailable, or unpredictable primary relationships may have advantages in the face of adversity. Moreover, it is likely that attachment status poses risk for emotional dysfunction in the presence of other risk factors.

When discontinuity in attachment status occurs, it is almost always associated with a specific form of adversity, that is, interpersonal problems directed at or occurring in the presence of children, such as family instability, interpartner conflict, or child abuse (Belsky, Campbell, Cohn, & Moore, 1996; Schneider-Rosen, Braunwals, Carlson, & Cicchetti, 1985; Waters, Weinfield, & Hamilton, 2000). As noted, child characteristics affecting emotion regulation must be understood in the context of multiple developmental influences, including the challenges with which child and family are dealing. The full range of environmental factors that can challenge children's capacity to regulate emotion is wide. They can include factors that stress and strain family resources (e.g., poverty) and interact with characteristics of caregivers and their relationships that bear down on parenting. When studies consider multiple influences, it generally appears that the effects of adversity, broadly defined, on child emotion regulation depend on caregiving qualities.

For example, poverty is a condition that captures a variety of circumstances that pose risk to children and their caregivers. Growing up in poverty is associated with less skillful child self-regulation, as indexed by both biological and behavioral indices, some of which include aspects of emotion regulation (Evans & English, 2002; Evans, Gonnella, Macynyszyn, Gentile, & Salpekar, 2005; Evans & Rosenbaum, 2008; Keenan, Shaw, Walsh, Delliquadri, & Giovanelli, 1997; West, Sweeting, Young, & Kelly, 2010; Vernon-Feagans, 2013). The effects of poverty may be most deleterious when present in infancy (e.g., Mistry, Benner, Biesanz, Clark, & Howes, 2010), but the evidence of these effects on behavioral indices of emotion regulation may take time to appear. For example, there are more significant effects on children's spontaneous self-initiated regulatory efforts after age 30 months, an age when self-regulation typically emerges (Caughy, Mills, Owen, & Hurst, 2013). However, poverty can be associated with many factors that can compromise the development of effective emotion regulation, including exposure to discrimination and racism, community violence, exposure to uncontrollable noise, and inadequate nutrition (Aber, Jones, & Cohen, 2000; Evans & Kim, 2013; Gibbons et al., 2012; Lozoff et al., 2008). In the presence of warm, supportive parenting, poor children and adolescents appear to develop effective regulation of anger and sadness (Brody et al., 2014; Burchinal, Roberts, Hooper, & Zeisel, 2000; Garner, Mahatmya, Moses, & Bolt, 2014; Garner & Spears, 2000; McCoy & Raver, 2011).

Thus, the caregiving circumstances that can interfere with the development of effective emotion regulation

warrant more detailed attention. These are proximal relationships that are likely to be potent influences on children's emotion regulation development, particularly in early childhood, and that can moderate the effects of other risk factors. As noted, caregiving quality may be particularly critical for children who bring their own vulnerabilities to the interactions (Ellis et al., 2011). The caregiving circumstances that are known to be associated with children's difficulties with emotion regulation include abusive and neglectful caregiving, parental psychopathology, and impaired coparenting relationships (e.g., due to marital conflict) that children experience or spills over to parenting (Goodman et al., 2011; Kim-Spoon, Cicchetti, & Rogosch, 2013; McCrory, DeBrito, & Viding, 2012; Schudlich, White, Fleischhauer, & Fitzgerald, 2011; Sturge-Apple, Davies, Cicchetti, & Fittoria, 2014; Suveg, Shaffer, Morelen, & Thomassin, 2011). Caregiving problems can confer risk on emotion regulation in three interrelated ways that have been identified as mechanisms of emotion socialization: as emotional partners, as models of emotion regulation, and as scaffolds for the development of self-regulation skills (Eisenberg et al., 1998; Morris et al., 2011).

When caregivers interact with their children, they implicitly convey information in all of these ways, and on some occasions they explicitly attempt to model and guide child emotion regulation. As emotional partners, caregivers communicate emotion and communicate about emotion. In many of the caregiving contexts associated with children's emotional dysregulation, caregivers communicate negative emotions. These often are processed by children as aversive stimuli to which children react and with which they must cope. Studies frequently report that mothers with different forms of psychopathology, such as mood, anxiety, or personality disorders react to their infants' and children's negative emotions with autonomic, neural, and behavioral responses, that is, appraisal/action readiness tendencies, indicative their own personal goals for well-being have been threatened or blocked, and that these caregivers do not readily recover from such reactions (Buckholdt, Parra, & Jobe-Shields, 2014; Burkhouse, Uhrlass, Stone, Knopik, & Gibb, 2012; Connell, Hughes-Scalise, Klostermann, & Azem, 2011; Creswell, Apetroaia, Murray, & Cooper, 2013; Hobson, Patrick, Crandell, Garcia-Perez, & Lee, 2005; Hudson, Comer, & Kendall, 2008; Kiel, Gratz, Moore, Latzman, & Tull, 2011; Oppenheimer, Measelle, Laurent, & Ablow, 2013; Silk et al., 2011; Shipman et al., 2007). These immediate emotional reactions suggest that the caregivers' appraisal/action readiness stances are oriented toward the caregivers' own well-being rather than focused on child needs for well-being. That is, the negative emotions on are on behalf of the caregiver, not the child. If caregivers cannot recover readily, these appraisal/action readiness stances are likely to interfere with their ability to sensitively respond to children's needs (Leerkes, 2010). Although caregivers' negative emotions may ready them to withdraw from caregiving, this is difficult to carry out when caring for young children; mothers who are emotionally competent manage to regulate this type of action readiness and to engage effectively with their children (Hajal, 2014). In situations in which children are challenging, caregivers may initially or subsequently appraise the situation as blocking their goals and be ready to approach; in these moments, caregivers are angry. This may be an explanation for why irritability is a common feature of emotional exchanges between stressed parents and their children.

Because emotions are a rapid radar and response system for meeting one's goals for well-being, it takes skill to be aware of such rapid reactions. Caregivers who are a source of adversity exposure to their children are often less emotionally aware, and they are therefore less mindful of their behavior with their children and less skilled at using emotional episodes as opportunities to learn about emotion regulation. Stressed caregivers are more likely to ignore or dismiss children's negative emotions, missing the messages children's emotions communicate and missing opportunities to validate the child's perception of need and to teach the child alternative coping (Katz, Maliken, & Stettler, 2012; Yap, Allen, & Ladouceur, 2008). Although stressed caregivers can be dismissive and invalidating of children's emotions, they can also be overly reactive or focused on children's negative emotions, and these reactions may model or suggest ineffective emotion regulation. Lower emotional awareness among mothers with depressive symptoms was associated with mothers suggesting cognitive or behavioral avoidance as ways to cope with negative emotion rather than direct problem solving (Monti, Rudolph, & Abaied, 2014). A longitudinal study found that mothers' dwelling on their adolescent children's negative emotions in response to a frustrating task contributed subsequently to youths' tendency to ruminate (Cox, Mezulis, & Hyde, 2010).

Recalling that appraisal/action readiness patterns often unfold rapidly in micro-momentary fashion, they influence interactions with children without caregiver awareness. Yet children, particularly very young children, are sensitive to caregivers' emotions. The evidence indicates that when caregivers communicate anger (irritability, hostility, criticism), it is often perceived as threatening to children, which

requires children to cope with and adapt to caregivers as aversive stimuli. Neurobiological and behavioral evidence suggests that children's initial responses to parental anger reflect appraisal/action readiness patterns involving fear, anxiety, or sadness (Davies, Cicchetti, & Martin, 2012; Shackman et al., 2007; Snyder, Brockman, & Stoolmiller, 2012), which again often occur outside of children's awareness. Caregiver emotional intensity and difficulty regulating emotion may lead some children to blunt their emotional experiences, which are not effective in eliciting adequate care, and which may contribute to problems with emotional awareness or emotional avoidance in later years (Gratz et al., 2014).

When these negative emotions are not well-regulated, caregivers and children may subsequently shift appraisal/action readiness, specifically to the appraisal that goals are blocked and renewed or intensified effort to regain the goal. Such emotional unfolding is often missed in studies of dyadic interaction but can be captured by dynamic analysis of the temporal flow of biological and behavioral indices of appraisal/action readiness (Dagne & Snyder, 2011; Sheeber et al., 2012; Snyder et al., 2012). Throughout the temporal sequences of interactions, emotional partners can shift appraisal/action readiness stances. The reactions described likely occur among typical caregivers but they are able to regulate these reactions (Hajal, 2014). However, this is more challenging with children whose behavior is disruptive or unresponsive or who are more emotionally reactive but less able to regulate themselves; these children are also more likely to be quite dependent on caregiving quality to regain emotional control and learn emotion regulation skills in the course of interactions (Cartwright et al., 2011; Cole et al., 2003; Gibb, Uhrlass, Grassia, Benas, & McGeary, 2009). The ability of caregivers to maintain or recover sensitive, supportive responsiveness with children provides opportunity to help children learn emotion regulation emotion even in the presence of family adversity (Howell, Graham-Bermann, Czyz, & Lilly, 2010). The availability of alternative adequate caregiving early in life, e.g., foster or adoptive parents, appears to mitigate pervasive, deleterious biobehavioral consequences of early exposure to adversity on regulatory processes (e.g., Almas et al., 2012; Dozier, Zeanah, & Bernard, 2013; Lipscomb, Leve, Shaw, Neiderhiser, Scaramella, Ge et al., 2012; Oosterman, DeSchipper, Fisher, Dozier, & Schuengel, 2010). As noted, this is critically important as circumstances in which caregiver behavior taxes very young children's ability to regulate emotion are likely to have pervasive, deleterious effects at all levels of functioning, including the emotion neurophysiology (e.g., Graham et al., 2013; Tottenham et al., 2010). For typically developing children whose caregivers' problems emerge later in the children's development, children's existing ability to engage in effective emotion regulation may buffer the links between adversity exposure and risk for psychopathology (e.g., Kim & Cicchetti, 2010). By early school age, children have more autonomy in regulating their emotional reactions, which may help them cope effectively, but they are still sensitive to and depend on caregiver guidance to deal with situations that challenge their self-regulation.

In sum, infant temperament, particularly effortful control, and attachment security appear to play a role but the robustness of their contributions will only be fully known when these child characteristics are studied in a multidomain longitudinal design. Exposure to adversity, particularly in the absence of adequately responsive caregiving, appears to have profound, enduring deleterious effects on the development of the neurobiological systems that support emotion regulation and on behavioral skill development. As the capacity for effective emotion regulation is established and flourishes in its range, flexibility and sophistication, older children and youth nonetheless face many new challenges; their bodies are changing in ways that are not always anticipated and valued, academic demands increase, peer pressures become more powerful, moral dilemmas that accompany greater autonomy increase and unpleasant and abusive interactions (e.g., bullying, sexual affronts) occur with more frequency, and decisions about the future begin to bear down. As they transition from middle school to high school age, there are increased expectations that youth should handle their autonomy and opportunities in well-regulated ways, although this period is associated with increased emotional intensity (e.g., Larson et al., 1990; Steinberg, 2005). During this same extended period of development, as noted above, the prevalence of psychopathology increases. Youth are increasingly exposed to stressed peers and to risky emotion regulation strategies. Adolescents engage in emotion regulatory strategies that they perceive as providing short-term relief but that increase their risk, including disordered eating behaviors, self-harm behaviors, and alcohol and drug use, strategies often used by youth who are overwhelmed by or disconnected from their emotions and who are unaware of or feel unable to engage in direct problem-solving strategies (Adrian, Zeman, Erdley, Lisa, & Sim, 2011; Goldstein, Vilhena-Churchill, Stewart, & Wekerle, 2012; McMahon et al., 2013; Wong et al., 2013).

Furthermore, in addition to being prepared to express emotion, which serves to engage caregivers in infant

emotion regulation, infants engage in rudimentary, limited self-initiated behaviors—self-soothing and gaze aversion—that serve as temporary regulators of infant state. Infant temperament, notably higher emotional reactivity and lower soothability, influence how easily infants and caregivers achieve regulate distress. When dyadic regulation of infant emotion falters in establishing a consistent, predictable pattern of distress relief, an insecure infant attachment is more likely. Attachment status involves mental representations about distress relief that organize infant behavior in the context of separation from caregivers and that appear to constrain the development of self-regulation of emotion. Of course, all of these developmental steps take place in interpersonal context. Exposure to adversity in early childhood compromises biological systems for stress regulation as well as behavioral skill development in self-regulation. These can have profound effects, particularly if that adversity involves deficiencies in caregiving. Quality caregiving can mitigate risk factors, capitalizing on the plasticity of early developing self-regulatory processes, but when caregiving is unresponsive or threatening, the risks in early childhood are considerable. For children who have navigated early childhood without significant risk, later emerging exposure to adversity may nonetheless overtax their self-regulatory capacities. Over the course of middle childhood and adolescence, there is likely growth in the range, flexibility, and sophistication but also the possibility of developing ineffective regulatory strategies such as experiential avoidance, passive aggressiveness, and rumination. The rapid and substantial biological, psychological, and social changes of adolescence are associated with greater resources, both intrapersonal and interpersonal, for regulating emotion but also with many new challenges and more frequent and intense emotion. Thus at each stage of development there are new emotion regulation skills and new challenges to be encountered and the development of effective emotion regulation is thought to rely in large part on strong, supportive relationships with at least some individuals, both in the family and in larger social networks. However, we lack multidomain longitudinal models that assess the cascading influences of risks associated with emotion regulation that chart the various developmental pathways to ineffective emotion regulation.

CONCLUSION AND FUTURE DIRECTIONS

The functionalist perspective on emotional development offers unique insights into the nature of emotion and emotional competence, insights that can advance the clinical relevance of research on the role of emotion in the development of psychopathology. The functional perspective conceptualizes emotion as a dynamic, context-sensitive, relational process by which individuals, regardless of their mental health status, appraise and prepare to act on the environment in relation their individual goals for well-being. Unless children have gross neurological impairments, they have the capacity to be emotional and they adapt to their circumstances. Generally then, individual differences do not rob children of the ability to function emotionally. Rather it is in the relational process, in how children and youth adapt to their perceived circumstances that must be examined to understand emotional dysfunction.

A very large and heterogeneous number of the world's children navigate the developmental tasks of infancy, childhood, and adolescence effectively. In terms of emotional development, most children come to access a full range of human emotions and to communicate and understand them. Moreover, they come to regulate emotion, which enables them to function in flexible, culturally appropriate, and effective ways. That is, most children develop the emotional competence that enables them to become productive, interpersonally successful adults. They effectively coordinate their individualistic goals for well-being with the individualistic goals of others as well as relinquish individualistic goals on behalf of relationship goals such as camaraderie, respect, empathy, love, and compassion.

Less often yet far too often children's circumstances challenge their goals for well-being. Although they may not be conscious of the nature of their risky conditions, they may nonetheless perceive at a most basic level that their needs are unmet, their goals unattainable, and their well-being threatened. In these circumstances, children's sensitivity to their emotional environments and their innate ability to adapt to their risky conditions creates the context for atypical emotional development and the potential for compromised emotional competence, which can contribute to a course toward psychopathology. From the functional perspective, individual differences with which children are born that make their development of emotional competence more challenging should be protected by caregiving environments that adjust to their relative difficulties, helping them achieve well-being and develop culturally appropriate skills for achieving their goals flexibly and effectively. Thus, the relational nature of emotion not only creates risk because of the inborn readiness to be sensitive to environmental conditions but also contributes to protection because of the dependence on how the environment relates to children's needs.

Thus, the greatest risk is posed by non-optimal caregiving circumstances in which children must adapt to atypical conditions. Examples discussed in this chapter include the heightened perceptual sensitivity to anger cues of physically abused children and the flattened cortisol function of children exposed to chronic stress. The evidence further suggests that early exposure to adverse circumstances, that is, prior to about age 2 years, constitutes a particular severe risk as it interferes with the very building blocks of emotional competence. These can be mitigated by the introduction of adequate caregiving, as seen in the case of Rumanian orphans placed in foster care prior to age 2. Unfortunately, the adversities to which at risk children adapt often include deficiencies and threats in the caregiving environment with limited access to supportive relationships outside of the caregiving environment. These are contexts in which atypical child-environment relations exist and these increase the chances that the child will have atypical emotional development that will manifest as emotional dysfunction.

This brings us then to discussion of the links between emotional competence and the emotional dysfunction associated with psychopathology. The hypothesis put forward from the functional perspective is that risk factors that interfere with the development of emotional competence will increase risk for the development of emotional dysfunction and for the development of psychopathology. From the functional perspective, this is best considered in terms of how individuals relate to and adapt to their circumstances. Evidence from longitudinal studies indicates that poorer performance in one or more domains of emotional competence usually precedes the emergence of formal symptoms of psychopathology and is often associated with symptom maintenance or exacerbation (Abela et al., 2002; Blandon et al., 2010; Broderick & Korteland, 2004; Cole et al., 2003; Das et al., 2013; Herts, McLaughlin, & Hatzenbuehler, 2012; Hill et al., 2006; Kim-Spoon et al., 2013; McLaughlin et al., 2011; Röll, Koglin, & Petermann, 2012; Stepp et al., 2014; Wirtz, Hofmann, Riper, & Berking, 2013). Only a few of these studies examined bidirectional effects. In general, emotional dysfunction precedes the onset of formal symptoms, although the development of symptoms can also heighten emotional challenges and further compromise emotional competence, as shown in longitudinal studies of adolescence or adults (Larsen et al., 2013; Stepp et al., 2014). In sum, the literature review in this chapter indicates ample research relating emotional competencies with success in life, ample research associating deviations in emotion expression, emotion understanding, and emotion regulation to psychopathology, and a growing body of research suggesting that those deviations precede and likely contribute to the development of psychopathology.

The merging of the developmental psychopathology framework and the functionalist perspective on emotional development offers new perspectives on the role of emotion in the development of psychopathology. These two models share appreciation of context, of the importance of change over time, both in terms of moments and of years, and of the complexities of emotional development. They also point to methods that offer significant promise for overcoming the limitations of the current knowledge base, limitations that temper conclusions and hinder the translation of science to the prevention of and intervention with child and adolescent psychopathology. Together, the models help to move the study of the development of emotional dysfunction away from outcomes defined by *DSM* diagnostic categories or overly general symptom checklists and point us toward examination of emotion processes that develop in complex contexts, that can lead to varied outcomes, and that under certain conditions can lead to the development of psychopathology. The emphasis on emotions as relating to and guiding adaptive action helps us understand how children, faced with adversity but without adequate caregiving support, adapt to less than ideal conditions and how the biological and psychological systems involved in that adaptation can be affected in ways that lead to maladaptive functioning in other contexts. A process-oriented developmental model that can document pathways from the earliest neurophysiological building blocks of the capacity to be emotional through its lifelong development, considering how each period affords new levels of competence and yet new vulnerabilities will help us understand how an adaptive function becomes a factor in psychopathology. In their shared focus on emergent processes involving adaptation to environments, these models suggest certain priorities for identifying turning points that promote or interfere with emotional expressiveness, understanding, and regulation, aiming children and youth toward emotional competence and clinically relevant emotional dysfunction. They offer the following research guideposts:

Personal Relevance

The capacity to be emotional is how the personal relevance of circumstances is evaluated and adaptation is directed. Typically, the biological equipment that enables this capacity reaches sufficient maturation to permit the newborn to

communicate information about well-being that is interpretable to caregivers. What constitutes personal relevance in the complex interpersonal world develops with experience, maturation, and socialization. At every point along the way, as the capacity grows, there are challenges that can catalyze competence or compromise it. Evidence suggests that personally relevant challenges can occur at any point, and that those that neglect the personal needs of or pose threat to the personal well-being of the developing child create the most risk. They create the most risk because they affect the neurophysiological building blocks of the capacity for emotional competence, rather than challenge more established competencies.

There is a dearth of evidence that is based on situations or stimuli that capture personal relevance. This is especially the case for research with children with known disorders, and very much the case in studies employing neuroimaging methods. It is critical that we study emotion processing in situations that create or closely approximate circumstances that we know are personally relevant for participants. There are significant limitations to what we can learn about clinically important individual differences in emotional processing from research using static emotion expressions on unfamiliar faces, inquiring about purported feelings, actions and interpretations in hypothetical situations, or making broad generalizations from questionnaires. However, there is work that seems to have overcome some of the important obstacles that lead to over-reliance on these methods. There is promise in observing neural and behavioral activity when children, including those who have been exposed to threatening anger, process their mothers' angry faces or voices (e.g., Shackman et al., 2007); observing nonverbal expressiveness and verbalizations when children and caregivers discuss actual evocative experiences (e.g., Bauer et al., 2005); observing neural activity and behavior in youth anticipating peer evaluation in a simulated social media context (e.g., Guyer, McClure-Tone, Shiffrin, Pine, & Nelson, 2009; Silk et al., 2012); observing children's nonverbal and verbal behavior in laboratory tasks that mimic circumstances that threaten, disappoint, or frustrate young children (e.g., Buss & Goldsmith, 1998; Cole et al., 1994; Cole et al., 2011; Leerkes & Wong, 2013; Moore, 2009); and observing interactions between caregivers and children or youth involving current or past real-life issues and events that are defined as significant by participants (Kuppens, Allen, & Sheeber, 2010; Pasalich, Waschbusch, Dadds, & Hawes, 2014; Sheeber et al., 2012). In addition, experience sampling methods, such as ecological momentary assessment, electronically activated recording and other technology-assisted methods (e.g., Repetti & Wood, 1997; Silk et al., 2003; Slatcher & Trentacosta, 2012) increase the chances of studying emotion processes in circumstances or with stimuli that come closer to capturing real-life emotion processing.

Dynamics

As detailed in this chapter, the processes that fall under the rubric emotion are better thought of as verbs than nouns. It is part of survival to constantly be processing the significance of circumstances for one's well-being, it is highly adaptive that most of this processing occurs outside of awareness, and it is highly adaptive to be able to re-orient physiologically and be prepared to act if circumstances suddenly jeopardize well-being. And it is clinically important to understand the *dynamics* of emotion processes even if we study them by inferential methods and not direct observation. Our argument has been that emotions ebb and flow over the course of daily functioning, occasionally reaching awareness to which we attribute feelings. The importance of the sequence of events in participants' relation to circumstances, and of the characteristics of the pace and variability in the dynamic unfolding of those moments that are personally relevant, cannot be overstated from the clinical perspective.

The time course of emotions, sometimes referred to as emotion dynamics (e.g., Thompson, 1994), is a critical matter for understanding the role of emotion in the development of psychopathology. As is often said, it is not being angry or sad or afraid that marks dysfunction; these are adaptive responses to perceived circumstances and palpable indices of them communicate to the self or others an appraisal/action readiness. But the moment that an emotion is generated (a particular appraisal/action readiness change occurs), the emotion itself, in addition to the circumstances, is a stimulus. Clinicians deal with emotions about emotions all the time (Cole et al., 2013). An adolescent whose parents have moved to terminate their parental rights may appraise this situation as a significant loss; but sadness may be intolerable for that adolescent and the reaction to sadness is intense anger. A child is enraged with a sibling and then is overwhelmed with shame about being so angry or furious with a parent and then afraid of his own anger. Moreover, changes in emotion are likely to activate associative networks that can intensity or modify the emotion in an iterative process (e.g., see Cunningham, Dunfield, & Stillman, 2013).

Sequential analyses can reveal emotional dysfunction is in the extended order of physiological, self-reported, or observed emotions and other behaviors in individuals or

partners. The earlier example of a child who is frustrated and persisting at a blocked goal (a toy in a clear, locked box), then becomes sad and momentarily withdraws from the task, and then briefly brightens, expressing optimism, before she furrows her brown and mutters as she returns to trying to open the box. Her anger appears to motivate appropriate task persistence (see Dennis et al., 2009), and her brief sadness perhaps gives her time to reflect and re-appraise the situation. This emotional sequence might indicate emotional competence in a 3-year-old, and lead to conclusions that are quite different than the child who is briefly happy to try to open the box, then gets frustrated and angry, and then sadly gives up and says I don't want to come here anymore. Each sequence tells us something quite different than the total number of seconds of anger, sadness, and joy would. These two children have the same total number of seconds of each emotion expression but the sequence is different and those differences may be clinically relevant; 4-month-olds who are frustrated by a blocked goal but become primarily sad have higher cortisol production than those who just stay angry, indicating different stress responses (Lewis, Ramsay, & Sullivan, 2006). Several studies used small time intervals (e.g., 1s or 10s) to examine dyadic or individual influences on changes in emotion using sequences between pairs of variables, such as emotion and child strategy or parent strategy (Buss & Goldsmith, 1998; Crockenberg & Leerkes, 2004; Morris et al., 2011; Silk et al., 2011).

These approaches, however, do not capitalize on the full extent of information in a time series. Lorber and Slep (2005), for example, found support for the hypothesis that the degree to which the emotions of mothers of young children are predicted by the mothers' previous emotions distinguishes patterned, predictable caregiving from more erratic behavior; time series analyses indicated that this form of predictability of maternal emotion was associated with organized versus ineffective parenting behavior. This study demonstrates a principle of functionalist perspective that changes in emotion organize changes in behavior. Creative applications of time series analyses have been applied to behavioral, neural, and autonomic response data in emotion-relevant ways (Bach, Daunizeau, Kuelzow, Friston, & Dolan, 2011; Bulteel et al., 2014; Dagne & Snyder, 2011; Fortunato, Gatzke-Kopp, & Ram, 2013; Hamilton, Chen, Thomason, Schwartz, & Gotlib, 2010).

In addition, the concept of emotion variability, which is integral to emotional competence that is defined by emotional responsiveness and flexibility (e.g., Saarni, 1999), can be studied in time series. We know little about normal variability in the emotional lives of children and youth, but evidence suggests that being emotionally rigid (Kuppens et al., 2012) or labile (Silk et al., 2003; Trull et al., 2008) are hallmarks of psychopathology. These conclusions are drawn from time series data, with time extended over minutes or days.

As seen, there are few but a growing number of studies examining emotional functioning as a process rather than as a trait or event. Consider the risks of ignoring this temporality. A recent unpublished finding from our lab illustrates: 48-month-olds who engage in overt verbal self-instruction during a challenging task (the transparent locked box) have *more* rather than fewer anger displays during the task. If verbal self-instruction aids emotion regulation, as would be predicted, then why would children who use this verbal strategy be angry more often? It appears that mounting frustration precedes and probably motivates verbal self-instruction, which then leads to persistence at trying to solve the dilemma appropriately. This illustrates the value of understanding behavior in the time series. Anger served appropriate problem solving and did not indicate dysregulation. Research that considers the dynamic nature of emotional processing may help us to understand clinically relevant phenomena like debilitating shame that follows anger or anger that covers up deep disappointment (Cole et al., 2013) as well as healthy emotional processes such as righteous anger that mobilizes a person after momentary sadness and hopelessness.

Context

Third, emotion research needs to take context into account to advance our understanding of the role of emotion in the development of psychopathology. Context is a broad term that can be applied to the study of emotional development in many ways. Consider as an example the clinical implications of the same emotion expression in different contexts. A toddler is having a full blown tantrum and her mother is expressing anger. The mother could be angry at her daughter for making her late for work or the mother could be angry with herself because she should have anticipated and avoided the circumstances that led to her daughter's tantrum. Self-focused versus child-focused emotions have different implications for maternal behavior (Leerkes, 2010). Alternatively, consider variations in happiness; the joy of a child who watches another child win a prize is different from the joy of a child who has just snatched that prize from the child's hand.

Another clinically relevant application of context to emotional functioning concerns emotion regulation. A person feels many strong emotions—fearful, angry, and

disgusted—by another person. The person does not leave the situation, does not tell the person to stop, and does not seek another person's assistance. Instead, she begins to dissociate, a maladaptive response. But is it? Let us imagine that the persons are a 4-year-old girl whose father is again using her for his sexual gratification; dissociation is thought to be one of the few emotion regulation strategies available to such a small child in such an impossible situation (Cole & Putnam, 1992). In the immediate context, this can be considered adaptive. In other contexts, such as in early adulthood when the young woman is approached by a potential romantic partner, it may not be. A person's history and associations are part of the context in which emotions can be understood. There are also different social contexts (better to be angry with a trusted parent than with a new teacher), cultural contexts (different consequences of expressing shame in with one's Nepalese relatives than with one's American relatives), and so on.

In addition to the need for emotional development research that is context-sensitive, process-oriented, and personally relevant for participants, there are research design issues derived from principles of developmental psychopathology that are needed to understand the role of emotion in the development of psychopathology. First, a priority is longitudinal research that addresses pathways to emotional competence and emotional dysfunction, and that carefully focuses in on proximal sequences in the developmental pathway. Links between early childhood characteristics, for example, temperament or attachment status, and later outcomes such as adolescent psychopathology have been documented. For example, if infants are highly reactive and hard to soothe, and caregivers have difficulty adjusting to the infant's special needs, developing a style of responding insensitively and intrusively, what are the near consequences for emotional functioning that pose risk for emotional dysfunction—an insecure-avoidant attachment? But there are likely advantages to that attachment style in certain unforgiving situations. So perhaps something more is needed to pave the path toward emotional dysfunction and psychopathology? What are the mitigating and exacerbating factors? Longitudinal research that more carefully documents the series of steps between points is needed and a focus on the domains of emotional competence should be useful in that regard. This will help to address the question of whether and when emotional dysfunction is a precursor of psychopathology, rather than a correlated symptom or consequence of another impaired process.

Second, emotion processes must be inferred; they cannot be studied directly. Therefore, there is a need for careful and clever use of multiple measures of emotion processing that heighten the ability that incorporates multiple measures of emotion, and selection of equally valid and reliable assessment of all predictors, correlates, and outcomes. Designs that include carefully selected variations in context (circumstances, stimuli) and that relate changes in indices of emotion processes with changes in context would be very useful. These can also incorporate the emphasis on process as a time series. We know of no study that has examined developmental changes in emotion processes on multiple time scales, for example, emotion regulation as a moment-to-moment time series that changes over the course of years.

Third, longitudinal studies using sophisticated and sensitive assessment of emotional processes need to include predictors and outcomes that represent multiple domains. There is no single path from a child or an environmental characteristic that will predict outcomes as complex as emotional competence and dysfunction. Nor is there a single child–environmental characteristic pairing that will sufficiently explain pathways from risk to clinically meaningful outcomes. As Sameroff (2009) argued, children and contexts shape each other. Emotion processes are central to the transactional nature of human development. Research that will advance knowledge on the role of emotion in the development of psychopathology will incorporate this model.

Translational Implications

Progress in the understanding of the nature of emotion, in emotional development, and in the role of emotion in the development of psychopathology not only has implications for future research directions but also for applications to clinical practice. Research founded on a functional approach to emotional development has potential to add to how children and youth are evaluated, how prevention of emotional problems is implemented, and how therapeutic interventions are aimed.

Emotional dysfunction is generally assessed through structured diagnostic interviews (PAPA, K-SADS; Egger et al., 2006) and by questionnaires, both self-report and caregiver report, such as Child Behavior Checklist (http://www.aseba.org), the Child Depression Inventory (http://www.mhs.com/product.aspx?gr=edu&id=overview&prod=cdi2), the MASC (http://www.mhs.com/product.aspx?gr=cli&id=overview&prod=masc2), and the Behavior Assessment Scale for Children (http://www.pearsonclinical.com/education/products/100000658/behavior-assessment-system-for-children-second-edition-basc-2.html) among

others. These tools assess emotion-related symptoms using a normative approach, yielding scores that allow practitioners to discern if children's symptoms reach clinical thresholds. Research instruments with potential to help us understand the function of emotional symptoms are less readily available. Consider, for example, two of the most commonly studied correlates or precursors of emotional dysfunction: attachment security and temperament. As yet, there is no widespread use of developmentally sensitive measures of these constructs used as clinical tools, in part because there has been limited efforts to translate these constructs into clinically practical, useful tools and the best measures are focused on very early childhood (e.g., Crittenden, Kozlowska, & Landini, 2010; Putnam, Helbig, Gartstein, Rothbart, & Leerkes, 2013).

Yet from the functional perspective, the nature of an emotion-related symptom can be informative. In a recent intake meeting in our clinic, we discussed information gleaned about a 15-year-old whose mother was concerned about her angry hostility and defiant behavior. The family had a history of significant relationship problems that had not been resolved effectively, and the 15-year-old had little insight into how these affected her or why she was angry other than wanting more freedom. Our team of developmental psychopathology-oriented faculty and student clinicians discussed the youth's angry presentation in terms of its immediate functional message and raised questions about her temperament and attachment history. Sharing a functional perspective, the discussion focused on initial hypotheses about the immediate function of anger for this youth, questions about the precise nature of what she was protesting, consideration that her anger may indicate that she had not yet perceived her goals as unattainable and that anger may be protecting against full-blown depression. The intake report suggested the clinician conduct a functional analysis of her anger and other emotions (anxiety, joy, sadness, shame, guilt), including exploring whether she would use a mood diary so that we could gain more detailed perspective on her experience. The continuing assessment was intended to understand her relation to her circumstances and to potentially generate information that would help her better understand, regulate, and express her needs. Moreover, a comprehensive life history interview, which is standard, would address the points in her life that family instability and conflict might have had implications for her attachment security and whether her temperament, as best it can be inferred retrospectively, might point toward the most sensitive tailoring of approaching behavior change.

Emotional competence is regarded as a central focus of preventive intervention and as a protective factor that helps children be resilient in the face of adversity (Gest & Davidson, 2011; Kellam, Koretz, & Mościcki, 1999). Approaches such as Providing Alternative THinking Strategies (PATHS, http://www.pathseducation.com) are based on developmental research on the components of social emotional learning that promote competence and prevent psychopathology (Domitrovich, Cortes, & Greenberg, 2007; Greenberg, Kusché, Cook, & Quamma, 1995) and have been empirically evaluated and shown to be effective (e.g., Bierman et al., 2008; Conduct Problems Prevention Research Group, 2010). PATHS and related social-emotional learning programs include components that teach parents and teachers to understand and affirm the emotions children are communicating and help them derive better solutions to their perceived needs. The Emotions Course (Izard et al., 2008) is founded on the view that emotions reflect information about children's perceived needs and the promotion of emotion understanding helps children more effectively use and regulate emotion (Izard, 2002; Izard, Stark, Trentacosta, & Schultz, 2008; Izard et al., *Emotion Review*).

A functional perspective on emotional competence should also inform therapeutic intervention (Cole et al., 1994; Suveg, Southam-Gerow, Goodman, & Kendall, 2007). At one level, all approaches to therapeutic intervention are designed to improve emotional functioning, whether directly or indirectly. However, few take a functional perspective of emotion in children and youth experience or a developmental psychopathology framework that guides hypotheses about how children or youth functioning deviates in terms of emotional competencies or emotional developmental factors in the etiology or maintenance of symptoms. There are many considerations that a functional perspective on emotional development offers. Cognitive behavioral approaches to therapy have proven effective, although they are often difficult to implement with family members whose functioning is not defined by a sufficient level of emotional competence. A functional perspective on emotion can help. Combat veterans, for example, benefit from sensitive application of anger management skill training; sensitive approaches appreciate the circumstances to which veterans were prepared to adapt, and their heightened sensitivity to environmental cues of potential threat (including posttraumatic stress responses) and to the skills they developed to adapt effectively (Mackintosh, Morland, Frueh, Greene, & Rosen, 2014). Parent management training is known to be effective for child and youth behavior problems. However, many referred families are unable to implement this otherwise effective approach; this method may

benefit from heightened awareness of (1) the function of emotions that motivate behavior problems and (2) the parental emotions that are involved in anticipating or responding to those behaviors (Maliken & Katz, 2013; Mazursky-Horowitz et al., 2014). Finally, there are lessons to be derived from Emotion-Focused Therapy (Greenberg, 2004). This approach views emotions as the organizing core of the self, a view that is consistent with the functional perspective, and argues that a process-experiential approach to emotion is necessary for meaningful symptom change. That is, it is insufficient to talk about emotion; unresolved emotions continue to motivate symptomatic behavior and that effective resolution requires experiencing the emotions in the presence of a supportive other such as a therapist. Clients are gently encouraged to re-experience painful emotions and through the therapeutic relationship to reappraise them as a means of resolving them. This model has not been applied to therapeutic interventions with children and youth but its relational emphasis, its appreciation that past emotional events can continue to exert pressure on perception and behavior, and its guide for reexperiencing and reappraising them has potential to improve therapeutic approaches with children and youth. Perhaps the functional perspective must first guide clinically relevant developmentally informed research to have a greater impact on clinical assessment and intervention.

OVERVIEW

Attachment theory is arguably one of the most important theoretical frameworks for understanding normal and abnormal development to have emerged in the field of developmental psychology in the last 60 years. By characterizing the interconnections and mechanisms that mediate between early experiences in primary attachment relationships and long-term emotional adjustment across the life span, attachment theory typifies, and indeed has made major contributions to, the developmental *psychopathology* approach (Cicchetti & Cohen, 1995; Rutter & Sroufe, 2000). The field of attachment—although not without a host of outstanding questions, conundrums, and fruitful seams of new research—could reasonably be described as a mature discipline, having tested, confirmed or clarified many of its major theoretical assertions. The theory remains a highly influential and important way of understanding the nature of a child's tie to primary caregivers, which coherently integrates data and theory from social-developmental psychology, cognitive psychology, life span developmental psychology, evolutionary psychology, and ethology. Its relevance for understanding emotional and behavioral maladjustment, and its value as a framework for *intervention* and prevention, seem undeniable.

In this chapter, our goal is to provide a comprehensive overview of attachment theory and research from its earliest origins to the very latest research findings, focusing on topics of most direct relevance for understanding the development of psychopathology. We begin with an overview

This work was supported in part by a postdoctoral fellowship provided by the National Institute of Child Health and Human Development (T32-HD07376) through the Center for Developmental Science, University of North Carolina at Chapel Hill, to Ashley M. Groh. Marian Bakermans-Kranenburg and Marinus van IJzendoorn were supported by research awards from the Netherlands Organization for Scientific Research (MHvIJ: SPINOZA prize; MJBK: VICI grant no. 453-09-003), and by the Gravitation program of the Dutch Ministry of Education, Culture, and Science and the Netherlands Organization for Scientific Research (NWO grant number 024.001.003).

of the historical beginnings of attachment theory and then outline the fundamental tenets of the theory. Next, we review the empirical literature on the developmental antecedents and consequences of attachment security and insecurity, exploring what is known about mediating mechanisms in the evolution of maladjustment. Next, we turn to work on adolescent and adult attachment. We conclude the chapter with a review of the current state of the art regarding attachment-based interventions and discuss directions for future research.

HISTORICAL OVERVIEW OF ATTACHMENT THEORY

With its primary focus on the nature of the child's tie to caregivers and the significance of these relationships for developmental adaptation across the life course, attachment theory builds on a long intellectual tradition. Indeed, questions concerning the legacy of early interpersonal experiences with primary caregivers predate the origins of formal developmental science and have their roots in the work of Sigmund Freud. Nevertheless, it is widely acknowledged that when John Bowlby began his thinking on the subject of attachment he was beginning a process, involving an intellectually rich and eclectic group of scientists and clinicians, that would lead to the development of a more or less revolutionary theory, radically different to those of the past. Fundamental to this sea change in thinking was his use of evolutionary theory as the basis for his theoretical approach, which was greatly inspired by Harlow's work on the Nature of Love, separating attachment from food and sex (see van der Horst & van der Veer, 2010).

Bowlby was particularly influenced by his experiences as a teacher caring for young children before World War II, which were to have a profound impact on him and his thinking (Bretherton, 1992; van Dijken, 1998). He was to work with children whose remote, or anxious and dependent personalities Bowlby viewed as having been caused by highly disturbed early primary relationships (Bretherton, 1992). He followed up this line of thinking in detailed case studies of 44 delinquent boys, of whom more than half had experienced significant periods of maternal separation during the first five years of life (Bowlby, 1944). After the war, at a time when displacement, loss, and separation were major preoccupations for all concerned with the welfare of children, Bowlby established a research unit dedicated to understanding the effects of separation on children's development. During this period, James Robertson, a psychiatric social worker, had joined Bowlby's team, bringing with him a keen interest in naturalistic observation—a method that, as a consequence particularly of Mary Ainsworth's later work, was to become fundamental to contemporary attachment research. Through extensive observational work, Bowlby and Robertson began to document children's profound response to separation from the mother, which began with protest, followed by despair, and then finally detachment (Bowlby, Robertson, & Rosenbluth, 1952). Such clinical observations raised important questions concerning why children respond so dramatically and predictably to separation from their mothers and what accounted for the intense affective tie between the child and mother. In addressing such questions, Bowlby viewed as inadequate Freud's (e.g., Freud, 1938) drive reduction account of the parent–child relationship in which it was argued that the infant's affective tie to the mother is the secondary result of the mother satisfying the infant's more primary drive for nourishment.

To a significant extent a consequence of this work, in 1949 Bowlby was commissioned by the World Health Organization (WHO) to write a report on the mental health of homeless children. In the course of his research for this report, he immersed himself in what was then known, scientifically and clinically, about separation, foster care, and child psychiatry more broadly, and consulted widely with colleagues in Europe and the United States. He found striking parallels between his own research and observations and those of others in Europe, notably that of his Dutch colleagues Tibout and De Leeuw (see van Dijken, 1998). Regarding the findings of their work, he stated:

> Frequent changes in foster home almost always had very adverse effects, leading the child to become withdrawn and apathetic. This was sometimes accompanied by a superficial sociability and, later, promiscuity. Some young children managed to weather a single change, but others could not stand even this and developed symptoms such as anxiety, depression, excessive clinging, and bedwetting. (pp. 146–147).

The report, once completed, sold 400,000 copies and was translated into 16 different languages, and famously concluded that for optimal development "the infant and young child should experience a warm, intimate, and continuous relationship with his mother figure (or permanent mother substitute) in which both find satisfaction and enjoyment" (Bowlby, 1951, p. 13). In his writing around this time, the first clear evidence also appears that Bowlby had begun to consider the evolutionary origins of attachment very seriously. He was strongly influenced by the earlier work of Konrad Lorenz on imprinting in birds and by Harry Harlow's work on rearing in rhesus monkeys

(Harlow & Zimmermann, 1959). These experiments appeared to demonstrate convincingly that evolutionary forces had favored the evolution of a parental bond to promote survival of young animals and that the child's tendency to cling to a parental figure is a primary instinct and not secondary to some other form of reinforcement such as nutrition.

Thus, drawing on evidence from his own research, and that of others, as well as insights from ethology, cognitive psychology, evolution, and biological systems theory, Bowlby (Bowlby, 1969, 1973, 1980) proposed an alternative account to explain the nature of the child's tie to the mother. According to Bowlby, human infants develop attachments to caregivers because it would have been evolutionarily adaptive to have done so. The infant's intense affective tie to caregivers is not the by-product of a more fundamental drive or motivation. Instead, according to Bowlby, attachment represents a primary, biologically based motivational system, selected through evolution to promote survival and inclusive fitness through maintenance of proximity to a primary caregiver(s) (the neo-Darwinian term inclusive fitness was incorporated into later editions of Bowlby's Attachment and Loss trilogy (see Fraley, Brumbaugh, & Marks, 2005; Simpson & Belsky, 2008).

Drawing on systems theory, Bowlby claimed that attachment behaviors are organized into an attachment behavioral system, in which the specific attachment behaviors are less important than the internal organization of such behaviors toward the goal of proximity. Bowlby adopted a control systems approach in which the attachment behavioral system becomes activated by both internal and external cues that signal potential threat. Once activated, the attachment system recruits a flexible set of behaviors (e.g., crying) organized around the goal of establishing contact with an attachment figure. Once the child's desired proximity to the caregiver is achieved, and a reduction in the perceived degree of threat occurs, there is a decrease in the activation of the attachment system, resulting in the termination of attachment behaviors. Bowlby theorized that the child's desired degree of proximity to the caregiver might depend on a number of factors, including (1) child conditions (e.g., child health), (2) mother conditions (e.g., quality of caregiving), and (3) environmental conditions (e.g., familiarity with the environment).

Bowlby (1969) also provided an account of the normative development of the parent–child attachment relationship, which highlights a hallmark of Bowlby's attachment theory—*universality*. According to attachment theory, essentially all infants are born with the building blocks that develop into the attachment behavioral system. All that is necessary for the infant to develop an attachment to a caregiver is that the caregiver has been interactively present over an extended period of time.

As described by Bowlby (1969), the normative developmental course of this relationship is believed to unfold through the series of four phases (see Marvin & Britner, 2008). Although Bowlby characterized attachment during these periods as undergoing distinctive shifts, he emphasized that the boundary between one phase and the next is blurred. The first phase, *orientation and signals with limited discrimination of figure* (birth to 2–3 months), is characterized by the infant being responsive to all social stimuli. According to Bowlby, infants respond to social stimuli in ways that promote continued social interaction, and attachment behaviors, in particular, are crucial in eliciting caregiving behavior from adults. During this phase, infants' signals are not directed toward any particular person, a feature Bowlby viewed as adaptive, as it would have promoted infant survival, even if the infant's biological caregiver were not available (e.g., if mother died after giving birth). During the second phase, *orientation and signals directed toward a discriminated figure* (2–3 months to 7 months), the infant begins to discriminate specific caregivers from strangers, attachment behaviors are activated and terminated by these specific caregivers, and preference for a particular caregiver begins to develop. The third phase, *maintenance of proximity to a discriminated figure* (7 months to 3 years), is characterized by the emergence of active attachment behaviors that the infant is able to more flexibly alter to achieve the goal of proximity. Goal-corrected behavior begins to be evident, as the infant begins to use the caregiver as a secure base from which to explore the environment and as a safe haven to retreat to in times of threat or challenge. It is early in this phase that the infant is said to become attached to the caregiver in a clear-cut, qualitative sense (and when stranger anxiety emerges). Finally, the fourth phase in the development of the attachment relationship is the *formation of a goal-corrected partnership* (beginning at around 3 years) between the child and caregiver. With the development of language and other cognitive skills, the child becomes able to consider the mother's perspective and consider her wishes in guiding the child's behavior. Thus, the relationship becomes more like a partnership, whereby the child weighs both the parent's and his or her own goals in planning behavior, and attachment needs can increasingly be negotiated collaboratively between parent and child.

Inherent in this view of development is the idea that personality becomes increasingly complex at every stage

of development and that, with development, the child becomes a stronger force in determining developmental pathways (Bowlby, 1969). Thus, Bowlby believed that early social experiences have important implications for subsequent development, with initial adaptations within relationships with primary caregivers serving to lay the foundations for subsequent development. In addition, Bowlby proposed that early experiences color encounters with later experiences through the action of working models, or cognitively embedded abstractions of direct experiences with caregivers. As will be described in more detail, such working models are carried with individuals into novel situations, informing expectations and behavior in interpersonal contexts.

Thus, it is fair to say that in its initial formulations, Bowby's attachment theory was primarily concerned with the fundamental nature of attachment, its evolutionary and biological dimensions, its development, and the impact on personality development of major disruptions to the integrity of the attachment bond, such as permanent or lengthy separation, or bereavement. It was through his collaboration with Mary Ainsworth that the theory broadened to incorporate variations in the quality, or security, of attachment in circumstances where no major disruptions to the integrity of the bond had occurred. This represents a critical turning point for attachment research in two fundamental respects. First, with this new perspective and the now-famous tools that Ainsworth and others developed for rigorously assessing individual differences in the organization or quality of attachment there opened up a highly tractable set of scientific possibilities that were to generate a vast wealth of important findings that has given the field much of its momentum ever since. Second, it represented a shift of focus to a different set of populations—initially children experiencing major separation or privation of attachment experiences, then subsequently to children having experienced a continuous and unbroken bond with their stable caregiver (in most cases their biological parent), but who vary in how their attachment relationship and their own attachment behavior is organized. Crucially, this shift moved the field to focus on fundamentally different aspects of attachment. Bowlby's early thinking was focused on the mechanisms by which a bond is established and what effects occur when it is disrupted. The later work on attachment tended not to address this, and instead examined how attachment behavior toward a consistent caregiver is shaped by that caregiver's behavior, particularly sensitivity.

We can think of these two different lines of inquiry as being fundamentally concerned with *attachment formation* on the one hand, *and attachment organization* on the other. Although research on attachment organization has blossomed, much less is known about the processes that shape attachment formation. Nevertheless, this latter topic is of great significance for attachment researchers and developmental psychopathologists, and has seen a relatively recent resurgence, as scientists have begun to rigorously study the impact of institutional rearing on children's growth and development and interest in the so-called attachment disorders has grown dramatically (e.g., see van IJzendoorn et al., 2011). It is also interesting to note that much, though not all, animal research on attachment has continued in the early tradition—examining the biobehavioral effects of separation and the role of critical periods in early development (Hofer, 1994). Bringing together our understanding of these different aspects of attachment and integrating the methods, findings and insights arising from the study of them is an important long-term goal for the field and a key priority if we are to advance attachment theory's capacity to inform understanding and treatment of psychological disorders. A proper treatment of the impact of institutional rearing, of severe privation more generally, and of the so-called reactive attachment disorders is beyond the scope of this chapter. However, the interested reader is encouraged to study the monographs of Kumsta et al. (2010), McCall, van IJzendoorn, Juffer, Groark, and Groza (2012) and Nelson, Fox & Zeanah (2014), as well as the review paper by Rutter, Kreppner, and Sonuga-Barke (2009).

INDIVIDUAL DIFFERENCES IN ATTACHMENT

As emphasized in the preceding section, Bowlby's major contribution to attachment theory was in the formulation of the basic tenets of the theory. Notwithstanding her important role in refining and elaborating that theory, Ainsworth's key contribution was the development of the methodology for testing it. Her seminal theorizing and groundbreaking research was vital for the field, by making possible the systematic assessment of individual differences in the quality of parent–child attachment relationships (Ainsworth, Blehar, Waters, & Wall, 1978a), and by richly documenting the interactive processes taking place between parent and child that offered a plausible account of the origins of such individual differences (Ainsworth, 1967; Ainsworth et al., 1978a).

Ainsworth's key work, which built upon her earlier observational research in Uganda and drew inspiration from her collaboration with Bowlby and her training in

security theory (Blatz, 1966), was to become a template for how to study the development of parent-infant relationships in naturalistic settings. Critically, it led to the development of what has now become the most widely used procedure for assessing individual differences in the infant–caregiver attachment relationship, the Strange Situation Procedure (Ainsworth & Wittig, 1969; Ainsworth et al., 1978a). This 20-minute procedure originally developed for 12- to 18-month-olds was designed to examine the balance between the infant's attachment and exploratory behavioral systems. Importantly, it capitalizes on several key anxieties that peak in infants at this age, including stranger anxiety and separation anxiety, to observe the infant's use of the caregiver as a secure base and safe haven. Over the course of the Strange Situation, the infant goes through a series of mildly stressful experiences designed to activate the attachment biobehavioral system. The Strange Situation begins with the infant and caregiver being introduced to a novel laboratory setting, with toys for the infant placed in the center of the room and seating for the mother on the perimeter. After 3 minutes, in which the infant is encouraged to play with the toys while the mother is seated at a distance, a stranger enters the room. While the stranger interacts with the infant, the mother departs from the room, leaving the infant in the room with the stranger. After 3 minutes (or less if the infant becomes distressed), the mother returns and the stranger leaves. Shortly thereafter, a second, more stressful separation occurs when the mother leaves the infant alone in the room. After a maximum of 3 minutes alone, the stranger returns, followed thereafter by the mother.

Individual differences in infant attachment in this procedure are revealed in the infants' flexible transition between using the caregiver as a secure base to explore the environment and as a safe haven in times of uncertainty. Based on the patterning of infants' secure base and safe haven behavior—particularly during the two reunion episodes—Ainsworth and her colleagues (1969, 1978a) established that the majority of infants demonstrated what became referred to as a *secure* attachment pattern. Such infants are able to use their caregiver as a secure base of exploration, evidenced in their exploration of toys at a distance from the caregiver in the novel laboratory environment. Although they may check back with caregivers, especially when the stranger enters, they appear confident to explore the environment. When separated from caregivers, infants classified as secure may become distressed, and, if they do, they use the caregiver as a source of effective comfort. Prototypically, the distressed secure infant seeks the caregiver upon reunion, is comforted by his or her presence, and eventually returns to exploration. Even if not overtly distressed by the separation, infants classified as secure tend to acknowledge the return of the caregiver, greeting the caregiver and initiating interaction. Although the term 'secure infant' is often used, the term 'security' more precisely refers to the child's attachment behavior to a particular caregiver and is thus better thought of as a characteristic of their relationship than of the infant per se.

In contrast to secure infants, insecure infants appear unable (or less able) to effectively use the caregiver as a secure base or safe haven. Based on variations in these behavioral themes, Ainsworth and her colleagues identified two types of attachment insecurity—avoidance and resistance. A large minority of insecure infants are classified as avoidant. *Avoidant* infants may explore the environment by engaging the toys before the separation. However, upon reunion, instead of acknowledging the caregiver's return, avoidant infants ignore or actively avoid their caregiver. A small minority of insecure infants are classified as resistant. *Resistant* infants tend to stay close to the caregiver and typically do not engage in play even prior to the first separation episode. When separated from the caregiver, resistant infants often become quite distressed, yet seem unable to use their caregiver effectively as a way of gaining comfort upon reunion. Such infants exhibit a kind of behavioral ambivalence, simultaneously signaling their desire for proximity, yet appear angry and resist contact when it is achieved.

Even though Ainsworth's pioneering study comprised only a small cohort of children, in many respects, this early work—and subsequent research conducted with Everett Waters' Attachment Q-Set (AQS, Waters & Deane, 1985) for characterizing children's secure base behavior in naturalistic settings—has scaled up quite well. Remarkably consistent evidence across all cultures in which individual differences in security have been examined provide evidence that the majority of infants demonstrate secure attachment patterns. In addition, such work has provided evidence that avoidant and resistant patterns of attachment behavior can be reliably identified in a minority of infants across cultures (although the distribution of these classifications has been found to vary both within and between cultures; van IJzendoorn & Sagi-Schwartz, 2008).

Another key contribution of this work is that Ainsworth demonstrated via extensive home observations that the individual differences observed in the laboratory Strange Situation mapped onto individual differences in the parenting children experienced in more naturalistic environments (Ainsworth et al., 1978a). Ainsworth and her colleagues developed behavioral rating scales for systematically

assessing the quality of mother caregiving behavior, which were to become extremely important for subsequent observational studies and for inspiring attachment-focused interventions. Analyses linking such caregiving behavior to infant attachment revealed that mothers who were more sensitive in their interactions with their infant, characterized by their awareness of, and prompt responsiveness to, infant attachment signals, were more likely to have a securely attached infant. Such evidence greatly contributed to theorizing regarding the origins of infant attachment variation. Indeed, virtually all hypotheses regarding the antecedents of individual differences in attachment, at least within attachment scholarship, emphasize environmentally mediated, and in particular, *interpersonal* processes that give rise to secure versus insecure attachment, with the dominant theoretical account being that secure parent–child attachment relationships largely result from sensitive exchanges between caregivers and children. Regarding the origins of the specific patterns of insecurity, it has been argued further that particular types of insensitive parenting give rise to avoidant versus resistant attachment patterns. Specifically, rejecting caregiving is thought to lead to the development of avoidant attachment, as a history of having attachment signals rebuffed by caregivers might understandably lead infants to develop a strategy of minimizing attachment behavior. On the other hand, inconsistently responsive caregiving is thought to promote the development of resistant attachment because such caregiving might lead the infant to develop a strategy of emphasizing or heightening the expression of attachment behavior (see Belsky & Fearon, 2008).

Shortly after Ainsworth and her colleagues introduced the Strange Situation to the field, evidence was presented that attachment behaviors were not highly intercorrelated, exhibited only weak stability over time, and varied across contexts (e.g., Coates, Anderson, & Hartup, 1972; Maccoby & Feldman, 1972), leading some to question not only findings from Ainsworth's work, but also the usefulness of the construct of attachment itself (Cairns, 1972; Gewirtz, 1972a, 1972b; Masters & Wellman, 1974; Rosenthal, 1973; Weinraub, Brooks, & Lewis, 1977). However, these critiques were misguided, focusing on the wrong level of analysis of attachment, at least from the point of view of attachment theorists (Sroufe & Waters, 1977).

The attachment biobehavioral system, according to Bowlby, Ainsworth and others, operates at the level of the goal-directed organization of attachment behavior within the individual, and in a given context. The emphasis thus is not on specific attachment behaviors, but on the patterning of such behaviors and what ends they are organized to achieve. For example, under conditions of threat, the infant may try any number of attachment behaviors (e.g., crying, crawling) to gain proximity to the caregiver, depending in large part on the context and the child's capabilities. Further, the behaviors enlisted by the attachment system are expected to change over the course of development, with, for example distance interaction (including language) becoming more significant in toddlerhood than in infancy (Ainsworth, 1972; Bowlby, 1969; Sroufe & Waters, 1977).

As best articulated by Sroufe and Waters (1977), this distinction between attachment behaviors and the attachment behavioral system is fundamental to the operationalization of individual differences in attachment security. When viewed as an organizational construct, evidence of weak associations among specific attachment behaviors and their weak stability over time and across contexts becomes largely irrelevant to the theory. Instead, what matters is the organization of such behavior around the caregiver within specific contexts (Ainsworth & Bell, 1974). The stability of patterns of attachment as measured at an organizational level is, however, a critical question; one that we return to in a later section.

The standard conceptualization of individual differences in attachment as originally formulated by Ainsworth and her colleagues has also been met with some ultimately generative challenges over the years. As more researchers began to use the Strange Situation, it became increasingly apparent that not all children could be classified as either secure, avoidant, or resistant using the traditional classification system. As first noted by Mary Main and her colleagues (Main & Hesse, 1990; Main & Solomon, 1986, 1990), a subset of infants (especially those living under conditions of high stress or abusive conditions), in addition to exhibiting these organized patterns of attachment behavior in the Strange Situation, also displayed momentary, yet striking, anomalous behaviors suggestive of a "breakdown" or *disorganization* of their attachment-relevant strategy. For example, throughout the course of the Strange Situation, such infants might exhibit stilling or freezing behaviors (i.e., frozen postures believed to represent indication of an approach–avoidance conflict), stereotypies, or marked contradictory behavior (e.g., strong approach followed by sudden avoidance). Or such infants may hit the parent in apparently positive mood or exhibit direct fear of the parent without apparent reason at reunion. In short, disorganization may manifest itself in a variety of ways, yet the common theme is that such displays of conflicted, contradictory, or disoriented behaviors are

indicative of a profoundly disturbed relationship with the attachment figure and of being unable to maintain an organized behavioral strategy when distressed.

Moreover, unlike the organized patterns of attachment (secure, avoidant, resistant) that are thought to result from variation in the sensitivity of caregiving, disorganized attachment is thought to result from frightening (e.g., abusive) or frightened (e.g., caregiver exhibits behavior indicative of apprehension of infant) caregiving. Such caregiving is believed to present disorganized children with an irresolvable dilemma in which the very individuals they are evolutionarily predisposed to seek out under conditions of threat are, in fact, a source of fear for the infant. According to the most influential model of disorganized attachment proposed by Main and Hesse (1990), fear, with the parent as its source, creates for the child an approach–avoidance conflict, in which the mutually opposing action tendencies of proximity seeking and avoidance vie for control of behavior. These opposing tendencies are believed to give rise to the oscillatory, fragmentary or contradictory behaviors characteristic of disorganized attachment.

A second challenge to the validity of the standard view of individual differences in infant attachment security has emerged as a result of more recent taxometric and factor analytic work conducted by Chris Fraley and Susan Spieker (2003) based on the NICHD Study of Early Child Care and Youth Development (SECCYD), one of the largest studies of the Strange Situation conducted to date (original $N = 1{,}364$). Fraley and Spieker's (2003) study focused on the distributional properties and latent structure of individual differences in infant attachment, and findings from their taxometric analyses have provided some evidence that instead of being categorically distributed, variation in attachment security may be compatible with a model in which individual differences in attachment are continuously distributed (see also Kroonenberg & van IJzendoorn, 1987; Richters, Waters, & Vaughn, 1988).

Fraley and Spieker (2003) also presented results from exploratory factor analyses demonstrating that attachment-related individual differences vary along two weakly correlated axes—one of attachment-related avoidance and one of attachment-related resistance (the latter a combination of resistance and disorganization indicators). Such findings challenge the current conceptualization of variation in attachment, in which it is implied that avoidance and resistance are mutually exclusive insecure organizations of attachment behavior. More specifically, such evidence raises the possibility that resistance and disorganization may not be empirically distinct and that an infant can be simultaneously high or low on avoidance and resistance or high on one dimension and low on the other. As discussed further, combined with similar evidence that has emerged from taxometric and factor analytic work (e.g., Fraley & Roisman, 2014; Haltigan, Roisman, & Haydon, 2014; Roisman, Fraley, & Belsky, 2007) on the most widely used developmental measure of adult attachment, the Adult Attachment Interview (AAI; Main, Kaplan, & Cassidy, 1985), we caution that some of the conclusions of prior research might need to be reevaluated in light of such emerging evidence that individual differences in attachment might be best represented by two weakly correlated dimensions reflecting attachment-related avoidance and anxiety. Indeed, one contributing factor to some of the mixed evidence regarding the distinctive antecedents and consequences of attachment variation might be the imperfect relationship between existing measures and their underlying latent structure. This possibility requires further exploration. One key limitation of existing taxometric studies is the reliance on rating scales whose individual validity and sensitivity have received relatively little attention. One particularly critical issue is whether the overlap currently observed in the dimensional framework between resistance and disorganization should be taken as an indication of their common underlying meaning, or a limitation in the way the two constructs are measured. Further work directly contrasting these differing measurement approaches in terms of their distinct or common outcomes or antecedents is an important area for future research (van IJzendoorn & Bakermans-Kranenburg, 2014).

INTERNAL WORKING MODELS OF ATTACHMENT

In contemporary attachment theory, and in keeping with Bowlby's original proposals, attachment behaviors in infancy are thought to be guided by underlying cognitive structures. These internal working models are thought to consist of representations of the parent, the self, and the attachment relationship that are derived from day-to-day experiences with the caregiver. Through repeated interactions the infant is thought to derive a set of interactional schemas or models of the attachment relationship which include sensorimotor, cognitive, and affective components. These representations are seen as a set of expectations regarding the future behavior of the attachment figure that allow the infant to act rapidly and adaptively in the event of threat in accordance with the demands of the

immediate situation and the likely actions of the parent. The Strange Situation, and other attachment assessments, are considered windows into the infant's internal working model of the attachment relationship.

Since Bowlby's early writings on internal working models several researchers have made efforts to recast his ideas in terms derived from modern theories of infant cognition and event representation. Most notable amongst these attempts has been the work of Inge Bretherton (Bretherton, 1990, 1995), who suggested that Bowlby's view of internal working models of attachment is highly compatible with Schank and Abelson's notion of scripts (Schank & Abelson, 1988). In Schank and Abelson's model infants are thought to extract constancies and generalizations from stored memories of repeated events. These invariant aspects of interactions come to form the basis of higher order representations or schemas of the relational structure of interactions. Through a continual process of integration and cross-referencing of new information with existing schema the infant develops a set of horizontally and vertically integrated representations that encode the spatiotemporal structure of common events (Bretherton, 1995). Event-schemas include information that is event-near (specific interaction type) as well as higher level representations that involve generalizations across many event classes (such as general representations of parental accessibility).

The conceptualization of attachment behavior as the functioning of internal working models of attachment has had a major impact on thinking in attachment theory and research and has played a vital role in the understanding of the organization of attachment behavior. Internal working models have been especially important in extending attachment theory beyond infancy into later childhood and adulthood (Greenberg, Cicchetti, & Cummings, 1990; Main, 1991; Main et al., 1985). The most important contribution to this development was made by Main and her colleagues (Main, Goldwyn, & Hesse, 2003; Main et al., 1985). Main and colleagues reformulated the concept of an internal working model from something predominantly behavioral and affective in nature to a representational construct, controlling behavior, thinking, feeling, cognition, and language. More specifically, according to Main et al. (1985, pp. 66–67):

> We define the internal working model of attachment as a set of conscious and/or unconscious rules for the organization of information relevant to attachment and for obtaining or limiting access to that information, that is, to information regarding attachment-related experiences, feelings and ideations.

This crucial reformulation opened up the possibility of investigating the organization and development of internal working models across the life span. The so-called move to the level of representation focused attention on narrative patterns as the expression of the organization and functioning of internal working models of attachment at a cognitive level and has become fundamental for assessing attachment beyond the preschool years.

MEASUREMENT OF INDIVIDUAL DIFFERENCES IN ATTACHMENT

Bowlby (1969) proposed that attachment relationships continue to be relevant across the life course. Initial efforts to assess individual differences in attachment were focused on children, but as interest in attachment across the life span grew, assessments of attachment in adulthood were developed. More recently, there has also been increasing interest in children's attachment representations, leading to a number of representational assessments of attachment being developed for use in early and middle childhood. In this section, we provide an overview of these attachment assessments, specifically focusing on those assessments that are most commonly used within the field of developmental psychology.

Childhood Attachment Assessments

Behavioral Assessments of Attachment

The most commonly used measure of attachment in infancy is the Strange Situation Procedure (Ainsworth & Wittig, 1969; Ainsworth et al., 1978a). As we have already extensively discussed this assessment, we turn our attention here to other behavioral assessments of attachment used in early childhood. In addition to providing an overview of these assessments, we provide evidence regarding the association between individual differences in attachment security as assessed with these attachment measures and as assessed by the Strange Situation. A more extensive discussion of the stability of attachment security across the life course is provided later in this chapter. However, because the Strange Situation generally serves as the standard by which all other attachment assessments are evaluated, we briefly discuss such evidence here when relevant data are available.

Several procedures designed to assess variation in attachment security beyond infancy have been developed that involve modifications to the standard Strange Situation procedure, including the Cassidy-Marvin assessment

of attachment for preschoolers (Cassidy, Marvin, & The MacArthur Working Group on Attachment, 1992) and the Main-Cassidy assessment of attachment for kindergarten-age children (Main & Cassidy, 1988). These modified Strange Situation procedures are similar to the Strange Situation, except that the caregiver and child are separated for a longer duration, a manipulation that is believed to elevate the level of stress in the child. As with the original procedure, in these modified Strange Situations, children's separation and reunion behavior are generally coded using similar categories to those used in the Strange Situation (secure, insecure-avoidant, insecure-resistant, disorganized) based on the child's ability to use the caregiver as a secure base and safe haven. Several longitudinal studies have included measures of both the Strange Situation and these modified Strange Situations, allowing for examination of the concordance between individual differences in attachment as assessed with these measures. Many of these studies have demonstrated stability in attachment security (vs. insecurity), and in studies in which discontinuity was found, it was lawful, in that shifts in security were explained by corresponding changes in mother–child interaction or changes in other attachment-relevant contextual variables (e.g., marital distress and separation, negative life events; Ammaniti, Speranza, & Candelori, 1996; Howes & Hamilton, 1992; Jacobsen, Huss, Fendrich, Kruesi, & Ziegenhain, 1997; Main et al., 1985; Wartner, Grossmann, Fremmer-Bombik, & Suess, 1994).

In contrast to the Strange Situation and modified Strange Situation, in the Attachment Q-Set (AQS, Waters & Deane, 1985), observations are conducted in the home for 2-3 hours or longer. This assessment was developed as an alternative to Ainsworth's extensive home observation narratives collected in the context of her Baltimore study that were used to validate the Strange Situation. Based on home observations, 90 cards reflecting aspects of secure base behavior are sorted into nine piles based on the extent to which the cards describe behavior characteristic of the child's observed behavior. The sort is then compared with a prototypical sort to assess attachment security continuously. A meta-analysis of over 100 investigations comprising over 13,000 children using the AQS conducted by van IJzendoorn and colleagues (van IJzendoorn, Vereijken, Bakermans-Kranenburg, & Riksen-Walraven, 2004) provided important information regarding the validity of this attachment assessment. Findings from this meta-analysis indicated a modest association between security as measured by the Strange Situation and the AQS ($r = .23$), and adequate predictive validity with parental sensitivity (averaging $r = .39$ across studies). The meta-analysis also indicated that the mother-reported AQS is not as psychometrically valid or reliable as the observer-reported AQS. Mother-reported AQS security exhibited a relatively weak association with security as assessed by the Strange Situation ($r = .14$) and a moderate association with temperamental reactivity ($r = .35$).

Representational Assessments of Attachment

As noted already, internal working models are believed to be encoded primarily in sensorimotor representations, making the aforementioned behavioral assessments of attachment particularly appropriate. Indeed, the quality of the attachment relationship is readily observable in the organization of the child's behavior around the caregiver in infancy and early childhood. With increased cognitive capacity, however, fewer stimuli elicit such strong manifestations of attachment behavior, making it increasingly difficult to assess individual differences in the quality of attachment relationships on the basis of the organization of manifest attachment behavior as the child matures. In addition, beginning in the preschool years, children begin to use symbolic forms of representation and to organize knowledge conceptually (Bretherton, 2005), allowing for the use of representational assessments of individual differences in attachment. Accordingly, there is a move in the assessment of individual differences in attachment from the level of behavior in infancy to the level of representation in childhood and adulthood.

A number of representational assessments of attachment have been developed for use in childhood. Such measures largely fall into three categories: (1) picture-response procedures; (2) doll-play scenarios; and (3) family drawings. There are far too many assessments of children's attachment representations to comprehensively review here (but see Solomon & George, 2008); thus, we focus our discussion on a general overview of these three categories of representational assessments. Picture-response procedures involve a series of pictures depicting a range of mildly to moderately stressful attachment-relevant scenarios (e.g., child watches parent leave), to which the child is asked to describe how the child in the scene feels and what the child will do (Klagsbrun & Bowlby, 1976). Both a classification system (Kaplan, 1987) that parallels the one used in the Strange Situation and attachment-relevant rating scales (Slough & Greenberg, 1990) have been developed to code children's responses on this task. Several prompted story-telling procedures using doll play have also been developed (e.g., MacArthur Story

Stem Battery—Bretherton & Oppenheim, 2003; Attachment Story Completion Task—Bretherton, Ridgeway, & Cassidy, 1990; Manchester Attachment Story Task—Goldwyn, Stanley, Smith, & Green, 2000; Attachment Doll-Play Interview—Oppenheim, 1997), and these procedures generally involve the narration and enactment of a series of attachment-relevant stories. Each story contains an attachment-relevant problem that occurs (e.g., child is hurt, parent–child separation). This problem is introduced by the adult, after which the child is prompted to enact the rest of the story. As with the picture response procedures, both classification systems and attachment-relevant scales have been developed to code children's narratives. Finally, in family-drawing procedures, children are asked to draw a picture of their family, and such drawings are evaluated using a classification system that parallels the one developed by Ainsworth for the Strange Situation (Kaplan & Main, 1986).

The diverse approaches to assessing attachment representations in childhood have been beneficial in that multiple measures allow researchers to thoroughly test the construct in a variety of ways. However, there is currently no dominant conceptual or methodological approach, and because researchers have primarily focused on assessment creation, information regarding the reliability and validity of the assessments is limited to only a handful of studies for each measure without independent tests (see Kerns, 2008; Solomon & George, 2008). Although this area of attachment research has produced many potentially useful measures of children's attachment representations, more research focused on the (discriminant) validity of the measures is needed, for example taking careful account of verbal abilities (which otherwise may lead to spurious findings and artificial gender differences).

Adult Attachment Assessments

In adolescence and adulthood, narrative-based measures are the most common way that researchers have approached the assessment of individual differences in attachment. As noted earlier, Mary Main and her colleagues developed the first of such assessments, the Adult Attachment Interview (AAI, George, Kaplan, & Main, 1985), which is a semistructured interview in which adults are asked to describe their early experiences with attachment figures and to provide autobiographical memories to support their evaluations of such experiences. Narratives produced within the context of the AAI are evaluated based on coherence, or the extent to which narratives are internally consistent without becoming emotionally overwrought. Paralleling the Strange Situation, individuals are typically classified by AAI coders into one of three categories. The majority of adults, classified as *secure-autonomous,* produce narratives characterized by the ability to freely and flexibly evaluate childhood experiences, regardless of whether they are described in retrospect as supportive or difficult in nature. A smaller, although substantial, number of adults defensively distance themselves from the emotional content of the interview by normalizing harsh experiences, claiming an inability to recall past experiences or idealizing caregivers and are classified as *insecure-dismissing*. Finally, a small minority of adults are classified as *insecure-preoccupied* and are unable to discuss early attachment-relevant experiences without becoming emotionally overwhelmed, as reflected in the production of narratives characterized by becoming either angrily or passively enmeshed in prior experiences with caregivers. In addition to classifying individuals into one of these mutually exclusive groups, individuals may also be classified as unresolved if their discourse becomes disorganized in the context of discussing the loss of a close loved one or experiences of abuse (see Bakermans-Kranenburg & van IJzendoorn, 2009; Hesse, 2008).

The AAI was developed with the aim of identifying individual differences in parents' representations of early attachment-relevant experiences according to individual differences in the quality of the attachment relationship infants developed with their parent. Accordingly, individual differences in parents' attachment representations as assessed by the AAI would be expected to map onto individual differences in their infant's attachment security. Indeed, a meta-analysis of 18 studies comprising 854 parent–child dyads indicated strong intergenerational continuity in attachment security (vs. insecurity; $r = .47$; van IJzendoorn, 1995).

Recently, Harriet Waters and her colleagues introduced the Attachment Script Assessment (ASA; Waters & Rodrigues-Doolabh, 2004), another narrative-based assessment of adult attachment in which adults are asked to develop attachment-relevant narratives using a set of words provided to them. Narratives produced within the context of the ASA are evaluated for adults' access to a secure-base script, as reflected in adults' ability to develop coherent, nonautobiographical, attachment-relevant narratives. More specifically, narratives are rated on a 7-point scale of secure base script knowledge for the extent to which they are organized around a secure base script. Narratives receive high scores if they contain a clear secure-base structure in which attachment-relevant threats are recognized, competent help from an attachment figure

is offered, such help is effective in resolving the problem, and the situation returns to normal. Narratives receive low scores if they lack this secure-base structure or include bizarre details (e.g., one of the members of the attachment relationship dies; see Waters & Waters, 2006).

In both attachment assessments, the narratives that adults produce, whether in relation to autobiographical attachment-relevant life stories in the case of the AAI or in relation to generic attachment-relevant stories in the case of the ASA, are implicitly evaluated by trained coders for adults' access to a secure attachment-relevant script—or an understanding that effective attachment relationships serve the complementary functions of the provision of a secure base of exploration and a safe haven in times of uncertainty (see Roisman, 2007). Given the similarity between the AAI and the ASA, it is not surprising that, at least in preliminary studies based on relatively modest samples, adults' coherence as measured by the AAI is highly correlated with adults' secure base script knowledge as assessed by the ASA (*r*'s range from .50–.60; H. S. Waters & Waters, 2006). In addition to the conceptual convergence of the AAI and ASA, there is increasing evidence for the empirical convergence of these assessments. Specifically, individual differences in adult attachment as assessed by both the AAI and ASA have been found to predict infant attachment security (Bost et al., 2006; van IJzendoorn, 1995; Verissimo & Salvaterra, 2006); maternal sensitivity (Coppola, Vaughn, Cassibba, & Costantini, 2006; De Wolff & van IJzendoorn, 1997); and physiological reactivity when confronted with attachment-relevant challenges (Beijersbergen, Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2008; Dozier & Kobak, 1992; Groh & Roisman, 2009; Holland & Roisman, 2010; Roisman, Tsai, & Chiang, 2004). Adolescent security (in the AAI) has also been found to correlate with the ASA at age 23 years in a sample of adoptees (Schoenmaker, Juffer, van IJzendoorn, Linting, van der Voort & Bakermans-Kranenburg, 2015). However, more work—in particular, focused on the developmental antecedents of variation in individual differences in attachment as assessed by the ASA—is needed to determine whether the ASA serves as a rough proxy for the AAI, which is a more costly measure in terms of both time and monetary expense (e.g., training, transcription, and coding).

THE DETERMINANTS OF INDIVIDUAL DIFFERENCES IN ATTACHMENT

Since the outset, the causal determinants of variations in attachment behavior have been a central concern of attachment researchers. As noted already, the preeminent causal influences on the development of individual differences in young children's attachments are believed to be located within the patterning or quality of parent–child interactions. Furthermore, contemporary theorizing about the origins of individual differences in attachment place great emphasis on the intergenerational transmission of patterns of attachment from parent to child, driven in large part by the adult's internal working model, or state of mind with respect to attachment (Main et al., 1985; van IJzendoorn, 1995). In the following sections, we review the evidence in support of this, and examine the evidence for alternative explanations including temperament, genetics, and other domains of parental behavior.

Intergenerational Transmission

As noted previously, one of the most robust and well replicated predictors of individual differences in attachment security and insecurity is the parent's state of mind with respect to attachment, as assessed using the Adult Attachment Interview (van IJzendoorn, 1995). van IJzendoorn's (1995) meta-analysis consisted of 18 studies that involved assessments of both parental AAI (either mother or father) and infant security of attachment measured either by the Strange Situation or the AQS. Overall, the net association across studies conducted at that time was very substantial, representing a correlation of .47 (which was homogeneous across studies). Indeed, only two studies in the meta-analysis failed to find cross-generational correspondence between the AAI and the Strange Situation (see van IJzendoorn, 1995). Overall, the three-way match between infant and parental attachment status was 70% (n = 661). The only significant moderator of the effect of overall parental security on infant security was the child's age at the time of the attachment assessment, with smaller effect sizes for groups of older children. The effect of dismissing adult attachment status on infant avoidance was also substantial with an effect size $r = .45$, although there was also significant between-study heterogeneity. Analyses of potential moderators also revealed some interesting differences between studies. Generally speaking maternal dismissing status was more strongly related to infant avoidance than was paternal dismissing classification and, as before, samples of older children produced smaller effect sizes. For parental preoccupation, a marginally smaller although nonetheless highly significant association emerged with infant resistance ($d = .91$, $r = .42$). There was again significant heterogeneity in effect sizes across studies. Two study characteristics appeared to explain some of this

between-study variability: samples of older adults generated smaller effect sizes, as did samples from non-American populations. Finally, there was significant correspondence between parental lack of resolution of mourning and infant disorganized attachment status with a combined effect size of .65, equivalent to a correlation of .31. An analysis based on four-way classifications of the AAI showed similar results as the aforementioned three-way results with the notable exception of the association between parental preoccupation and infant resistance, which was considerably weaker once parental U status and infant disorganization were taken into account ($d = .39$, $r = .19$).

In the same paper, van IJzendoorn (1995) was able to examine the association between parental state of mind with respect to attachment and their observed caregiving behavior, which also revealed quite large effects (meta-analytic average $r = .34$). By the application of the tracing rules of path analysis, van IJzendoorn highlighted an important possible paradox. The direct effect of adult attachment on infant attachment ($r = .47$) was substantially larger than the estimated mediating pathway between adult attachment status to child security via the parent's caregiving behavior (.34 [AAI to caregiving] x .32 [caregiving to attachment, as estimated from a previous meta-analysis] = .11). This led to the coining of the term the *transmission gap*, which refers to the fact that observational measures of parental care seemed unable to account for all of the (very large) association between the AAI and infant attachment security. How to make sense of this transmission gap has been, and continues to be, a key question for attachment research. In the next section, we examine in greater detail the evidence concerning the role of *parental sensitivity* in the development of attachment as it currently stands, and explore possible explanations for the so-called transmission gap. Before doing so, we should also note that it seems prudent, given the amount of time that has elapsed since this meta-analytic work, to assume that the effect size for the AAI–SSP link will have declined somewhat (Verhage et al., 2015).

Parental Behavior

Since Ainsworth's seminal work, the sensitivity of parental care has long been considered the primary determinant of variations in child attachment security. In Ainsworth's ground-breaking study (Ainsworth et al., 1978) she carefully documented, in great detail, and from lengthy observations in the home, the key features of parent–child interactions that appeared to distinguish secure from insecure attachments. A critical insight of Ainsworth's, which paralleled Bowlby's insight regarding the organizational nature of attachment, was that specific caregiving behaviors were less important than the way in which parental responses to the child's signals were appropriately matched to the particular needs and characteristics of the child as well as the situational and temporal context. In that sense, Ainsworth's conception of sensitivity is clearly an organizational construct, pertaining to the caregiving system rather than the attachment system (see George & Solomon, 1999). Ainsworth defined sensitivity as the parent's ability to be appropriately responsive to the child's attachment cues, and distinguished four aspects:

1. Awareness of the child's cues
2. Appropriate interpretation of the child's cues
3. Timeliness of the parent's response
4. Appropriateness of the parent's response

According to Ainsworth, a parent scoring high on sensitivity is continually aware of the child's whereabouts, state, focus of attention, activities and feelings and so is able to detect quite subtle attachment cues, understand the context in which they occur, and notice the incipient signs of distress so that prompt and in some cases preemptive action can be taken. This awareness is no doubt partly what allows a sensitive parent to come to appropriate interpretations of what the attachment signals mean. On the other hand, insensitive parents, according to Ainsworth, may be aware of the child's cues but interpret them inaccurately and negatively, perhaps as a result of their own past experiences, biases, or defenses (Ainsworth et al., 1978). The kinds of interpretations Ainsworth had in mind here included those regarding the infant's subjective experience or mental state. Indeed, the parent's ability to think about and hold in mind the child's experience and to take that appropriately into account when attending to the child's needs was central to Ainsworth, Bell and Stayton's (1974) thinking on sensitivity (pp. 127–128):

> Interpretation has three main components (a) her awareness, . . . , (b) her freedom from distortion, and (c) her empathy . . . . . The mother must be able to empathize with her baby's feelings and wishes before she can respond with sensitivity.

The elaboration of the sensitivity construct to encompass the parent's mind-mindedness, insightfulness, or reflective function is therefore a very natural evolution of Ainsworth's original thinking.

Even if a parent has noticed the infant's attachment cue, and correctly interpreted it, the parental response

needs to be timely so that, from the infant's point of view, it is experienced as contingent upon his or her signal. According to Ainsworth the infant needs to be able to connect, in time, his signal with the mother's response so he feels a sense of efficacy in having his needs met. Finally, the parental response itself needs to be appropriate and provide the infant with what it seems he needs. According to Ainsworth, these aspects of sensitivity collectively form steps in a chain of events that allows a parent to respond optimally to the child's attachment-related signals and communications. A thorough understanding of Ainsworth's definition of sensitivity is important when considering some of the complexities of the literature concerning the link between sensitivity and attachment. It is also essential when considering how attachment concepts can be translated into effective interventions aimed at promoting the quality of parental care.

Since Ainsworth's early observations, which led to a grounded hypothesis of a strong connection between attachment and sensitivity, an impressive database of findings has emerged, broadly confirming her original work (De Wolff & van IJzendoorn, 1997). As the field developed and differentiated, a wide range of ways of measuring sensitivity arose, and the constructs that were chosen as foci for investigating the antecedents of attachment broadened. Although the outcome of this work was not entirely uniform, it has become clear that secure attachment is associated with higher parental sensitivity, a finding replicated across numerous countries and social contexts (Belsky & Fearon, 2008). Summarizing the extant findings of the time, and following-up findings of previous work by Goldsmith and Alansky (1987), De Wolff and van IJzendoorn's (1997) meta-analysis of studies of sensitivity and attachment came to several key conclusions. First, across all studies included in the meta-analysis (k = 30, N = 1,666) the average correlation between sensitivity and attachment security was .22, which was highly significant, but also highly heterogeneous (i.e., the effect size varied substantially across studies to a degree greater than expected by chance). The broad trend across studies was thus entirely in keeping with Ainsworth's hypothesis, although for some scholars the effect size was interpreted to be smaller than expected. A second important finding to emerge from this meta-analysis was that when different characterizations of the sensitivity construct were analyzed separately, those studies that used Ainsworth's original definition (and rating scales) produced somewhat larger effect sizes (r = .24) than those more distantly related to the original. Notably, this focused set of studies was also homogeneous, meaning that across studies the variability in effect sizes was not greater than would be expected as a result of chance fluctuations, and no study characteristics were identified that moderated the effect size. Within the broader set of sensitivity studies however, a number of important moderators did arise. First, studies with older infants tended to produce larger effect sizes (older than age 1, r = .27) than those with younger infants (r = .20). Similarly, studies that measured attachment at later ages tended to obtain larger associations (r = .25) than those with younger age groups (r = .19), as did studies with shorter time intervals between the assessment of sensitivity and attachment. These results might suggest that the attachment relationship, as indicated by parental sensitivity on the mother's side, and attachment security on the child's, coheres progressively over time (De Wolff & van IJzendoorn, 1997). As we will describe further, the long-term predictive significance of attachment also appears to strengthen as attachment is measured later in development, which could also be taken to imply a gradual consolidating process taking place sometime after the first or second year. One notable further development in the field is an increase in interest in the role of paternal sensitivity in the development of father–child attachment. A recent meta-analysis of eight studies found a significant overall association (r = .13), although the effect size was clearly smaller than the meta-analytic average for mothers (Lucassen et al., 2011). A recent paper by Brown, Mangelsdorf, and Neff (2012) found more robust associations between attachment and paternal sensitivity at age 3 (β = .53) than in infancy (β = .33), which mirrors the pattern referred to previously regarding mothers (De Wolff & van IJzendoorn, 1997). Whether this pattern is more marked in fathers is worthy of exploration, but currently we do not have direct evidence of this.

Despite the fact that meta-analytic work has identified study-level variables that seem to be associated with larger effect sizes, it is clear that at best the association between sensitivity and attachment is modest, and there may be several explanations for this (Belsky & Fearon, 2008). First, the modest association may result from a *technological gap*, resulting from limitations in the quality, intensity, or context of measurement of sensitivity. There is no doubt that measurements of sensitivity (and indeed attachment) are noisy, and the extent of noise in any measure sets an upper limit on its capacity to correlate with a criterion (Shrout & Fleiss, 1979). In that regard, work by Dallaire and Weinraub (2005) is notable. They analyzed data on maternal sensitivity across the first six years of life, using the NICHD Study of Early Child Care and Youth Development data set and found that although correlations

between specific sensitivity indicators at one time point and the next were consistently in the $r = .30–.40$ range, latent variables representing common variance among several indicators correlated at around $r = .60$. This latent variable approach removes some, though not all, of the measurement error in sensitivity assessments, and suggests that sensitivity may be a highly stable construct once error is partialed out. Furthermore, it indirectly suggests that the modest association between sensitivity and attachment might be substantially higher than is commonly assumed. If one assumes that only 70% of the variance in measurements of attachment and sensitivity is reliable (which may be generous given that reported interrater reliabilities are often close to this figure and this is only one source of unreliability), then a correlation of .24 rises to .34 after correction for attenuation. Higher levels of measurement error would of course lead to larger increases in the association after correction for attenuation. Measurement error is a (sometimes underappreciated) key issue when interpreting results from observational studies (see also De Wolff & van IJzendoorn, 1997). These considerations also underline the importance of continuing to refine measurement protocols for attachment related constructs, so that more stable and reliable measurements can be obtained. A particularly important study in that regard was recently conducted by Lindheim, Bernard and Dozier (2011), who undertook 10 repeated home observations of sensitivity in a small ($N = 25$), high-risk sample of mothers and babies. Critically, they found insecure/nonautonomous mothers, as assessed with the AAI, showed greater variability in their sensitivity than secure/autonomous mothers, and that the lowest, but not the highest, level of sensitivity observed during the repeated assessments discriminated nonautonomous from autonomous mothers. The same was true with regard to the discrimination of infants who were removed from the home due to child protection concerns. Lindheim et al. (2011) also plotted the degree of association between sensitivity and maternal state of mind as a function of the number of observation episodes, and found that it rose in a curvilinear fashion (increasing rapidly initially, then plateauing), from $r = .37$ for a single observation to $r = .54$ after ten observations. The steepest increment in predictive validity was observed between one and two observations, and inspection of the curve would suggest that three observations may represent the optimal balance between predictive validity and researcher burden. Though only a single study and in a small and high-risk sample, this study powerfully demonstrates the importance of studying the measurement properties of sensitivity assessments to minimize error. The same logic applies, of course, to measurements of attachment. In that context it may be significant that van IJzendoorn and colleagues (van IJzendoorn et al., 2004) found the correlation between security derived from the AQS and the SSP to be stronger for studies that used longer observations when conducting the AQS ($r = .23$ for <1.5 hours, $r = .42$ for > 1.5 hours). Further work of this nature is vital for scientific studies aiming to reveal the etiological mechanisms driving the development of attachment and for practitioners who need to be able to reliably assess attachment and sensitivity as part of their routine work.

Aside from measurement error, other technological limitations may hamper efforts to find strong and consistent associations between sensitivity and attachment. One critical factor has been highlighted by two recent studies, which both indicate that sensitivity-attachment associations are stronger when the measurement context affords opportunity to observe the parent's sensitivity to the child's distress (Gaensbauer, Connell, & Schulz, 1983; McElwain & Booth-LaForce, 2006). In the first (McElwain & Booth-LaForce, 2006), maternal responsiveness to distress at 6 months cues was found to be a somewhat stronger predictor of attachment than responsiveness to nondistress cues. However, as noted by Leerkes (2011), a substantial proportion of the sample did not become distressed during the observation and were therefore excluded from the analysis. To address this limitation, Leerkes (2011) observed mothers in two different tasks, one free play, the other involving two brief distress-eliciting tasks (each 4 minutes in duration, one fear-evoking, the other frustration-evoking). As predicted, sensitivity during the distress tasks was more robustly associated with attachment security than sensitivity in the free play context. Along similar lines, several studies have suggested that sensitivity may be a stronger predictor when the observational context places competing demands on the parent (Smith & Pederson, 1988). Such contexts may increase the frequency of distress cues emitted by the child, as well as possibly stretching parents' capacities in ways that may mimic common attachment and sensitivity experiences outside of the laboratory, and hence increasing ecological validity. Because of the extensive observations in the natural setting, the Maternal Behavior Q-set (MBQS; see Pederson et al., 1990) might nicely combine the two facets that seem important for valid sensitivity measurements: observation of infant distress episodes in combination with competing demands on the parent. This may in turn explain the apparently larger associations between attachment and sensitivity produced by studies using the MBQS. Interestingly though, when Atkinson and

colleagues (2005) examined the contributions of sensitivity, as measured using the MBQS, and maternal security derived from the AAI, they did find strong associations between each of these and infant security, but they did not find strong evidence of mediation. In other words, despite the stronger correlation between sensitivity and attachment when measured this way, sensitivity and adult attachment security were partially, if not largely, independent. As a consequence, despite the substantial variance in security being accounted for overall, a transmission gap nevertheless remained. As a rejoinder to this, the authors also noted that in both the samples they analyzed (one using the MBQS, and another using an event-coding of a short lab observation), there was some indication that sensitivity and parental state of mind might interact to predict attachment security. In particular, sensitive parenting tended to block the transmission of insecure patterns from parent to child (Atkinson et al., 2005).

Another relatively clear-cut piece of evidence seeming to implicate methodological factors in the modest association between attachment and sensitivity is the notable stronger association between attachment and sensitivity when attachment is measured using the Attachment Q-Set (average $r = .39$, see van IJzendoorn et al., 2004). The AQS differs in several respects to the Strange Situation which may be relevant in interpreting this stronger association. First, it is based on a longer period of observation of behavior (typically 1.5–2 hours), and is conducted in the home environment. The AQS may therefore capture a larger sample of representative attachment behavior than the Strange Situation. However, another important consideration is the age at which the AQS is usually conducted, which is generally between the ages of 2 and 3. As noted already, there is reason to believe that the association between attachment and sensitivity becomes more robust with age. Currently, it is unclear which of these interpretations is the more accurate, although of course they are not mutually exclusive.

The second general class of explanations for the modest association between sensitivity and attachment could be termed the *domain gap* (Belsky & Fearon, 2008). What is intended here is consideration of ways novel aspects of parental behavior, partially but not fully overlapping with the sensitivity construct, might more closely match the causal inputs to the development of security and insecurity and therefore reveal stronger concurrent or predictive associations in observational studies. Although one could imagine a potentially wide ranging search for such candidates, there has been particular interest in recent years in operationalizations of sensitivity related to the parent's tendency to imagine and make sense of their child's mental states, such as their thoughts, feelings, or desires. For example, Slade and colleagues (Slade, Grienenberger, Bernbach, Levy, & Locker, 2005) found that parental reflective functioning as coded from verbatim transcripts of the Parent Development Interview at 10 months predicted 14-month attachment security, as well as the mother's parenting (Kelly, Grienenberger, & Slade, 2005). Focusing on a related construct in two separate studies, Oppenheim, Koren-Karie and colleagues found maternal insightfulness (e.g., the sophistication of thinking regarding the child's thoughts and feelings, the degree of insight into the child's motives) to predict the infant's later attachment security (Koren-Karie, Oppenheim, Dolev, Sher, & Etzion-Carasso, 2002; Oppenheim, Koren-Karie, & Sagi, 2001). Meins and colleagues have conducted perhaps the most comprehensive series of studies on the role of parental *mind-mindedness* and attachment, by coding spontaneous mind-related statements that parents make during their interactions. Four separate studies (Laranjo, Bernier, & Meins, 2008; Lundy, 2003; Meins, Fernyhough, Fradley, & Tuckey, 2001; Meins et al., 2012) have found maternal mind-mindedness to be predictive of attachment security. In all four of these studies, the typical effects sizes were consistently and substantially higher than the meta-analytic average reported in De Wolff & van IJzendoorn's original article (Laranjo et al.: $r = .41$; Lundy: $r = .58$ and .60 for mothers and fathers, respectively; Meins et al., 2001: $r = .45$; Meins et al., 2012: approx., $r = .54$), although such work was, of course, based on small or moderate sample sizes.

These studies are promising in pointing toward domains of parental care that may more robustly predict infant attachment security. However, by focusing on patterns of speech (during interactions or during semistructured interviews) these studies beg the question of the immediate, proximal, behavioral mediators. Rather than consider these studies as describing a novel domain of parenting—conceptualized at the same level of analysis as sensitivity—it is arguably more appropriate to consider them as social-cognitive processes residing in the parent, whose behavioral correlates, as they affect attachment, remain to be determined.

A third explanation of the modest association between attachment and sensitivity is that the connection is moderated by other third variables (the *moderator gap*; Belsky & Fearon, 2008). Some examples of course were already discussed in the context of the De Wolff and van IJzendoorn meta-analysis. In that meta-analysis, evidence emerged that sensitivity may be more strongly associated with attachment in middle-class samples ($r = .28$) than in lower

socioeconomic (SES) samples ($r = .15$), a finding echoed in at least one more recent study (Meins et al., 2012). As noted already, genetic factors have been suggested as possible moderators of the association between sensitivity and attachment, but the robustness of these findings may be limited (Luijk et al., 2011). A recent study nevertheless found some evidence in a relatively large sample that the sensitivity–attachment association may be moderated by genetic variability in the mineralocorticoid receptor gene (Luijk et al., 2011). Furthermore, there is reason to believe that sensitivity-focused interventions may be more successful in enhancing security for temperamentally reactive infants (see especially Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011), but whether the same is true in typical development is currently unclear. We referred to another example of moderation previously, in the study by Atkinson et al. (2005), but in this case the moderation was by sensitivity itself: high-levels of sensitivity (presumably arising for reasons partially unrelated to parental security) attenuated the association between insecure parental attachment status and the security of the parent-infant attachment relationship.

The clearest example of a domain gap arises in the context of disorganized attachment, where studies have consistently revealed a weak association with traditionally conceived sensitivity (meta-analytic average, $r = .10$, van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). There is quite consistent evidence that disorganized attachment is markedly more common among infants and children who have experienced maltreatment (Cyr, Euser, Bakermans-Kranenburg, & van IJzendoorn, 2010; van IJzendoorn et al., 1999). However, research just as clearly shows that other factors also play a role in disorganized attachment, particularly anomalous patterns of parental care. The evidence implicating anomalous parental behavior in disorganization is relatively clear, with the basic association having been found consistently in at least 10 independent studies (Abrams, Rifkin, & Hesse, 2006; Goldberg, Benoit, Blokland, & Madigan, 2003; Jacobvitz, Leon, & Hazen, 2006; Kelly et al., 2005; Lyons-Ruth, Bronfman, & Parsons, 1999; Madigan, Benoit, & Boucher, 2011; Madigan, Moran, & Pederson, 2006; Schuengel, Bakermans-Kranenburg, & van IJzendoorn, 1999; Tomlinson, Cooper, & Murray, 2005; True, Pisani, & Oumar, 2001). A meta-analytic review of the evidence published in 2006 (Madigan et al., 2006) found the overall association between anomalous parental behavior and disorganized attachment to be equivalent to a correlation of $r = .34$. It is worth bearing in the mind that while the original theorizing regarding disorganized attachment focused on fear, and particularly parental frightening or frightened behavior (FR), the broader term *anomalous parenting* includes a variety of disturbances in the affective qualities of parental behavior beyond the FR construct, including parental dissociative behavior, disturbances in affective communication, role-reversal, and more broadly defined extreme insensitivity (see Out, Bakermans-Kranenburg, & van IJzendoorn, 2009). Thus far, few studies have been conducted that have simultaneously measured all of these to determine their relative importance or to test whether they are independently predictive of disorganization. In one recent study, Out and colleagues (2009) found that only the constellation of parenting behaviors falling under the category of frightened, frightening or dissociative behavior was predictive of disorganization and not extreme insensitivity (e.g., harsh, highly intrusive parenting). This finding is broadly consistent with a tendency for dissociative behavior to be the numerically stronger predictor of disorganization in some studies (e.g., Abrams et al., 2006; Madigan, Moran et al., 2006; Schuengel et al., 1999). In addition to anomalous parental behavior, it is also notable that a recent study found that parental mind-mindedness, particularly nonattuned mind-related comments, was quite strongly predictive of attachment disorganization (Meins et al., 2012).

There is thus rather strong evidence regarding the primary determinants of disorganized attachment, although the causal status of the association between disorganization and anomalous parental behavior cannot be inferred from these data alone. Reasons to be optimistic that the association might be a causal one are provided by results of a longitudinal study by Forbes and colleagues (Forbes, Evans, Moran, & Pederson, 2007), which examined cross-lagged associations between anomalous parental behavior and disorganization from 12 to 24 months. The critical finding in this investigation was that earlier anomalous parental behavior predicted subsequent disorganization, even after prior disorganization was statistically controlled for. However, causal status is most powerfully tested using experimental studies. Thus far, intervention studies have shown that rates of disorganized can be improved through therapeutic intervention (as we will review), but whether the mechanisms of action involve changes in parental frightening, frightened and dissociative behavior remains to be definitively established.

Genes, Environments, and Temperament

Attachment theory provides a clear and coherent model of the mechanisms by which variations in the quality of

parental care influence the child's attachment organization, and subsequently biases the child's socioemotional development in systematic ways. In light of the findings of contemporary behavioral genetics research, which has documented strong and pervasive genetic influences on emotion, personality, and cognition right across the life span (Plomin, DeFries, Knopik, & Neiderhiser, 2013), attachment theory makes rather bold predictions about the environmental causation of individual differences in attachment security and insecurity (O'Connor, Croft, & Steele, 2000).

Questions about the environmental or genetic causes of attachment security and insecurity originally centered on the role of temperament (for a review, see Vaughn, Bost, & van IJzendoorn, 2008). In particular, temperament researchers argued that differences in secure-base behavior observed in the strange situation are in fact constitutionally based differences in proneness to distress. Associations with maternal sensitivity, according to this view, simply represent the noncausal parenting correlates of infant temperament (e.g., Calkins & Fox, 1992). Goldsmith and Alansky (1987) carried out an early meta-analysis of 18 studies that had assessed infant temperament and infant-parent attachment and found that temperament predicted resistant behavior in the Strange Situation. However, the effect size was small and no association was found for overall attachment classification. Hints of associations between attachment and measures of temperament have come and gone in more recent research. For example, Kagan (1994) subsequently found resistant infants to be overrepresented in groups of infants who showed high levels of behavioral inhibition in early infancy. In Van den Boom's study (van den Boom, 1990; 1994), highly irritable infants were more likely to be classified as avoidant at 12 months than less irritable infants. Belsky (1996) on the other hand reported that only one association out of eight comparisons showed a relationship between temperament and attachment with father and none for attachment with mother. Mangesldorf et al. (Mangelsdorf, Gunnar, Kestenbaum, Lang, & Andreas, 1990) found no direct links with temperament but one out of four possible interactions between temperament and maternal personality. Difficult infant temperament, in conjunction with high maternal constraint, seemed to lead to insecure infant-mother attachment at 12 months. In fact there is some suggestion that difficult temperament may represent a risk factor for the development of insecure attachments. Crockenberg (1981), for example, found that temperament was associated with attachment classification only in the context of low maternal social support. The data regarding temperamental influences on attachment are certainly mixed. The interpretation of any associations, however qualified or moderated, also needs to be tempered by a recognition that temperament itself is influenced by both genetic and environmental factors, and hence cannot be straightforwardly attributed to endogenous causes (van IJzendoorn & Bakermans-Kranenburg, 2012).

Thus, broadly speaking, the debate regarding the role of temperament led to an accumulation of evidence that quite clearly underscored the rather distinctive nature of attachment, and the limited associations between attachment and temperament. However, such studies do not directly address the question of genetic or environmental causes of variation in security and insecurity. Only behavioral-genetic studies are capable of doing so. The first twin study of attachment using a standardized assessment tool was conducted by O'Connor and Croft (2001). This study used the Cassidy and Marvin (Cassidy et al., 1992) modified Strange Situation Procedure in 125 3.5 year-old twin pairs, and found substantial correspondence between twins in attachment security (67% for security). When twin similarity was assessed separately for monozygotic (MZ; identical) and dizygotic (DZ; fraternal) twins using a continuous measure of security, the correlation was .48 for MZ twins, and .38 for DZ twins. Quantitative genetic analysis of these patterns of twin-twin similarity led to estimates of 32% for the shared environment, 53% for the nonshared environment 53%, and 14% for genetic influences. In the latter case, the genetic effect was not significantly different to zero. Given the more limited validation (in relative terms) of the preschool attachment assessment compared with what in some respects might be considered the gold standard attachment assessment (12-month Strange Situation), as well as the modest sample size, these findings, while highly consistent with attachment theory, were open to question, and certainly required replication.

Bokhorst and colleagues (Bokhorst et al., 2003) conducted a somewhat larger twin study ($N = 157$ twin pairs) using the standard 12-month Strange Situation in two parallel groups seen in labs in Leiden and London. Overall similarity between twins for attachment security was 56% for MZ twins and 60% for DZ twins. Quantitative genetic modelling estimated that 52% of the variance was attributable to the shared environment and 48% to the nonshared environment (plus measurement error), leaving the estimate of heritability at zero. The findings were thus quite consistent with O'Connor and Croft's study (2001), but indicated even more strongly the role of the environment, and particularly the shared environment. Subsequently, a third twin study was completed

by Roisman and Fraley (2008), using a modified version of the Attachment Q-sort (conducted in the home) in a substantially larger sample of twins aged 2 years (485 twin pairs). The heritability estimate of the continuous security score from the modified AQS was .17 and nonsignificant. The shared environment, by contrast, was estimated to account for 53% of the variance in security, and 36% was attributable to nonshared environment and measurement error.

Despite the differing ages and methodologies, the three studies are remarkably consistent in documenting strong evidence of the primacy of environmental influences in the development of individual differences in attachment security, and collectively reflect a rather resounding confirmation of a key assumption of attachment theory. It is important to also note that the levels of twin correspondence in these studies converges remarkably well with studies of nontwin siblings (Teti & Ablard, 1989; van IJzendoorn et al., 2000; Ward, Vaughn, & Robb, 1988), which goes some considerable way to addressing concerns that the twin design might in some way lack validity or generalizability in this context. Furthermore, each of these studies used rigorous observational measures with strict blindness protocols, so that coders knew nothing about the co-twin's attachment security or twin zygosity.

Of course, attachment theory also makes specific predictions regarding the nature of the environmental influences on attachment security, and so to be fully consistent with theory the environmental influences on attachment security, particularly the shared environmental influences, should be traceable to variation in the sensitivity of care. This key corollary of the theory was first examined by Fearon and colleagues (Fearon et al., 2006). Using the same twin sample referred to already, Fearon et al. (2006) coded home observations of maternal sensitivity obtained at 10 months, and related these to infant attachment security in the Strange Situation at 12 months. Maternal sensitivity in this study was found to be highly consistent between twins regardless of their zygosity, indicating sensitivity to be a highly shared environmental variable. As predicted, when the shared environmental variance in sensitivity was isolated from the nonshared variance (there was no genetic variance in sensitivity), it correlated significantly with the shared environmental component of attachment security. In other words, a significant portion of the shared environmental influences on attachment was attributable to similarities in how sensitive, or insensitive, mothers were to both of their infants. Roisman and Fraley (2008) subsequently replicated this finding using home observations of parenting from the Early Childhood Longitudinal Study-Birth cohort.

Behavioral genetic methods have proved to be key tools for testing the critical environmental hypotheses of attachment theory, and have produced remarkably consistent, and cumulatively persuasive, evidence that these basic assumptions are robust. Several further issues regarding the etiology of attachment warrant consideration. First, as indicated before, the nonshared environment includes measurement error, which is likely to be quite significant for assessments of attachment, and hence estimates of the shared environment are almost certainly *underestimates*. Second, standard genetic modelling of twin data does not take account of gene–environment interaction. When ignored, gene × shared environment interactions are estimated as genetic effects in the twin design, and gene × nonshared environment interactions are estimated as nonshared variance (Johnson, 2010). This is important for two reasons. First, although genetic effects (e.g., observed in other domains of behavior) could, and probably do, mask gene-by-shared environment interactions, shared environmental influences, such as those observed to influence attachment, represent pure environmental effects. Second, in the only study that attempted to estimate the heritability of disorganized attachment (Bokhorst et al., 2003), marked evidence of nonshared environmental influence was found. Although this could be taken to indicate twin or sibling-specific environmental influences (such as parental differential treatment), it could also reflect interactions between genes and the nonshared environment. When these considerations are set alongside the fact that very limited numbers of disorganized cases have been subjected to quantitative genetic analysis, it is appropriate to conclude that uncertainty still remains about the genetic and environmental influences on disorganized attachment.

This latter caveat takes on particular significance in light of the fact that some studies have reported associations between disorganized attachment and directly measured genetic polymorphisms. The first of these was conducted by Lakatos and colleagues (Lakatos et al., 2000), who, in a community sample of 90 infants, examined the association between disorganized attachment and a polymorphism of the dopamine D4 receptor gene. Of 17 infants classified as disorganized, 12 (71%) had a variant of this gene containing 7 or more repeats of a 48 base pair sequence in the third coding region of the gene, which is thought to alter dopamine signalling. A follow up paper (Lakatos et al., 2002) reported that a single nucleotide polymorphism in the promoter region of the same gene (a C>T substitution) amplified the effect of the

DRD4 gene on disorganization. Neither of these genes, nor their interaction, was found to relate to attachment disorganization in two independent samples studied by Bakermans-Kranenburg and van IJzendoorn (Bakermans-Kranenburg & van IJzendoorn, 2004; van IJzendoorn & Bakermans-Kranenburg, 2006). Numerous studies followed also attempting to replicate the association, but none of them did so (see Bakermans-Kranenburg & van IJzendoorn, 2007; Frigerio et al., 2009; Gottfried Spangler, Johann, Ronai, & Zimmermann, 2009; Luijk et al., 2011). A meta-analytic average of available samples in 2007, including the Lakatos sample, was $d = .05$ ($r = .02$), $p = .66$, $N = 542$ (Bakermans-Kranenburg & van IJzendoorn, 2007). In the largest replication study, which combined two relatively large cohort studies from the United States and the Netherlands (Luijk et al., 2011), involving 478 and 543 participants respectively, the associations between the DRD4 7+ VNTR and attachment disorganization were nonsignificant $r = .03$ and $r = .04$. The conclusion is unavoidable that the evidence does not indicate that the DRD4 polymorphism is involved in the development of attachment disorganization. Having said that, as we will elaborate, contemporary genetics is strongly pointing to the fact that main effects of single genes, where they exist, are typically of extremely small magnitude, and hence that past studies have lacked power by several orders of magnitude. It is therefore conceivable that single genes, such as the DRD4, might play a very small role in disorganized attachment but we have so far lacked power to detect them reliably. Nevertheless, the current evidence does not lend support to the DRD4 gene being a more promising gene candidate than polymorphisms in any other region of the genome.

Another line of work that has emerged in this area is the investigation of gene-by-environment interactions. For example, evidence of gene-by-environment interaction was found by Bakermans-Kranenburg and van IJzendoorn (2006) in a sample of 85 mothers who were selected on the basis of having experienced an important loss. These authors found that the DRD4 gene interacted with maternal unresolved loss, as assessed using the Adult Attachment Interview. Infants that had the 7+ allele of the DRD4 gene and whose mothers were unresolved with respect to loss were more likely to be disorganized. Put another way, it appeared that the effect of maternal unresolved loss was stronger for infants with the DRD4 7+ allele. Or, put the other way around, the findings indicated that carriers of the 7+ repeat were the least disorganized when their mothers were not unresolved, and in that sense this study was an early example of evidence indicating genetic "differential susceptibility" (Bakermans-Kranenburg & van IJzendoorn, 2007). Spangler and colleagues (2009) found no DRD4-by-parental care interactions in relation to attachment disorganization in a sample of 106 infants from the Regensburg longitudinal study. They did however find a GxE effect of parental care on disorganization in relation to a different gene—the 5HTTLPR polymorphism of the serotonin transporter gene (with the short form being associated with disorganized attachment, but only when parental responsiveness was low). Notably, Barry, Kochanska and Philibert (N = 88, Barry, Kochanska, & Philibert, 2008) found the short form of the 5HTTLPR gene to be associated with attachment *insecurity* overall (they did not report effects specifically on disorganization), and that the short-form predicted insecurity more strongly (indeed, only) when maternal responsiveness was low. The form of this effect, though not the precise nature of the outcome (insecurity, rather than disorganization) mirrors that found by Spangler and colleagues quite closely. However, a recent report by Raby and colleagues (Raby et al., 2012) failed to replicate this 5HTTLPR × parental responsiveness interaction.

The picture concerning gene environment interactions in the development of disorganized (or indeed insecure) attachment is thus quite mixed, and currently it is unclear whether replicable associations exist. The recent, larger scale investigation by Luijk and colleagues (Luijk et al., 2011) favors the view that gene–environment interactions, in addition to the genetic main effects referred to earlier, may not be reliable. In both US and Dutch samples, data were available on several other genes in addition to DRD4 (5HTTLPR, DRD2, COMT, OXTR) and on observed maternal sensitivity. After taking account of multiple hypothesis testing, no reliable genetic main effects, or gene x sensitivity interactions were apparent in relation to security or disorganization. However, although this is the most statistically powerful test of molecular genetic main effects and interactions conducted thus far, it did not involve measures of the most promising candidate environmental factor with respect to disorganization: parental anomalous, or frightening/frightened parenting. We await large-scale tests of such GxE predictions.

Broadly speaking then, the extant work on the molecular genetics of attachment in infancy, in contrast to the behavior genetic studies, is marked by inconsistency and failures to replicate. Overall, the net implication of both the twin and candidate gene studies is that, in keeping with the predictions of attachment theory, attachment in early life is strongly influenced by the environment and shows little evidence of being determined by genes.

Should we therefore conclude that further genetic research is not warranted? In our view, this would be a premature conclusion to draw. Some useful lessons can be drawn from the larger field of psychiatric genetics. As Kendler (2013) notes, quantitative behavioral genetics convincingly demonstrated that all major forms of psychiatric disorder show marked genetic influence, but early studies selecting candidate genes involved in neurotransmitter function (the so-called usual suspects in candidate gene studies, see Ebstein, Israel, Chew, Zhong, & Knafo, 2010) largely failed to find replicable associations. As larger-scale studies emerged, and researchers increasingly recognized the importance of several methodological issues (particularly the need for strict controls on type I error), initial findings tended not to be replicated. Genome-wide association studies (GWAS), which genotype very large numbers of polymorphisms (often > 500,000 single nucleotide polymorphisms [SNPs]), came to subsequently dominate the field, with an emphasis on blind identification of genes without any prior selection based on biological plausibility. Initially, these studies, which required very large samples, also failed to find replicable effects. However, with even larger samples (often *N*s greater than 20,000) what has emerged is quite clear evidence of replicable gene associations for several major conditions (e.g., schizophrenia, bipolar disorder, see Kendler, 2013). Thus, GWAS appear to indicate quite convincingly that the majority of genes associated with liability to psychiatric disorder have reliable but extremely small main effects, and require very large samples to detect. Second, GWAS studies tend to suggest that the replicable genetic associations are not those that would have been chosen on the basis of, in hindsight, a perhaps simple-minded model of psychiatric disorder. Instead, replicable associations for several psychiatric disorders have involved genes with diverse and largely unanticipated functions, such as inflammatory processes, calcium channel signaling, cell adhesion, and myelination. The meaningfulness of these findings is supported not only by the statistical data, but also by the fact that the identified genes are consistently found to be expressed in the brain and that a substantial proportion of the heritability of psychiatric conditions can be "recovered" from an analysis of variability in common SNPs across the genome (Kendler, 2013).

In light of the fact that, unlike most psychiatric disorders, the overall heritability of attachment security appears low (at least in infancy/toddlerhood), it seems fair to say that the search for genetic main effects on attachment faces considerable hurdles. However, GWAS studies, for the most part, focus on genetic main effects. Somewhat stronger effects have been found for studies of candidate gene × environment interactions, although even here the picture is complex. Arguably the most promising gene–environment interaction—the interaction between the short form of the 5HTTLPR gene and life stress in determining depression (Caspi et al., 2003)—has been fraught with nonreplications and remains controversial to this day. For example, meta-analytic studies have drawn widely divergent conclusions regarding the reliability of the effect, in part as a result of their differing inclusion criteria (Uher & McGuffin, 2010). The most recent meta-analysis by Karg et al. (Karg, Burmeister, Shedden, & Sen, 2011) did, however, find strong overall evidence of G×E interaction in depression, based on over 40,000 individuals, but the results were notably more robust for childhood maltreatment than for life stress/life events. A review by Uher and McGuffin (2010) concluded that the evidence in favor of G×E in depression is quite strong, and that the quality of environmental measures is a key determining factor in the strength and reliability of findings. In particular, objective measures of the environment produced more clear-cut evidence of interaction than subjective self-reports. Thus, we may conclude that gene–environment interaction studies hold more promise for understanding the development of attachment than studies of genetic main effects, but that high-quality measures of the environment, and of the phenotype, and large-scale epidemiologically rigorous samples will likely be necessary to detect them. More, and larger scale, quantitative genetic studies (e.g., twin and adoption studies) are also needed to guide molecular genetic studies to the most promising aspects of attachment (i.e., those with the highest heritability) and to the right environmental moderators.

Thus far, we have only addressed the genetic and environmental determinants of attachment in the first three years of life, but of course attachment is considered an important aspect of human functioning across the life span. Given the modest stability in measures of attachment over time, it is not appropriate to assume that the genetic and environmental determinants of childhood, adolescent or adult attachment are the same as those that obtain in infancy or toddlerhood. Furthermore, it is important to note that to the extent that behavior genetic studies have found evidence of shared environmental effects on other aspects of development, this has tended to be early in the life span (infants and preschoolers). The shared environment may thus represent a set of causal influences that are more dominant in early life and that may diminish with time (Plomin et al., 2013). Another important

consideration is that attachment status in childhood, adolescence, and adulthood is measured and conceptualized very differently to the separation-reunion or secure base tools used in the early years, a difference that may alter the balance of genetic and environmental determinants one observes. Indeed, Main (1996) argued that the ability to reflect on and integrate what might be difficult early experiences, which is central to adult/adolescence measures of attachment, may place greater weight on individual characteristics that are partly heritable (Main, 1996).

Several studies have examined the role of genes and environments in attachment styles (as indicated by self-reports, such as the Experiences in Close Relationships Scale; Fraley, Waller, & Brennan, 2000) in adults. In a sample of 239 adult twin pairs, Brussoni and colleagues (Brussoni, Jang, Livesley, & MacBeth, 2000) estimated that 37% of the variance in attachment anxiety was due to genetic differences and 60% to nonshared environment. Attachment avoidance on the other hand was not heritable, and 29% of the variance was attributable to shared environment. These results were replicated by Crawford and colleagues (Crawford et al., 2007), finding 40% heritability for attachment anxiety and no genetic influence on avoidance. However, Picardi and colleagues (Picardi, Fagnani, Nistico, & Stazi, 2011), using a relatively large sample of young adult twins ($n = 677$ twin pairs), replicated the findings for attachment anxiety (45% heritability; 55% nonshared environment), but not those for avoidance (finding 36% heritability, and 64% nonshared environment). In a recent large-scale study of middle age men, Franz et al. (2011) found that genetic differences accounted for 38% of the variance in attachment anxiety and 27% of the variance in attachment avoidance. Notably, they found that the genes involved in attachment anxiety and avoidance only partly overlapped and that attachment avoidance in particular showed distinct genetic influences that were independent of measures of depression and personality (see also Donnellan, Burt, Levendosky, & Klump, 2008). There is thus quite consistent evidence that self-reported attachment anxiety is influenced by genetic factors, and larger twin studies also tend to indicate genetic influence on attachment avoidance. Inconsistencies between studies may also reflect the different measures used, as the two studies that found shared environmental effects on avoidance used the Relationship Scales Questionnaire (Griffin & Bartholomew, 1994), while those that did not used the ECR or the Adult Attachment Scale (Collins & Read, 1990).

These findings provide a partial picture of the genetic and environmental determinants of attachment in adulthood, as measured using self-reports. However, one cannot infer from this the pattern of heritability of attachment as measured using representational/interview measures, because numerous studies show these two measurement approaches to be essentially orthogonal (Roisman et al., 2007). Recent studies with adult or adolescent siblings using the AAI provide some useful data in that regard. Two independent studies have found effectively no correspondence between siblings in their overall security of attachment as assessed in the AAI (Fortuna, Roisman, Haydon, Groh, & Holland, 2011; Kiang & Furman, 2007). Although these data do not bear directly on the role of genes, they do suggest that the shared environment may not play as strong a role in adult attachment as that observed in infants (cf. van IJzendoorn et al., 2000). Currently, the strongest available direct evidence regarding the role of genes and environments in representational measures of attachment comes from a recent relatively large-scale twin study by Fearon and colleagues (Fearon, Shmueli-Goetz, Viding, Fonagy, & Plomin, 2014). Fearon et al. used the Child Attachment Interview (Shmueli-Goetz, Target, Fonagy, & Datta, 2008) to study the attachment representations of 551 adolescent twin pairs (aged 15 years), drawn from the Twins Early Development birth cohort study (TEDS, see Trouton, Spinath, & Plomin, 2002). The results differed quite dramatically from the findings of the earlier twin studies of infant/toddler attachment. First, no evidence of shared environmental influence was found; DZ twins, much like the previously described siblings, showed no significant correspondence in their attachment classifications, and only weak correlations for the continuous security scale ($r = .20$, $N = 261$ twin pairs). Second, strong evidence of genetic effects emerged. In contrast to the DZ twins, MZ twins showed marked resemblance for security and coherence, with the correlation between twins for coherence being double that observed for DZ twins ($r = .40$). Standard genetic analysis showed that after controlling for gender and age, 38% of the variance in coherence, and 35% of the variance in binary security was attributable to genetic factors. The remaining variance was attributable to the nonshared environment and measurement error. When one considers that measurement error attenuates the genetic effect, these heritability figures are likely to be underestimates. The same considerations of course would caution against ruling out a modest shared environmental effect, as attenuation could have occurred to such a degree that it could not be reliably detected in this sample.

These findings are striking in their marked contrast to those identified in very young children. We cannot at this stage ascertain whether they reflect a distinct

feature of the adolescent period (where we know normative increases in dismissing speech can be observed, see Bakermans-Kranenburg & van IJzendoorn, 2009; Waters, Weinfield, & Hamilton, 2000; Weinfield, Sroufe, & Egeland, 2000), or are reflective of a broader unfolding process of developmental change taking place between early childhood and adolescence. They certainly draw attention to the possibility that the genetic and environmental determinants of attachment may not be constant across development, and raise the possibility that genes may begin to shape the organization of attachment, at least at the representational level, in adolescence, and possibly beyond. If these findings prove to be correct, a key question to be addressed by future research is how such changes in the genetic profile of attachment between infancy and adolescence come about. We can imagine mechanisms operating at two distinct levels: it may be that these genetic effects occur via gene–environment interplay, such that heritable traits in the child begin to affect parent–child interactions (e.g., evoking hostility/negativity, see Avinun & Knafo, 2013; Narusyte et al., 2008), which in turn impact on the adolescent's attachment organization. Such a mechanism is an example of *gene–environment correlation*. Another possibility is that these effects arise at the level of the individual's response to attachment-related experiences. For example, genetically influenced traits may affect adolescents' emotion-regulation skills, bias their interpretations of attachment experiences, or influence their ability to integrate them coherently within an internal working model. All of these processes might feed into adolescents' states of mind with respect to attachment as they shift with time developmentally. It would be wrong of course to emphasize only the genetic findings regarding adolescent attachment. In keeping with studies of infants and toddlers, attachment in adolescence clearly demonstrates marked nonshared environmental influence and these findings compel the field to investigate the environmental mechanisms leading to differences in security between children raised in the same family. Finally, we note that an urgent research question is whether genetic influences also characterize attachment into adulthood as assessed in the Adult Attachment Interview. In that context, there is of course already existing evidence that representational assessments of adult attachment are associated with earlier caregiving experiences (e.g., Beijersbergen, Juffer, Bakermans-Kranenburg, & van IJzendoorn, 2012). Furthermore, even were one to find genetic influences on adult attachment, this would not necessarily imply that the intergenerational transmission of attachment from parent to child is mediated by genes (D'Onofrio et al., 2007). In that regard, evidence of intergenerational continuity from parent to child among children in foster care (Dozier, Stovall, Albus, & Bates, 2001), where caregivers and their children are not biologically related, would seem to indicate environmental transmission.

CONTINUITY AND CHANGE IN ATTACHMENT SECURITY ACROSS THE LIFE COURSE

The nature of internal working models contributes to an implicit assumption in attachment theory that individual differences in attachment security are relatively stable over time. To be sure, according to attachment theory (Bowlby, 1969), relative stability in internal working models is thought to be ensured through the increasing automatization of parent–child interactions, ultimately decreasing attentional demands and conscious revision of working models. Such habitual interaction patterns also lead to negative or positive perceptual biases that color expectations and interpretations of subsequent experiences. Moreover, because both the caregiver and child hold working models of the relationship, if one partner attempts to change routinized relationship patterns, the other is likely to resist and attempt to maintain the established pattern. Bowlby also acknowledged, however, that updates to internal working models are expected under certain environmental conditions, including changes in parent–child relationship quality or changes in life circumstances that improve or undermine the caregiver's perceived or actual ability to sensitively respond to the child's attachment needs. Thus, although attachment security is expected to remain relatively stable across the life course, it is also recognized that lawful change in security is possible given attachment-relevant changes in life circumstances (see Bretherton & Munholland, 2008).

Questions concerning stability and lawful change in attachment security have garnered a great deal of interest and have been the focus of much empirical inquiry. Initial investigations in this area focused on short-term stability in the organization of attachment behavior during childhood. In the first investigation of this kind, Waters (1978) provided evidence for remarkably strong stability in infants' organized attachment patterns in relation to their mother as measured by the Strange Situation from 12 to 18 months (see also Goossens, van IJzendoorn, Tavecchio, & Kroonenberg, 1986). However, subsequent investigations of the stability of mother–child attachment security from the Strange Situation to another standardized observational assessment of attachment during early childhood (e.g., Strange Situation, AQS, modified Strange Situation)

provided mixed evidence. Although some studies found significant stability (Howes & Hamilton, 1992; Main et al., 1985; Main & Weston, 1981; Owen, Easterbrooks, Chase-Lansdale, & Goldberg, 1984; Vaughn, Egeland, Sroufe, & Waters, 1979; Wartner et al., 1994), others did not (Belsky, Campbell, Cohn, & Moore, 1996; Egeland & Farber, 1984; Thompson, Lamb, & Estes, 1982).

An understandably more challenging question to address concerns the stability of attachment security from infancy to adulthood, as empirically addressing such questions necessarily requires prospective, longitudinal data (for an overview of such studies, see Grossmann, Grossmann, & Waters, 2005; Roisman & Haydon, 2011). As such, evidence regarding stability and change in attachment security from infancy into the years of maturity emerged only relatively recently, dating to 2000 when a handful of studies were published simultaneously in the journal of *Child Development* (Hamilton, 2000; Lewis, Feiring, & Rosenthal, 2000; Weinfield et al., 2000). As with the literature on short-term stability in attachment security, the extant longitudinal studies have provided mixed evidence, with some studies finding stability in attachment security from infancy, as assessed with the mother in the Strange Situation, to adulthood, as assessed with the AAI (e.g., Hamilton, 2000; Main, 2000, 2001; Main, Hesse, & Kaplan, 2005; Waters, Merrick, Treboux, Crowell, & Albersheim, 2000), and other not (Beijersbergen et al., 2012; Lewis et al., 2000; Weinfield et al., 2000; Zimmermann, Fremmer-Bombik, Spangler, & Grossmann, 1997).

Although the apparent discrepancy among these findings regarding attachment stability across the life course can be explained in a number of ways, one interpretation that has emerged in the literature in light of evidence that studies focused on middle-class, relatively low-risk families have generally provided evidence for stability in attachment security (e.g., Main et al., 2005; E. Waters, 1978) and studies focused on at-risk samples have not (e.g., Egeland & Farber, 1984; Weinfield et al., 2000) is that attachment security is generally stable, except in populations that are at higher risk for experiencing life stress and, thus, more profound changes in the caregiving environment (e.g., Waters, Weinfield et al., 2000). To test such claims and provide a more accurate estimate of the stability of attachment security across the early life course, Fraley (2002) conducted a meta-analysis of this literature, specifically including studies that reported on the association between attachment security as assessed by the Strange Situation and another behavioral measure of attachment (Strange Situation, AQS, modified Strange Situation) or the AAI. Findings from this meta-analysis provided evidence that attachment security is moderately stable from infancy to adulthood ($r[\Phi] = .39$), and consistent with prior conclusions, attachment security was found to be less stable in samples considered to be at higher risk ($r = .27$) than those at lower risk ($r = .48$).

Pinquart, Feusner, and Ahnert (2013) provided an update of this effort in light of more recently published work in their meta-analysis on the stability of attachment security. Similar to Fraley's (2002) findings, Pinquart and his colleagues (2013) provided evidence for moderate stability in attachment security across early childhood (r's range from .24 to .46 depending on the time interval between assessments) and that the effect was significantly weaker in at-risk samples ($r = .21$) than in not at-risk samples ($r = .36$). In contrast to findings from Fraley (2002), however, Pinquart and colleagues (2013) found that attachment security was not significantly stable from infancy to adulthood ($r = .14$). Unfortunately, because Pinquart and colleagues (2013) included a range of adult attachment assessments, whereas Fraley (2002) focused on studies employing the AAI as the assessment of adult attachment, it is difficult to determine whether this discrepancy is due to the emergence of new evidence of the relative instability in attachment security published in the interim between Fraley's (2002) and Pinquart et al.'s (2013) meta-analyses or due to differences in the scope of the two meta-analyses.

It is even more important to note that, due to the small sample size of many of the investigations of attachment stability across the early life course, the total number of individuals studied from infancy to young adulthood in the extant literature is, by most standards, quite modest, resulting in a relatively limited corpus on which to estimate the stability of attachment security. In fact, only about 785 participants have been studied across all investigations to date (Roisman & Haydon, 2011). In the most recent wave of the NICHD Study of Early Child Care and Youth Development (SECCYD)—a longitudinal study following over 1,000 low-risk participants from infancy to adulthood and comprising several early observational assessments of mother–child attachment security (Strange Situation administered at 15 mo., AQS administered at 24 mo., modified Strange Situation administered at 36 mo.)—857 participants were administered the AAI at age 18, making it the largest, most comprehensive single investigation of the stability of attachment security to date. Helping to reconcile prior mixed evidence in the literature, findings from this study indicate that although attachment security is significantly stable over the early life course, the magnitude

of such stability is quite weak by conventional standards (r = .12; Groh et al., 2014).

As with prior investigations of attachment stability, caregiving and contextual sources of variation that might contribute to stability and lawful change in attachment security were also examined in the SECCYD (Booth-LaForce et al., 2014). Prior investigations have identified several theoretically relevant aspects of the caregiving environment that might contribute to stability and change in attachment security (e.g., Beijersbergen et al., 2012; Egeland & Farber, 1984; Frodi, Grolnick, & Bridges, 1985; Hamilton, 2000; Lewis et al., 2000; Main et al., 2005; NICHD Early Child Care Research Network, 2001, 2006; van Ryzin, Carlson, & Sroufe, 2011; Waters, Weinfield, et al., 2000; Weinfield et al., 2000; Weinfield, Whaley, & Egeland, 2004). However, studies have varied in terms of the contextual factors investigated and findings across studies have not always converged, making it difficult to draw firm conclusions regarding whether instability in attachment security is lawful and which environmental factors contribute to positive and negative deflections from infancy to adulthood.

The large longitudinal SECCYD sample includes assessments over time of important potential sources of change and continuity in attachment security; thus, it is well positioned to address questions concerning environmental factors associated with stability and change in attachment. Consistent with expectations that internal working models are reinforced by stability in parent–child relationship quality over time, evidence from this study indicated that stability in attachment security (vs. insecurity) is associated with higher levels of maternal sensitivity, higher levels paternal physical presence in the home, and lower levels of paternal psychopathology over the course of development from infancy to adulthood. Overall, findings from this investigation were also consistent with claims that instability in attachment-relevant variation across the early life course is lawful, in that change in attachment security can be explained by comparable changes in attachment-relevant life circumstances. Specifically, individuals who experienced high quality relationships in infancy but came to develop insecure attachment representations in adulthood experienced higher levels of paternal physical absence from the home, larger increases in negative life events, and larger declines in the quality of maternal sensitivity over the course of development. In contrast, individuals who overcame early insecurity and developed secure attachment representations in adulthood were found to experience higher levels of maternal sensitivity over the early life course (Booth-LaForce et al., 2014).

Taken together, findings from across the literature on continuity and change in attachment security provide evidence that attachment security is not especially stable across the life course, but that when discontinuity exists, it can be explained by attachment-relevant changes in the caregiving environment. That said, several limitations of this literature should be noted and addressed in future research. The literature on attachment stability is largely a literature of *mother–child* attachment. Pinquart and colleagues (2013) have provided evidence in their meta-analysis that the stability of father–child attachment security (r = .27) is comparable to that of mother–child attachment security. However, such evidence is based on a relatively limited corpus of data. Indeed, only two studies based on relatively small samples have investigated the concordance between father–child attachment security in infancy and the security of attachment representations in adulthood (Steele & Steele, 2005; Zimmermann et al., 1997). As it may be the case that attachment security with both the mother and father, rather than security with the mother alone, is more predictive of states of mind with respect to attachment in adulthood, there is a clear need for more comprehensive investigations of the stability of attachment security that include assessments of attachment with both mothers and fathers.

In addition, two diverging perspectives of attachment stability have emerged in the literature. According to what has been referred to as the *revisionist* perspective, working models are revised and updated in light of ongoing experiences, and thus, it is not necessarily expected that working models in adulthood will correspond with those developed in infancy. In contrast, according to the *prototype* perspective, while updating of working models in light of new experiences is acknowledged, it is also argued that models developed in infancy remain unchanged and continue to anchor interpersonal experiences throughout the life course (see Fraley, 2002). Because evaluating such claims requires attachment security to be assessed repeatedly over developmental periods, longitudinal investigations of attachment stability that only include two assessments of attachment security, which is typical in the extant literature, are unable to distinguish between these two perspectives. Fraley (2002) meta-analytically evaluated the empirical support for such claims in light of available evidence at the time, providing evidence consistent with the prototype perspective. However, in light of evidence from Pinquart and colleagues' (2013) meta-analysis and findings from the SECCYD (Groh et al., 2014) of relatively weak stability in attachment security from infancy to adulthood, such

claims might have to be reevaluated in light of this more recent evidence.

Inherent in the study of attachment stability is the assumption that stability and lawful change in attachment security is environmentally mediated. However, nearly all studies on the stability of attachment security have relied on samples in which parents and children are genetically related (but see Beijersbergen et al., 2012), leaving open the possibility that stability and lawful change in attachment security might be attributed to the genetic relatedness between the parent and child. Initial evidence from a study of adopted children and their mothers indicates that greater levels of maternal sensitivity in infancy and adolescence are associated with stability in attachment security and that positive changes in maternal sensitivity from infancy to adolescence are associated with positive deflections in attachment security (Beijersbergen et al., 2012), supporting an environmentally mediated pathway (although such findings could also be explained by gene–environment correlation). Given the centrality of this issue to attachment theory, future work should further employ genetically informed research designs (including studies of monozygotic and dizygotic twins) to thoroughly address issues concerning environmental or genetic mediation of stability and lawful change.

Finally, the literature on the stability of attachment security is predicated on the assumption that the key test of stability in security should involve the prediction from infant assessments of attachment security (e.g., Strange Situation) to adult assessments (e.g., AAI). Such a focus might be an error of emphasis for at least two reasons. First, given that Bowlby (1973) theorized that internal working models are only tolerably accurate representations of prior experiences, such a focus may be an overly conservative test of attachment stability. For example, when examining the contribution of attachment-relevant experiences with caregivers over the course of childhood to adults' states of mind with respect to attachment as measured at age 18 with the AAI in the context of the SECCYD, 20% of the variance in dismissing states of mind and 11% of the variance in preoccupied states of mind were accounted for by prior experiences with mothers and fathers (Haydon, Roisman, Owen, Booth-LaForce, & Cox, 2014). Second, there is a very clear need for studies that examine stability and change in security *across adolescence and into adulthood* (see Allen, McElhaney, Kuperminc, & Jodl, 2004; Crowell, Treboux, & Waters, 2002), not incidentally a period of development when it is possible to use a common assessment of security over assessments.

CHILDREN'S ATTACHMENT SECURITY AND PSYCHOPATHOLOGY

Bowlby was particularly interested in the developmental origins of children's emotional disturbance, and believed that early relational experiences were of great importance in the ontogeny of mental health and illness. Yet, the majority of initial work on the developmental significance of individual differences in early attachment security primarily focused on children's normative development, and in particular on the contribution of early attachment relationships to subsequent interpersonal competence (Berlin, Cassidy, & Appleyard, 2008; Groh et al., 2014; Schneider, Atkinson, & Tardif, 2001). However, as the field of developmental psychopathology took shape (see Cicchetti, 1984) and early attachment insecurity was further conceptualized as a risk factor for the development of behavioral problems (Sroufe, 1988), there was renewed interest in the significance of early parent–child attachment relationships for the development of psychopathology (see DeKlyen & Greenberg, 2008). In the past few decades, a sizable literature on the links between early attachment and psychopathology has emerged, establishing attachment theory as a dominant theoretical framework guiding research on the role of early experiences in the development of psychopathology. In this section, we provide an overview of this now vast literature and offer new insights in light of recent meta-analytic evidence (Fearon, Bakermans-Kranenburg, van IJzendoorn, Lapsley, & Roisman, 2010; Groh, Roisman, van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012; Madigan, Atkinson, Laurin, & Benoit, 2013). Following the focus of research in this area, we primarily discuss investigations of the links between early mother–child attachment security and externalizing (e.g., aggression) and internalizing (e.g., anxiety, depression) symptomatology.

A number of (nonmutually exclusive) mechanisms have been proposed to explain why early attachment experiences might be associated with psychopathology. The dominant explanation concerns the internal working models (IWM) construct (Bowlby, 1973, 1980; Bretherton & Munholland, 2008). As described previously in this chapter, based on caregivers responsiveness to attachment signals, infants develop cognitive-affective representations, or IWMs, that encompass views of the caregiver as (un)responsive, and in turn, views of the self as (un)worthy of love and care that over time become generalized into views of the self, others, and the nature of relationships. As a result of the care they receive, insecure infants are believed to develop IWMs characterized by anger, mistrust, anxiety, or fear,

coloring their subsequent social experiences and ultimately heightening their risk for developing psychopathology, whereas secure children are believed to develop IWMs characterized by inner confidence, efficacy, and self-worth, helping to buffer them against developing mental illness.

Because both theory and research have established the importance of emotion regulation in the etiology and maintenance of internalizing and externalizing problems (Chaplin & Cole, 2005; Izard, Youngstrom, Fine, Mostow, & Trentacosta, 2006), another powerful explanatory framework concerns the contribution of early attachment relationships to children's developing capacity to tolerate and manage affect. More specifically, it has been argued that within the parent–child attachment relationship, children develop either adaptive (in the case of secure children) or maladaptive (in the case of insecure children) emotion regulation strategies (Cassidy, 1994; Isabella, 1993; Sroufe, 1979, 1996) that serve, respectively, as either protective or risk factors for later psychopathology (e.g., Carlson, 1998; Guttmann-Steinmetz & Crowell, 2006).

Another potential avenue through which early attachment experiences might contribute to the development of psychopathology occurs at the level of behavior. Through the history of care they receive, children develop specific behavioral strategies for interacting with their caregivers that might be considered adaptive organizations of behavior given the constraints of the quality of caregiving the children have experienced. For example, on the assumption that resistant infants experience a history of inconsistently responsive care, it would be considered adaptive (at least in the narrow, proximal sense) to exaggerate attachment behavior to increase the likelihood that the caregiver will respond to the infant's needs (Simpson & Belsky, 2008). However, such behavioral strategies might be considered maladaptive *outside the context of the parent–child relationship*, placing insecure children at heightened risk for social exclusion and developing psychopathology (Greenberg, Speltz, & DeKlyen, 1993; Weinfield, Sroufe, Egeland, & Carlson, 2008). Other potential mechanisms that have been proposed to buffer secure children from the development of internalizing and externalizing symptoms include (1) developing a sense of self-confidence stemming from experiences of support and comfort and through effective exploration of the environment (Goldberg, 1997), (2) generalized positive social expectations (e.g., Dodge & Coie, 1987), (3) socialization of moral emotions and values (Kochanska, 1997; van IJzendoorn, 1997), (4) continuity in ongoing supportive caregiving (Lamb, Thompson, Gardner, Charnov, & Estes, 1984), and (5) social regulation of biological systems mediating effective stress and arousal regulation (e.g., Suomi, 2003; Weaver et al., 2004).

Although Bowlby's ideas concerning the significance of children's early experiences with primary caregivers for subsequent developmental (mal)adaptation were highly influential, the development of the Strange Situation procedure greatly facilitated the empirical investigation of the correlates and consequences of the quality of early parent–child attachment relationships. One of the earliest and most influential longitudinal studies of the developmental sequelae of early attachment variation was launched in Minnesota by Byron Egeland and Alan Sroufe (see Sroufe, Egeland, Carlson, & Collins, 2005a). It was in the context of this landmark longitudinal study that the conceptual links between attachment and psychopathology were elaborated on, providing the field with more specific hypotheses regarding the legacy of early attachment experiences for the development of psychopathology.

Specifically, this relatively large, high-risk cohort has been followed for over 35 years beginning at birth, and results from extensive assessment of adaptive and maladaptive behavior have provided consistent evidence that individuals who developed an insecure attachment relationship with their mother in infancy are at heightened risk for developing psychopathology across the life course (Sroufe et al., 2005a). Results have also revealed that specific types of attachment insecurity serve as distinct diatheses for the development of externalizing versus internalizing symptomatology, with insecure-avoidant infants found to be at heightened risk for developing aggression (believed to result from feelings of anger derived from early rejection by caregivers) and resistant infants found to be at heightened risk for developing anxiety (believed to result from feelings of worry derived from early inconsistent or unresponsive care; Sroufe, 2003). Such evidence has contributed to the hypothesis that early avoidance increases risk for developing externalizing symptoms, whereas early resistance increases risk for developing internalizing symptoms. In addition, with the discovery of attachment disorganization, it was further hypothesized that because disorganized infants show contradictory and fragmentary behaviors—indicative of a breakdown of an organized emotion regulation strategy in the face of stress—they might be at heightened risk for developing both internalizing and externalizing symptoms (Carlson, 1998).

A second hypothesis to emerge from the work at Minnesota is that early attachment experiences play an enduring, if probabilistic, role in shaping developmental (mal)adaptation. Consistent with Bowlby's (1973)

view that current adaptation is a function of both prior and current circumstances, Sroufe and his colleagues (Sroufe, Egeland, & Kreutzer, 1990) claimed that current experiences have the power to transform adaptation without erasing the history of prior adaptation. Thus, early attachment-relevant experiences are thought to contribute in enduring ways to adaptation across the life course.

Although consistent evidence from the Minnesota study has been presented in support of these hypotheses (Sroufe et al., 2005a; Sroufe, Egeland, Carlson, & Collins, 2005b), other investigations have not always found a significant link between early attachment insecurity and disorganization and symptoms of psychopathology. Indeed, in the same monograph in which the first evidence was presented from the Minnesota study of a significant link between attachment insecurity and behavior problems (e.g., hostility, withdrawal; Erickson, Sroufe, & Egeland, 1985), evidence from another longitudinal study of 120 middle-class families was presented in which no association between individual differences in mother–child attachment security and behavioral problems was found (Bates, Maslin, & Frankel, 1985). This lack of consistent evidence across studies might be explained in a number of ways, but because investigations of middle-class, relatively low-risk families have tended to not find a main effect of attachment insecurity on psychopathology (e.g., Bates et al., 1985; Fagot & Kavanagh, 1990; Lewis, Feiring, McGuffog, & Jaskir, 1984), whereas studies focused on more at-risk samples have (e.g., Easterbrooks, Davidson, & Chazan, 1993; Goldberg, Gotowiec, & Simmons, 1995; Lyons-Ruth, Easterbrooks, & Cibelli, 1997; Shaw, Keenan, Vondra, Delliquadri, & Giovannelli, 1997; Shaw & Vondra, 1995), one explanation that has emerged in this literature to explain such divergent findings is that attachment insecurity and disorganization should be thought of as interactive risk factors that are more predictive when considered with other potential risk factors (e.g., socioeconomic disadvantage, parent psychopathology; Belsky & Fearon, 2002; DeKlyen & Greenberg, 2008; Fearon & Belsky, 2011; Kobak, Cassidy, Lyons-Ruth, & Zir, 2005). That said, it is important to note that some studies have found risk status not to heighten insecure children's risk for developing symptoms of psychopathology (e.g., Cicchetti, Rogosch, & Toth, 1998), and main effects of attachment insecurity on symptoms of psychopathology have emerged in low-risk samples (e.g., Bohlin, Hagekull, & Rydell, 2000).

Given the sheer volume and diversity of studies that have examined the contribution of early attachment in security to the development of psychopathology and the complex pattern of findings that have emerged from such investigations, it has become virtually impossible to provide a clear narrative review of this literature. Accordingly, we recently conducted a series of meta-analyses to quantitatively evaluate the extant empirical evidence in light of key hypotheses regarding the significance of early attachment insecurity and disorganization (using observational assessments of mother–child attachment administered between 1 and 6 years) for the development of externalizing (Fearon et al., 2010) and internalizing (Groh et al., 2012) symptomatology. The need for such quantitative reviews of this literature to draw clearer conclusions regarding links between early attachment variation and psychopathology is evident by the fact that shortly after the publication of our meta-analysis on early attachment and internalizing symptoms, a second meta-analysis on the same topic was published (Madigan et al., 2013). As the results of this meta-analysis largely converged with our own, we focus our discussion on the results from our own work.

Overall, these meta-analyses provide support for the hypothesis that early attachment insecurity heightens children's risk for developing externalizing and internalizing symptoms (Fearon et al., 2010; Groh et al., 2012; Madigan et al., 2013). More importantly, however, as the meta-analysis on early mother–child attachment variation and externalizing symptoms includes nearly 70 independent samples comprising nearly 6,000 children and the meta-analysis on early mother–child attachment variation and internalizing symptoms includes over 40 independent samples comprising over 4,000 children, these meta-analyses provide a more precise estimate of the magnitude of such effects. Specifically, findings from these meta-analyses indicate that the effect of early mother–child insecurity on externalizing symptoms is modest ($d = 0.31$; Fearon et al., 2010) and significantly stronger than the surprisingly weak association between early mother–child insecurity and internalizing symptoms ($d = 0.15$; Groh et al., 2012).

Consistent with perhaps one of the most provocative hypotheses that has emerged in this literature that early attachment-relevant experiences have enduring implications for developmental (mal)adaptation (Sroufe et al., 1990), the magnitude of the effects of early insecurity we documented in our meta-analytic work were not found to vary with the age at which internalizing and externalizing symptoms were assessed (Fearon et al., 2010; Groh et al., 2012), indicating that the association between early mother–child attachment insecurity and symptoms of psychopathology does not wane over the course of development from infancy to early adolescence. In light

of such evidence, there is an urgent need for increased, theory-driven investigation of the mediating processes accounting for such effects. Indeed, questions remain regarding whether long-term continuities in the effects of attachment are due to the ongoing supportive function provided by attachment relationships or the early effects of attachment experiences on the construction of stable psychological structures, such as internal working models. Currently, there is evidence in the literature to support both processes. For example, Belsky and Fearon's (2002) analysis of the NICHD Study of Early Child Care and Youth Development data at 1–3 years suggested that the effect of attachment tended to persist primarily when there was continuity in the quality of maternal care. An analysis of the same data set by Haltigan, Roisman, and Fraley (2013) revealed that early maternal sensitivity, a robust predictor of early security (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003; De Wolff & van IJzendoorn, 1997), had an enduring effect on children's psychopathology as rated by teachers through age 15, even after accounting for concurrent effects of maternal sensitivity. Given the importance of understanding how variation in the early mother–child attachment relationship exerts an enduring force on children's mental health, we return to this topic in the next section of this chapter.

Regarding the contribution of specific types of insecurity to the development of specific symptoms of psychopathology, results from these meta-analyses provide scant evidence for claims regarding the differential predictive significance of insecurity sub-types (avoidance, resistance, disorganization) for the development of externalizing versus internalizing symptomatology (Fearon et al., 2010; Groh et al., 2012; Madigan et al., 2013). Specifically, in contrast to claims that early avoidance increases risk for developing externalizing symptoms and early resistance increases risk for developing internalizing symptoms, we found that early avoidance was significantly associated with both internalizing (d = 0.17) and externalizing (d = 0.12) symptoms, and that early resistance was not significantly associated with internalizing (d = 0.03) or externalizing (d = 0.03) symptoms. However, partially supporting claims that early disorganization increases risk for developing both internalizing and externalizing symptoms, early disorganization was found to be significantly associated with externalizing (d = 0.34), but not internalizing (d = 0.08), symptoms (Fearon et al., 2010; Groh et al., 2012). In light of recent factor analytic and taxometric evidence (e.g., Fraley & Roisman, 2014; Fraley & Spieker, 2003; Haltigan, Leerkes, et al., 2014; Haydon et al., 2012; Roisman et al., 2007), a potential reason that such theoretically unanticipated effects emerged in these meta-analyses might be that the traditional categorical coding systems used in developmental assessments of attachment may not completely capture the latent structure and taxonicity of attachment-related variation. In some studies, when empirically derived dimensions of adult dismissing and preoccupied states of mind have been used, distinct and theoretically anticipated correlates of adult attachment variation have been identified (Fraley & Roisman, 2014; Fraley & Spieker, 2003; Haydon, Roisman, Marks, & Fraley, 2011; Whipple, Bernier, & Mageau, 2011). As such, the continuous avoidance and resistance dimensions of early attachment might prove useful in identifying distinctive links between specific patterns of attachment insecurity and the development of internalizing versus externalizing symptomatology beyond what the conventional categories are able to achieve.

Following arguments that the magnitude of the effect of early attachment insecurity might vary according to whether the child experiences other psychosocial stressors (Belsky & Fearon, 2002; DeKlyen & Greenberg, 2008; Kobak et al., 2005), several moderators of the effect of attachment insecurity on the development of psychopathology were also examined in these meta-analyses. Focusing first on contextual risk factors that have been theorized to amplify the effect of attachment insecurity on the development of psychopathology, in contrast to expectations, socioeconomic status was not found to moderate the effect of early insecurity on internalizing or externalizing symptoms (Fearon et al., 2012; Groh et al., 2012; Madigan et al., 2013). Such evidence therefore does not provide support for a diathesis stress model in which the influence of early attachment on maladaptation is theorized to be strongest in economically deprived populations. Regarding psychological risk factors, our meta-analytic work did indicate that insecure children were at especially heightened risk for developing externalizing symptoms (but not internalizing symptoms [Groh et al., 2012; Madigan et al., 2013]) if they were diagnosed with a clinical disorder or had a parent suffering from psychopathology (Fearon et al., 2010). Taken together, findings from these meta-analyses provide limited support for claims that the effects of early insecurity on psychopathology are magnified when children experience other risk factors.

However, it is important to note that relatively few studies have systematically examined the effect of multiple risk factors in combination (e.g., low SES, parental psychopathology, and clinical status). For example, evidence from the NICHD SECCYD indicates that the association

between attachment and psychopathology is amplified under conditions of multiple contextual risk factors (Belsky & Fearon, 2002). Furthermore, in a recent paper, also using data from the SECCYD, Fearon and Belsky (2011) found statistically rather strong evidence that disorganized attachment, in particular, foreshadowed marked increases in teacher-reported externalizing behavior problems across the primary school years for boys reared in low-SES circumstances. Thus, these findings suggest that both gender and low-SES status might be relevant when considering attachment and the development of externalizing problems in childhood. In light of such evidence and theoretical arguments that the experience of multiple risk factors might be especially important for heightening children's risk for psychopathology (Rutter, 1979), further research in this area focused on children experiencing multiple forms of psychosocial risk is needed.

Partially supporting claims that insecurity might heighten the risk for developing externalizing symptoms in boys and internalizing symptoms in girls (DeKlyen & Greenberg, 2008), the association between early mother–child insecurity and externalizing symptoms was found to be stronger for boys than girls (Fearon et al., 2010). In contrast, early mother–child insecurity was not more strongly associated with internalizing symptoms for girls than boys (Groh et al., 2012; Madigan et al., 2013). Instead, Madigan and colleagues (2013) found that insecure boys were also at significantly heightened risk for developing internalizing symptoms. Although Groh and colleagues (2012) also found that the effect of insecurity on internalizing symptoms was larger for boys than girls, the difference was not quite statistically significant ($p = .06$). This almost certainly nonsignificant difference in findings is attributable to the slightly different selection criteria of the meta-analyses. Importantly, however, findings from both meta-analyses clearly demonstrate that insecure girls are not at higher risk than boys for developing internalizing symptoms.

In addition to providing more precise estimates of the magnitude of the effects of early insecurity on internalizing and externalizing symptoms and identifying moderators of such effects, quantitative reviews of the literature on early attachment and psychopathology have also identified key gaps in this literature. For example, there is a clear paucity of research on the significance of children's attachment relationships with fathers for social and emotional development. Because of the relative neglect of father-child relationships in research on early attachment and internalizing (but see Fagot, 1995; Rothbaum, Rosen, Pott, & Beatty, 1995; Suess, Grossmann, & Sroufe, 1992) and externalizing (but see Aviezer, Sagi, Resnick, & Gini, 2002) symptomatology, firm conclusions regarding the significance of such attachment relationships for the development of psychopathology cannot yet be drawn. There is clearly an urgent need for further research on the developmental significance of early father–child attachment security. Such research, in addition to examining the unique effects of father-child attachment on children's development, should also incorporate a broader family systems approach in which the interactive effect of attachment security with both parents is examined. For example, recent evidence suggests that developing a secure attachment relationship with one parent might offset the negative effects of developing an insecure attachment relationship with the other on children's mental health (Kochanska & Kim, 2013; see also Suess et al., 1992; van IJzendoorn, Sagi & Lambermon, 1992).

In addition, the overwhelming majority of investigations of attachment and psychopathology have used the mother-reported Child Behavior Checklist (Achenbach, Edelbrock, & Howell, 1987) or the Teacher Report Form (Achenbach, 1991) of the Achenbach System of Empirically Based Assessment (ASEBA) as measures of children's externalizing and internalizing symptoms. Because parents and teachers might find it more difficult to report on internalizing symptoms than externalizing symptoms due to the more "public" and observable nature of externalizing versus internalizing symptoms, the heavy reliance on such reports in this literature might have contributed to the surprisingly small effect for early mother–child attachment security on internalizing symptoms. Accordingly, future research in this area should make use of trained observers (e.g., clinicians) of internalizing symptoms to determine whether the effect of early insecurity on internalizing symptoms is stronger when such reports are used.

Taken together, evidence from across the literature on the developmental significance of early attachment-relevant experiences for psychopathology suggests that the quality of the early attachment relationship that children develop with their mother has a modest, yet enduring, influence on the evolution of children's mental health over the early life course. Such evidence clearly demonstrates that avoidant or resistant attachment relationships are not inherently pathological. Instead, early attachment security and insecurity are best considered as protective or risk factors, respectively, that should be considered in a broader developmental model of psychopathology. The status of disorganized attachment is more difficult to outline due to a lack of systematic research efforts in clinical populations using adequate outcome parameters. Its strong association

with child maltreatment (Cyr et al., 2010) and with growing up in institutional settings (Bakermans-Kranenburg et al., 2011) might make disorganized attachment a clearer candidate for a direct causative agent in the emergence of psychopathology, perhaps particularly for disorders with a dissociative component (Carlson, 1998; Sroufe et al., 2005b) or for problems related to aggression (Fearon et al., 2010; Lyons-Ruth et al., 1997).

THE SEARCH FOR MEDIATORS

Although an extensive volume of research has examined the basic connection between attachment and children's functioning, considerably less has been done to track the longitudinal mediating processes, residing in the child, that could help account for attachment's beneficial or detrimental effects. However, quite a number of studies have examined cross sectional and longitudinal associations between attachment and a range of theoretically plausible mediating variables. A diverse set of processes has been explored, from the underlying biology of stress regulation, to cognitive and social-cognitive mechanisms involved in social perception and social action. Understanding these mediating factors is extremely important for a full account of the role of attachment in the development of psychopathology and, in principle, in the use of attachment concepts in intervention.

Physiological Mediators

Attachment behavior is assumed to serve as the infant's primary means of regulating stress, and hence a logical mechanism mediating long-term outcomes associated with attachment security and insecurity is via alterations in the functioning of the stress system. Extensive work in humans and animals testifies to the deleterious effects of chronic stress exposure, and of the role of sympathetic, parasympathetic, endocrine, and immune systems in these effects on both emotional and physical health (Juster, McEwen, & Lupien, 2010). Furthermore, recent animal studies suggest that variations in parental care during an early critical period induce a set of more or less permanent epigenetic changes to the stress system (Weaver et al., 2004). While these fascinating findings are difficult to investigate directly in humans, they nevertheless underline the close connections between early care and the neurobiology of stress. Seminal early work by Sroufe and Waters (Sroufe & Waters, 1977) and Spangler and Grossman (G. Spangler & Grossmann, 1993) first studied the relationship between attachment patterns and heart rate during the Strange Situation Procedure. Sroufe and Waters's original paper, based on detailed case studies, appeared to indicate that the heart rates of secure infants, relative to both resistant and avoidant infants, decelerated most quickly upon reunion, and also that avoidant infants, despite their outward demeanor, showed similar elevations in heart rate to the other attachment categories during separation. These initial findings thus provided support for two key predictions of attachment theory: (1) that avoidance is a secondary behavioral strategy for coping with attachment-related stress, and not an indication of a lack of distress; and (2) that secure attachment behavior affords the infant a more efficient means of regulating physiological arousal. It is notable, however, that rather limited replication studies have been conducted to confirm these biobehavioral profiles of the secure and insecure attachment groups in the Strange Situation (see Fox & Hane, 2008) and the limited work done has not consistently found the same effects. Spangler and Grossman's (1993) study did not find differences in heart rate between secure and insecure infants during reunion, nor did Zelenko and colleagues (2005) or Oosterman and Schuengel (2007) in a sample of older children. However, Spangler and Grossman (1993) did find elevated heart rate in insecure infants, particularly disorganized infants, during the final separation episode in the Strange Situation. More recently, Hill-Soderlund and colleagues (2008) found that avoidant (vs. secure) infants exhibited greater decreases from baseline to separation in respiratory sinus arrhythmia (RSA), a marker of parasympathetic activity, suggestive of a greater recruitment of internal resources toward actively coping with stress. In a sample of 4.5-year-olds, Stevenson-Hinde and Marshall (1999) found that secure children who also scored low on behavioral inhibition showed lower heart rate after reunion than other children. This may indicate therefore that temperament and attachment interact in determining the level of physiological stress observed during separation and reunion. This is a highly plausible explanation, as the former relates to children's reactive fearfulness or innate disposition to negative affectivity while the latter concerns how attachment behavior is deployed to regulate fear or negative affect. Similarly, Nachmias, Gunnar, Mangelsdorf, Parntz, and Buss (1996) found that more behaviorally inhibited children had higher poststress cortisol levels if they were also insecure, but not when they were securely attached to their mother. Security of attachment may thus buffer against stress or act as a moderator of the initial physiological disposition (see van IJzendoorn & Bakermans-Kranenburg, 2012).

Rather more work has explored the role of markers in the endocrine axis of the stress system, and in particular the hormone cortisol, which is a key player in the hypothalamic-pituitary-adrenocortical (HPA) axis (see Juster et al., 2010). In a now classic study, Spangler and Grossmann (1993) measured 41 infants' salivary cortisol concentrations before and 15 and 30 minutes after the Strange Situation (in keeping with the relatively slow rise time of the cortisol response). Their results indicated that insecure infants showed greater increases in cortisol from baseline to post–Strange Situation, an effect that was most pronounced in the disorganized group. Nachmias and colleagues (1996) also found elevated cortisol responses to the Strange Situation in insecure infants, although in this case only among those infants who were assessed as temperamentally inhibited. Spangler and Schieche (1998) similarly found higher cortisol responses in the Strange Situation amongst insecure infants who were also highly temperamentally inhibited. Notably, it was the resistant infants in this case that showed the highest cortisol concentrations following the Strange Situation within this group.

A more recent study by Bernard and Dozier (2010) found evidence that disorganized infants ($N = 8$) may in fact show lower basal cortisol levels than infants in the other attachment categories ($N = 24$). Unlike all other studies conducted previously, Bernard and Dozier contrasted cortisol responses to the Strange Situation to a control task (play interaction), and found that disorganized infants showed a greater increase in cortisol specifically in response to the Strange Situation. For secure and organized insecure infants, neither the Strange Situation nor the play task elicited a significant change from baseline in cortisol concentration. In light of the modest sample size, the lack of effect for the insecure organized groups is difficult to interpret. However, the study is very valuable in indicating the specific relevance of an attachment-related context for eliciting heightened stress responses from disorganized infants. Frigerio et al. (2009) failed to find heightened cortisol reactivity to the Strange Situation in a sample of 114 infants. In the largest study to investigate physiological function and attachment to date ($N = 369$), Luijk and colleagues (Luijk, Saridjan, et al., 2010) did not find evidence of greater cortisol reactivity to the Strange Situation among disorganized infants, but instead found that resistant infants showed the largest increases in cortisol from baseline to post-SSP, which was particularly pronounced when their mothers reported high levels of depression. The study also examined diurnal variation in cortisol, and demonstrated that disorganized children showed a more flattened diurnal cortisol pattern compared to nondisorganized children. In a follow-up paper on the same sample, Luijk, Velders, et al. (2010) found that the cortisol reactivity effect of resistant attachment was greater still for infants with the T allele of the FKBP5 gene, which is involved in glucorticoid receptor function (and which showed a significant main effect on cortisol response as well). Related to that, Frigerio et al. (2009) examined several gene polymorphisms that had been previously related to physiological stress sensitivity (5HTTLPR, GABRA-6 [GABA receptor gene], and COMT), and although no attachment-by-gene interactions were found for cortisol, two of these three genes interacted with attachment for another stress marker, alpha amylase. Alpha amylase, which is produced in saliva, is a sensitive marker of sympathetic nervous system activity, and results indicated that insecure children with relevant alleles in the 5HTTLPR (short-form) and GABRA-6 (CC genotype) genes were prone to larger increases in alpha amylase in response to the Strange Situation. Taken together, although the evidence is not uniform, results of psychophysiological studies of attachment suggest that insecure infants show greater physiological arousal to separation or poorer down-regulation of stress during reunion. Several studies suggest that these effects are stronger or more robust when endogenous factors such as fearful or inhibited temperament, or certain gene polymorphisms, are also present.

In addition to the question of physiological function during separation-reunion situations, several studies have addressed the relationship between attachment security and stress sensitivity in contexts outside the Strange Situation, thereby addressing the generalizability of stress-attachment associations and their broader developmental significance. These studies indeed indicate that attachment influences stress responding outside the Strange Situation, particularly when combined with temperamental traits related to negative affect. Thus, in a cross sectional study by Nachmias and colleagues (Nachmias et al., 1996) insecure infants who were also temperamentally inhibited were found to show greater cortisol responses to a challenging/fear provoking task (not involving separation). Furthermore, in the same sample, Gunnar and colleagues found that insecure (as assessed at 18 months) and temperamentally inhibited infants showed greater cortisol responses to an inoculation at 15 months relative to secure, inhibited infants (Gunnar, Brodersen, Nachmias, Buss, & Rigatuso, 1996). Schieche and Spangler (2005) also found that infant attachment and temperamental inhibition interacted in their contribution
