to toddlers' cortisol responses to a challenging task. Specifically, resistant and disorganized, though not avoidant, infants who were also temperamentally inhibited, showed less of a decrease in cortisol concentration than secure inhibited toddlers and noninhibited toddlers. The implication was that the flattened decline in this group reflected an increase in cortisol output superimposed on the standard diurnal pattern. Van Bakel et al. (2004) failed to find direct evidence of greater cortisol reactivity to a challenging task in insecure 15-month-olds, assessed using the attachment Q-set, but they did find that secure attachment moderated the association between stress responsiveness and cognitive function. Gilissen, Bakermans-Kranenburg, van IJzendoorn, and van der Veer (2008) showed that temperamentally fearful children with less secure relationships showed the highest skin conductance reactivity to a scary film clip, whereas comparable children with more secure relationships showed the lowest skin conductance activity. A particularly important example of work addressing the role of attachment in children's stress responses outside the Strange Situation is the work of Ahnert and colleagues (Ahnert, Gunnar, Lamb, & Barthel, 2004). These authors looked at children's stress response during the transition to childcare. Large increases in cortisol relative to baseline were observed during the transition to care in these toddlers, and differences in this response were found in relation to attachment security during the adaptation phase, when the toddlers' mothers remained present in the childcare setting. As expected, secure toddlers showed lower cortisol levels during this phase than their insecure counterparts. This difference was not apparent at later phases of the transition to childcare, when the mothers were no longer present.

Rather little work has directly tackled the *longitudinal* associations between attachment and physiological function. However, an important study by Burgess, Marshall, Rubin, and Fox (2003) found that avoidant attachment, though not concurrently associated with RSA in infancy (14 months) was predictive of *lower* resting heart rate and RSA at age 4 years. Avoidant infants, particularly those that had also been assessed as temperamentally uninhibited at age 2, also had higher rates of externalizing behavior problems. This set of associations is significant in light of the fact that lower resting heart rate is a consistent correlate of externalizing behavior problems in later childhood (Ortiz & Raine, 2004). It has been argued that this pattern of physiological hypoarousal, in addition to being influenced by genetic and temperamental factors, may result from developmental changes in the stress system in which early chronic stress leads to a subsequent dampening of the stress system (Gunnar & Quevedo, 2007). Thus, one might speculate that one pathway from attachment insecurity to externalizing problems occurs via downward alterations in the stress system brought about by early physiological hyperarousal associated with avoidant attachment. The modest effect size for the association between avoidance and externalizing problems referred to earlier might suggest that this association is contingent on other risk factors, either temperamental in nature, or related to other psychosocial variables.

One key issue that has not been rigorously addressed thus far is the role of parental behavior in accounting for associations between attachment and children's stress functioning. There is ample evidence that the quality of parental care is linked to the effectiveness with which the child's physiological arousal is regulated, and it is unclear whether this can explain the effects of attachment, or whether the child's attachment behavior or pattern makes a unique and distinctive contribution (Gunnar, 2005). This is an important area for future research.

Of particular note, two studies have reported positive effects of attachment-focused interventions on cortisol function in young children. Dozier, Peloso, Lewis, Laurenceau, and Levine (2008) found that their Attachment and Bio-behavioral Catch-up (ABC) intervention, which is focused on promoting security of attachment and in supporting the child's stress regulation through sensitive and responsive care, led to a reduction in basal cortisol in a sample of infants and toddlers in foster care, relative to a randomly assigned control treatment (RCT). Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, and Juffer (2008) also examined changes in cortisol function in an RCT of a sensitivity-focused video-feedback intervention for toddlers at risk of behavioral problems. Although these authors found no main effect of the intervention on cortisol activity, as assessed at home during the course of the day, they found an interaction between the intervention and variation in the dopamine D4 VNTR. Among children with the 7-repeat allele of the dopamine receptor gene, who might be considered at risk of cortisol hyper-reactivity, the intervention appeared to lead to a reduction in basal cortisol. Of course, what cannot be determined is whether changes in security of attachment, sensitivity of care, or both, mediate these physiological outcomes, although the latter study also indicated that children with the 7-repeat allele showed the strongest decrease in externalizing problems when their mothers increased more than average in the use of sensitive discipline strategies (Bakermans-Kranenburg, van IJzendoorn, Pijlman, et al., 2008). These studies provide important evidence

concerning the causal role of parental sensitivity either via attachment or independently, on the child's functioning at the level of biology. Further work along these lines in the future would be highly desirable, particularly studies testing the mediating role of treatment-related changes in physiology for children's subsequent adjustment.

In summary, there is reasonably consistent, albeit mostly correlational, evidence that attachment security and insecurity relate in theoretically predicted ways to variations in young children's stress functioning. There is evidence that this relationship, particularly with respect to cortisol, but possibly other stress markers as well, is moderated by a range of factors, including maternal depression, temperament and genetic factors considered more broadly. In general, the evidence tends to suggest that the disorganized and resistant groups are most prone to increased cortisol responses to separation or other stressors. Further, it remains unclear whether attachment plays a specific role that can be distinguished from the ongoing effects of parental support in these associations. Finally, children's stress physiology appears to be modifiable by attachment-focused interventions, although how generalizable and sustained these effects are remains to be established. Thus far, no study has directly tested the role of stress physiology in mediating the links between attachment and children's developmental outcomes in correlational or treatment studies.

Cognitive, Social-Cognitive, and Affective Mediators

As noted previously, a range of *psychological* mechanisms has been proposed as potential mediators of the effects of attachment insecurity and disorganization on children's adaptation and risk for maladjustment. However, remarkably little work has systematically investigated the psychological or affective mechanisms mediating longitudinal associations between attachment and later outcomes. Nevertheless, studies do suggest that attachment is coherently linked to several cognitive and affective functions, in ways that are broadly in line with predictions from attachment theory. For an excellent in-depth review, the reader is encouraged to read Dykas and Cassidy (2011). In the following sections, we summarize the results of studies testing links between attachment and (1) social information processing, (2) theory of mind, and (3) emotional reactivity and regulation.

Social Information Processing

A number of studies have investigated the natural interpretation arising from attachment theory that internal working models should influence children's encoding and interpretation of social experiences or socially relevant cues in systematic ways. One of the earliest studies to examine this idea was conducted by Cassidy and colleagues (Cassidy, Kirsh, Scolton, & Parke, 1996). In the first of their reported experiments they followed a group of 60 3.5 year-old children who had been observed in the Strange Situation at 15–18 months to assess several aspects of their representations of, or social-information processing about, peers. In the first experiment, children were read several stories involving social interactions in which the participant was the imagined protagonist. Following a social-challenge event (e.g., the child is hit by a ball, a child's toy is broken by a peer), the experimenter asked a number of questions regarding peer intentions, imagined social responses that the child might engage in, and their thoughts about their peers' feelings. Although inferred intentions did not vary by prior attachment status, avoidant children tended to imagine engaging in more negative social actions in response to the challenge (than previously secure and resistant children). In a second experiment, older children's (Grade 1) responses to the same stories were examined in relation to concurrent attachment security as assessed using the Main and Cassidy (1988) procedure. In this older sample ($N = 33$), evidence emerged of insecure children's tendency to infer hostile intentions to peers, to entertain negative social actions in response to peer challenge and to provide less positive responses regarding their peers' feelings after the event had occurred. The findings also indicated that these differences in thinking style were related in turn to the quality of children's peer relations, as assessed via a sociometric instrument. A subsequent study by Kirsh and Cassidy (1997) looked at children's attention to attachment-relevant stimuli (pictures of mother–child interactions of varying valence) using the same cohort as study 1 in Cassidy et al. (1996). In the first task, they showed children three pictures side-by-side, depicting positive, negative, and neutral interactions. Although no differences were found in children's looking time to pictures of differing valence, avoidant children tended to look away from the stimuli more frequently than the other groups in general. Of course, while the content of the stimuli may well have been relevant to this difference, it is also possible that general inattentativeness could also explain such a finding. To test this, they showed children attachment-relevant and attachment-irrelevant images side by side and measured their looking time. Consistent with expectations, the authors found that insecure children spent less time looking at the attachment-relevant images, compared to the attachment-irrelevant images,

than their secure counterparts. In the same sample, Kirsh and Cassidy also found evidence to suggest that recall for attachment-relevant stories may be biased by attachment security, with previously secure children showing better memory for stories involving responsive care than insecure children. More recently, in a sample of 7–8 year-olds, Ziv, Oppenheim, and Sagi-Schwartz (2004) used films depicting negative, neutral or ambiguous peer responses to a bid by the study child to initiate play, to test the association between early attachment and attributional biases. Possibly reflecting Cassidy et al.'s finding in their experiment 1, Ziv et al., did not find differences associated with attachment at the level of attribution, but rather in their evaluations of prosocial responses. In particular, secure children tended to endorse a greater belief in the value (and positive consequences) of competent social responses to the peer challenge than insecure children. Although working with a much older age group, Dykas, Woodhouse, Ehrlich, and Cassidy (2012) recently presented fascinating evidence regarding the connections between social-information processing and adolescent attachment. In this study, adolescents interacted with an unfamiliar peer for 10 minutes, and were then subsequently interviewed regarding their perceptions or recollections of that interaction. Immediately after the interaction adolescents' perceptions of the interaction did not differ according to their attachment status. However, when the same assessment was repeated two weeks later, insecure adolescents' recollection of the interaction shifted in a negative direction more steeply than secure adolescents, viewing the interaction as having been less positive and more hostile (on the part of the unfamiliar peer). The majority of these studies (with the exception of Cassidy et al., 1996; experiment 2) have not directly tested whether these social-cognitive processes might mediate attachment effects on social competence or psychopathology (though see Raikes & Thompson, 2008, for one study not finding mediation).

Theory of Mind

Several authors have suggested that attachment may promote the development of children's Theory of Mind, or mentalizing abilities, and that this might provide an account of the longitudinal benefits associated with secure attachment. At least nine papers have been published reporting on the association between attachment and theory of mind, as assessed by a range of procedures designed to measure false belief understanding or perspective taking. These studies have produced mixed results. One of the first of these was a report by Meins and colleagues (Meins, Fernyhough, Russell, & Clark-Carter, 1998). Using an unexpected transfer task, they found that children who had been secure in infancy showed superior false belief understanding at age 4 (though not age 5). This longitudinal finding from infancy to age 4 was replicated more recently by McElwain and Volling (2004), although not by Meins et al. (2002) or Symons and Clark (the latter relating age 2 security to age 5 false belief understanding; see Symons & Clark, 2000). Laranjo and colleagues (2008) did not find overall associations between attachment, as assessed with the AQS at age 15 months, and perspective taking at age 2 years, although an association was apparent for boys. In an early cross sectional study, Fonagy, Redfern, and Charman (1997) found that attachment, as measured with the Separation Anxiety Test, was associated with belief-desire reasoning in a sample of 3–6-year-olds (see also De Rosnay & Harris, 2002). Other cross sectional studies have also produced positive findings (Arranz, Artamendi, Olabarrieta, & Martin, 2002; Repacholi & Trapolini, 2004; Symons & Clark, 2000) as well as at least one negative finding (Greig & Howe, 2001). Broadly speaking then, there is evidence that attachment may be related to theory of mind performance, but the association is not consistently replicated, particularly in longitudinal studies. Meins and colleagues (2002) argue that maternal mind-mindedness, which as we noted already is correlated with attachment security, is a more robust predictor of children's theory of mind performance than attachment, and may account for its apparent effects.

There is relatively consistent evidence that attachment is associated with children's recognition and understanding of emotions (as opposed to false beliefs). For example, Steele and colleagues (Steele, Steele, & Croft, 2008; Steele, Steele, Croft, & Fonagy, 1999) found that children aged 6 (though not 11) who had previously been insecure with their mothers in infancy were poorer at labeling emotional faces, particularly positive emotions, and understanding mixed emotions, than secure children. In a cross sectional study of 7-year-olds, Colle and Del Guidice (2011) found that insecure children (as assessed with the Manchester Child Attachment Story Task [MCAST]; Goldwyn et al., 2000) performed less accurately in matching pairs of dynamic emotional faces. Laible and Thompson (1998) found that secure children (using mother-completed AQS) between the ages of 2.5 and 6 years performed better on an emotional perspective taking task (after controlling for age), an effect which was mostly apparent in relation to negative emotions. These results were also replicated by Greig and Howe (2001) in a sample of 4.5-year-olds assessed using the Attachment Story Completion Task of Bretherton, Ridgeway and Cassidy (1990) and in two

low-SES samples of preschoolers (Kidwell et al., 2010; Raikes & Thompson, 2006). Notably, in the Raikes and Thompson (2006) study, mother–child conversations in secure dyads tended to involve more frequent reference to emotion terms, which itself was associated with children's emotional perspective taking/understanding (see also Oppenheim, Koren-Karie, & Sagi-Schwartz, 2007; Raikes & Thompson, 2008). Although few studies have examined clinical samples, Barone and Lionetti (2012) found that disorganization in the MCAST was associated with poorer overall emotion comprehension (indicating recognition of emotion, understanding the causes of emotion and emotion regulation strategies) in a sample of late-adopted preschoolers.

Overall then, there is relatively consistent evidence that attachment security is related to better emotion recognition and emotion understanding in preschool and school aged children, although existing studies tend to be based on modest samples, using a wide range of tools for assessing attachment and emotion understanding, and longitudinal data beginning in infancy is limited. Few studies have thus far directly tested the mediating role of emotion understanding or theory of mind in the association between attachment and psychopathology. The broader literature on the developmental significance of social-cognitive skills in children's social competence suggests that this is a hypothesis worthy of further investigation (e.g., see Astington, 2003). As eloquently summarized by Oppenheim (2006), many authors in the field see deep connections between security of attachment, the coherence of internal working models, and the ways parents and children co-construct affectively meaningful narratives of social and relational experiences during interactions. These internalized, co-constructed narratives, scripts or models may then shape future interpersonal and emotional functioning, in ways that may enhance or undermine adaptation and adjustment. The evidence reviewed in the previous sections appears broadly consistent with this way of thinking.

Emotional Reactivity and Self-regulation

The first longitudinal studies of attachment and later child development drew attention to the potentially important mediating role of the child's emerging capacity for self-regulation (Arend, Gove, & Sroufe, 1979). Arend and colleagues (1979) for example found that infants classified as secure at 18 months showed greater ego-resiliency and ego-control as preschoolers, based on both laboratory observations and reports from kindergarten teachers. Similarly, in the well-known Minnesota study (Sroufe et al., 2005b), consistent evidence was found suggesting that insecure children were more dependent on teachers in preschool and preadolescence (Urban, Carlson, Egeland, & Sroufe, 1991). Gilliom, Shaw, Beck, Schonberg, and Lukon (2002) examined emotion-regulation strategies directly in a sample of low-SES 3.5 year-old boys by observing emotion-regulatory behaviors during a task designed to elicit frustration. The authors coded regulatory behaviors, including active distraction, seeking information, passive waiting, and comfort seeking as well as the child's overall emotional response. In addition to showing that the hypothesized regulatory behaviors did reduce children's levels of anger in temporal contingency analyses, they also found that secure boys tended to employ more of these regulatory behaviors during the frustration task than insecure boys. These connections between emotional reactivity and regulation appear to emerge early in development. For example, Leerkes and Wong (2012) found that during a frustration task avoidant infants engaged in greater self-soothing and used fewer mother-directed regulatory behaviors than secure infants, and that resistant infants showed more negative affect and engaged in fewer adaptive regulatory strategies. Similarly, Sherman, Stupica, Dykas, Romas-Marcuse, and Cassidy (2013) found that resistant infants at age 1 showed the greatest emotional reactivity in a frustration task, and avoidant infants the least, with secure infants falling in the middle. Somewhat consistent with this, Martins and colleagues (Martins, Soares, Martins, Tereno, & Osorio, 2012) found that avoidant infants showed less emotional reactivity during object-focused play with the mother than secure or resistant infants. Underscoring the potential importance of emotion-related processes for psychopathology, Murray and colleagues (2011) recently found that the association between maternal postnatal depression and later offspring depression was mediated by a pathway involving insecure (primarily avoidant) attachment at 18 months and low ego resilience in childhood. Finally, Dawson and colleagues (Dawson et al., 2001) have also presented data indicating that insecurely attached infants show differences in EEG spectra—specifically reduced relative left frontal alpha power—than securely attached infants. Such neural effects are interesting, because alpha asymmetries of this nature have been found to be quite stable over time (Vuga, Fox, Cohn, Kovacs, & George, 2008) and are associated with negative emotionality and behavior problems in infancy and toddlerhood (e.g., Dawson et al., 2003).

Berlin and Cassidy (2003) directly addressed the suggestion indicated by several past studies that mothers of insecurely attached infants react in systematic ways to encourage or discourage the infant's affect expressiveness. Mothers were asked a series of questions regarding their attitudes to their child's emotions, and in particular their tendency to control their child's expression of negative affect. Mothers of avoidant children reported exerting greater control, and mothers of resistant children less control, over their child's emotions than mothers of secure children. These findings are quite consistent with theorizing by Cassidy (1994) and Berlin and Cassidy (1994), that parental working models of attachment influence mothers' unconscious responses to the child's affect that in turn serve to regulate or maintain the parent's state of mind with respect to attachment.

In addition to emotion-regulation, some studies have also indicated that security of attachment may influence children's self-regulation skills more broadly. For example, using data from the NICHD SECCYD study, Fearon and Belsky (2004), found that insecure attachment in infancy was associated with later attentional control, as measured objectively using a continuous performance test at age 54 months. The connections between attachment and attentional control in this study also appeared to be amplified by social-contextual risk, particularly for boys. In a more recent paper, Drake, Belsky and Fearon (2013) examined teacher's reports of social self-control between Grades 1 and 5 and found that earlier security, at both 15 months and 3 years, predicted higher levels of social self-control. Social self-control in turn predicted Grade 5 school engagement, and mediated the effects of early attachment on school engagement.

Thus, there is evidence that attachment is associated with a broad range of cognitive, social-cognitive, and emotional competencies that are plausible candidates for mediating mechanism in the effect of attachment security and insecurity on children's adjustment. Relatively little work has systematically examined these processes longitudinally and tested mediation directly, and fewer studies still have examined these various candidate mediators simultaneously, to tease apart their joint and independent effects. The greater capacity for flexible emotion-regulation or self-regulation might plausibly underpin some of the other competencies associated with security, including emotion understanding and empathy (e.g., see Panfile & Laible, 2012), as well as mediate effects of attachment on later emotional and behavioral problems (e.g., see Belsky, Fearon, & Bell, 2007), but large-scale studies designed to test this programmatically have yet to be done.

ADULT ATTACHMENT AND PSYCHOPATHOLOGY

The conceptual links between attachment and psychopathology have been examined for both infant attachment and adult attachment classifications. Past theorizing tended to assume that children with a resistant attachment should show more internalizing problems, and avoidant children would be at risk for externalizing problems, whereas children with disorganized attachment relationships might be at a heightened risk for developing either internalizing or externalizing symptoms (see previous section). As noted earlier in this chapter, meta-analytic results provided only partial support for these hypotheses, in particular the role of resistant attachment appeared to be less clear-cut than expected (see Fearon et al., 2010; Groh et al., 2012).

The expected associations between the organized adult attachment classifications and psychopathology were roughly analogous to those suggested for children: preoccupied attachment representations might be associated primarily with internalizing disorders such as depression or borderline personality disorder, whereas dismissing representations were expected to be associated with externalizing indices of distress, such as eating disorders, conduct disorders, and hard-drug use (Tyrrell & Dozier, 1997; Tyrrell, Dozier, Teague, & Fallot, 1999). Contrary to infant disorganized attachment however, the hypothesis concerning the psychopathological correlates of unresolved attachments were more distinctively suggested to be in the range of disorders with a dissociative component such as posttraumatic stress disorders (Harari et al., 2009; Hesse, 1999; Liotti, 2004; Sroufe et al., 2005b).

From the number of studies involving clinical samples it is evident that from the early years onward the AAI has been considered relevant to psychopathology. Selecting studies that were based on the original coding system with the conventional three-way and four-way classifications of the AAI (Main et al., 2003), Bakermans-Kranenburg and van IJzendoorn showed in a review of the first 10,000 AAIs that 76 out of 218 studies involved clinical samples, whereas "only" 36 studies focused on nonclinical low-risk mothers and 13 on fathers (Bakermans-Kranenburg & van IJzendoorn, 2009).

The nonclinical low-risk North American mothers provided a norm distribution for comparison with classification frequencies in clinical groups. They showed a combined distribution of 23% dismissing, 58% autonomous, and 19% preoccupied classifications ($N = 748$). With the unresolved category included, the norm distribution was 16% dismissing, 56% autonomous, 9% preoccupied, and

18% unresolved classifications (N = 700). These distributions were quite similar to those in the larger group of all nonclinical and not at-risk groups (irrespective of gender, country, age, and parenthood), with a three-way distribution of 29% dismissing, 56% autonomous, and 14% preoccupied (N = 4,392), and a four-way distribution of 24% dismissing, 50% autonomous, 9% preoccupied, and 16% unresolved (N = 4454). Thus, albeit a "clean" and therefore selective group of North American nonclinical low-risk mothers, its usefulness as a norm group is corroborated by its similarity to the larger, more global group of nonclinical samples.

As expected, the combined clinical groups showed an extremely deviating distribution of AAI classifications compared with the norm group. In the combined clinical samples, 37% were classified as dismissing, 27% as autonomous, and 37% as preoccupied. In short, a large majority (73%) of the clinical adults (N = 1956) were classified as insecure. Clinical samples were more often dismissing than the norm group, and in contrast to samples at-risk (e.g., single low-SES mothers, adolescent mothers) they were also more often preoccupied. With the unresolved category included, the combined sample of clinical individuals showed the following distribution: 23% dismissing, 21% autonomous, 13% preoccupied, and 43% unresolved. The unresolved category was strongly overrepresented, and the dismissing and preoccupied categories were overrepresented as well, but to a lesser extent than the unresolved category.

In search for links between specific disorders and one or more of the insecure attachments we compared the combined distributions of clinical samples of a similar kind with those of the norm group. Disorders with an internalizing orientation, in particular borderline personality disorders, have been suggested to be associated with maximizing attachment signals. Indeed, the three-way distribution of suicidal and borderline patients showed a significant overrepresentation of preoccupied attachments, whereas dismissing attachments were not significantly overrepresented. In the four-way distribution unresolved attachments were also overrepresented. Similarly, individuals with abuse experiences or current PTSD were particularly characterized by unresolved loss or trauma. In contrast, depressive symptomatology was not related to higher rates of unresolved attachment, but both in the three-way and four-way distributions dismissing and preoccupied classifications were overrepresented.

The strong association between PTSD and unresolved loss or trauma is perhaps to be expected given the similarity in indicators, notably intrusive symptoms and avoidance (Fearon & Mansell, 2001). Stovall-McClough and Cloitre (2006) found that abused women who were classified as unresolved with regard to trauma were 7.5 times more likely to be diagnosed with PTSD. Examining combat veterans with PTSD, the continuous score for unresolved deployment-related trauma overlapped almost completely with severity of PTSD (r = .80) in one study (Harari et al., 2009). The overlap between unresolved loss and PTSD in the other study was 50%, but in that study combat-related traumatic experiences were not queried in the AAI, decreasing the overlap between PTSD and unresolved state of mind (Nye et al., 2008). Such results could be considered as validation of the unresolved category; however they also show the limits of the coding system in terms of the incremental validity of the classification over existing PTSD measures such as the CAPS (Clinician Administered PTSD Scale; Blake et al., 1998).

Schizophrenia appeared to be related to dismissing attachment, but only one study was available at the time of the meta-analysis (Tyrrell & Dozier, 1997). More recently, one study using the AAI added to that database, confirming the link with dismissing attachment in a sample of 34 patients with a first episode of psychosis (MacBeth, Gumley, Schwannauer, & Fisher, 2011). Self-reported schizotypal symptomatology was related to AAI unresolved trauma and unresolved loss in a psychiatric sample of trauma survivors (Riggs et al., 2007). Other studies used self-reported adult attachment measures and are thus basically incomparable, and the results were inconsistent (versus Ponizovsky, Nechamkin, & Rosca, 2007; e.g., Ponizovsky, Vitenberg, Baumgarten-Katz, & Grinshpoon, 2013).

Externalizing problems, in particular antisocial or conduct disorders, were expected to be associated with dismissing attachments, which was confirmed; however at the same time the preoccupied category was also overrepresented. The four-way distribution demonstrated that externalizing problems were associated with increased rates of unresolved loss or trauma as well. When distinguishing between the various types of violence, that is violence within the family (against partner or child), against the outside world (criminal offenders), or against their own body (eating disorders, drug addiction), we found that family violence was associated with more preoccupied representations, whereas violence against the outside world was strongly associated with dismissing attachment representations, and self-directed violence with both dismissing (three-way) and preoccupied and unresolved (four-way) classifications. The three-way and four-way distributions of samples with self-directed violence were based on

samples that showed hardly any overlap (the majority of these studies presented *only* three-way or four-way distributions). This may explain the pattern of results with an overrepresentation of the dismissing classification in the three-way distribution, and an overrepresentation of the preoccupied classification in the four-way distribution. A more recent study on incarcerated women, most of whom had been convicted for drug-related crimes, showed an underrepresentation of secure classifications and an overrepresentation of preoccupied and unresolved classifications (Borelli, Goshin, Joestl, Clark, & Byrne, 2010).

Given that the AAI was developed in the context of the prediction of infant-parent attachment and child socioemotional development, one might expect an enhanced risk of parental insecurity in samples with child psychopathology. Insecure parental attachment increases the likelihood of insensitive parenting (van IJzendoorn, 1995), biased perceptions of child behavior and intentions, harsh discipline (Verschueren, Dossche, Marcoen, Mahieu, & Bakermans-Kranenburg, 2006), and instability of the caregiving environment (e.g., Crowell, Treboux, & Brockmeyer, 2009). Indeed, the large majority of parents of children with psychopathology were found to be insecure (83%). Both the dismissing and preoccupied classifications were overrepresented. Importantly, only psychological problems appeared associated with more insecure attachment, not physical disability, even if they were severe and with hampering consequences for social interactions, like blindness or deafness. The set of studies with adults with physical handicaps was small, but the finding that their attachment distributions did not significantly deviate from the norm is important in terms of discriminant validity (Bakermans-Kranenburg & van IJzendoorn, 2009).

From a clinical perspective, the Cannot Classify classification might be of particular interest. This category, identified by Hesse (1999, 2008), was intended to capture AAIs that showed a global collapse of coherence across the entire discourse. Contrasting strategies for maximizing and minimizing the expression of attachment within the context of one and the same interview is a hallmark of this classification. Minde and Hesse (1996) presented a case study of a mother with highly conflicted feelings toward her role as a caretaker, where the identification of her attachment representation as Cannot Classify (incoherent and switching between contrasting strategies) helped the therapist in choosing a specific treatment approach. In normal, nonclinical samples hardly any adult is assigned this classification, but in samples of criminal offenders (van IJzendoorn et al., 1997), victims of sexual abuse (Stalker & Davies, 1998), and suicidal adolescents (Adam, Sheldon-Keller, & West, 1996) the category was overrepresented. However, at the time of the meta-analysis an insufficient number of AAI studies with separate Cannot Classify ratings hampered testing the association of this category with psychiatric disorders, and that situation has not changed since.

One study reported on the association between psychopathology and reflective functioning. Reflective functioning in the context of the AAI refers to the adult's capacity to reflect upon memories of the childhood relationship with the parents in mentalizing terms, that is, showing awareness of mental states in others, and the ability to experience one's own and others' emotions in a nondefensive way without becoming overwhelmed (Fonagy, Target, Steele, & Steele, 1998; Slade, 2005). Reflective functioning is closely related to metacognitive monitoring during the AAI, and indeed associated with AAI security (Fonagy, Steele, Steele, & Holder, 1997). During the AAI, female inpatients with depression showed significantly lower capacity for mentalization as assessed with the Reflective Functioning scale than healthy controls (Fischer-Kern et al., 2013).

A literature search with the key words *adult attachment* and *psychopathology* shows that not that many studies with clinical samples have accumulated after our meta-analysis was published in 2009. The majority of the studies on clinical samples used self-report measures of adult attachment, such as the Attachment Style Questionnaire (Feeney, Noller, & Hanrahan, 1994), or the Experiences in Close Relationships questionnaire (Bartholomew & Horowitz, 1991; see also Mikulincer & Shaver, 2007). The preference for an efficient paper-and-pencil or website-based instrument is not difficult to understand, but the results are—notwithstanding some early optimism (e.g., Bernier & Dozier, 2002; Shaver & Mikulincer, 2002)—not directly comparable with those of the AAI. As demonstrated meta-analytically for nonclinical samples, the overlap between the AAI and adult attachment questionnaires is trivial to small (r =.09; Roisman, Holland, et al., 2007). Similarly, in a psychiatric sample of trauma survivors self-report and AAI attachment classifications were not related, and different associations with psychological dysfunction emerged for the two measures (Riggs et al., 2007). In a study on pregnant women from deprived backgrounds, Pianta, Egeland, and Adam (1996) found that preoccupied adult attachment representations appeared to be associated with highest levels of self-reported psychopathology (as assessed with the Minnesota Multiphasic Personality Inventory-2 [MMPI-2]) whereas females with dismissing attachments showed the lowest levels of psychopathology

as they emphasized independence and low anxiety. The secure-autonomous individuals scored in-between the two insecure groups. This suggests that self-reports of attachment, parenting style or psychopathology may suffer from systematic response biases with overly negative and worried reports by individuals with preoccupied attachments, and overly positive and defensive reports by dismissing individuals.

In sum, whereas the original hypotheses suggested that preoccupied attachment representations might be associated primarily with internalizing disorders, dismissing representations with externalizing problems (Tyrrell & Dozier, 1997; Tyrrell et al., 1999), and unresolved attachments would predispose to the development of disorders with a dissociative component such as posttraumatic stress disorder, the emerging evidence confirms only the latter hypothesis consistently: indices for unresolved loss or other trauma are strongly correlated with posttraumatic stress symptoms assessed independently. Externalizing and internalizing disorders both show elevated levels of preoccupied and dismissing attachments but more specific associations have remained equivocal across studies. Firm evidence on the causal direction of the associations is still largely absent because the overwhelming majority of studies in this area are correlational with most of them concurrently measuring both attachment and psychopathology. More experimental studies are therefore badly needed.

MECHANISMS IN ADULT ATTACHMENT AND PSYCHOPATHOLOGY

What are the neural mechanisms underlying attachment-related individual differences in parenting behavior? Adults with insecure internal working models of attachment may process attachment-relevant social information in one of two ways, either defensively excluding the information from further processing, or processing the information in a negatively biased manner, congruent with their negative attachment-related experiences (Dykas & Cassidy, 2011). In the past decade, the neural mechanism underlying the perception of infant attachment signals, in particular infant crying, has been the focus of several functional Magnetic Resonance Imaging (fMRI) studies. These studies have shown that a highly interactive cognitive-affective neural network is involved in the perception of infant crying (Bos, Panksepp, Bluthe, & van Honk, 2012).

The amygdala is an important functional hub within this network. The amygdala is part of the limbic system and plays a role in the detection of threat and the experience of fear and aversion (Davis & Whalen, 2001; Fusar-Poli et al., 2009; Gamer, Zurowski, & Buchel, 2010; Morris et al., 1998). It is activated during exposure to infant crying (Lorberbaum et al., 2002; Riem et al., 2011; Seifritz et al., 2003) and connected with other brain regions that are involved in the perception and evaluation of crying such as the orbitofrontal cortex and the anterior cingulate cortex (Riem et al., 2012). Heightened amygdala activation is an indication of hyperemotionality and has been observed in depression and anxiety disorders (Rauch et al., 2000; Yang et al., 2010) and in intrusive mothers (Atzil, Hendler, & Feldman, 2011).

Several fMRI studies also point to a role of the amygdala in the processing of attachment-related information. For example, Buchheim et al. (2006) found elevated amygdala activation in individuals with unresolved loss during the Adult Attachment Projective (AAP). In 10-year-old children amygdala hyperactivity was found to mediate the association between adverse early attachment experiences (growing up in institutionalized care) and decreased eye-contact during dyadic interaction (Tottenham et al., 2011). This indicates that early adverse attachment experiences affect amygdala activity, possibly because of the vulnerability of the amygdala to environmental exposures in early life (Lupien, McEwen, Gunnar, & Heim, 2009; Sabatini et al., 2007) which in turn influences social behavior. Amygdala hyperactivity might thus be one of the mechanisms underlying the association between adult attachment representation and insensitive parenting.

A number of fMRI studies on the influence of adult attachment have focused on the perception of infant facial expressions. Strathearn et al. (2009), examining neural responses to own infant smiling and sad faces, found that mothers with an insecure attachment representation (as assessed with the Crittenden coding system) showed less activation in dopaminergic reward regions such as the ventral striatum compared with secure mothers. Lenzi et al. (Lenzi et al., 2012) found that individuals with a dismissing AAI classification showed more activation in the limbic and mirror neuron system and greater deactivation in the OFC and ACC in response to infant facial expressions compared with individuals with a secure representation. The authors suggest that hyperactivation of limbic and mirror system areas may reflect emotional dysregulation of infantile experiences of rejection and lack of protection, whereas increased deactivation of fronto-medial areas may be the expression of the inhibition of attachment behaviors, which is a typical aspect of dismissing attachment. Galynker et al. (2012) examined the influence of depression and AAI insecurity on neural responses to

images of the participant's mother, friend, or a stranger. No effects of attachment security on amygdala activation were found, perhaps because of the absence of negative affective stimuli.

The amygdala thus seems to be involved in both adult attachment and the perception of infant signals. Riem et al. (2012) explored whether amygdala hyperactivity played a role in the relation between insecure adult attachment representations and negative emotional and behavioral responses to infant crying. Adults with insecure attachment representations showed heightened amygdala activation when exposed to infant crying compared to individuals with secure attachment representations. In addition, they reported more irritation during infant crying, and they used more excessive force as indicated by grip strength using a hand-grip dynamometer during exposure to infant crying. The relation between attachment representation and emotional or behavioral responses to infant crying was however not mediated by amygdala activation, indicating that feelings of irritation and the use of excessive force in response to infant crying in insecure individuals cannot be solely explained by a hyperactive amygdala. Other brain regions involved in attachment-related influences on the perception of infant crying may be regions important for empathy and emotion understanding, such as the insula and the inferior frontal gyrus (IFG). Interestingly, intranasal administration of oxytocin decreased amygdala responses and increased insula and IFG responses to infant crying (Riem et al., 2011).

Disruptions in amygdala *connectivity* may also play a role in the negative perception of infant crying in insecure individuals. The amygdala is strongly connected with other brain regions within a neural network involved in the perception and evaluation of crying (Riem et al., 2012), and neural disorganization within this network has been associated with anxious parenting (Atzil et al., 2011). Disruptions in amygdala connectivity have been observed in patients with depression and anxiety disorders (Dannlowski et al., 2009; Pillay, Gruber, Rogowska, Simpson, & Yurgelun-Todd, 2006) and might also play a role in insecure attachment representations.

It has been proposed that the attachment system would be located in the orbitofrontal cortex (OFC; Schore, 2001). The OFC is involved in reward processing, emotional regulation, and the perception of infant signals (Banks, Eddy, Angstadt, Nathan, & Phan, 2007; Kringelbach, 2005; Kringelbach et al., 2008; Stein et al., 2007; Swain & Ho, 2010). The OFC shows a very rapid and specific response to infant faces and it has been suggested that this might be the brain basis for the "innate releasing mechanism" described by Lorenz (Kringelbach et al., 2008). However, it is by no means the only brain region involved in attachment, as evident from the significance of amygdala activity in attachment-related studies. Coan (2008) suggested that searching for the identification of a single attachment neural construct is like "trying to find the real artichoke by peeling away all its leaves." (pp. 242). The attachment system most likely relies on a comprehensive neural network and no single neural construct is decisive. Indeed, given the emotion, attention, motivation, empathy, decision-making and other thinking processing involved, it has been suggested that networks of hypothalamic–midbrain–limbic–paralimbic– cortical circuits act in concert to support sensitive parenting (Swain, 2011).

ATTACHMENT AND INTERVENTION

The field of attachment, with its empirically well-placed emphasis on the environmental causes of security and insecurity, its clearly specified mechanisms of influence, and its well-developed evidence base regarding the longitudinal outcomes linked to insecurity, provides a coherent framework for intervention. In this final section, we first focus on interventions developed to promote parental sensitivity or secure infant attachment, and then turn to interventions aimed at affecting insecure adult attachment, and the role of adult attachment (of both client and therapist) in clinical process and outcome. Intervention studies in this field serve several crucial functions: first, they help establish the plasticity of attachment to environmental modification. Second, they provide highly relevant information for examining causal questions about the mechanisms driving attachment security and insecurity. Third, and most importantly, they are vital for demonstrating the potential impact and clinical value of attachment as a focus for improving outcomes for children and adults.

Parenting Interventions

In light of the extensive evidence concerning the environmental determinants of early attachment and the consistent association between parenting sensitivity and attachment security, a vital question is whether early preventive interventions are effective in enhancing parental sensitivity and in doing so can they improve rates of infant attachment security. Furthermore, important secondary questions concern the type of intervention is most successful and for whom. A great deal of work has gone into the development and testing of attachment-inspired intervention or

prevention programs. The interventions apparent in the literature vary widely in intensity, duration, and focus, and the relevant studies have used highly divergent outcome measures. Some programs aim at enhancing parental sensitivity, others at affecting adult insecure attachment representations and still others at the parent-infant relationship (infant attachment). The vast majority of intervention studies have aimed to bring about change at the level of parental sensitivity or the level of infant-parent attachment, but a few address adult attachment as an outcome measure. We focus here on attachment-based parenting interventions and we do not include parent behavior-management interventions aimed at helping parents of children with severe behavior problems or conduct disorders (e.g., Scott & O'Connor, 2012; Webster-Stratton, Reid, & Hammond, 2004; Webster-Stratton, Rinaldi, & Reid, 2011). A meta-analysis on the effectiveness of sensitivity and attachment interventions with 81 studies (N = 7,636) on sensitivity and 29 studies (N = 1,503) on infant–parent attachment showed that randomized interventions with a focus on sensitive behavior were most effective in changing insensitive parenting (d = 0.33) as well as infant attachment insecurity (d = 0.20; Bakermans-Kranenburg et al., 2003). The most effective interventions did not include a large number of intervention sessions with the families, and they did not necessarily start before birth or even early in life. Indeed, it was notable that interventions with up to a maximum of 16 sessions, starting 6 months after birth or later, were most effective. Surprisingly, intervention studies were generally effective regardless of the presence or absence of multiple problems in the family. It might be expected that at-risk groups would have different needs, and thus may profit from different types of interventions, particularly more intensive interventions, than lower risk or normative populations. However, in the set of multiproblem samples (30 studies, N = 4,119 families), interventions focusing on sensitivity were more effective (d = 0.48) than all other types of intervention combined (d = 0.25). The most effective interventions consisted of fewer than 16 sessions.

A key finding from this meta-analytic work was that attachment insecurity emerged as being more difficult to change than maternal insensitivity. Nevertheless, the fact that sensitivity-focused interventions led to significant improvements in security, and that those studies that achieved a greater change in sensitivity (ds >.40) tended to yield better outcomes for the child's attachment security (d = .45). Interventions that were less effective in promoting sensitivity did not appear to lead to consistent changes in attachment security. Similar to intervention effects on parenting sensitivity, highly effective interventions (with a behavioral focus, i.e., improving parental sensitivity) were effective in improving attachment regardless of the presence or absence of multiple problems in the family.

For disorganized attachment, the overall effectiveness of parenting interventions was evaluated in two more recent meta-analyses (15 studies, N = 842) and, in marked contrast to findings regarding the impact of interventions on secure attachment, no significant overall impact of the interventions was found for disorganized attachment, d = 0.05 (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2005, 2008). However, interestingly, the five intervention studies focusing on parental sensitivity were found to be effective in reducing rates of disorganized attachment (d = 0.26), and were significantly more effective than interventions with a different or broader focus (d = –0.08). This finding is intriguing as disorganized attachment has been more strongly and consistently associated with frightening and atypical parenting (e.g., Madigan, Bakermans-Kranenburg, et al., 2006) than parental sensitivity which was the focus of the effective interventions. It is possible that despite the focus on sensitivity, these interventions may also have been successful in reducing frightening or extremely intrusive or unresponsive parental behavior, or in reducing parental dissociation by focusing parents' attention on the child's behavior (Bakermans-Kranenburg et al., 2005). Unfortunately, thus far studies have not explicitly measured parental frightening or anomalous behavior as an outcome to test whether this might account for observed effects on disorganized attachment.

One of the interventions effective in reducing disorganized attachments is video-feedback intervention to promote positive parenting (VIPP; Juffer, Bakermans-Kranenburg, & van IJzendoorn, 2008) which is a short-term, home-based intervention directed at sensitive parenting behavior via video feedback. VIPP has been tested in a series of randomized control trials on a range of nonclinical and clinical samples (children with autism spectrum disorders—Poslawsky et al., 2014; including samples with eating disordered mothers—Stein et al., 2006; children at high risk for externalizing problems—Van Zeijl et al., 2006). The main objective of VIPP is to promote the parent's sensitivity by showing and stimulating mentalization of moments of sensitive parenting of the parent in carefully selected video fragments. In a randomized control trial with early adopted children the VIPP appeared to significantly reduce rates of disorganized attachment, probably because parents had learned to mentalize their interactions with the child, reflect on their own role in the relationship, and to keep the child's

attachment signals more in focus, and thus, were less distracted or dysregulated by other external or internal stimuli (Bakermans-Kranenburg et al., 2005).

Only a few intervention programs have the explicit goal of decreasing disorganized attachments by diminishing threatening behaviors. One of them is the Attachment and Biobehavioral Catch-up (ABC) program (Bernard et al., 2012; Dozier et al., 2008; Dozier et al., 2006; Lewis-Morrarty, Dozier, Bernard, Terracciano, & Moore, 2012), designed as an intervention for parents of young children in foster care and for parents identified by child protective services as being at high risk of maltreating their children. Children in the ABC intervention showed significantly lower rates of disorganized attachment and higher rates of secure attachment compared to the control children (Bernard et al., 2012). Indeed, there is increasing evidence that attachment outcomes can be improved in very high-risk families through the promotion of parental sensitivity. Targeting a group of maltreating families, a Canadian attachment-based home-visiting intervention with a behavioral focus enhanced parental sensitivity, improved children's attachment security, and reduced attachment disorganization (Moss et al., 2011; Tarabulsy et al., 2008). Inspired by the VIPP intervention, this intervention included elements identified as effective in the meta-analyses of attachment-based interventions (Bakermans-Kranenburg et al., 2003). The intervention was brief, including eight home visits. The main focus of the intervention was parental sensitivity. The intervention sessions with video feedback were structured in a fixed order, including videotaping interactive parent–child behavior and video feedback during which the intervener played back and discussed the video fragment (see also Juffer et al., 2008).

Additionally, a major randomized control study by Cicchetti et al. (Cicchetti, Rogosch, & Toth, 2006) has demonstrated the remarkable effectiveness of an attachment-based intervention for maltreated children and their biological parents. After going through 23 sessions of child–parent psychotherapy focusing on enhancing maternal sensitivity through maternal reinterpretation of past attachment experiences, a substantial reduction in infant disorganized attachment, and an increase in attachment security was observed for the intervention group. Interestingly, Cicchetti and his colleagues (2011) also searched for moderators of intervention effectiveness from the perspective of differential susceptibility theory. Differential susceptibility theory suggests that individuals differ in their susceptibility to the influence of the environment, for better and for worse, and that intervention effects might be substantially underestimated when we only look at overall effects across the whole sample (Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011). Genetic markers of differential susceptibility tested in the Cicchetti et al. (2011) intervention were dopamine- and serotonin-system related genes. However, they did not find significant genetic moderation of the treatment effect. One might speculate that genetic moderation was absent because the effects of the environment on disorganized attachment overrode the influence of any genetic component. It may be that differential susceptibility to the environment operates within certain environmental margins, beyond which they are overwhelmed (e.g., maltreating families, orphanages) or remediated as a result of major transitions to vastly improved environments (e.g., through intervention, foster care, or adoption).

The Bucharest Early Intervention Project (BEIP; Drury et al., 2012), however, seems to disconfirm this latter interpretation. In this unique randomized control trial 2-year-old children growing up in Romanian orphanages were pretested with the Disturbances of Attachment Interview for levels of disorganized and disturbed attachments and indiscriminate friendliness, and subsequently randomly assigned to either care as usual or high-quality foster care. The children were genotyped for the Brain Derived Neurotrophic Factor (BDNF) SNP and the serotonin transporter Variable Number Tandem Repeat (5HTTLPR). The posttest at 54 months showed that children with the short 5HTTLPR alleles or met66 BDNF genotype displayed lowest levels of indiscriminate friendliness at posttest and highest levels at pretest. Their peers without the susceptibility genotypes did not change their indiscriminate friendliness as a consequence of the foster care, a clear demonstration of differential susceptibility (Drury et al., 2012). This study illustrates the importance of considering risk modifiers or differential susceptibility markers in treatment outcome studies at the genetic, biological, and social level.

It is remarkable to note the similarities in the results of the meta-analyses addressing maternal sensitivity, attachment security, and attachment disorganization. They all provide evidence for the "less is more" adage: interventions with a focus on parenting sensitivity turn out to be most successful. A focused approach, centering an intervention on a small set of well-defined targets, is also clearly preferable from a methodological perspective as well (van IJzendoorn et al., 2005). Broadband interventions may be very effective on certain outcome measures but it may remain unclear which ingredients are responsible for

the effects. A piecemeal approach to constructing effective interventions, starting with testing the effectiveness of small building blocks or intervention modules that, after successful evaluations, can be combined into an even more effective overall program can produce more unambiguous insights than beginning with a complex multimodal intervention. Also, the modular approach might suit the differing needs of clients and services more efficiently, because it allows for a stepped-care approach in which a single intervention module is deployed to address the most common and least complex problems, and additional modules are added in more severe cases, or when earlier intervention efforts do not bear fruit.

Taking into account the enormous effort that goes into planning and conducting an intervention study, meta-analysis offers an indispensable tool for identifying generalizable, effective interventions and to facilitate evidence-based decision-making in the public health arena. It is therefore remarkable that the Triple-P program (Sanders, Markie-Dadds, & Turner, 2003) has been used on a whole-population basis as a public health intervention and enjoys adoption at a large scale across the world, with substantial cost implications, notwithstanding a lack of randomized controlled studies showing its effectiveness. A recent meta-analysis showed no between-group differences for studies with an adequate control group, and substantial selective reporting bias (Wilson et al., 2012). Interestingly, 32 of the 33 eligible studies were authored by Triple-P affiliated personnel (Wilson et al., 2012)—meta-analysis uncovers telling details.

Holding and Trauma Therapies

So-called *attachment therapy* and similar approaches such as *holding* or *trauma therapy* have received a great deal of public attention and enjoy considerable popularity on numerous internet sites for parents of troubled children. The American Professional Society on the Abuse of Children (APSAC) Task Force published an important report on the controversial *attachment therapies* provided to maltreated children and their biological, foster, or adoptive parents (Chaffin et al., 2006). In some cases such therapies have already proven to be harmful for children. In holding therapy, children are forced to make physical contact with their parent or other caregivers although they strongly resist these attempts. Physical force may even be used to reach the goal of proximity. The child would thus, according to this way of thinking, be enabled to regress to an earlier stage of bonding, and the reexperience of this crucial stage would stimulate the reconstruction of a secure attachment relationship. Holding therapy, however, has not been proven to be effective, and might even be dangerous (Chaffin et al., 2006; O'Connor & Zeanah, 2003; Sroufe, Erickson, & Friedrich, 2002). In fact, holding therapy is not implied at all by attachment theory. Therapists force the parent or caregiver to be extremely insensitive and to ignore clear signs from the child not wanting physical contact. At the core of sensitive parenting is the careful reading of children's attachment signals and needs, and to respond promptly and adequately to those signals (Ainsworth, Blehar, Waters, & Wall, 1978b). Holding therapy may well encourage the antithesis of sensitive care (Cyr et al., 2010).

Adult Attachment and Reflective Functioning in Interventions

As noted earlier, evidence suggests that it may be more difficult to change insecure adult attachment representations than it is to enhance infant attachment security or parental sensitivity (Korfmacher, Adam, Ogawa, & Egeland, 1997; van IJzendoorn, Juffer, & Duyvesteyn, 1995), particularly in clinical samples. Nevertheless, there is evidence that effective change can be achieved. Stovall-McClough and Cloitre (2003), working with women with PTSD following a history of childhood sexual abuse, with high rates of unresolved trauma, showed that unresolved AAI attachment status was most strongly associated with PTSD avoidant symptoms, and used imaginal exposure therapy to address the avoidant symptoms. The treatment appeared effective, not just for PTSD but also for unresolved loss. They observed a 62% reduction in unresolved attachment and absence of PTSD diagnosis for women in the exposure group. In a randomized trial with 90 Borderline Personality Disorder patients, Levy and colleagues (Levy, Beeney, & Temes, 2011) showed the effectiveness of one of the intervention modalities on changing attachment representations. Patients were assigned to one of three types of therapy, transference-focused psychotherapy (TFP), dialectical behavior therapy (DBT), or a modified psychodynamic supportive psychotherapy (SPT). The primary goal of TFP is to reduce symptomatology and self-destructive behavior through the modification of representations of self and others as they are enacted in the treatment. During the first year of treatment, TFP focuses on the identification of dominant relational patterns as they are experienced and expressed in the transference relationship. Based on the AAI the representation of attachment was classified and Reflective Functioning (RF) was coded. After 12 months of treatment, TFP participants showed a significant increase in secure classifications and

RF that was absent for the other two treatments. However, no changes in resolution of loss or trauma were observed across treatments. Toth and colleagues (Toth, Rogosch, & Cicchetti, 2008; Toth, Rogosch, Manly, & Cicchetti, 2006) administered the AAI before and after parent–child psychotherapy in a sample of mothers with major depressive disorder and their young children. The randomized controlled trial included a depressed control group and a nondepressed control group. After treatment, mothers in the depressed group showed a significant increase in RF in the AAI, as well as more positive relationships with their children.

The social-cognitive and affective concept of mentalization has become increasingly important to theory in clinical treatment in general, and psychoanalysis in particular. RF was first described by Fonagy, Steele, Steele, Moran, and Higgit (1991) as the ability to put oneself in another's shoes and to think about the thoughts, feelings, and intentions that may guide or have guided the other's behavior. The concept of RF arose out of the AAI state of mind scale metacognition, defined as monitoring and correcting one's own speech and thoughts during the interview (Main et al., 2003). RF expresses itself in response to AAI questions that demand reflection by asking "why" questions (Steele, Steele, & Murphy, 2009), such as: "Why do you think your parents behaved as they did during your childhood?" Fonagy and colleagues coined the term mentalization (Fonagy, Gergely, Jurist, & Target, 2002; Fonagy & Target, 1996, 2006) to describe the capacity to interpret or make sense of behavior in oneself and others in terms of intentional mental states such as thoughts, feelings, and beliefs. Thus, mentalization is the capacity to evoke and reflect on one's own experience to make inferences about behavior in oneself and others. RF has been operationalized to evaluate the quality of mentalization in the context of attachment relationships, and has been used as an outcome measure in several randomized controlled trials. It is related to such concepts as insight, intraception, and self-observing capacities of the ego, mindfulness, and mind-mindedness.

Although the concept of reflective functioning is broadly embraced (e.g., it has been argued that in the treatment of narcissism increasing self-reflective functioning is crucial to recovery, Bennett, 2006), it has also been noted that its validity and stability as an outcome measure are uncertain because adequate reports on its test-retest reliability and convergent and discriminant validity are absent (Choi-Kain & Gunderson, 2008). Moreover, it may be that individuals vary in their reflective functioning depending on who he or she is mentalizing about (Choi-Kain & Gunderson, 2008). Indeed, the RF scale has been used with a variety of interviews and that may in part be responsible for the relatively fuzzy boundaries of the concept and difficulties in the assessment. Nevertheless, the introduction of the concepts of mentalizing and reflective functioning was a catalyst for the development of a range of novel and potentially effective treatments, in particular for patients with bipolar disorder.

Attachment Fit Between Client and Therapist

The attachment representations of both patients and clinicians may play a role in the process and outcome of treatment. Dozier (1990) reported that individuals with a more dismissing stance to attachment were less likely to disclose symptomatology, more likely to minimize the interventions of case managers, and less likely to engage with treatment. In an intervention study involving mothers with an insecure attachment representation, dismissing mothers did not profit from discussion about attachment issues, and tended to view four home-based intervention sessions as requiring too much time investment from them (Bakermans-Kranenburg, Juffer, & van IJzendoorn, 1998). They were evaluated as less invested than other mothers in an intervention focusing on parenting sensitivity (Korfmacher et al., 1997). Adult attachment style has also been found to relate to adolescent's approach to treatment, with preoccupied adolescents in a residential treatment program showing the highest levels of truancy, rule breaking, and externalizing behavior problems (Zegers, Schuengel, van IJzendoorn, & Janssens, 2008).

Process research in psychoanalysis and psychoanalytic psychotherapy has indicated various factors that are related to positive treatment outcome. Patient–therapist fit is a factor that is generally indicated as predictive of treatment success (Fonagy et al., 1996; Kantrowitz, 1993; Stolk et al., 2008), but evidently there may be a wide variety of models of what is meant by *fit*. Both interpersonal theory and attachment theory suggest that a central task of the therapist is to resist the tendency to respond to the client's interpersonal or attachment orientation in a complementary manner, so as not to reinforce the client's rigid way of approaching relationships (Bernier & Dozier, 2002). Providing the client with a contrasting relational orientation appears to be beneficial in psychotherapy (Andrews, 1991), case management (Tyrrell et al., 1999), and academic counseling (Larose & Bernier, 2001), and indeed the corrective emotional experience may be a key

factor in therapeutic change. Bowlby (1988) suggested that the therapist should help the client recognize and change insecure working models or maladaptive relational patterns. He proposed that the therapist should challenge the client's beliefs about relationships by flexibly adopting a stance that is in contrast to the client's expectations. It is not far-fetched to argue that for a therapist with a secure representation of attachment it will be easier to respond in a contrasting (noncomplementary) way to the client's relational orientation than for an insecure therapist. In support of this idea Dozier, Cue, and Barnett (1994) have shown that clinicians with an autonomous AAI were more effective at providing noncomplementary responses than were nonautonomous clinicians. That is, autonomous clinicians worked in greater depth with clients presenting dismissing features than with preoccupied clients, whereas nonautonomous clinicians provided complementary responses, working in greater depth with preoccupied clients. This may explain why Gerber, Fonagy and their colleagues (Gerber, Fonagy, Bateman, & Higgitt, 2004), in a quasi-experimental trial of psychoanalysis and psychoanalytic psychotherapy, found that patients who became progressively more insecure on the AAI in the first phase of treatment were significantly more likely to improve in terms of their symptomatology by termination (Gerber et al., 2004): these patients may have been challenged to take a stance contrasting with their previous representation, temporarily leading to more insecurity or even less organization of attachment representation, which led to a better outcome in the end. If this line of reasoning is correct, then therapists' own tendencies to more dismissing or more preoccupied representations within the range of security may play a facilitating or impeding role in treatment, depending on the client's attachment representation. Consistent with this idea, clients and therapists showing dissimilar attachment tendencies on the dismissing–preoccupied dimension were shown to have better alliances and more productive relationships (Tyrrell et al., 1999). In such dyads, the natural style of the therapist appears to make him or her more likely to adopt an interpersonal stance that is contrary to what the client "pulls for," thereby disconfirming the client's rigid perceptions and strategies (Bernier & Dozier, 2002).

It should however be noted that the vast majority of the therapists in the Tyrrell et al. (1999) study were rated as autonomous based on a modified version of the Attachment Q Set (Kobak, 1989). Direct comparison with AAI classifications of the mentors in the adolescents' residential treatment institution of the Zegers et al. (2008) study is thus not possible, but the 55% of autonomous mentors in that study—although similar to the norm distribution—is considerably less than those in the Tyrrell study. At 3 months into treatment, no difference in therapeutic relationships between adolescents and secure versus insecure mentors could be traced, but between 3 and 10 months into treatment, the psychological availability of nonautonomous mentors decreased in the perception of the adolescents, whereas the perceived psychological availability of autonomous mentors increased. Similarly, reliance on autonomous mentors increased between 3 and 10 months, but reliance on nonautonomous mentors decreased over time (Zegers, Schuengel, van IJzendoorn, & Janssens, 2006).

The AAI can also be part of the intake and treatment process. As an interview it goes beyond available screening instruments by tapping into experiences in the family of origin, and it also opens up the perceived state of mind of the individual with respect to these experiences, including experiences of loss and other trauma. When multiple losses or abusive events are presented, it is informative which experiences are reported in a coherent way, and when disorganized speech, indicative of unresolved loss or trauma, takes over (Steele et al., 2009). Who should administer the AAI in the therapeutic context, and when should the interview take place? Steele and colleagues (2009) advise that the AAI be administered early in the treatment by the clinician himself or herself, unless the fragility of the patient would ask for postponement until a therapeutic alliance is in place. They argue that in other cases the AAI is likely to promote alliance. Over time, it is expected that content from the interview will filter through material covered in the course of the therapy (Steele et al., 2009).

In sum, secure adult attachment representations and associated mentalizing competence can be stimulated by therapeutic interventions although the evidence base still is disappointingly small. Psychotherapy is about creating more coherent autobiographical narratives (Bowlby, 1988), which implies a shift from preoccupied or dismissing representations of the past to more balanced, open and coherent discourse from a mentalizing stance. Some of the most promising attachment-related psychotherapy studies show that attachment representations of both client and therapist might help us understand why some client–therapist combinations are more effective than others. It is not the perfect match but a mild mismatch of counterbalancing representational biases that might be most productive in creating positive change.

CONCLUSIONS

Attachment theory and research has had a major impact on thinking regarding the developmental mechanisms contributing to adaptation and risk for psychological disorder. Its contribution to the field has occurred at a number of levels. First, it pioneered, in many respects, the developmental approach to understanding psychopathology, particularly its treatment of the connections between levels of analysis—the evolutionary, biological, cognitive/affective and relational—and their unfolding interactions and transformations across development. Second, the field has revealed a host of rich phenomena relevant to understanding psychopathology, and worthy of serious scientific and clinical investigation: protest, despair, detachment, secure base behavior, avoidance, resistance, disorganization, sensitivity of care, frightened/frightening parenting, coherence of mind, lack of resolution or mourning or trauma, to name some of the most prominent. Third, the field has established a strong evidence base supporting its major tenets, most notably: (1) the environmental origins of individual differences in attachment security and insecurity; (2) the important predictive, and likely causal, role of parental sensitivity; (3) the long-term developmental disadvantages associated with insecure attachment in the domains of internalizing problems, externalizing problems, and social competence; and (4) the intergenerational transmission of patterns of attachment. In the process of establishing this evidence base, attachment research has also highlighted the limits of the attachment construct, at least as currently measured and conceptualized, the role of important moderators in modifying or qualifying its effects, and the potentially complex developmental pathways by which attachment is connected to later outcomes. Finally, and perhaps most importantly, the field has developed a range of approaches to intervention and prevention that are delivering reliable positive outcomes for children and families.

INTRODUCTION

Autonomy, Growth, and Psychopathology

Autonomy, defined as self-regulation and integration in acting, is central to healthy psychological development and functioning. Classic organismic and dynamic theories have long considered the movement toward greater autonomy and integration to be a hallmark of optimal development (e.g., Hartmann, 1947/1964; Jahoda, 1958; Loevinger, 1976; Piaget, 1971; Werner, 1948), a focus that continues in developmental psychologies today (see Sokol, Grouzet, & Muller, 2013). Because of the importance of children developing capacities for autonomy and integrated behavioral regulation, support for autonomy is recognized as a central aspect of optimal parenting by many theorists (e.g., Bretherton, 1987; Grolnick, 2002; Grusec & Goodnow, 1994; Hmel & Pincus, 2002).

Issues of autonomy and integration are in fact frequently implicated in the development of psychopathology (Ryan, Deci, Grolnick, & La Guardia, 2006). Historically, clinical literatures have highlighted that many forms of behavioral and mental disorders are characterized by autonomy disturbances (e.g., Shapiro, 1981; Winnicott, 1965). In many disorders, people's behaviors, emotions, and thoughts are experienced as pressured, compelled, or controlled, or alternatively uncontrollable (Ryan et al., 2006). For example, people can feel unable to regulate specific behaviors (e.g., some addictive and impulsive disorders). In other pathologies there is highly controlled, intentional behavior (e.g., restrictive eating, obsessive rituals) that is not well integrated or reflectively self-endorsed, whereas in other forms of psychopathology, usually involving considerable trauma at the hands of others, behaviors are enacted without being intentionally mediated by the self (e.g., dissociative disorders). In still others the motivation

for pursuing intentions and goals is absent or depleted (e.g., some forms of depression). In short, compromised autonomy is entailed in a wide range of pathologies, from those involving a lack of behavior regulation to those that entail rigidly enforced self-controls and compulsive behaviors. Corresponding to this, caregivers' obstruction of children's autonomy in conjunction with genetic vulnerabilities has been shown to foster a broad range of negative effects on development and is thought to contribute to the onset of varied disorders (e.g., Bruch, 1973; Depue & Lenzenweger, 2001; Ryan, 2005).

Given the role played by autonomy (or its absence) in both optimal development and developmental psychopathology, it is not surprising that autonomy support is emerging as an important, indeed critical, element in successful treatments for psychopathology (e.g., Mansour et al., 2012; Zuroff et al., 2007). In fact, most current behavioral and psychological intervention approaches attempt to support autonomy, albeit through different means, and with more or less explicit foci (Ryan, Lynch, Vansteenkiste, & Deci, 2011). In some treatment approaches, support for autonomy is seen as important in its own right for building essential inner resources that can buffer vulnerabilities and enhance adjustment (e.g., Ryan & Deci, 2008). Yet even when capacities for autonomy are not a focus, enhancing autonomous motivation for treatment enhances clinical success and engagement in behavior change over time (e.g., see Ng et al., 2012; Savard, Joussemet, Pelletier, & Mageau, 2013; Zuroff, Koestner, & Moskowitz, 2012).

Recognition of the importance of autonomy for healthy development and wellness has contributed to a fast-rising number of empirical studies on the topic of autonomy and its developmental dynamics. New research is coordinating phenomenological, functional, and mechanistic viewpoints in understanding autonomy and what influences it. Salient within this research is the power of social contexts (e.g., parents, teachers, coaches, peers) to facilitate the development and expression of autonomy and capacities for self-regulation in children. Salient as well is how the thwarting of autonomy, through either excessive control, conditional regard, or lack of empathy, disrupts development, and especially in vulnerable individuals, leads to dysregualtion and ill-being. Indeed, autonomy thwarting plays an important etiological role in many forms of psychopathology.

In this chapter we review the growing body of research on autonomy and autonomy disturbances primarily through the lens of Self-determination theory (SDT; Deci & Ryan 2000; Vansteenkiste, Niemiec, & Soenens, 2010). SDT is an empirically grounded theory informed by philosophical, clinical, and cross-cultural analyses of autonomy. SDT argues that among the predominant factors that foster resilience in development are opportunities to satisfy people's *basic* psychological needs, namely those for autonomy, competence, and relatedness (Ryan, 1995). Briefly, the need for autonomy refers to the necessity of experiencing a sense of volition; competence refers to the experience of effectiveness; and relatedness refers to the experience of warmth and reciprocal care. Support for the satisfaction of these needs is said to promote growth and well-being. Indeed, when social conditions support these psychological need satisfactions, individuals develop inner resources that allow them to better cope with adversity and flourish in their adult development. Interestingly, even individuals who do not explicitly value or desire these need satisfactions benefit from their fulfillment (Chen et al., in press). In contrast, the thwarting and frustration of these basic psychological needs is conducive to maladjustment and psychopathology (Ryan & Deci, 2000; Vansteenkiste & Ryan, 2013).

As an organismic theory, the principles informing SDT are fully consistent with a developmental psychopathology perspective (e.g., Cicchetti, 2006; Cicchetti & Toth, 2009). In particular, SDT focuses on nonclinical, subclinical, and clinical populations, connecting the conditions conducive to optimal psychological development with depriving and thwarting conditions that redirect developmental energies into self-protection, defense, and maladaptive coping. SDT sees the pervasive experience of having basic psychological needs frustrated during development as setting the stage for later difficulties and deficits in one's capacity for self-regulation of action and experience, often through cascading negative effects (Vansteenkiste & Ryan, 2013). In short, SDT suggests that the very same mechanisms, namely the satisfaction and frustration of people's basic psychological needs, accounts for substantial variance both in situational motivation and wellness and in developmental trajectories in self-regulation, well-being, and psychopathology.

In addition, and again in line with both developmental psychopathology (Cicchetti & Toth, 20009) and organismic perspectives more generally, SDT sees multiple pathways to both health and illness. By identifying the resources associated with integrative tendencies and psychological resilience, SDT allows for considerable flexibility and equifinality in development (Ryan, 1993), and conversely identifies many pathways of harm leading to diverse outcomes. Conditions affecting basic psychological need satisfaction versus frustration range from biologic to cultural, and the consequences of need supports are manifest at every level of analysis, from physiological to phenomenological. SDT additionally seeks to coordinate

these varied levels of analysis within its empirically driven framework, an aspiration that also characterizes the field of developmental psychopathology (e.g., Cicchetti, 2006; Cicchetti & Toth, 2009).

Chapter Overview

This chapter consists of three major sections. First we define autonomy as it is classically understood and currently applied within the SDT perspective. In doing so, we not only specify what autonomy entails, but also distinguish it, both theoretically and operationally, from other developmental constructs with which autonomy is often confounded. These include the constructs of independence (Silk, Morris, Kanaya, & Steinberg, 2003; Smetana, Campione-Barr, & Dadis, 2004); individualism (e.g., Iyenger & Devoe, 2003); individuation (e.g., Blos, 1979); and emotional autonomy (e.g., Steinberg & Silverberg, 1986). Next, we elaborate on the type of social environments that are conducive to autonomous regulation via the satisfaction of individuals' psychological needs and those that have been found to obstruct and undermine autonomous regulation by eliciting need frustration.

Then we discuss the different healthy manifestations of autonomy, thereby reviewing in greater detail its developmental origins. Using research from both SDT and attachment theory, we begin by highlighting that secure attachments in childhood are developed through autonomy supportive and involved caregivers, who not only hold and protect (i.e., provide security) but also stimulate the budding initiative and self-expression of the infant (i.e., support autonomy), setting the stage for developing further capacities for mature self-regulation (e.g., Miklikowska, Duriez, & Soenens, 2011; Whipple, Bernier, & Mageau, 2009). Apart from being conducive to secure attachments, autonomy supportive relationships support the integrative functions of the self that allow for greater internal psychological coherence and more effective behavioral regulation. Exemplifying this, we then turn to evidence concerning how autonomy supportive contexts facilitate developmentally relevant integrative processes including: (1) intrinsic motivation; (2) internalization and integration of social regulations; (3) the development of emotion regulation; and (4) the formation of identity. We pay particular attention to how socializers, especially parents, either facilitate or thwart the developing child's autonomy, thereby supporting or hindering the individual's inner resources for successfully negotiating each of these developmental lines.

These reviews of autonomy in psychological development, and of parental nurturance versus thwarting of autonomy, provide the foundation for examining autonomy disturbances in varied types and presentations of psychopathology. The next section focusing on psychopathology is twofold: we consider autonomy depriving and thwarting environments as an *etiological factor* in psychopathology; and we highlight how autonomy frustrations are often a *symptomatic factor* in various disorders and sometimes a by-product of other cascading effects. Moreover, we identify three general types of psychopathology in which autonomy is differently implicated. These are *internally controlling disorders*, in which there is excessive self-control or internal compulsion; *impairments of internalization*, reflecting both impoverished development of self-regulation capacities or lack of value for social regulations; and finally *fragmented self-functioning,* which we relate to chronic or traumatic need thwarting. We conclude this section by considering implications not only for clinical interventions, but also for the design of social institutions such as schools and workplaces that can support persons vulnerable to psychopathology. Finally, we provide a summarizing overview and discuss a number of critical future research directions.

AUTONOMOUS REGULATION AND FACILITATIVE ENVIRONMENTS

Autonomous Regulation of Behavior

Before proceeding to the intricacies of autonomy in development we begin with some basic definitions and distinctions. The term autonomy is derived from the Greek words *autos* (self) and *nomos* (rule). Autonomous actions are thus those that are self-ruled or governed by the self. The opposite of autonomy is heteronomy, when one's behavior is regulated or ruled by forces experienced as *heteron* or alien to one's sense of self.

Phenomenological analyses suggest that, when people act autonomously, they feel a sense of ownership of their actions (Pfander, 1967/1908). When autonomous, people are willingly engaged in activities. Accordingly, their actions are characterized by an *internal perceived locus of causality* (de Charms, 1968; Ryan & Connell, 1989). This quality of self-endorsement indicates that autonomous actions are informed by, and reflective of, individuals' abiding preferences and values and are congruent rather than discordant with their sense of self (Ryan Legate, Niemiec, & Deci, 2012; Shapiro, 1981; Weinstein, Prybylski, & Ryan, 2013). In contrast, when behaviors are heteronomous they are experienced as *controlled*. The actor experiences a sense of external or internal control, compulsion, or pressure to enact the behavior (Deci & Ryan, 2000). In attribution terms, people have an *external*

perceived locus of causality with respect to controlled behaviors. Interestingly, the functional effects of autonomy can be detected from early development and a sense of initiative and ownership of action is apparent from early infancy (Stern, 1985).

Although the concept of autonomy refers to integrated regulation by the self, autonomy is nonetheless a relative concept insofar as actions vary in their degree of autonomy. Autonomous functioning reflects the extent to which ongoing behaviors, thoughts, and feelings match with one's interests and values. Since most actions are both multiply motivated and more or less congruent, autonomy is inevitably a dimensional concept, and differentially associated with different types of motives. It is therefore basic to our view that autonomy is a *quality* of behavioral regulation, which is characterized by and requires an open processing of possibilities such that ongoing behaviors and underlying experiences are maximally integrated and volitional. This quality of behavioral regulation is relevant across the life span, even as the contents and focus of activities and values change with development.

Phenomenological analysis also points to the relationship between autonomy and integration in functioning. When autonomous, people are wholeheartedly behind their actions, and this is reflected in the coherence and lack of internal conflict involved in those actions. Yet to varying degrees behavioral regulations can represent compartmentalized or defended motives, or can be enacted because of external or internal pressures without reflective ascent or full endorsement. Thus the experience of autonomy is directly related to the relative integration of one's motivations and valuing (Ryan & Deci, 2008).

Although SDT's definition and understanding of autonomy is relatively unique within empirical psychology, it is strongly informed by philosophical treatments of the topic (e.g., Dworkin, 1968; Friedman, 2003). It can also be related to psychodynamic (e.g., Schafer, 1968; Loevinger, 1976; Shapiro, 1981) and humanistic (e.g., Rogers, 1963) traditions that have considered autonomy and integration to be highly important. Whether addressed in terms of self-endorsement, congruence, self-actualization, authenticity, will, or operating from the true self (see Ryan et al., 2006) many of these prior thinkers were addressing a shared idea, which is termed autonomy within SDT.

In addition, both the underlying sensibilities (e.g., recognition of values or interests in acting) and abilities (e.g., reflective capacities, goal selection, self-regulation skills) entailed in autonomy must develop, and accordingly there are individual differences in autonomous functioning (Deci & Ryan, 1985a; Weinstein, Przybylski, & Ryan, 2012). Yet autonomy is also situational, in part because social contexts differ in the extent to which they are autonomy supportive, controlling, or amotivating. This is true at all levels of development as parents, teachers, coaches, managers, and spouses, for example, can all facilitate or stifle autonomy in an individual, with significant mental health consequences. Yet whether due to dispositional or proximal supports, people evidence fuller functioning and more positive behavioral and psychological outcomes when more autonomous, including more sustained persistence, enhanced creativity, and higher quality performance (Vansteenkiste & Ryan, 2013).

Although phenomenologically autonomy is characterized by the experience of actions as being self-organized and volitionally supported, in terms of the quality of behavior, autonomy is manifest at varied levels of analysis. For example, evidence is emerging concerning the distinct neural basis of autonomous functioning relative to controlled, nonautonomous, motivational processes (e.g., Lee & Reeve, 2013; Murayama et al., 2014). In general terms, autonomy depends on the coordination between prefrontal cortical regions and subcortical striatal-thalamic areas that promote or inhibit motivation as well as on inputs from the hippocampus and amygdala that can provide contextual and affective information (e.g., Bradley, 2000; Chambers, Taylor, & Potenza, 2003). Autonomy requires supervisory and selective functions that are fully informed by affective and memory related processes (Di Domenico, Fournier, Ayaz, & Ruocco, 2013; Ryan, Kuhl, & Deci, 1997). Impairment in the development of prefrontal areas and interconnections with limbic structures produces vulnerability to autonomy disturbance (e.g., Bechara, Tranel, Damasio, & Damasio, 1996).

Interestingly, under autonomy-supportive conditions people appear more capable to recruit and use self-regulation strategies associated with executive functioning, a fact with important implications for development. For example, Bernier, Carlson, and Whipple (2010) examined whether maternal sensitivity and autonomy support were related to toddlers' capacity for executive control, which was assessed via a set of cognitive indicators involving flexible goal setting, impulse control, and planning. After controlling for children's cognitive capacity and maternal education, both sensitivity and maternal autonomy support, assessed when children were 12–15 months old, related to executive control at 18 and 26 months, with maternal autonomy support emerging as the most consistent predictor of enhanced executive control.

In fact, exposure to particular social contexts shapes the use of neurological resources required for autonomous functioning. For example, Di Domenico et al. (2013) argued, based on SDT, that people's abilities to develop

and act from a coherent sense of self are facilitated by satisfaction of the basic psychological needs. Using functional near-infrared spectroscopy (fNIRS), they examined the effect of need satisfaction on activity in the medial prefrontal cortex (MPFC), an important brain region for integrative processing of information about the self (Ryan et al., 1997). Participants engaged in a task involving a series of forced choices expressing personal preferences. Decisional conflict (i.e., choice difficulty) between the response options was manipulated using participants' previously collected preference ratings. Findings revealed that need satisfaction predicted elevated MPFC activity during high-conflict situations, suggesting that need satisfaction may facilitate access to and utilization of self-knowledge.

To summarize, autonomy is integrated self-regulation, and it is accompanied by a phenomenological experience of self-organization and volition, which is described in attribution terms by an internal perceived locus of causality (Deci & Ryan, 2000). Autonomy thus involves an experience of regulation by the self, and it is contrasted with actions experienced as pressured, controlled, or caused by sources external to the self. These later experiences are central to many forms of psychopathology, and can increasingly be mapped to neurological underpinnings.

Distinguishing Autonomy from Independence

An important distinction, particularly relevant to development, is that between *autonomy* and *independence*. Although autonomy and independence have been clearly distinguished in philosophical analyses, theorists in developmental psychology have often equated or conflated these concepts (e.g., Silk et al., 2003). *Dependence* is reliance on others for resources or guidance, so independence is not relying on others. Autonomy, by contrast, connotes willingness or volition. Given this, in the SDT view individuals can be autonomously dependent or autonomously independent, depending on circumstances. They can also sometimes be controlled or pressured into dependence, as when they feel forced to rely on others because of illness or financial hardship, or they can be heteronomously independent, as when pushed away from relying on others, who are unavailable or unwilling to provide assistance.

SDT suggests that autonomous forms of dependence (for example, when a teenager willingly turns to parents for guidance) are often quite beneficial, a view that stands in contrast to some developmental perspectives that have equated autonomy with separation or independence (Ryan & Lynch, 1989). For instance, Blos (1979) portrayed normative development in terms of an increasing relinquishing of both dependency on, and attachment to, parents. He viewed moving away from parental supports as indicative of increasing *individuation*. Based on Blos, Steinberg, and Silverberg (1986) developed a construct labeled *emotional autonomy* that was intended to be a marker of individuation. Scale items assessing emotional autonomy made reference to "not using parents as resources," "disagreeing with parents," and "being different when not with parents."

Working from the SDT lens, Ryan and Lynch (1989) reexamined the emotional autonomy scale, suggesting that it captured a detached relationship with parents rather than autonomy and they argued that such detachment or separation from parents is neither a necessary nor ideal pathway of development. They also suggested that such detachment might be more likely in adolescents who did not have autonomy-supportive parents. They therefore predicted that emotional autonomy as thus measured, rather than being indicative of positive maturation, would predict poorer adjustment. Consistent with this reasoning, findings indicated that adolescents high in emotional autonomy were those feeling less accepted by their parents and less lovable. These teens also evidenced poorer wellness outcomes overall. Ryan and Lynch (1989) interpreted these findings as highlighting the need to differentiate independence or nonreliance from autonomy.

Extending SDT's distinction between autonomy and independence, Van Petegem, Beyers, Vansteenkiste, and Soenens (2012) directly examined adolescents' level of independence, as well as their motives for both independent and dependent functioning. They found that autonomous (i.e., volitional) and controlled (i.e., pressured) motives for both independence and dependence played a more significant role in predicting adolescents' psychosocial functioning than did their level of independence as such. More autonomous forms of motivation for either dependence or independence were strongly associated with greater well-being and less problem behavior, whereas the level of independence was less predictive of these outcomes.

Because of the widespread interest within the developmental literature in assessments of autonomy and independence, Van Petegem, Vansteenkiste, and Beyers (2013) undertook a comprehensive study of 15 prevailing measures in adolescent psychology relevant to these constructs. Using higher order factor analyses, Van Petegem et al. (2013) showed that two basic dimensions provided the most parsimonious summary of the existing heterogeneity across available measures. A first dimension denoted the degree of *distance versus proximity* in the parent–child relation; a second dimension represented *volition versus pressure* in the relationship. The crossing of these two dimensions gives support for SDT's distinctions between autonomy and independence. For example, the

emotional autonomy scale (Steinberg & Silverberg, 1986), characterized by Ryan and Lynch (1989) as reflecting more detachment than autonomy, fell in the quadrant tapping pressured distance. In contrast, a scale of *emotional reliance* (Ryan, La Guardia, Solky-Butzel, Chirkov, & Kim, 2005), tapping adolescents' willing reliance on parents, fell in the volitional proximity-seeking quadrant. Van Petegem et al. (2013) further showed that the dimension of distance (versus proximity) was positively related to both avoidance and anxiety-based forms of attachment, whereas the dimension of volition (versus pressure) was negatively related to these insecure attachment styles. Such studies thus support the SDT literature in strongly distinguishing, both theoretically and empirically, autonomy from independence.

The distinction between autonomy and independence is critical to developmental psychology not only in childhood and adolescence, but also across the life span. For example, with advanced age people inevitably become more reliant or dependent on others. Nonetheless, there are important differences in wellness outcomes as a function of whether an older person's reliance on others feels autonomous and volitional or forced upon them (e.g., V. Kasser & Ryan, 1999; Vallerand, O'Conner, & Hamel, 1995). When elderly individuals can feel volitionally dependent and still experience a sense of choice in everyday living they remain more vital and resilient.

This distinction is also critical to cross-cultural psychologies. Various scholars have suggested that, because collectivist cultures emphasize duty and obligation to the group, autonomy is not very important for their members (e.g., Iyengar & Devoe, 2003; Markus, Kitayama, & Heiman, 1996). Yet this is a misinterpretation of the concept of autonomy, as it assumes people cannot autonomously engage in a duty, willingly comply with their parents' choices, or, with full volition, adhere to collectivistic cultural norms. In a direct examination of the distinction between autonomy and independence in the cross-cultural area, Chen, Vansteenkiste, Beyers, Soenens, and Van Petegem (2013) demonstrated that both Chinese adolescents' volitional reliance on parents as well as their volitional independent functioning yielded unique well-being benefits. Overall then, considerable data suggest that across cultural contexts, support for autonomy matters in both the internalization of ambient practices and in fostering individuals' overall wellbeing (Chirkov, Ryan, & Sheldon, 2010).

Finally, it should be noted that the concepts of independence and autonomy yield a different relation to individuals' development of relatedness and intimacy. Excessive strivings for independence often come at the cost of the development of trustful and warm relations, suggesting that, for individuals to develop most optimally, they need to balance their strivings for independence and relatedness. Yet, from the SDT perspective, the experience of volition and autonomy does not necessarily stand in conflict with the development of warm relations, because as one volitionally relies on another, a sense of intimacy can be maintained without giving up one's autonomy. Thus, instead of autonomy development extracting a price in terms of increased relational distance or tension, in SDT's view autonomy and relatedness optimally stand in a mutually reinforcing relation to each other (Hodgins, Koestner, & Duncan, 1996; LaGuardia, Ryan, Couchman, & Deci, 2000). Indeed, parental support for children's autonomy enhances parent-child relatedness, a pattern that persists across the age-related changes in types and foci of dependencies.

Facilitating Environments: The Key Role of Need-Supportive Socialization

As an organismic theory, SDT endorses a transactional-ecological conceptualization of development (e.g., Cicchetti & Valentino, 2006), in which growth and competencies, as well as impairments and liabilities at earlier stages of development impact the direction and quality subsequent development. Within such an organismic model a critical issue concerns the necessary nutrients for optimal development, which for SDT are represented by the satisfaction of the needs for autonomy, competence, and relatedness (Ryan, 1995). That is, individuals are prepared to optimally develop psychologically and socially when their caregiving environments support these basic needs. When these needs are thwarted, people are prepared with other protective, even defensive, responses, and both the healthier and the more defensive processes can have cascading developmental consequences (Vansteenkiste & Ryan, 2013).

Already in the earliest SDT parenting research (Grolnick & Ryan, 1989), three distinct parenting dimensions were identified as being critical for satisfying children's basic psychological needs and thus fostering more integrative development and wellness (Grolnick & Pomerantz, 2009; Soenens & Vansteenkiste, 2010). Specifically, these dimensions are parental *autonomy support*, parental *structure*, and parental *involvement*. Environments that supply these three core nutrients for basic psychological need satisfactions energize healthy self-development. SDT's focus on the satisfaction of children's psychological needs and facilitation of intrinsic growth tendencies is relatively unique in the prevailing parenting literature because few models are clear about the exact processes underlying

children's growth. At the same time, SDT maintains that the very blocking and direct thwarting of these needs not only prevents children from growing but also can even elicit maladjustment and psychopathology. Children's psychological needs will get more readily frustrated when parents are *controlling, chaotic,* and *neglectful*. In what follows we discuss the SDT model of parenting in detail, comparing it with alternative perspectives and contrasting constructs.

Parental Autonomy Support and Control

Being autonomy supportive literally means that one person is supporting the other's self-management or self-rule. Research has identified a number of elements in interpersonal interactions that enhance experiences of autonomy. Most important, in being autonomy supportive a parent (or other caregiver) attempts to understand and acknowledge the child's perspective. Critical to taking the children's frame of reference is an authentic curiosity from the side of the caregiver, who is sincerely interested in what is going on for the child. When this occurs, one is in a position to be responsive to whatever issues are salient. In addition, autonomy support entails using minimal controls to foster behavior, and instead providing a meaningful rationale for behavioral requests and limits where possible to help anchor internalized motivation. Autonomy support requires respecting the children's pace of development, so demands can be volitionally and effectively engaged, and providing opportunities for choice and voice when possible, all facilitate autonomy. In contrast, being controlling involves parents pressuring the children to do what they want or value, emphasizing obedience and compliance (Grolnick, 2002; Soenens & Vansteenkiste, 2010) and, in more extreme contexts, using punishments and physical threats. Dozens of studies have convincingly shown that autonomy-supportive parenting yields various benefits, including greater teacher-rated competence and grades (e.g., Grolnick & Ryan, 1989), more personal well-being (e.g., Chirkov & Ryan, 2001; Lekes, Gingras, Philippe, Koestner, & Fang, 2010), and better social adjustment (e.g., Soenens & Vansteenkiste, 2005).

Importantly, much like the experience of autonomy cannot be equated with independent functioning, the *support of autonomy* in SDT does not denote the *promotion of independence*. This was demonstrated in four studies by Soenens and colleagues (2007), who showed that parental promotion of independence and parental autonomy support were only moderately positively correlated. Moreover, while both independence promotion and autonomy support were positively associated with psychosocial functioning at the correlational level, when the two competed for variance in predicting these outcomes, only autonomy support was a significant predictor. In other words, the aspect of parenting accounting for better outcomes was autonomy support rather than the promotion of nonreliance. Soenens, Vansteenkiste, and Sierens (2009) subsequently showed that adolescents who perceived parents as allowing volitional dependence reported better psychosocial functioning than those who felt parental pressure toward either independence or dependence.

Rather than working from their children's perspectives, controlling socializing agents alter, minimize, or deny the children's perspectives, thereby projecting their own wishes and standards upon the children and pushing the children in the parent-desired directions. SDT's formulation of controlling parenting can be further differentiated into two categories (Soenens & Vansteenkiste, 2010). Parents can be controlling using *externally controlling* methods, such as the reliance on controlling reward or punishment contingencies. Externally controlling methods can be explicitly stated, but often the controlling contingencies are implicit and learned over time. A second subtype of controlling parental practices is *internally controlling* practices. This style of parenting has some overlap with *psychological control* as discussed in the frameworks of Schaefer (1959), Barber (1996), and Steinberg (2005). In this case, parents attempt to instill in the child positive and negative self-related feelings contingent upon compliance with parental standards and goals.

Internally controlling parental practices have been a concerted focus of research within SDT, especially through work on parental conditional regard. *Parental conditional regard* (PCR) describes parents or other caregivers using their attention, affection, and love to control their children's behavior (Assor, Roth, & Deci, 2004). As a socializing method, PCR is a widely used and sometimes advocated parenting practice (e.g., Sears, Maccoby & Levin, 1957; Fu & Markus, 2014). Yet from the SDT perspective PCR is theorized to be controlling and therefore to have both subtle and more manifest detrimental effects on self-functioning. Indeed, parents who use conditional regard are essentially pitting the children's needs for relatedness and autonomy against each other. The message conveyed is essentially "to get my love you need to give up your autonomy." To maintain positive relatedness, the children have to comply, irrespective of the fit of the parental demands with their own developing interests, skills, or values. Yet, even when complying, children who experience PCR do not feel accepted but instead evidence resentment, because what is conveyed is that they are not being accepted for who they are but instead for whether they live up to their parents' demands. As such, the use

of PCR with children serves to thwart the needs for both relatedness and autonomy, with resulting decrements in adjustment and well-being (e.g., Assor, et al., 2004; Roth & Assor, 2012).

Parental Structure and Parental Chaos

Apart from parental autonomy support, SDT also highlights the critical role of parental *structure*, which concerns the degree to which parents or other caregivers create the necessary conditions for children to begin developing a sense of mastery and provide ongoing assistance to optimize competence development (Farkas & Grolnick, 2010; Grolnick & Pomerantz, 2009; Reeve & Halusic, 2009). Structure entails the provision of an environment that makes optimal demands on children's expanding skills. Structuring parents provide guidance and scaffolding upon which the unfolding processes of development can climb. Specifically, provision of structure by parents includes: helping to adjust environments so that they can be mastered by the children without excessive anxiety; conveying consistent and clear expectations; providing guidance about the contingencies between behaviors and outcomes; offering meaningful informational feedback as the children engage in activities; and other elements of support focused on promoting the children's feeling of effectance in acting. In the research by Grolnick and Ryan (1989), parental structure predicted children's understanding the sources of control over outcomes in their lives, enhancing both the children's sense of predictability, and of competence or efficacy. In the educational domain, Mouratidis, Michou, Vansteenkiste, and Lens (2013) showed that competence need satisfaction largely accounted for the relation between perceived teacher structure and children's wellness and use of self-regulation strategies.

Although structure aids the building of competence, this process might be more or less facilitated depending on whether an autonomy-supportive or controlling style is used when introducing and maintaining the structure (Soenens & Vansteenkiste, 2010). Specifically, the competence-enhancing impact of structure is likely strengthened when the structure is communicated in an autonomy-supportive way and diminished when done in a controlling way.

The differential impact of providing structure in autonomy supportive versus controlling ways was demonstrated early within SDT research, most notably in an experimental study by Koestner, Ryan, Bernieri, and Holt (1984). In a school setting first- and second-grade children came individually to an art room to do a painting project. An experimenter set limits on their behaviors, advocating neatness and organization, either in a controlling or autonomy-supportive way. The autonomy-supportive method was based on SDT and included a rationale, an expression of empathy, and a clear limit. The controlling method simply directed the child to follow the limit. It was found that the controlling limits undermined the enjoyment of painting and creativity relative to autonomy-supportive limits.

Overall then, structure is in no way antithetical to support for autonomy; on the contrary, the two often go hand in hand (Stipek & Seal, 2001). Yet this conceptual point can easily be lost if parental structure is described as, or equated with, parental control. That is, if parental structure involves parents exerting pressure and control over children's functioning, that parental structure would indeed stand in contradiction to parents' encouragement of children's volitional functioning. Similarly, if parents are permissive, granting unmitigated freedom rather than specifically supporting autonomy, this would be contrary to providing structure. Parental autonomy support, in fact, can and optimally does involve parents introducing and maintaining structure, and does not entail avoiding all guidance and scaffolding (Grolnick & Pomerantz, 2009; Soenens & Vansteenkiste, 2010). SDT also expects that structure can be imposed in controlling ways, with less beneficial outcomes. Thus, the concepts of autonomy support and structure allow for a clearer differentiation between critical dimensions needed in parenting.

Consistent with this reasoning, Jang, Reeve, and Deci (2010) showed that structure and autonomy support were modestly positively (rather than negatively) correlated and independently contributed to positive educational outcomes. Along similar lines, examining a broad set of components of parental structure, Farkas and Grolnick (2010) found parental structure and autonomy support to yield unique positive associations with seventh- and eighth-grade children's perceived competence and actual grades. Overall, then, past research has found structure and autonomy support to be positively related to each other rather than antagonistic, and often each has yielded unique associations with a host of different outcomes. Moreover, by distinguishing the two concepts, one can assess the meaningful combinations between them, with expectations that controlling structure will have negative effects on development, whereas autonomy-supportive structure will be more positive. In fact, a number of studies in the domains of education (e.g., Vansteenkiste et al., 2012) and sports (e.g., Curran, Hill, & Niemiec, 2013) indicate that

the most optimal outcomes are attained under conditions of high autonomy support and high structure.

Parental Involvement and Parental Neglect

SDT also suggests that more than structure and autonomy support are needed to facilitate development. In addition, *involvement,* especially autonomy-supportive involvement is also helpful. Involvement refers to a parent's dedication of attention and caring, which both supports the child directly and conveys relatedness and connection as he or she faces developmental challenges (Grolnick & Ryan, 1989). Parental involvement has long been found to have positive effects on children's behavioral regulation and well-being (e.g., Baldwin, 1955). In the Grolnick and Ryan (1989) study, assessment of involvement included the time parents spent with their children in interactive ways, their knowledge of their children's day-to-day life, and the warm tone of interpersonal contact. Parental involvement and in particular the mothers' involvement predicted children's achievement and grades in school, and was negatively correlated with teachers' ratings of children's acting out behaviors. Subsequently, Grolnick, Ryan, and Deci (1991) found that parental involvement, along with autonomy support, predicted children having greater inner resources for school engagement, especially greater feelings of autonomy and competence. Further, Cheung and Pomerantz (2011) found that in both U.S. and Chinese samples, involvement predicted engagement and achievement in schools. In both nations, when such involvement was accompanied by autonomy support children also had greater perceptions of competence and better emotional functioning.

More recently, Grolnick (in press) looked at parents' motivation for their involvement with children. This is a particularly interesting area of investigation because parents can be involved both out of controlling motivations such as introjection or external pressures or because of value and interest in their children. Grolnick found that the more autonomous the parental motivation, the higher the level of involvement. Moreover, identified regulation was especially predictive of child outcomes one would expect from such willing involvement, such as more positive academic self-concept and better school grades.

These and related findings speak to the ways parents are involved, which can vary considerably. For example, much like the dynamic involved in conditional regard, parents can make their involvement (i.e., their devotion of time and resources to the child) dependent on obedient behavior, which SDT suggests will come with a cost. Consistent with this idea, Weiss and Grolnick (1991) studied the relations of parental involvement and autonomy support to adolescents' internalizing and externalizing symptoms. Adolescents rated their mothers and fathers on dimensions of involvement and autonomy support and completed a self-report profile of symptoms. Analyses indicated that parents who were perceived to be both highly involved and autonomy supportive had children who reported very low levels of either internalizing or externalizing symptoms. Yet there were significant interactions between perceived parental involvement and autonomy support on both types of symptoms, indicating that the combination of high involvement and low autonomy support yielded a high level of symptoms.

This general pattern of findings has been observed in other studies. Wouters, Doumen, Germeijs, Colpin, and Verschueren (2013) found that high parental responsiveness strengthened the relations between psychologically controlling parenting and contingent self-esteem in university students. Aunola and Nurmi (2004) found in a three-year longitudinal study among 5–6-year-old children that parents' exertion of controlling practices slowed children's progress in mathematics, a trend that was exacerbated in cases where parents displayed high affection. Interestingly, the combination of high parental control and responsiveness appeared not only to yield a personal well-being cost but also to generalize to young adults' empathic responses. In this context, Kanat-Maymon and Assor (2010) showed that parental control related positively to the child perceived distress when their romantic partners were in need, whereas parental control was negatively related to empathic responding as reported by the partners, both effects being strengthened when parents were experienced as highly responsive.

It thus appears that feeling close to very controlling parents can be detrimental to a developing child's personal and social well-being, presumably because these children's psychological needs for autonomy and relatedness are insufficiently met. That is due to the high yet controlling involvement of parents, which may leave the children feeling as if they have no other choice than to connect with their parents by complying with their demands. Similar to the dynamics characterized by enmeshed families, however, the children's connections are likely to be fueled with feelings of internal conflict and pressured loyalty, thereby causing heightened emotionality and self-preoccupation, which may interfere with their capacities to respond empathically to others (Kanat-Maymon & Assor, 2010). In short, the combination of high parental control and high

responsiveness may create confusion because parents are sending conflicting messages to the their children (Aunola & Nurmi, 2005).

Parent's Psychological Needs: Contextual and Reciprocal Influences

Thus far, our focus has been on how parents affect children's development and problem behavior through the nurturance or undermining of children's psychological needs. Yet parents themselves are subject to influences that can either support or thwart their capacities to support their children's development. That is, to the extent that parents engage in need-satisfying activities in their own lives, they are likely to have more energy available to be involved with their children, thereby being better attuned to the children's perspectives and, hence, being more capable of supporting children's unfolding interests, values, and skill development. To the extent that parents' psychological needs get thwarted, their energy levels would be more readily eroded so they would become more self-centered rather than open and receptive for their children's concerns and interests. Such self-centered preoccupation may either manifest through a direct withdrawal and involvement from the children or, to the extent that they are involved, parents would be more easily enforcing their own viewpoint or be unpredictable and inconsequent. This reasoning is graphically displayed in Figure 9.1, in which parents' own need satisfaction and need frustration are part of the proximal determinants of their approach to their children. In an examination of this dynamic, De Haan, Soenens, Dekovic, and Prinzie (2013) found need satisfaction as reported by the parents in the parent–child relationships relate negatively to the adolescents' reports of negative parental styles (e.g., overreactive or controlling).

At the same time, a variety of more distal factors, either pressuring or facilitative, will impact on parents' experiences of need satisfaction and need frustration. Pressures on parents can come from their children's behaviors in the interactions of the parents and children. That is, there are both *reciprocal influences* from the children and proximal and distal social and economic pressures on parents from other sources that impact their resources (Deci & Ryan, 2012). For example, research on child temperament suggests that children with difficult temperaments may make it harder for parents to refrain from controlling behaviors. Within the SDT literature, Grolnick, Weiss, McKenzie, and Wrightman (1996) found that parents who perceived their adolescents to be more difficult in temperament were also more controlling. In addition, it has been found that when children evidence poorer performance or get poorer grades in schools, parents often become more controlling (Aunola & Nurmi, 2005; Grolnick, Gurland, DeCourcey, & Jacob, 2002). In a particularly interesting study, Pomerantz and Eaton (2001) found that a child's low achievement was

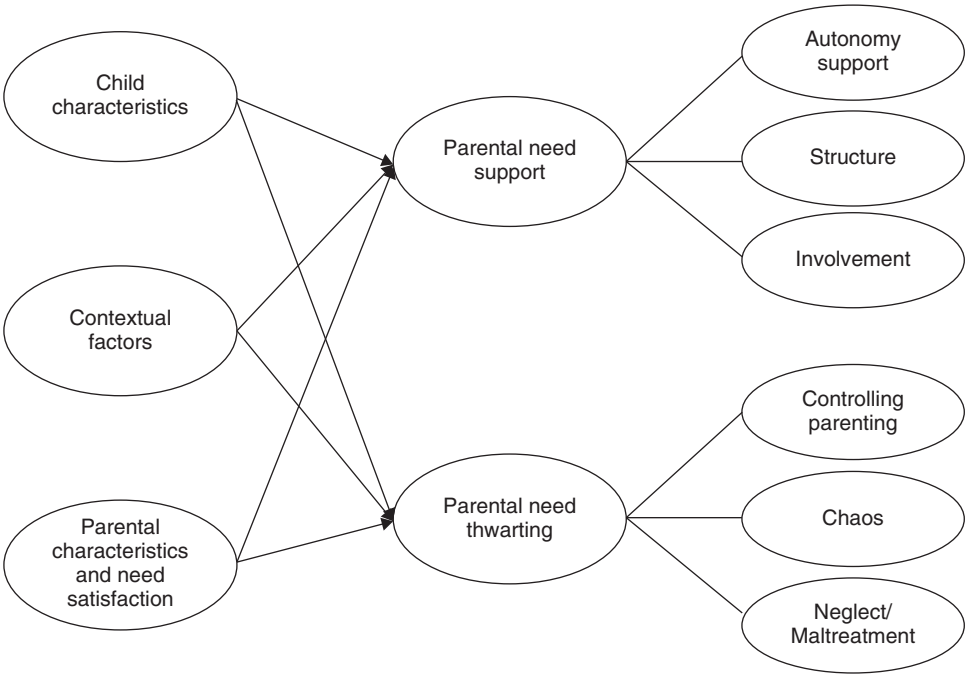

Figure 9.1 Graphic overview of the role of antecedents of parental need support and need thwarting.

associated with increased maternal worry, and worry predicted more controlling behavior, which in turn negatively affected the child's achievement. Similarly, adolescents' defiance against parents' moral rules elicited a more controlling parental approach over time (Vansteenkiste, Soenens, Van Petegem, & Duriez, 2014).

The parents' own supports can also bear on their capacity to nurture their children. For instance, Landry et al. (2008) showed that mothers who experienced greater social and partner supports were more able to trust the developmental process and thus support their children's autonomy. Similarly, Bouchard, Lee, Asgary, and Pelletier (2007) found that fathers' involvement and satisfaction in parenting was related, not only to their own perceived competence, but also to their perceptions that their partners placed confidence in their parenting abilities. In addition, Assor et al. (2004) found that many parents display the same parenting approaches (e.g., conditional regard) they were exposed to as children, thus exhibiting the intergenerational transmission of parenting styles.

Also parents often face a host of contextual pressures, which lead them to adopt a more controlling approach toward their children. Economic strain (Kasser, Ryan, Zax, & Sameroff, 1995), stressful life events (Grolnick, Bridges, & Connell, 1996), and experimentally induced stress (Grolnick et al., 2002) have all been associated with controlling parenting behavior. In one illustrative experimental study, Grolnick, Price, Beiswenger, and Sauck (2007) examined the effects of situational pressures on mothers' autonomy support, relative to control, in the social domain. The authors had 60 mothers work on a laboratory task with their fourth-grade children, presumably in preparation for meeting new children. Mothers in an evaluation condition were told that their children would be evaluated by other children and that based on this, the researchers would determine how much each child was liked and accepted by their peers. In the no-evaluation condition, mothers received no mention of peer evaluation. Results revealed that mothers in the evaluation condition spent more time giving answers to their children, especially mothers with more controlling parenting attitudes, and they also exhibited more controlling behaviors. In addition, mothers with high social contingent-self-worth who were in the evaluation condition exhibited the most controlling behaviors.

Apart from contextual pressures, internal forms of pressure, such as anxieties and worry, have also been associated with more controlling parent behaviors, especially when the worries concern their children. Gurland and Grolnick (2005), for example, examined mothers' perceptions of environmental threat regarding such issues as future economic instability and resource scarcity. Perceptions of future threat were positively associated with more controlling behaviors exhibited during parent–child tasks. In turn, these controlling behaviors were negatively associated with children's volitional motivation. Moreover, the relation between perceived threat and children's motivation was mediated by controlling parenting.

As can be noticed in Figure 9.1, parents' own personality functioning may also lead them to rely on certain parenting strategies more than others. Critical in this respect is parents' organismic trust in the development of their children (Landry et al., 2008), with parents high in organismic trust being more relaxed in their expectations regarding milestones and engaging in fewer social comparisons. Landry and colleagues showed that such organismic trust led mothers to rely on different parenting strategies during a play session where they and their 12–13-month-old infants were given problems to solve together. Mothers' autonomy support and structure were assessed using ratings of the extent to which the mothers took the children's perspectives, followed the children's pace, and structured the situation to be fitting with the children's skills. Autonomy thwarting behaviors were also measured, including tallying empathic failures and interfering in the children's pace, among other indicators. Results revealed that organismic trust, even when controlling for parental income and education and children's temperament and level of development, was significantly associated with greater autonomy support as opposed to autonomy thwarting.

Other personality factors within parents are also relevant. For example, Deci and Ryan (1985a) early on reported that persons with a stronger control orientation were less prone to support autonomy in others. The reason that parents with a stronger controlled orientation are more likely to use controlling techniques is because they more easily hinge their own self-worth upon their children's achievements. Thus, control oriented parents extend their ego-involved function to their offspring, thereby measuring their own success and worth versus failure and shame as parents through their children's accomplishments (Wuyts, Vansteenkiste, Soenens, & Assor, in press). Further, Soenens, Vansteenkiste, Duriez, and Goossens (2006) hypothesized that parents who have high separation anxiety may perceive expressions of their children's autonomy as threatening, and may be more likely to restrain autonomous behavior through controlling techniques. In addition, they argued that self-critical perfectionism in parents would lead them to project higher demands

on their children, thereby pressuring toward specified outcomes. Their results supported these hypotheses.

Together such findings underscore that parenting behaviors are themselves influenced by a variety of factors both external and internal—from the socioeconomic pressures on parents that stretch their resources and lead to insecurities, to internalized social pressures to make their children achieve. Pressures on parents in the form of threats thus interrupt organismic trust and capacities for nurturance. On the other hand, it is important to highlight that most parents, because of their inherent attachment and love for their children, naturally seek to provide support and guidance so that even their controlling behaviors are often, despite their negative consequences, expressions of their parental caring (e.g., see Chua, Wong, & Koestner, 2014).

Summary

SDT is primarily focused on nurturing, facilitating environments that support the growth of the self. The theory specifies three operationally distinctive nutritive dimensions, namely, autonomy support, structure, and involvement. These parenting dimensions are systematically related to the satisfaction of children's basic psychological needs and allow for greater specification of optimal parenting relative to mixed constructs such as Baumrind's (1996, 2012) construct of authoritative parenting and confrontive power (see Grolnick, 2002, 2012). Further, in discussing the need-thwarting role of parents, we especially emphasized the role of controlling parenting, with conditional regard being the most studied controlling practice within SDT. Finally we suggested that parent behaviors do not occur in a vacuum. Parental stress, sense of threat, and ego involvement can all lead to controlling behaviors and can detract from positive involvement and capacities for autonomy support.

AUTONOMY AND AUTONOMY SUPPORT IN MAJOR DEVELOPMENTAL PROCESSES: ATTACHMENT, INTRINSIC MOTIVATION, INTERNALIZATION, EMOTION REGULATION, AND IDENTITY FORMATION

Having elucidated the critical parenting dimensions fostering growth, in this section we elaborate the role of autonomy in development and personality functioning. First, we focus on the relations between autonomy and *attachment security* (Bowlby, 1969). SDT suggests that autonomy support is an underemphasized yet critical predictor of secure attachment experiences (e.g., Whipple et al., 2009). Even more, we argue that security provision is insufficient in accounting for healthy self-development, which requires the more active notion of autonomy support. We then turn to a review of research on four critical developmental processes in which autonomy figures heavily, namely, intrinsic motivation, internalization, emotion regulation, and identity formation, and we explicate the role of autonomy and the impact of contextual supports for it.

Autonomy and Attachment Security

Connections between autonomy and relatedness have been hotly debated in both developmental and social psychologies. Some authors see autonomy and relatedness as largely orthogonal if not antithetical constructs (e.g., Blos, 1979; Ingeyar & DeVoe, 2003; Jordan, 1992). As noted already, SDT differs, viewing autonomy and relatedness as being interrelated and, indeed, integral to one another. This is so from the earliest phases of life, in which the strength and security of attachment is, according to SDT, in very large part a function of the autonomy support afforded by caregivers.

Attachment and Autonomy in Infancy

It is particularly difficult to think about autonomy without its foundations within relatedness during the child's first years of life and vice versa. During early development, establishing a core self is a primary agenda for the infant (Stern, 1985). Although the self that is consolidated within the first six months does not take the form of a conscious representation, it can manifest as coherence and volition. Yet because infants are highly dependent on caregivers—not only for biological necessities such as food and temperature regulation but also for interpersonal necessities such as love, contact, and comfort—these earliest experiences of the self as initiator of action typically occur within the context of close parent–child relationships.

Bowlby (1969) and later theorists elaborating his attachment theory framework (e.g., Mikulincer & Shaver, 2007) have argued that early social relations with primary caregivers shape both the security of attachment and the corresponding working models of self and others that will organize future social relations. Perhaps the most emphasized feature within attachment theory that contributes to security of attachment is caregiver responsiveness or *sensitivity* (Ainsworth, Blehar, Waters, & Wall, 1978). Sensitivity is defined as the provision of contingent, appropriate, and consistent responses to the child's signals and needs (Lamb & Easterbrooks, 1981). Sensitivity thus conveys that caregivers are responsive to the child's initiations

in ways that are empathic and appropriate to the child's needs. In our view, sensitivity is part of autonomy support, though by no means encompasses that construct.

Within SDT it has been suggested that when one unpacks the kind of parenting that fosters growth and security, chief among them will be autonomy support (e.g., Ryan, 1993; Ryan, Brown & Creswell, 2007). As noted, in autonomy support what one is being sensitive to are the child's initiations, strivings, and the needs of the developing self (rather than the caregiver's agendas or projected needs). Indeed, Bretherton's (1987) description of sensitivity as "maternal respect for the child's autonomy" (p. 1075) captures the essence of such active responsiveness. The sensitive caretaker responds to the initiations, cues, concerns, and needs that emerge from the child, and this contingent responsiveness gradually strengthens the child's inner sense of agency and coherence, and thus the meaningfulness of the child's self-initiated action and expression. When responded to, the child experiences a sense of safety and interconnection that is lacking for one whose biddings and expressions have been neglected.

Autonomy support is thus a critical component of early parent-child relationships, for it facilitates not only the solidity of attachment but also self-development more generally. Numerous past studies support this perspective by linking sensitivity or autonomy support to more curiosity, effectance, initiative, and adjustment (e.g., Stevenson & Lamb, 1981; Waters, Wippman, & Sroufe, 1979; Yarrow, Rubenstein, & Pederson, 1975). Specifically applying SDT, Grolnick, Frodi, and Bridges (1984) found that mothers rated as autonomy supportive had 1-year-old infants who both explored more and were more persistent at a play task than infants of mothers rated as controlling. Further, Frodi, Bridges, and Grolnick (1985) reported similar results for the persistence and competence at 20 months of age. Such studies suggest that in early stages of development, parental attunement and support for autonomy are enhancing the child's inner resources for self-regulation.

We suggest, in fact, that autonomy support is an aspect of caregiving that is far too underemphasized in attachment theory's foundational focus on security, protection, and responsiveness. Underscoring this argument, Whipple, Benier, and Mageau (2011) drew from SDT in using observational assessments of maternal autonomy support during infant (15 months) exploration. They also assessed maternal sensitivity with a 90-item measure of the quality of maternal behaviors during a home visit and security of attachment using an observational Q-sort method. Results showed that not only sensitivity but also autonomy support explained independent variance in attachment security. This shows how autonomy support is not encompassed by traditional conceptions of sensitivity.

This interrelation between autonomy support, attachment, and self-development is nonetheless consistent with some of Bowlby's (1969) speculations concerning infant exploration and mastery motivation. Bowlby postulated that to the extent that a child experiences security (i.e., caregiver accessibility and responsiveness in times of need), then the child will feel enabled to venture forth to explore with interest. Yet SDT would suggest, beyond Bowlby, that security is much more than protection and comfort; it is in fact responsiveness *to the self* of the child that fosters secure relationships, not simply reliable protection (Ryan, Brown, & Crewell, 2007).

It is worth noting in this regard that for Bowlby, attachment was first and foremost about safety and protection rather than facilitating growth and development. As Kobak, Cassidy, and Zir (2004) stated, attachment is a "behavioral system activated by appraisals of danger and accompanying signals of fear" (p. 388). Adult attachment theorists concur, arguing that "the goal of the system is a sense of protection and security" (Mikulincer & Shaver, 2007, p. 5). Without doubting the importance of protection and the value of reducing anxiety in moments of danger, one can question whether this is a sufficient foundation for a full theory of self-development (see Ryan et al., 2007). Although moments of dangers and strangers can be salient, they are episodic, and comfort following them may be a necessary, but not a sufficient, condition for the interpersonal support for self-development. Even among the object-relations theorists in Bowlby's time, figures such Winnicott (1965) more strongly pointed to the importance of ongoing positive supports for the nascent self to not only feel safe, but to develop and flourish. Winnicott highlighted not only a safe haven but also active empathy and having spontaneous initiations amplified through mirroring and responsive care. Like Winnicott, SDT argues that support and nurturing relationships in infancy extend well beyond security and protection to the *active facilitation* of self-functioning. Indeed, security and protection are likely key to prevent experiencing of need frustration, yet, for children to experience autonomy, competence, and relatedness, more active support of these needs is required. In fact, as we turn to other developmental processes such as intrinsic motivation, internalization, emotion regulation, and identity formation, the role of caregivers' support for the child's psychological needs, including autonomy, emerges as a critical facilitator of self-development.

This brief analysis of the role of autonomy and relatedness in infancy thus suggests that autonomy support is

a critical component of caregiving in infancy that shapes both the experienced quality of relatedness (as reflected in the security of attachment) and the consolidation and vitality of the self (as reflected in both well-being and mastery motivation). Caregiving that is low in autonomy support, by contrast, will set the stage for attachment disturbances and impoverished agency.

More recent studies have begun to examine the independent role of parental autonomy support and attachment security per se in young children's development. For instance, Verschueren, Doumen, Vervoort, and Vansteenkiste (2013) showed in a longitudinal sample of preschool children that both a secure attachment and maternal autonomy support, as observed during a problem solving task, related to higher achievement on a standardized language and mathematics test taken at the end of the first elementary school year, through partially distinct pathways. Attachment security in preschool was related to greater closeness in the teacher–child relation in the first school year, whereas maternal autonomy support related to both greater teacher–child closeness and more learning based in interest and enjoyment (i.e., intrinsic motivation), which in turn predicted greater actual achievement. These findings suggest that a secure and autonomy-supportive child–parent relationship promotes a more successful transition from preschool to elementary school, with need-supportive interactions generalizing to new socialization figures.

Attachment and Autonomy in Adolescence and Beyond

There is increasing evidence that at whatever age attachment security is assessed, the provision of autonomy support from attachment figures will be a critical predictor of attachment security. Adolescence, for example, is a critical period of life in which teens are rapidly developing capacities for independence, while still needing considerable support and nurturance. As noted previously, in SDT's view, rather than individuating *from* parents, healthy adolescent development is characterized by continued attachment and dependence along with autonomy. In fact, evidence suggests that security of attachment and reliance on parents in this age is quite important for well-being and that these are facilitated by caregivers' support for autonomy.

First, several studies support the view that adolescents continue to benefit from secure attachments to parents rather than by the detachment that Blos (1979) advocated. Ryan, Stiller, and Lynch (1994) investigated the contributions of felt security with parents, teachers, and friends to the motivation, adjustment, and self-esteem of early adolescents. They found that felt security with parents and teachers, as well as utilization (reliance on) these figures, predicted adjustment. Further, they found evidence that felt security with parents predicted security with both teachers and peers, and appeared to have priority among working models. Similarly, Bober and Grolnick (1995) assessed adolescents' felt security with and emulation of parents. Adolescents who displayed internalizing symptomatology reported low levels of felt security with parents yet emulated them. Adolescents with externalizing symptomatology reported low levels of felt security and low emulation of parents.

Ryan and Kuczkowski (1994) examined felt security with parents as it relates to the emergence of *private audiences* in the cognitive development of adolescents. Following Elkind (1967), they argued that the private-audience phenomenon initially represents a heteronomous influence on behavior for most adolescents, who become more self-conscious and more prone to conformity. Yet with self-development the salience of private audiences has been hypothesized to lessen. Ryan and Kuczkowski (1994) predicted and found that whereas felt security with parents was unrelated to the strength of private audiences in early adolescence (when it is a normative aspect of development), it was more strongly related in later adolescents. Adolescents experiencing insecurity with parents remained more preoccupied with private audiences, showing one pathway through which the growth of autonomy is hampered.

Ryan and Lynch (1989) examined the issues of autonomy and attachment in early, middle, and late adolescent samples. They argued that autonomy is typically *facilitated* by secure attachment to, and dependence on, parents rather than by detachment and nonreliance on them. They further suggested that among the primary reasons that adolescents are insecure with or detached from parents is that parents are overly controlling. Their studies confirmed that adolescents with more secure attachment to parents were, in fact, better adjusted, and had parents who were more autonomy supportive. These findings have been well replicated, including recent studies of both referred and nonreferred youth and their mothers, in which parental autonomy support related to lower anxiety-based attachment, while parental responsiveness and sensitivity related to lower avoidance-based attachment (Brenning, Soenens, Braet, & Bal, 2012; Karavasilis, Doyle, & Markiewicz, 2003).

The importance of autonomy supports for secure attachments extends to early adulthood. La Guardia, Ryan, Couchman, and Deci (2000) studied the attachment experiences of college students with multiple social partners such

as their mothers, fathers, best friends, and romantic partners. They found, as classical attachment theory predicts, that individual differences in security of attachment were a moderately significant predictor of patterns of security of attachment across social partners. Yet they also hypothesized and found significant variability in students' security of attachment with these different social partners as a function of the different qualities of interpersonal supports provided within each relationship. In three studies, La Guardia and colleagues applied multilevel modeling to reveal that within-person variability in attachment security was systematically explained by relationship-specific autonomy support. In fact autonomy support was an especially consistent predictor of felt security, relationship satisfaction, and willingness to rely on that person.

In a more recent study of adult attachments, autonomy support, and emotional reliance, Lynch (2013) collected daily data on autonomy support and security of attachment to predict patterns of *emotional reliance*—that is, the individual's willingness to turn to another person for emotional support (see Ryan et al., 2005). It has been assumed by attachment theorists that secure attachments would be associated with positive abilities to recruit support from others when distressed (e.g., Belsky, 2002). Yet Ryan et al. (2005) argued that autonomy support was also particularly crucial in facilitating such emotional reliance, as people are less prone to rely on others who are controlling. Lynch (2013) therefore allowed measures of both attachment security and autonomy to compete at both trait and state levels in predicting emotional reliance. At the trait level both security of attachment and trait autonomy predicted greater tendencies to emotionally rely on others. At the within-person level, results showed, as predicted by SDT, that people were specifically more willing to turn to those people whom they perceived to be autonomy supportive. Noteworthy is that at both within- and between-person levels of analysis, emotional reliance was more strongly linked with autonomy than with attachment security.

Summary

SDT and attachment theory thus concur that attachment security is associated with higher well-being and ability to rely on others. SDT additionally maintains that autonomy support is critical to experiencing attachment security, including primary attachment figures. Moreover, through the more active nurturance of explorative behaviors, emerging interests and personal values, autonomy-supportive agents do more than provide comfort; they promote children's healthy development.

Intrinsic Motivation: A Spontaneous Expression of Human Autonomy

Intrinsic Motivation: Definition

Perhaps the most direct catalyst of empirical research on autonomy within both social and developmental psychologies has been interest in the phenomenon of intrinsic motivation. *Intrinsic motivation* is defined as motivation derived from the inherent satisfactions of an activity—it applies when actions are experienced as interesting or enjoyable for their own sake (Deci & Ryan, 1985b).

Harlow (1950) was, to our knowledge, the first scholar to employ the term intrinsic motivation. He used it in reference to the persistence of primates, curiously working at mechanical puzzles without reinforcements or rewards. In fact, he was an early observer of an "undermining effect" of rewards, noting that attempts to enhance curious behaviors with reinforcements disrupted such intrinsic motivation. Subsequently, White (1959), drawing on both comparative psychology and developmental studies, argued that this type of interest-driven behavior underlies much of human social and cognitive development. Indeed, this idea of an innate, natural propensity toward the exercise and growth of capacities has been an important postulate in the study of developmental and learning processes (Deci & Ryan, 2013; Flavell, Miller, & Miller, 2002; Koestner & McClelland, 1990).

Intrinsic motivation reflects a natural assimilative tendency, which is evident in the active exploration, manipulation, curiosity, and playful exercise of skills we observe in healthy children. Intrinsically motivated play and activity foster learning and the growth of competencies, as developmental theorists have long argued (Harter, 2012). Also studied as *mastery motivation,* intrinsic motivation is clearly evident in infancy (e.g., Yarrow et al., 1975) and differentiates into more specific interests as children grow (Deci & Ryan, 2013). Numerous studies have linked intrinsic motivation to deeper learning (e.g., Grolnick & Ryan, 1987; Yamauchi & Tanaka, 1997), creativity (e.g., Amabile, 1983), and other indicators of high-quality assimilation.

Social Contexts and Intrinsic Motivation

Although intrinsic motivation is posited to be natural, its unfolding and development is nonetheless viewed within SDT as being dependent on specific social and contextual nutrients (Deci & Ryan, 1985b; Ryan, 1993). A substantial amount of research has therefore explored the effects of various social contexts on intrinsic motivation, and this

body of research has been described within a specific mini-theory of SDT called *cognitive evaluation theory* (CET; Deci & Ryan, 1985b). In brief, CET argues that intrinsic motivation is dependent on experiences of both autonomy and competence. Social contexts that are either controlling or autonomy inhibiting (Grolnick & Ryan, 1989) or that lack challenges or feedback that supports felt competence (e.g., Abuhamdeh & Csikszentmihalyi, 2012; Mouratids et al., 2013) are expected within CET to diminish intrinsic motivation. In contrast, environments that support autonomy (e.g., provide choice, are responsive to initiatives) and competence (are well structured, provide positive feedback) are expected to maintain or enhance intrinsic motivation. Finally, in contradistinction to social-cognitive approaches (e.g., Bandura, 1989), CET holds that that intrinsic motivation requires autonomy satisfactions; self-efficacy alone will not sustain this spontaneous form of activity.

Studies testing CET have been done with toddlers to adults, allowing us to draw inferences about some fundamental, age-invariant aspects of intrinsic motivation. One type of evidence comes from experimental studies. In the typical paradigm children or adults work on an activity under different conditions that vary in terms of contextual factors affecting perceived autonomy, perceived competence, or both. Subsequently, intrinsic motivation is assessed by a free-choice behavioral measure. Participants are given a postexperimental period without demands, in which the target activity is available along with alternative activities (e.g., reading a magazine). The time participants spend spontaneously engaging the target activity is recorded and used as the *free-choice measure of intrinsic motivation*. Ratings of how interesting and enjoyable participants find the task are a complementary measure of intrinsic motivation.

One interesting factor affecting intrinsic motivation is external rewards. CET postulates that because rewarded participants are more likely to see the impetus or cause of their activity as stemming from external sources, when they are offered rewards for acting they are vulnerable to losing an internal perceived locus of causality and sense of autonomy. When originally proposed (Deci, 1971), this CET hypothesis was provocative because many psychologists then held a view, based in operant psychology (Skinner, 1953), that all behavior was controlled by external contingencies of reward and punishment. CET not only assumes this is not the case, but moreover suggests that some types of rewards that are very effective in shaping behavior can at the same time yield detrimental effects on intrinsic motivation, precisely because of their negative effect on autonomy. In contrast when rewards are not controlling, but rather provide more *informational* (or competence relevant) feedback, they can be more motivationally positive (Ryan, Mims, & Koestner, 1983).

Danner and Lonky (1981), combining Piagetian and CET frameworks, presented a classic study illustrating some of the developmental implications of this undermining effect of rewards on intrinsic motivation. Children were classified with regard to their level of cognitive development using a Piagetian assessment. They then worked on additional cognitive tasks either explicitly for, or without, externally offered rewards. Subsequently, children were given a free choice period in which they were allowed to select activities during a play opportunity. Children who did not receive external rewards gravitated to tasks that were optimally challenging—those stretching their assessed cognitive capacities. In contrast, children who had been externally rewarded sought easier tasks and avoided challenges during free play. These results illustrate how attempts to enhance development through controlling rewards can backfire.

Another example comes from studies of young children's intrinsic interest in helping others, which many argue is a deeply evolved human propensity (see Ryan & Hawley, in press). To demonstrate that early altruism constitutes an intrinsic or a natural inclination Warneken and Tomasello (2008) created situations where 20-month-old toddlers could help adults (e.g., pick up dropped objects). In one condition they gave children a concrete reward every time they helped, whereas children in another condition did not get rewards. In a second phase, they found that children previously rewarded for helping were less helpful than those never rewarded. Presumably, the reward undermined children's spontaneous, intrinsically motivated tendency to be helpful, a finding paralleling adult findings (e.g., Weinstein & Ryan, 2010). This experiment is notable in finding the effect in children before they can cognitively weight or discount the motives underlying their behavior, ruling out so-called overjustification explanations of this effect (e.g., Lepper, Greene, & Nisbett, 1973).

Despite a plethora of studies documenting undermining effects, debate about the undermining effect was resparked by Eisenberger and Cameron (1996). who presented meta-analyses of reward effects that seemingly contradicted previously published summaries and meta-analyses on the topic. In their analysis they surprisingly found no evidence for an undermining effect by rewards, and they labeled the undermining effect a myth. Their null findings were immediately heralded by many behaviorists. Yet detecting serious methodological problems, Deci, Koestner, and

Ryan (1999) reanalyzed these experimental data, taking care to include all studies summarized by Eisenberger and Cameron (1996). The reanalysis, presented in *Psychological Bulletin,* not only confirmed this well-known undermining of intrinsic motivation by rewards, but more importantly, supported the differentiated pattern of reward and feedback effects on intrinsic motivation predicted by CET. Data indicated that controlling reward contingencies undermined intrinsic motivation, whereas noncontrolling and informational rewards did not.

Many studies continue to document this important effect. One study of particular interest focused on neurological supports for intrinsic motivation (Murayama, Matsumoto, Izuma, & Matsumoto, 2010), providing a new way of demonstrating the undermining effect of rewards on intrinsic motivation. These researchers had participants engage in an interesting task under reward and no-reward conditions, tracking activations with fMRI. The no-reward group found the task interesting and cognitively engaging, and these inherent satisfactions were associated with meaningful striatal and lateral prefrontal cortical activity. For the reward group, Murayama et al. (2010) provided a performance-contingent monetary reward, and as predicted both striatal and lateral prefrontal cortical activity increased significantly, suggesting that the reward added to task motivation and engagement. Yet in a second phase of the study, participants repeated the task, but in this phase no rewards were offered. The researchers again examined the striatal and lateral prefrontal cortical activity the task generated. For participants in the prior no-reward condition, striatal and lateral prefrontal cortical activation were essentially stable; the task remained just as rewarding and engaging as before. Yet for those in the reward condition, striatal and lateral prefrontal cortical activity declined—the task now failed to generate pleasure (striatum) or cognitive engagement (lateral prefrontal cortical), as predicted by CET.

SDT scholars do not question the power of rewards to control behavior. However, SDT emphasizes that, at the same time, the very power of externally administered rewards can also lead individuals away from their intrinsic inclinations. Powerful extrinsic rewards, whether they be tangible rewards or conditional love, can lead people to forego autonomy, forget their values and preferences, and neglect their interests and relationships. That is precisely what unhealthy regulation and alienation is all about (Ryan & Deci, 2000a). Not only can controlling rewards undermine intrinsic motivation, so can motivational tactics such as controlling praise (e.g., Ryan, 1982); threats of punishment (e.g., Deci & Cascio, 1972); salient surveillance (e.g., Enzle & Anderson, 1993; Plant & Ryan, 1985); controlling-directive language (e.g., Hooyman, Wulf, & Lewthwaite, 2014; Reeve & Jang, 2006); and grades (e.g., Pulfrey, Buch, & Butera, 2012). These and other frequently used methods of controlling behavior can have a psychological meaning, or *functional significance*, of being controlling, which in turn negatively affects people's experience of autonomy and engagement. To the extent that adults use salient prods, prompts, or pressures to induce children to perform interesting activities, they are likely to disrupt intrinsic motivation and autonomous functioning (Assor et al., 2004).

Effects Across Developmental Periods

Although many experimental studies of intrinsic motivation have been in school and college settings, the effects of autonomy support versus control on intrinsic motivation are robust across developmental epochs and interpersonal settings. We review some examples.

Earlier we cited studies by Grolnick and colleagues (1984; 1985) in which infants and toddlers whose mothers were more controlling evidenced less mastery motivation and persistence than those whose mothers more actively supported their initiations and autonomous play. As another illustration, Grolnick et al. (2002) observed mothers and their third-grade children working together on an assigned task of problem solving and constructing poems. Following the interaction, children were asked to complete similar tasks on their own, without their mothers being present. Children whose mothers interacted with them in a more controlling manner had performed just as well as other children when with their mothers, but, when completing tasks on their own, they were less accurate in problem solving, and wrote less creative poems.

Deci, Driver, Hotchkiss, Robbins, and Wilson (1993) looked at maternal autonomy support and control with five- to seven-year-olds. They recorded mothers' vocalizations during an interactive-play period, and had raters code the interactions for autonomy supportive and controlling contents. After sessions in which mothers were rated, children's intrinsic motivation was assessed using persistence observations during solo play. Children whose mothers were rated as more autonomy supportive were more intrinsically motivated.

The significance for development of this general effect concerning autonomy support and control on intrinsic motivation cannot be overstated. Children's exploration, challenge seeking, and curiosity are inherent and natural resources for cognitive and emotional development, and a wellspring from which specific competencies derive.

Also, when led by curiosity and exploration, children gradually learn to discover their interests, a first step toward pursuing their interests and gradually building their skills. Yet this resource is curtailed by controlling environments. Intrinsic motivational tendencies that support growth can be stifled by even well meaning caretakers as they attempt to elicit development through reinforcement or control.

The significance of intrinsic motivation, and the impact of social contexts on it, has been documented in various domains, including education, exercise, and work. For example, within schools Deci, Schwartz, Sheinman, and Ryan (1981) collected teacher's reports about their classroom motivational strategies before they met their students for the year. Several weeks into the school year Deci et al. (1981) returned to assess student motivation and well-being. They found that students assigned to teachers who were oriented toward supporting autonomy displayed higher levels of curiosity, perceived cognitive competence, and self-esteem than those assigned to teachers espousing more controlling orientations. Ryan and Grolnick (1986) reported parallel results using elementary school children's perceptions of their teachers. Notably, even in an "elective" domain such as sport, O'Rorke, Smith, Small, and Cumming (2012) found that young athletes' autonomy for playing sport was related to the motivational climate created by parents. Parents focused on mastery motivation with little ego-involvement had children with higher levels of autonomy and intrinsic motivation for sport. A prospective analysis over the course of a sport season showed, in fact, that ego-involved parents had children whose autonomy for playing decreased over the season.

Indeed there is now an extensive literature that continues to document the beneficial effects of autonomy-supportive socialization, including their generalizability across cultures. For example, Chirkov and Ryan (2001), studied Russian and U.S. high school students, finding that perceived autonomy support from parents and teachers was associated with more internalized academic motivation and better mental health in both samples, to comparable degrees. Jang, Reeve, Ryan, and Kim (2009), in a prospective study of South Korean high school students found that teacher autonomy support predicted greater intrinsic motivation in school. Jang, Kim, and Reeve (2012) extended these findings in a multiwave longitudinal study of more than 500 South Korean students, testing a complex path model. As expected, teacher autonomy support enhanced student need satisfaction and engagement, resulting in better achievement. But reciprocal effects were also apparent, such that when students' need satisfaction was high, teachers were influenced to be less controlling. This kind of longitudinal approach reveals the complex dynamic effects between autonomy support and autonomous motivation, which are truly interpersonal and in which influences can be reciprocal.

Intrinsic motivation is quite contextually sensitive, fluctuating over time with perceived autonomy support. For example, Tsai, Kunter, Ludtke, Trautwein, and Ryan (2008) showed that German public school students, followed over multiple days in three different required courses, showed considerable lesson-to-lesson variability in interest. Yet the fluctuations were systematic: they were directly associated with variability in teacher autonomy support. On days when the teacher was more controlling students' interest waned. These findings were extended by Mouratidis, Vansteenkiste, Lens, and Sideridis (2011). Rather than following daily variations in perceived teaching behavior, they instructed teachers to randomly build in autonomy supportive segments within their more typical teaching approaches. In classes where the strategies were inserted adolescents reported enjoying the class more and feeling more vital and energized. Moreover, these effects from inserting autonomy-supportive strategies were specifically accounted for by students' reports of autonomy need satisfaction.

Factors that support a person's autonomy can, of course, enhance interest and intrinsic motivation. For example, a meta-analysis by Patall, Cooper, and Robinson (2008) showed that in general the affordance of meaningful choices to people has an enhancing effect on intrinsic motivation (see also Katz & Assor, 2007). Autonomy support is also conveyed by taking the person's *internal frame of reference*, or understanding their point of view (Deci & Ryan, 1985b; Koestner, et al., 1984). In fact, Patall, Dent, Oyer, and Wynn (2012) found that teachers' perspective taking and provision of choice were both autonomy-enhancing factors for high school students. Such studies indicate that providing choice and acknowledging perspectives can enhance intrinsic motivation, as these events leave individuals feeling more autonomous.

Summary

Experiments and field studies in diverse domains, including parenting, teaching, and coaching, suggest that social contexts that are experienced as *controlling* (i.e., as pressure to think, feel, or behave in specific ways) undermine autonomy, resulting in diminished intrinsic motivation and more negative self-related emotions. In contrast, contexts that are *autonomy supportive* (i.e., that consider

the individual's frame of reference, provide choice, and encourage self-initiation) have positive effects on intrinsic motivation and persistence.

Internalization: Assimilating Social Regulations and Values

The Internalization Continuum

Intrinsic motivation is a prototype of autonomous motivation that occurs spontaneously, as an expression of our active, assimilative human nature. Many behaviors, however are not intrinsically interesting, but parents, school systems, or other authorities believe them to be in children's best interests and therefore important for them to acquire. Although parents and teachers, as primary socializing agents, attempt to motivate children to perform such activities, the methods they use vary. Some may be controlling and authoritarian, forcing the child to conform to norms or expectations; others may be autonomy supportive, influencing through reasoning, modeling, and guidance of choices. SDT predicts that whereas controlling methods foster at best short-term compliance, autonomy support, structure, and involvement in conjunction enhance the *internalization* and *integration* of behavioral regulations.

Ryan, Connell, and Deci (1985) defined internalization within SDT as the means through which individuals can become more autonomous in performing an activity that was initially externally prompted. In this view internalization is an active process of selecting and transforming ambient regulations into personally endorsed values or motivational propensities. Through internalization, people acquire values and behaviors that allow them to be effective, connect with others, and experience volition—that is, to get their psychological needs met. When functioning optimally, the internalization process results in values and regulations that are more self-endorsed, that is, are fully integrated within the self.

SDT further hypothesizes that supports for autonomy, competence, and relatedness are necessary for such optimal, integrated internalization (Deci & Ryan, 2000; Ryan, 1993). Unfortunately, these ideal contextual conditions are not widely prevalent, and full integration of regulations is not often attained. Instead, when socializing agents are controlling or uninvolved, internalization results in values and regulations that are only poorly internalized. SDT therefore places importance on distinguishing between types of internalization for predicting the nature and quality of behavioral and psychological functioning. Specifically, SDT specifies a continuum of regulatory styles that spans from low to high autonomy for acting.

At the low end is *external* regulation, which describes extrinsically motivated behavior that is initiated and maintained by external rewards or punishment avoidance. A child who does chores to avoid parental nagging would be externally regulated, as would one who does them to get tangibly rewarded. External regulation is characterized by a lack of internalization, and although external rewards and punishments can be powerful motivators, externally regulated behavior is poorly maintained in the absence of direct control.

Somewhat more autonomous is regulation based on *introjection*. Introjected regulation is motivated by feelings of self-worth and loveability for acting as one should, and guilt or self-disparagement for failing to meet the standards or goals. Introjected regulation is thus often rigid and accompanied by feelings of internal pressure and tension. A child who does chores because she feels pressured to avoid feeling guilty and to feel like a "good girl" is displaying introjection. Indeed, introjection supplies the developmental basis for *internally controlling* regulation, as exemplified in ego involvement (Ryan, 1982), contingent self-worth (Deci & Ryan, 1995; Kernis, 2003), and self-critical perfectionism (Frost et al., 1993; Soenens, Vansteenkiste, Duriez, Luyten, & Goossens, 2005). Accordingly, research has related introjection to rigidity, anxiety, self-derogation, and other maladaptive patterns (e.g., Assor, Vansteenkiste, & Kaplan, 2009; Weinstein, Deci, & Ryan, 2011).

Still somewhat higher on this continuum of autonomy is *identified regulation* of behavior. In this type of regulation the person consciously identifies with a value or behavioral goal—accepting it as his or her own. It is therefore enacted with less resistance and conflict, and often with persistence, diligence, and efforts based in valuing. Children who clean their rooms because they understand that a clean room allows them to more easily find what they need have concurred with the importance of cleaning, that is, they have more fully internalized the value and reason for cleaning. Finally, *integrated* regulation represents the most autonomous form of internalized regulation, as it indicates that an identified value and its accompanying regulatory process have been reciprocally assimilated with other values and important personal goals. Various identified values may be more or less challenging to integrate, but if integrated, are wholeheartedly endorsed and performed.

These four modes of extrinsic regulation lie along a continuum of relative internalization and autonomy, where external regulation represents the least internalized and autonomous mode and integrated regulation represents the most internalized and autonomous mode of extrinsically

motivated behavior. Intrinsic motivation is also on the high autonomy end of this dimension, yet does not require internalization of regulation as the behavior already spontaneously manifests when people act out of enjoyment and interest. Considerable evidence backs up the continuum nature of this array. Ryan and Connell (1989) provided the initial studies assessing children's external, introjected, identified and intrinsic regulatory styles, and their data confirmed that these were reliably ordered along a continuum of increasing autonomy. Moreover, the more autonomous forms of regulation (identified and intrinsic) were positively correlated with positive affect and proactive coping, whereas the less autonomous forms (external and introjected) were correlated with negative affect and maladaptive coping. Introjection, in particular, was associated with anxiety and anxiety amplification following failure, highlighting the inner stress and tension associated with this internally controlling form of regulation.

Enhancing internalization and integration is a valuable goal in its own right, yet when students have more autonomous forms of motivation they also tend to more deeply process the learning material (Sobral 2004; Yamauchi & Tanaka, 1998), to be more fully absorbed in the task at hand (e.g., Abuhamdeh & Csikszentmihalyi, 2012), and to perform better. For example, De Naeghel, Van Keer, Vansteenkiste, and Rosseel (2012) examined elementary students' motives for reading, both in school and in leisure time. They found that more internalized, autonomous motives not only related positively to teacher-rated engagement in reading, but also to children's scores on a standardized reading comprehension test. At the other end of educational development, Kusurkar, TenCate, Vos, Westers, and Croiset (2013) found that autonomous motivation is positively associated with the use of a deeper study strategy and better GPA in medical students. In fact, a recent meta-analysis by Cerasoli, Nicklin, and Ford (2014) supports this pattern of findings, with intrinsic/autonomous motivation predicting both better quality and quantity performance, while incentives related only to better quantity performance.

The relations of internalization and autonomy to higher quality behavior are not limited to learning and achievement domains. For example, Ryan and Connell (1989) found that more autonomous regulation in the prosocial domain was associated with greater empathy, more mature moral reasoning, and more relatedness. Blais, Sabourin, Boucher, and Vallerand (1990) assessed adults' reasons for maintaining their primary relationship, finding that regulatory styles representing lower autonomy were negatively associated with dyadic adjustment and relationship satisfaction. Ryan, Rigby, and King (1993) examined the internalization of religious values, finding that introjected regulation of religious behaviors was positively associated with symptoms of depression, anxiety, and low self-esteem, whereas identified regulation was negatively associated with these indicators of ill-being. Neyrinck, Vansteenkiste, Lens, Hutsebaurt, and Duriez (2006) found that greater internalization of religious activities was associated with a more open and flexible interpretation of doctrines, stronger adherence to beliefs, and greater well-being. In the health care domain, Williams, Rodin, Ryan, Grolnick, and Deci (1998) showed that patients who had more strongly internalized the self-importance of taking their medication were more likely to effectively take them. Finally, although parents constitute primary socialization figures in the transmission of values, only the autonomous agreement with parental values relates positively to well-being, even after for controlling for the degree of parent-child agreement as such (Knafo & Assor, 2007). Across these domains and others, findings consistently show that the more autonomous people's motives, the more effective their functioning and psychological experiences.

Social Contexts and Internalization

Given these benefits of fuller internalization, the developmental conditions that foster or facilitate internalization and autonomous regulation are an important focus of research. Although like intrinsic motivation, internalization is hypothesized within SDT to be a natural process (Ryan & Hawley, in press), it too requires specific nutrients and supports from the social context. In fact, all three needs are critical to foster the full integration of socially prescribed norms and values. That is, a sense of competence is an important yet not sufficient condition for fuller internalization of an activity, as one can feel fairly competent, yet externally pressured to do the activity. Similarly, a sense of relatedness is conducive to taking in the behavioral regulation, yet a sense of internal conflict can still be underlying the behavior if it is emitted to avoid feelings of disloyalty and guilt vis-à-vis the socialization figure. For full internalization to occur, a sense of autonomy is critical. Consistent with this idea, Markland and Tobin (2010) showed that the satisfaction of the three needs maps in theoretically meaningful ways to the different types of regulation for exercising. Whereas relatedness satisfaction yielded a unique positive association with introjected regulation, it is only when all three needs were fulfilled, that the exercisers identified with the importance of exercising.

To promote autonomy need satisfaction and subsequent internalization, the use of control has been found

to be harmful, whereas provision of autonomy support has been shown to be critical, a finding that generalizes across cultures (e.g., Ahmad, Vansteenkiste, & Soenens, 2013; Barber, Stolz, & Olsen, 2005; Chirkov et al., 2011; Jang et al., 2009). There are many elements to autonomy support, but they all start from an empathic grasping of an individual's perspective so as to better understand why the person refuses to engage in the noninteresting activity. By taking the frame of reference of that person, the socializing agents can provide a more relevant and meaningful rationale, provide additional competence-enhancing information, if needed, and offer choices concerning how and when an activity is carried out. Along with support for relatedness, provision of such autonomy support and structure deepens internalization and contributes to social integration and wellness.

The critical role of need-supportive socialization for children's internalization has been documented in dozens of studies. For instance, in the study by Grolnick and Ryan (1989), parents who were rated as more autonomy supportive from interviews had children whose motivation for schoolwork was more fully internalized. Notably, many parents who were rated as controlling were clearly involved in their children's lives, and many were well intended, some highly invested in their children's success (Wuyts et al., in press). Yet in attempting to control the children to ensure that they attained certain outcomes, they often failed to promote their children's ownership of these goals or the children's personal investment in achievement, instead creating a reliance on external regulation.

As noted, the practice of *parental conditional regard* (PCR), or the degree to which a parent shows more attention and affection after compliance or success, and less affection and attention after noncompliance or failure, has received increasing recent attention. For instance, Assor et al. (2004), studying four domains (i.e., academics, sports, prosocial behavior, emotion regulation), showed that student perceptions of PCR, assessed separately for mothers and fathers, predicted compliant behavior that was largely based in introjection and inner compulsion. PCR appeared also negatively associated with identification and feeling a sense of choice about the activities, whereas PCR was positively related to contingent self-esteem, shame, guilt after failure, and short-lived satisfaction after success—all variables one would expect to be associated with introjection. Most tellingly, students who experienced more PCR also reported more anger and resentment toward their parents.

Interestingly, the negative repercussion of PCR may not only manifest at the personal, but also at the interpersonal level. Moller, Roth, Niemiec, and Deci (2014) found that late adolescents who experienced parents as being higher on PCR not only reported less secure attachments with them; they also reported more conditional regard and less secure attachments with their current romantic partners and best friends. The experience of being conditionally regarded thus appears to generalize from experiences of parents to other close relationships. Along similar lines, Soenens, Vansteenkiste, Goossens, Duriez, and Niemiec (2008) found that parental psychological control, which compromises conditional regard as one of its central components, was associated with more physical aggression and poorer peer relationships

Conditional regard, as a form of internally controlling parenting, can be differently valenced—it can take a more seductive form of *positive parental conditional regard,* involving the provision of more attention and affection than usual in case of desirable child behavior, and a more punitive form of *negative conditional regard,* involving the withholding or even withdrawal of attention and affection in case of undesirable child behavior. Although most theorists might expect negative PCR to be problematic, some approaches (e.g., many social learning and cognitive approaches) might argue that positive PCR is an effective form of parenting. Indeed, some theorists appear to justify and even advocate tiger mom tactics that involve the display of PCR (e.g., Fu & Markus, 2014). Unfortunately, it appears that also positive PCR comes with a cost. For instance, Roth, Assor, Niemiec, Ryan, and Deci (2009) showed that parents using positive PCR to promote academic success had adolescents who reported internal compulsion to do school work rather than a sense of autonomy, and their teachers reported them to be grade-focused. In addition, extending Assor et al.'s (2004) findings, these adolescents reported greater resentment toward parents. Negative PCR was also related to resentment of parents, and was related negatively with school engagement. Thus negative PCR does not promote internalization (not even introjection) although years earlier Sears et al. (1957) had proposed that it would. Most likely the parents who used love withdrawal in their samples also used positive conditional regard, and it may have been the positive PCR that led to their proposal. In a second study by Roth et al. (2009), positive PCR was compared to autonomy support as parenting methods for children's school achievement. Results showed that both mothers' and fathers' positive PCR were positively related to the child exhibiting grade-focused engagement, and negatively to interest-focused engagement. Further, these relations were mediated by the experience of internal compulsion

(i.e., introjection), as predicted. In contrast, autonomy support from each parent predicted interest-focused engagement, a relation that was mediated by a sense of choice.

While internally controlling strategies, such as conditional regard, may elicit partial internalization of parental demands through introjection, parents' reliance on external controls is likely to merely elicit external regulation, representing a complete lack of internalization of the behavioral regulation. Even more, in response to external controls, children may be noncompliant or even reactive. In an illustrative observational study among Mexican children, Brunstein (1994) showed that parents' engagement in externally controlling practices (e.g., orders, reprimands, and threats) related positively to both children's observed inattentive obedience and their passive and rather blunt resistance to comply with parents' requests. More recently, Talwar and Lee (2011) conducted a field experiment comparing two West African schools, which strongly varied in terms of their use of physical punishment as a discipline practice. Specifically, 3–4-year-olds of the one school, who were very frequently exposed to the physical punishment, were 12 times more likely to lie during a toy game and to conceal their lies.

Thus, for socializing agents to promote internalization and ownership of regulations, a controlling approach would best be avoided. Yet the absence of control does not imply the absence of guidance, as would be the case with a laissez-faire climate. What is critical for children to begin to internalize societal expectations is that prescribed behaviors and limits need to be clearly communicated; in other words, sufficient structure and guidance need to be provided. Furthermore, in communicating and monitoring these limits, an autonomy-supportive style is essential.

Consistent with this, Vansteenkiste, et al. (2014) showed that the style of introducing prohibitions to adolescents affects their acceptance of (i.e., internalization) versus oppositional defiance against the prohibitions. Specifically, their one-year longitudinal study revealed that a more autonomy-supportive style of introducing and monitoring prohibitions elicited greater identification with and ownership of the limits, while a perceived controlling style predicted either increases in externally enforced compliance with the prohibitions or oppositional defiance against them. Notably, these effects were found to be reciprocal such that a virtuous positive cycle unfolded when autonomy support was salient, and a vicious negative cycle was instigated in the case of a controlling style. These effects occurred regardless of whether the prohibitions had a more personal character (e.g., friendships) or were moral in nature.

Summary

A crucial task for socializing agents is to transmit norms, values, and regulations, such that children and adolescents will not stick to these norms out of strict, slavish obedience but rather out of volitional commitment, presumably because they have come to fully own (i.e., internalize) the norms. Whereas controlling socialization practices, such as positive PCR from parents, can produce compliant behavior, it is often at the cost of a sense of volition to behave. Negative PCR and more externally controlling practices may even be more counterproductive, eliciting at best externally driven obedience, and, at worst, anger and resentment as well as blunt defiance against requested norms. What is needed to foster full internalization of norms is an autonomy-supportive approach in combination with clear communication of expectations (structure) and involved guidance.

Emotion Regulation

Distinguishing Different Styles of Emotion Regulation

Similar to the process of internalization, the development of emotional self-regulation can be conceptualized as movement from reliance on outside sources to identify, modulate, and regulate affect, toward a growing capacity for autonomous, flexible, and adaptive regulation (Cicchetti, Ganiban, & Barnett, 1991; Grolnick et al., 1996). Deci and Ryan (1985b) early on drew from Greenspan (1979) in referring to the development of regulatory processes for autonomously managing emotions as *integration at the internal boundary*. This was contrasted with the development of regulatory processes for engaging in behaviors deemed important by the social world as *integration at the external boundary*. Although these two developmental functions, referred to, respectively, as the development of emotion regulation and internalization, are distinct, they are similar in many respects. Both involve gaining the capacities to regulate oneself with respect to behavior that is not intrinsically motivated and both entail a developmental progression in which the child gradually relies less on cues and structures from the social context and more on internal cues and structures. Equally clear, deficits in the regulation of emotion and the ability to use emotions to appropriately inform or guide behavior are cardinal features of most forms of psychopathology. Accordingly, we turn now to this critical issue of emotional regulation and its healthy development.

We begin with acknowledging the complexity of emotions, and the multiple dimensions that impact upon their regulation and expression (see Cacioppo, Bernston,

Sheridan, & McClintock, 2000). In particular, there are salient individual differences in people's tendencies to experience emotions (e.g., Gable, Reis, & Elliot, 2000) based on both genetic and temperament-based factors and their interactions with early environmental events. Individual difference factors make the problem of emotional regulation and integration much more formidable for some persons, whose sensitivity or lack thereof make the task of accessing, modulating, expressing, and using emotions much more challenging (Assor et al., 2004). Nonetheless, any reasonable summary of that complex literature makes clear that even given such individual differences or tendencies, social environments play a significant and interactive role in fostering healthy emotion regulation (Vansteenkiste & Ryan, 2013). To more concretely understand what it is about social environments that can facilitate versus debilitate a growing person's capacities for emotional awareness and regulation first requires a clear conception of what healthy emotion regulation involves.

SDT's conceptualization of healthy emotional regulation begins with the assumption that emotions are *informational* inputs essential to guiding action and growth (Deci & Ryan, 1985b). In this view, specific emotions are neither good nor bad; they simply provide organismically valuable guidance (Deci & Ryan, 2000; Parrott, 1993). A similar view is expressed by Levenson (1999), who suggested that emotions provide organisms with a built-in feedback system that signal them to inspect, explore and evaluate their environment and act in accord with that evaluation.

SDT views wellness in terms of a person being fully functioning—being able to exercise potentials, connect with others, find meaning, and experience vitality. This *eudaimonic* view (Ryan, Curren, & Deci, 2013) suggests that rich access to both positive and negative feelings, a capacity to express them, and the ability to integrate and use them to inform one's behaviors and goals is optimal. This in turn supports personal growth, self-acceptance, and abilities to intimately connect with others.

To capture this quality of emotional regulation we distinguish *emotional integration* as an autonomous form of emotional regulation from notions of *emotional control* and *emotional dysregulation*. Specifically, emotional integration involves a differentiated awareness of one's emotional states and the capacity to use this sensitivity and awareness in the volitional regulation of action. Autonomous behavioral functioning is dependent on emotional integration, because emotions, when openly received, supply essential information that guides one in setting goals and adjusting them toward the fulfillment of psychological needs (Ryan et. al 2006). Healthy emotional integration is thus characterized by an allowing of and interest in inner experience, rather than the control or stifling of emotions (Deci, Ryan, Schultz, & Niemiec, in press).

Yet emotions can be experienced as more than just information; they can be experienced as evaluative and controlling, as when affect overwhelms self-regulation or automatically drives action. Even the etymology of the term emotion conveys this idea of a force that propels motion. Alternatively, emotions can be so overcontrolled such that people lose access to them, and in such cases the emotions can fail to move the individuals when they should. Controlled emotional regulation is manifest through the ignorance, suppression, or denial of emotions and, as we will see later, is implicated in specific forms of psychopathology and ill-being. Accordingly any conception of healthy or integrated emotional regulation is based neither on emotions controlling people nor on people controlling (e.g., suppressing) their emotions. When the self can access feelings without being controlled by them, the opportunity for autonomous self-regulation is maximized. This of course is a capacity that only develops over time and that requires contextual supports, in the form of guidance and need satisfaction.

Indeed, the process of increasingly integrating one's emotions and regulatory capacities is a continuation of the work a child does in gaining regulatory capacities with respect to emotions, but it represents a mature version of that process. Whereas emotional regulation is concerned with the modulation of emotional experience and expression, emotional integration is concerned with the flexibility and choice people feel in the regulation of emotions and emotion-related actions. Individuals high in emotional integration are more likely to be receptive to emotional signals, to take interest in them, and to experience them as valuable inputs to actions. In contrast, if regulatory processes are rigidly introjected and thus in conflict with the emotions, people are likely to suppress the feelings and thus ignore their personal meaning.

Consistent with the idea that integrative emotional regulation allows for a more open and nondefensive processing of emotion-related stimuli, Roth et al. (in press) showed that, after having seen a fear-eliciting movie, individuals high in emotional integration were more likely to make use of self-referenced words, to make use of causal language and to write in the past tense, all indicative of a more open and full processing of the emotional event. In contrast, individuals high in suppressive regulation made use of fewer self-referenced and past tense wording, while at the same time using less negative emotional words, all indicative of the avoidance and lack of processing of the negative event.

This capacity for integrative emotion regulation of one's fear and sadness has also been found to promote a greater ability to support a romantic partner's difficulties in handling negative emotions (Roth & Assor, 2012). In contrast, suppressive regulation or dysregulation of fear and sadness was found to compromise individuals' capacity for intimacy. Individuals who tended to suppress fears and sadness reported more difficulties in disclosing negative emotions vis-à-vis their romantic partner, as well as feeling less capable of providing emotional support to their partner. Individuals who tended toward emotion dysregulation equally reported being less able to support their partner emotionally, presumably because they were so overwhelmed by their own negative emotions. Brenning, Soenens, Van Petegem, and Vansteenkiste (in press) further showed that self-esteem is affected by emotion regulation. They reported that increases in integrative regulation covaried with increases in self-esteem among young adolescents over a one-year interval. In contrast, increased use of suppressive regulation predicted increases in depressive symptoms.

Autonomy as an Antecedent of Emotional Integration

A number of studies have examined whether greater autonomy would be associated with more effective emotion regulation, and better long-term coping with negative events. For instance, Weinstein and Hodgins (2009) had participants view an emotionally distressing movie twice, at least a day apart. The film was a graphic Hiroshima–Nagasaki documentary that was challenging to assimilate. In an initial study they showed that participants with greater trait autonomy, when given an opportunity to express emotional reactions, later had more positive well-being, energy, and memory after the second viewing. In a second study they created situational motivation by priming autonomy and control. Results showed that dispositionally controlled individuals received the same benefits as autonomous individuals, but only when primed with autonomy and encouraged to express emotions. Weinstein and Hodgins (2009) coded the contents of the emotion expressions and found that the positive outcomes associated with autonomy were mediated by nondefensive processing, as reflected in varied indices such as more self-referencing, more words reflecting internal cognitive processes, and lower use of concrete words. In short, their results suggest that autonomy facilitates ownership and expression of feelings, enhancing emotional integration over time.

Koestner, Bernieri, and Zuckerman (1992) explored the relation of autonomy to the integration and synchrony of emotions, cognitions, and behavior. They separated participants into a more autonomy-oriented group and a more control-oriented one (Deci & Ryan, 1985a) and then explored the consistency of behaviors, attitudes, and traits within each of these two groups. In the first of two experiments, they found high correlations between behavioral persistence and self-reports of intrinsic interest within the autonomy-oriented group, but no significant correlations within the control-oriented group, suggesting less congruence in the latter. In a second study, Koestner et al. (1992) had participants complete a measure of conscientiousness, and then gave them an opportunity to behave conscientiously in succeeding days. Participants' self-reported conscientiousness and their actual conscientious behaviors were significantly more highly correlated within the autonomous group than the controlled group. Self-ratings and peer ratings of conscientiousness were also more highly correlated for the autonomy oriented. Together these studies provide support for the proposition that autonomy is associated with greater congruence among traits, behaviors, and feelings, reflecting greater integration in personality functioning.

Related to the issue of emotion regulation and integration is that of people's *open* versus *defensive* functioning. Openness versus defense can be manifest in various ways, but in social interactions it entails being honest, transparent, trusting and receptive, whereas defense in contrast entails concealment, distrust, and often self-distortion of experience (Hodgins & Knee, 2002). Investigating openness versus defensiveness using a diary methodology, Hodgins et al. (1996) found that people with a more autonomous orientation evidenced more disclosure, trust in others, and honesty in their daily interpersonal interactions, whereas those with a controlled orientation showed lower honesty and openness.

Another indicator of openness versus defensiveness concerns the alignment or *congruence* between implicit and explicit attitudes and motives. Thrash and Elliot (2002) found that persons higher in trait autonomy had lower discrepancies between implicit (projective) and explicit (self-report) assessments of achievement motivation. Hodgins, Brown, and Carver (2007) found that control-primed individuals evidenced greater discrepancies between explicit and implicit self-esteem. Weinstein, Ryan, and colleagues (2012) found that children of controlling parents showed a greater discrepancy between their implicitly assessed sexual attractions to same sex others and their self-reports of sexual orientation. This discrepancy, in turn, related to greater hostility toward gay targets, indicative of *reaction formation* (Freud, 1966). In other words,

parental autonomy thwarting can foster incongruence, and the defensive behaviors it spawns. Indeed, the mere priming of a controlled orientation has been sufficient to elicit defensive responding, as indexed by the use of hostile humor (Weinstein, Hodgins, & Ostvik-White, 2011), the avoidance of negative experiences (Hodgins, Yacko, & Gottlieb, 2006), or avoidance of emotionally distressing information (Weinstein, Deci, et al., 2011; Weinstein & Hodgins, 2009). Across these studies of emotional integration and congruence it seems clear that controlled people show less integrity, whereas autonomy is conducive to more integration in both attitudes and less defensive and more open functioning.

Social Contexts: Developing Emotional Integration

The development of capacities to regulate and integrate emotions in flexible and autonomous ways is assumed within SDT to be supported by responsive, need supportive caregivers. Grolnick, Bridges, and Connell (1996) explored this with 12- to 32-month-old children. They observed toddlers in two stressful situations: waiting to play with an attractive toy (or to eat a food) and having a brief separation from mother. The children's emotionality (upset) and strategies to regulate this upset were coded. Results supported an autonomy continuum in that the more autonomous strategies were associated with the least upset, whereas the more controlled or passive strategies were associated with the most upset. Further, there were increases with age in the use of autonomous, proactive strategies, indicating development of emotion regulation through these toddler years.

As noted, the regulation of emotions and impulses can be done in a fairly controlling way. Some children, when in a negatively arousing situation such as being asked to delay gratification, exert great effort, forcing themselves to push emotions out of their minds. But controlling themselves in this way requires attention and energy, which can diminish the capacity for adaptive engagement with the environment. When used as a chronic way to deal with distress, it leads children to experience being controlled by their own harsh thoughts and to display nonadaptive engagement. In contrast, other children in the same stressful settings may be more flexible (i.e., less rigid and pressured) in dealing with the situation, for example by doing alternative activities or expressing their disappointment or frustration, signifying that they have developed more adaptive capacities for both accessing and regulating emotion.

This developing capacity for emotional regulation is not just a function of time and maturation. In fact, it is very much an *interpersonal* process. It is in the interpersonal realm, within which caregivers regulate children's expressed emotions more or less responsively and effectively, that children learn to regulate their own emotions. Autonomy-supportive interpersonal contexts are theorized within SDT to afford access to and expression of emotional experience, and to facilitate more reflective engagement and executive guidance of subsequent behavioral regulation (Grolnick et al., 1996; Gross & John, 2002). Calkins and Johnson (1998) found evidence for this in demonstrating that mothers' use of positive guidance (akin to an autonomy-support approach) was associated with greater use of distraction and constructive coping in emotion inducing situations. On the other hand, children of mothers who used high levels of negative control during free play spent more time orienting to a desired but forbidden stimulus. They used less self-distraction and were less physiologically well regulated during a waiting situation relative to those of mothers who used less negative control.

Grolnick, Kurowski, McMenamy, Rivkin, and Bridges (1998) also examined strategies mothers use to help their young children regulate distress. Children of mothers who maintained their active assistance beyond what the children needed were less able to regulate their distress when on their own. Thus, while responsiveness to distress was important, parents who took responsibility for regulating children's distress and did not allow the children opportunities to self-regulate appeared to undermine children's self-regulatory capacities. Because the capacity to effectively modulate distress is so integral to mental health and the prevention of psychopathology, an environment supporting this capacity is of crucial importance.

More recently, Roth, Asssor, et al. (2009) showed in a sample of ninth-grade adolescents that parents who made use of conditional regard when adolescents expressed negative emotions (e.g., showing less acceptance and positive regard) had children who more frequently engaged in *suppressive regulation* of emotions, reported greater dysregulation of emotions and more resentment vis-à-vis the parents. In contrast, both mother and father autonomy support related to children showing greater *integrative regulation* of negative emotions. These adolescents allowed their emotions to be more fully experienced and could then, with a greater sense of choice, decide whether and how to express them. Along similar lines, Roth, Ron, and Benita (2009) showed that parents' use of conditional regard related to reduced disclosure of difficulties at school among 14–16-year-old teenagers. Presumably, with contingently regarding parents, children tend to keep the encountered problems for themselves rather than opening up, as they anticipate critical reactions from their

mothers. A longitudinal study of adolescents by Brenning et al. (in press) further supported these associations. They found that parental autonomy support predicted increases in emotional integration and decreases in suppressive emotion regulation, whereas higher levels of emotional dysregulation were related to lower perception of parental autonomy support.

Further, Roth and Assor (2010) showed that the costs of a controlling parenting approach are apparent by the ages of five or six. Parents reported the degree to which they used both conditional regard with their children to socialize them regarding regulation of sad emotions. These parent reports were then related to various assessments of their children's emotional skills. Results indicated that parental use of conditional regard was related to children being less aware of sad feelings in themselves, less able to recognize sad feelings in other children, and less empathic in responding to other children who felt sad.

Although parents' display of contingent regard for showing negative emotions may lead them to suppress their negative emotions, it is also often the case that some parents may pressure their children to express (rather than withhold) negative emotions (Roth & Assor, 2012). Although such a practice may seem benign at first sight because negative emotions get shared, the pressure to share negative emotions to gain parental appreciation may come at the cost of adequate emotion regulation. Consistent with this, late adolescents experiencing conditional regard to express negative emotions reported more emotional dysregulation, which hampered their capacity for intimate relations with romantic partners. In contrast, an autonomy-supportive approach was related to more integrative emotion regulation.

Summary

Developing the capacities for respecting others and delaying gratification represents a central agenda from toddlerhood through adulthood; it involves learning when and how it is reasonable and appropriate to express one's feelings and being able to use that information in a way that enhances the autonomous regulation of behavior. Thus, emotional regulation entails children internalizing caregiver-provided values and regulatory structures to manage their internal urges—a process that, similar to the internalization of behavioral regulations for uninteresting tasks, is facilitated by supports for the children's basic psychological needs. Although differences in autonomous functioning contribute to a greater congruence between felt emotions, held thoughts, and enacted behaviors, differences in contextual need support also played a role. Previous studies suggest that controlling parental practices regarding emotions, whether involving pressure to keep negative emotions to oneself or to express them before one is ready to do so, come with costs. In contrast, need-supportive parents respect the children's rhythm and pace of expressing emotions, displaying an active interest and concern with what is emotionally salient for them. They also set appropriate limits on behavior while allowing adequate expression of feelings. This facilitates the children's attunement to the social world, and acceptance of self in the process of adapting to it.

Identity Formation

An SDT View of Identity and Self

Identity formation is among the most formidable of developmental challenges (Kroger & Marcia, 2011; Soenens & Vansteenkiste, 2011). This is especially so in modern cultures within which apparent options for identities are greater than ever before and in which there are fewer of the explicit vertical constraints that have historically channeled people into preordained roles and identities (Ryan & Deci, 2011). For many scholars this fluidity and opportunity for choice represents a potential for persons to be better matched in their life roles with their interests and sensibilities (see Appiah, 2005), whereas other scholars emphasize the psychological burdens that such latitude and choice present to developing individuals (e.g., Schwartz, 2000). Both positions have substantial evidence in their favor.

Identities are self-representations—they are what and who people understand and describe themselves to be. Once adopted, maintaining and defending identities can be a strong motivator of behaviors, and can orient people's learning, behaviors, and friendships (Vallerand, 2010). Different types of identities can be distinguished (Vignoles, Schwartz, & Luyckx, 2011), with some being more personal (e.g., personal interests), others being social in nature (e.g., roles), and still others being collective in nature, thereby reflecting the groups and institutions with which we are affiliated, and supplying varied venues through which people can be recognized and valued.

Particularly during adolescent and young adult years, a challenging task is to form a meaningful identity that will serve to organize and guide an adult life. This is a period when people are particularly vulnerable to external forces. With the emergence of adolescent egocentrism and self-consciousness (Elkind, 1967), teens tend to see themselves in ways they imagine others see them, and they show a greater tendency to conform in an effort to be accepted by others. Thus, as they are attempting to formulate a sense

of their own identity, they are also struggling with real or imagined social pressures from many sources including, not only peers but also parents, teachers, role models, and advertisers. As adolescents develop they must work to explore, try on, and accept or reject possible identities, sometimes painfully. During this process, pressures from parents and other socializers can detract the young people from smooth identity formation insofar as the offered identities are incongruent with their developing and abiding interests and sensibilities. Indeed, all people, but perhaps especially adolescents, are today exposed to the wide reach of media, which attempts to orient them toward particular types of identities and affiliations (Dittmar, 2011; Kasser, 2002). Advertisers work to have people define themselves in terms of the brands they purchase and the media cultures they engage.

Central to the process of forming identities is people's inherent desire to experience solid connectedness to individuals, groups, or cultures. By accepting the values, mores, missions, attitudes, and behaviors of others, people do not feel alone. Rather, they feel part of a group, experiencing a sense of relatedness to others and a place in the social order (Baumeister & Leary, 1995; Ryan, 1993). Further, identities can also support the need for competence. Often people orient toward identities—perhaps being a painter or physicist, for example—that require skill acquisition, offer optimal challenges, and allow them to feel effective. Finally, the formation of identities can fulfill people's need for autonomy if they engage the relevant activities with a sense of choice and as an expression of their own values and interests. In short, people tend to gravitate toward those identities that allow maximal satisfaction of their basic psychological needs (Luyckx, Vansteenkiste, Duriez, & Goossens, 2009).

Need satisfaction then serves as the energetic basis for anchoring identities within one's sense of self. Thus, although the terms *identity* and *self* are often used interchangeably in the identity literature, they get clearly differentiated within the SDT perspective. That is, although we have multiple identities, each is more or less internalized and integrated within the self (Soenens & Vansteenkiste, 2011; Ryan & Deci, 2011).

Anchoring Identities Within the Self

SDT suggests that there are two interrelated means through which identities form and become integrated to different degrees within people's self-functioning: (1) through the discovery and differentiation of intrinsic interests and talents; and (2) through the internalization of values and self-representations.

People manifest individual differences in their competencies, interests, and inclinations. Some children seem inclined toward music, others toward physical activity. The forms that such inclinations take in people's lives is a function of their interactions with the social world, but having the inclinations—for music, or sports, for example—does increase the likelihood that related activities will become important parts of identity (Deci & Ryan, 1985b). Their inclinations lead them to explore different options and, over time, to gravitate toward others with similar interests, such that the activities, values, and relationships associated with those interests become central aspects of their lives and come to define who they are. They also are likely to experience greater competence, further enhancing their interests in the activities. In other words, people are fortunate when they adopt identities that engage intrinsic motivation (Krapp, 2002).

Still, for identities to develop out of intrinsic interests often requires both enduring affordances and social supports. A child who is naturally inclined to be physically active but who has no access or opportunities to play sports might not develop an identity as an athlete. In short, the development of an identity depends to some extent on the cultural affordances available to the person (Erikson, 1994). Further, to form an identity as an athlete will require the experience of need supports in relation to the engagement of sport activities. Supports for autonomy, competence development, and relatedness in sport will be critical in facilitating identity formation as an athlete. This is the same for identities in every domain, whether it be academic, religious, family, or career related.

Few identities are sustained solely out of intrinsic interests. Instead most are taken on or elaborated through processes of internalization. Importantly, however, much like behavioral regulations, identities can differ in the degree to which they are integrated with the self. When identities are adopted within the context of pressure and control, it is likely that they will be introjected. That is, people will take them on as "shoulds," or as identities they must enact, which essentially means that they will be identity deficits. Often in college settings, for example, there are individuals who identify as pre-med because they have always been told they will be a doctor, regardless of their interests or predilections. In fact, the students' sense of worth and esteem may depend heavily on the enactment of such an introjected identity, leading to a defensive adherence to identity and inner conflict when failing to engage in identity-consistent behaviors. Nonetheless, for identities to be not just adopted, but also autonomously engaged, the individuals will need to integrate the identities with

their other available identities, values, beliefs, behaviors, and interests, which will allow them to be both authentic and vital in their pursuit.

Soenens, Berzonsky, Dunkel, Papini, and Vansteenkiste (2011) assessed late adolescents' identity commitments, and their autonomous and controlled motives for committing to particular identities. Even after controlling for the strength of identity commitments per se, those commitments that were autonomously motivated were associated with more positive adjustment, whereas controlled identity commitments were predictive of poorer adjustment. Thus, although adolescents could commit themselves to particular self-representations (e.g., musician, basketball player), such commitments must be accepted and integrated to ensure adjustment.

Fostering Identity Development: The Role of Need Support

Given that identities may involve intrinsic motivation, and may be anchored by either introjected or more integrated regulations, it becomes clear how a need-supportive environment is important in the process of identity formation (Soenens & Vansteenkiste, 2011). As Assor (2012) pointed out, parents vary in the extent to which they foster inner valuing and allow adolescents to explore different interests and values, thereby nurturing self-discovery. To the extent such need supportive practices are provided, children and teenagers are more likely to develop an *inner compass* when making critical identity-related decisions. In contrast, finding life roles and self-definitions that are congruent with interests and integrated values is more difficult in controlling contexts. Consistent with this, Luyckx, Soenens, Vansteenkiste, Goossens, and Berzonsky (2007) showed that college students who perceived their parents as using psychologically controlling strategies were more inhibited in making identity-related decisions and in truly endorsing and identifying with the identity decisions being made.

Importantly, the development of an integrated set of regulations is presumed to be critical for subsequent need satisfaction, such that a positive spiral would develop. Evidence for such a model was obtained in longitudinal research on high school and college students by Luyckx et al. (2009), who focused on the extent of exploration, commitment, and ruminative thought these students displayed with regard to the directions and identities they were adopting. Results showed that satisfaction of SDT's basic psychological needs was in general positively related to making and identifying with particular identities, and to enhanced breadth and depth of identity explorations. Those with less consolidated identity commitments and those associated with more rumination had lower basic need satisfaction. Moreover, cross-lagged analyses provided evidence for reciprocal relations—need satisfaction both facilitated more positive identity formation, and more positive identity formation facilitated greater need satisfaction.

Although there are clear advantages to integrating identities, some identities are socially stigmatized, and some may conflict with other identities or roles to which a person aspires. Such identities often remain poorly integrated. These identifications can be resisted, or remain relatively isolated or compartmentalized, as opposed to being integrated with other identities, needs, and value attachments of the self (Ryan & Deci, 2011). For instance, suppose in his political considerations a man identifies with an ideology that is oppressive to certain minorities, and yet in his religious considerations he endorses being a generous and loving human being. Both might be values that he deems important, but their inconsistency requires that he keep them compartmentalized. Advocating harm to others might catalyze guilt or uncertainty when he is in his more religious identity. Yet integrating these might require change in one or both identities, and the psychological threat or loss of relatedness that might accompany such change.

The more autonomy supportive one's social context, the more easily the person can integrate identities and self-characteristics. For example Weinstein, Deci, et al. (2011) examined how autonomous versus controlled motivation, operationalized through either individual differences or the semantic priming of autonomy versus control, facilitates or inhibits the integration of positive and negative past identities. Results of their studies showed that more autonomously motivated participants felt closer to, and were more accepting of, both negative and positive past characteristics and identities, whereas more control-motivated participants were closer to and more accepting of only their positive, but not negative identities and characteristics. Moreover, defensive processes, as reflected in the use of nonpersonal pronouns and stronger escape motives, mediated these effects, indicating that lower defensiveness allowed fuller integration of negative identities. Finally, results demonstrated that when participants did more fully integrate both positive and negative past identities, they exhibited greater vitality and sense of meaning.

Toward Qualitatively Different Types of Identities

Finding identities that are need satisfying is often a struggle, as many social contexts pressure individuals to adopt identities that may or may not befit their interests or talents. Social contexts also can reject or demean other identities and roles. Thus, identities can be adopted for

controlled reasons, with the predicted negative outcomes for both well-being and persistence.

Identities can also be motivated as a response to need thwarting. SDT argues that, when needs are strongly thwarted in development, persons may adopt need substitutes referred to as *extrinsic aspirations*, such as those involving the pursuit of materialism, an appealing outer image, or ideas of fame and popularity (Kasser & Ryan, 1996). These identity pursuits often serve a defensive function, blocking feelings of vulnerability, and often are pursued to compensate for a lack of support and acceptance from others during development. In line with this, Kasser, Ryan, Sameroff, and Zax (1996) predicted that identities focused on materialistic life goals might be associated with (and compensating for) experiences of autonomy and relatedness thwarting from caregivers. Using a longitudinal dataset, they showed that adolescents whose mothers were less warm and autonomy supportive when the children were 14 years old were more materialistic at age 18.

Adolescents who experience need thwarting may be especially vulnerable to extrinsic ideals promoted within the media and advertising, which often suggest that the pursuit of extrinsic ideals will yield the confidence, love, or self-esteem such teens do not feel. For example, women high in autonomy frustration may be more susceptible to ambient extrinsic ideals for thinness and self-objectification. Mask and Blanchard (2011) examined this by having individuals differing in general levels of autonomy watch and react to a video depicting the thin ideal. After watching the video, women low in autonomy reported greater pressure to be thin, more dissatisfaction with their bodies, and increased concern with the quantity of food they ate. In contrast, women high in autonomy became more concerned with the quality of the food they ate, but they did not feel increased pressure or self-dissatisfaction (see also Pelletier, Dion, & Levesque, 2004). Thus, to the extent adolescents have built up a stronger inner foundation, they can rely on it to more autonomously decide how to handle identity pressures, which suggests that autonomy is an important factor in resilience.

Summary

We have discussed how the formation of identities and self-representations that are well internalized and integrated represents a major challenge for contemporary adolescents. Research suggests that without sufficient contextual need support, adolescents' development of a strong inner compass (Assor, 2012), and the adoption of identities truly grounded in their emerging interests and personally held values, may be forestalled.

AUTONOMY DISTURBANCES IN DEVELOPMENT AND PSYCHOPATHOLOGY

Need Frustration and Psychopathology

The development of the self proceeds most optimally in social contexts where children experience ongoing supports for their basic psychological needs. When needs are supported in domains and activities appropriate to their developmental level children display increasing amounts of autonomy. The situational and cumulative effects of support for psychological needs are expected to yield inner resources in the developing persons that further contribute to subsequent wellness and adaptation. Yet often development does not proceed optimally, especially when social contexts thwart the children's basic needs and in doing so amplify vulnerabilities and potentiate psychopathology.

Many forms of psychopathology entail *impairments of autonomy,* as failures in organismic integration and in the development of self contribute to a range of dysfunctions. From the perspective of SDT, explicating autonomy impairments involves a consideration of the interplay between the psychological needs for autonomy, competence, and relatedness that support the developmental processes of attachment, intrinsic motivation, internalization, emotional regulation, and identity formation, and the social contexts, such as parent or institutional behaviors, that either support or thwart the satisfaction of these basic psychological needs. In what follows we focus on specific types of disorders, both in terms of a theoretical account of autonomy impairments and a review of relevant research. Specifically we discuss three general categories of psychopathology, all of which involve serious autonomy disturbances but each of which has particular forms of autonomy impairments, leading to one of the categories of pathology, as is graphically illustrated in Figure 9.2.

First, we consider disorders in which *internally controlling regulation* of behavior predominates. These are disorders that, despite their many differences, are characterized by the salience of introjection or rigid internalizations and the associated feelings of anxiety, self-criticism, and threat. We especially focus on obsessive-compulsive disorders, paranoid personality, self-critical depression, and controlled eating disorders (i.e., anorexia and bulimia).

A second type of autonomy disturbance concerns *impairments in internalization* of social values and regulations, characterized by difficulties in the self-regulation of behavior. To illustrate these types of autonomy disturbance, we discuss problems of impulsivity and aggression, including oppositional defiance, conduct, and antisocial

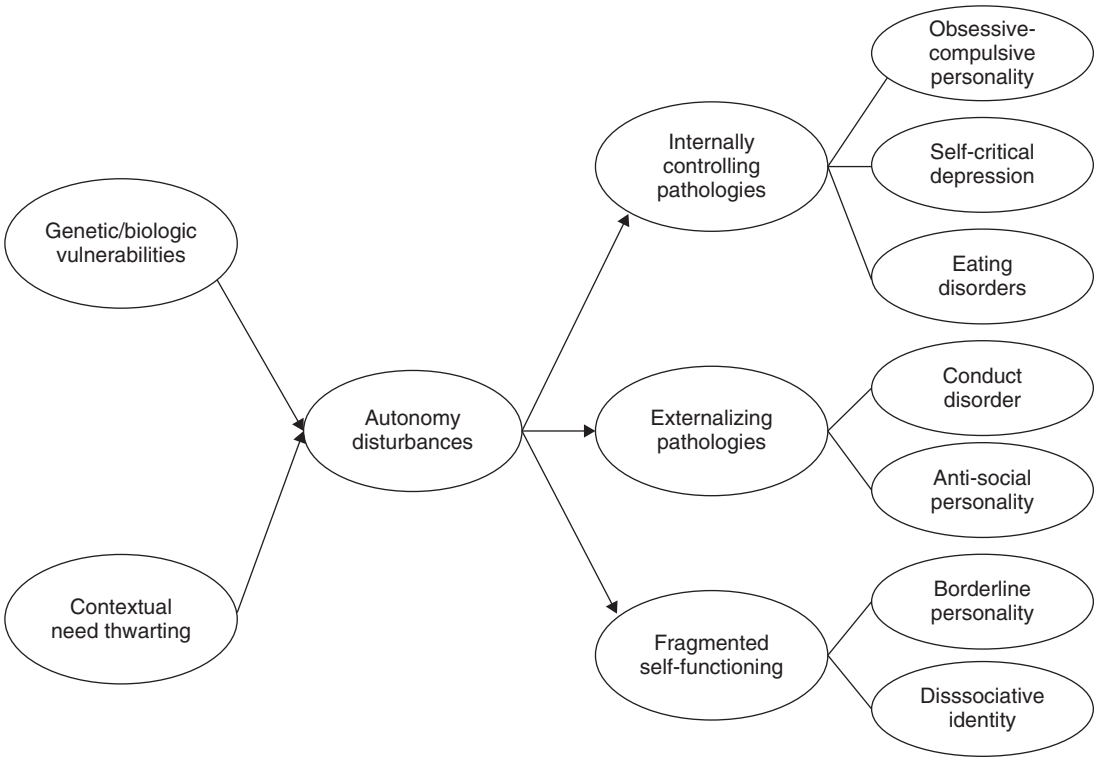

Figure 9.2 Graphic overview of selected psychopathologies reflecting autonomy disturbances.

personality disorders. A third category of autonomy disturbances we discuss are disorders associated with more severe thwarting of psychological needs in development, namely disorders associated with *fragmented self-functioning*. Here we focus especially on persons with borderline personality disorder and dissociative identity disorders, and on the integrative difficulties posed by controlling, inconsistent and intrusive others who thwart basic psychological needs and damage self-development.

In discussing each of these types of autonomy disturbance we address the experience of autonomy within each, and discuss factors relating to the social contexts of development that may contribute to impairments in autonomy and integration. Although it is the case that any factor that disrupts the organizational tendency, whether biological, interpersonal, or cultural in nature, can potentiate disturbances of autonomy, in many cases the sources of disrupted autonomy can be strongly related to deficiencies in the social environment—that is, to its failure to provide appropriate autonomy support, structure, or involvement (Ryan & Deci, 2000b; Vansteenkiste & Ryan, 2013). Yet even in those cases where the causes of the disorder do not lie in need thwarting contexts, the symptoms associated with such impairments can themselves interfere with autonomous functioning, and are often experienced as not under volitional control. In short, we discuss autonomy issues both as both an etiological factor and as a symptomatic factor, in varied forms of psychopathology.

Disorders Involving Introjection and Internally Controlling States

There are rich and variegated literatures concerning internalizing disorders, in which a person is beset with internal pressures, judgments, compulsions, and other self-directed mandates to act. These disorders, associated with both anxiety and depression, centrally involve a lack of autonomy and volition, as often motivations to act are highly controlled and even coercive. This literature also indicates that caregiver styles characterized by a lack of autonomy support and the presence of controlling or authoritarian strategies contribute to *internalizing disorders*, especially in vulnerable children (e.g., Bayer, Sanson, & Hemphill, 2006; Muhtadie, Zhou, Eisenberg, & Wang, 2013). What SDT's perspective adds to this literature is a rich body of findings concerning how controlling environments foster the development of internally controlling regulations—that is, how such conditions lead to regulation through *introjects* (Deci & Ryan, 1995; Ryan & Deci, 2008).

Introjects are understood within SDT as motivations characterized by internal pressure, enforced by contingent self-worth. Introjection involves an ongoing salience of strict internalized demands. Such demands and standards are introjected in the sense that one's motivation is based largely on internalized self-related emotions and appraisals. In introjection people adopt external standards as their own and determine self-worth based on whether they meet them, without making the standards a part of their integrated sense of self. Often the process of introjection entails a type of *self-deception* in which people think they want what the authority originally prescribed (e.g., Weinstein, Ryan, et al., 2012). This is akin to what Winnicott (1960/1965) referred to as *false self*, in which cognitive functions gradually lose their grounding in organismic processes. Yet heteronomy is phenomenally manifest in the pressured, have-to nature of experience, backed by threat of anxiety and self-criticism that drives much of the person's behavior. Introjects can indeed be highly motivating, and represent the core driving forces in people's lives. Thus, even when not formally diagnosed, the dynamics of introjection can catalyze significant inner distress. In addition, when rigid, punitive, or overly pervasive, they can be highly dysfunctional. This is particularly true for persons who are diagnosed as having an internalizing disorder.

Although, as we shall stress, the etiology, presentation, and course of internalizing disorders are complex and multidetermined, evidence that caregiver styles can contribute to such problems is also relatively clear. For example, consider that factors such as loss of parents (and thus of attachment supports), depression in parents (and thus low involvement or autonomy support), and excessive parental control (thus thwarting autonomy needs) have all been implicated in the development of childhood depression and self-critical styles (Ryan et al., 2006). SDT more specifically relates the formation of introjects to the thwarting of autonomy and relatedness needs, a process central to a variety of clinical presentations (Ryan et al., 2006). Thus, we look at parental thwarting of autonomy and relatedness as factors in internally controlling disorders.

The Obsessive-Compulsive Disorders

Two separable diagnoses carry the rubric of obsession and compulsion: obsessive-compulsive disorder (OCD) and obsessive-compulsive personality (OCP). These distinct entities share some common features in the dynamics of behavior regulation, but they also differ in meaningful ways.

OCD is characterized by the experience of intrusive thoughts and demands that typically can be alleviated only by engaging in ritualistic, rigid behavior. The thoughts are often ego-dystonic, in that they are unwelcome and anxiety provoking, and thus such thoughts are experienced as having an origin outside the self. Indeed, these thoughts often are inconsistent with the person's conscious values and ideals. An example is an OCD-diagnosed woman who reported continual intrusive thoughts concerning hurting her baby whenever she was near certain objects. These intrusive thoughts raised considerable anxiety precisely because they ran against her strongly held desire to keep her child safe. To alleviate this anxiety she was compelled to check continuously for dangerous objects in her vicinity. OCD is classified as an anxiety disorder precisely because obsessions and rituals often have the function of regulating anxiety, albeit usually with only temporary success.

An important feature of the dissonant thoughts often found in OCD is that they are persistent, unwanted, and difficult to control. From the perspective of the individual the unwanted thoughts befall him or her and are not autonomous or volitional. The person then feels coerced or compelled into ritualistic behaviors; he or she must do them or face dreadful anxiety. The actions that alleviate obsessional thoughts therefore have an external perceived locus of causality. As an aspect of this external causality, compulsive behavior patterns typically are performed under strict constraints—there is an inner demand to engage in actions in rigidly prescribed ways. These orders are experienced as heteronomous, albeit within the person. The cost of failure is guilt, anxiety, and self-disparagement, and in other cases a sense of panic and fragmentation of the self. The regulatory process of compulsive acts is thus accompanied by a sense of inner pressure that we would describe as internally controlling. That is OCD has the regulatory form of introjection, even though it may not always have social roots.

Like OCD, OCP is characterized by living in a very structured and orderly way, which can have both positive and negative consequences depending on how severe it is. In less severe cases, the regulation of behavior is still introjected and thus has the negative psychological consequences associated with introjection. Nonetheless, the order that is manifest from mild OCP can have adaptive aspects, for example in getting homework done or organizing possessions in orderly ways. Yet OCP is often more severe and compromising, with debilitating pressure and anxiety, and behaviors that are rigid and extreme. For example, people's collecting which is likely to be based in mild OCP is likely to become hoarding when the pathology becomes more serious, and their organizing may become

intensely rigid with threats of self-disparagement and self-punishment hanging over their heads to keep them in line.

Unlike OCD, there appears to be a less robust biological contribution to OCP, even though there are some common symptom dynamics. Supporting the differential role of biology, results by Jenike as early as 1991 found responsiveness among OCD patients to pharmacological interventions, but not among those with OCP. Also OCP, in contrast to OCD, is more a lifestyle than a symptom, and in many ways OCP can be viewed as a continuum from a somewhat rigidly focused set of attitudes to a disorder that interferes with ongoing functioning. Accordingly, many features of this controlled lifestyle are ego-syntonic rather than disturbing (Sperry, 2003). For example, individuals with OCP who organize their possessions and become distraught when things get moved or misplaced might go into treatment not because they view the orderliness as problematic, but because their pattern of living, which seems fine to them is causing interpersonal or vocational difficulties. In addition, as reported by Othmer and Othmer (2002), persons with OCP often display their characteristic drivenness, compulsiveness, and inflexibility when events involving authority, intimacy, or lack of structure trigger them. Nonetheless, the surface structure of these behaviors share similarities with the controlled behaviors so often manifest in OCD.

The internally controlling nature of regulation in OCP can, in some instances, be highly stable and self-sustaining, in part because it can come with ongoing external approval and derivative internal gratifications. For example, Assor and Tal (2012) examined adolescents' perceptions of their mother's use of parental conditional positive regard (PCPR) to motivate them to academically achieve. Those teens whose mothers applied contingent positive regard evidenced more self-aggrandizement following successes yet greater self-devaluation and shame following failures. This hypersensitivity to outcomes in turn predicted compulsive over-investment and maladaptive self-feelings, even when controlling for the effects of conditional negative regard. Thus, it appears that the experience of maternal conditional positive regard to promote school achievement leads to self-esteem dynamics in which the adolescents vacillate between feelings of grandiosity following success and self-derogation and shame following failure, representing significant emotional costs. These general population findings are reminiscent of the distress many OCP patients vividly describe.

It is particularly clear with OCP that the pathology of obsessive-compulsive actions is not always defined by the behavior itself, because as noted the behavior can be effective and functional. Rather, it is the rigid regulatory processes underlying behavior that are dysfunctional. Persons with OCP, while not acutely afflicted with intrusive thoughts sometimes befalling those with OCD, are often inordinately concerned with carrying out the actual or presumed demands of authority. For example, a person with this personality style can be quite industrious and fastidious in complying with introjected demands, and this may yield high activity and even productivity. However, rigidly controlled workaholics, who are likely to have OCP, tend to evidence a range of ill-being consequences (Van den Broeck et al., 2011). Clearly, the industriousness and rigidity of people with OCP is quite different from the vitality and spontaneity that characterizes autonomously functioning individuals, even ones who work excessively. Ryan and Deci (2008) argued that vitality concerns the free energy a person has at his or her disposal. The internally controlled regulation of an individual with OCP is often experienced as energy draining and without joy. As Sperry (2003) noted, the demeanor of someone with OCP can be "grim and cheerless" (p. 178). Moreover, resistance to inner dictates, when possible, may feel like a gargantuan effort.

There is an interesting point about OCP that highlights an important aspect of its disturbed autonomy. Although obsessive-compulsive individuals often act with determination in carrying out introjected dictates, they also sometimes display confusion and indecision. The problem especially arises when there is no dictate, no established course to follow—that is, when there is uncertainty and one needs to fall back on inner guidance. At such times, these people may be rocked with indecisiveness and ambivalence. This illustrates clearly how dependence on controlling regulations, being unintegrated, leaves one without self-direction. The anxiety of indecision highlights how the seeming determination behind many obsessive-compulsive acts is not autonomous; there is no inner compass to rely on when external direction is lacking.

Although the obsessive-compulsive disorders represent clear instances of psychopathology with disturbed autonomy, it is not clear, nor theoretically necessary that they are exclusively *outcomes* of parental control. Evidence has, in fact, been compelling for robust biologic contributions to OCD, whereas parental factors appear to play a larger role in the development of OCP. Indeed, case literatures concerning OCP have more frequently pointed toward controlling, often intrusive parenting (e.g., Millon, Davis, Millon, Escovar, & Meaghan, 2000). Benjamin (2003) suggested that persons with OCP often come from demanding, even coercive parenting environments. Moreover she argued that the controlling emphasis is more often

on punishment for failures than on acknowledgement for success. Yet, here too, systematic investigation of the social context of development of OCP individuals is not extensive. It does appear, however, that the controlling regulatory styles of those with OCP are more likely to be linked with excessive parental controllingness than is the case for OCD.

Introjection and Self-Disparagement: Self-Critical Depression

At the core of a number of pathologies are introjected demands that organize intentional behavior. Although this type of autonomy disturbance involves conflict and tension, individuals with rigid character are often able to behave intentionally and satisfy their introjects. There are other types of introjected demands, however, that individuals cannot easily attain, and these invariably result in experienced failure and self-disparagement. These forms of disturbed autonomy, like those of rigid character, begin with individuals' introjecting the demands of authorities and basing their self-worth on living up to those demands. But here, the pathology and experience are quite different, for the individuals' predominant experience is failure and worthlessness. Thus, not only is their autonomy undermined by introjects and the social conditions that instilled them, but they also feel incompetent and unloved by significant others. Two such pathologies of introjection are self-critical depression and eating disorders. We focus first on self-critical depression.

Research on depression and its etiology has increasingly pointed toward two distinct pathways to the disorder, each of which can build on biological vulnerabilities (Luyten & Blatt, 2013). The first is concerned primarily with internalization of excessive demands for achievement and is characterized by harsh self-criticism and guilt, and the second is concerned more with the loss of relatedness, love, or attachment. Although both of these vulnerabilities involve self-esteem dynamics, and issues of autonomy and relatedness are intertwined in both, the former, self-critical form of depression is particularly relevant to our discussion of autonomy disturbances, internalization, and internally controlling regulation. We thus focus on the self-critical depression syndrome, which has been labeled variously as a disorder of achievement-autonomy (Neitzel & Harris, 1990), introjection (Blatt, 1974), and autonomy (Beck, 1983).

By whatever label, this syndrome involves a type of disturbed autonomy in which people experience dysphoric affect and lethargy resulting from the belief that they are failures. In this disorder there are rigid standards or ideals that have been introjected, along with the belief that failure to attain them means they are unlovable and unworthy. Thus, the punitive introjects, with their ties to contingent self-worth, leave people vulnerable to ongoing self-scrutiny. Because with such introjects there is little individuals can do that is good enough, they will invariably experience a sense of worthlessness. In other words, self-disparagement tends to be ubiquitous. Individuals with such introjects are harsher in their self-judgments than in their judgments of others, and these self-judgments often form the precursors to depressive episodes (Beck, 1983). Their harsh self-judgments may even manifest outwardly, through engagement in nonsuicidal self-injurious behaviors, which reflect the scars of the inner critic (Claes, Soenens, Vansteenkiste, & Vandereycken, 2012). Accordingly it is hardly surprising that adolescent depression and low self-esteem are associated with low autonomy (e.g., Noom, Dekovic, & Meeus, 1999).

The phenomenological functioning underlying *self-critical perfectionism* is particularly relevant to the understanding of depression as involving disturbed autonomy. With respect to significant self-goals people see themselves as responsible yet as incapable. Thus, the absence of felt competence to attain internalized goals results in a sense of amotivation (Deci & Ryan, 1985a). At the same time many of the specific demands on the self to achieve or succeed have the character of *have-to* and *must* revealing their phenomenological character as having an external perceived locus of causality (i.e., as being heteronomous with respect to the self). Consistent with such an analysis, self-critical perfectionism has been found to be associated with more controlled functioning (e.g., Miquelon, Vallerand, Grouzet, & Cardinal, 2005) and increased psychological need frustration over time (Boone, Vansteenkiste, Van der Kaap-Deeder, Soenens, & Verstuyf, 2014).

There has been recent interest in the development of perfectionism, a characteristic related to self-critical depression. In line with our argument that such internally controlling characteristics reflect disturbed autonomy, evidence suggests that individuals with high levels of self-critical perfectionism frequently report having experienced harsh and authoritarian parenting (see, e.g., Flett, Hewitt, & Singer, 1995; Frost, Novara, & Rheaume, 2002; Kawamura, Frost, & Harmatz, 2002). For example, Enns, Cox, and Clara (2002) found support for a model in which harsh parenting led to maladaptive perfectionism, which in turn was associated with an increased proneness to depression.

Such findings suggest perfectionism as a pathway through which controlling environments might increase

depressive symptoms. Consistent with this, investigations of the backgrounds of self-critical depressives point to controlling parental styles. In one illustrative investigation, McCranie and Bass (1984) found that women high in self-critical depression had parents who maintained strict control, demanded high achievement, and were inconsistent and contingent in their conveyance of love. Whiffen and Sassville (1991) reported similar results for both males and females. Research based in SDT concurs, with longitudinal data showing that children growing up in controlling families are more likely to adopt self-critical perfectionistic attitudes, which, in turn, relate to elevated depressive symptoms (Soenens, Luyckx, et al., 2008). Moreover, the adoption of self-critical perfectionistic standards in controlling environments may not elicit depressive symptoms but may also involve self-esteem deficits (e.g., Soenens, Vansteenkiste, Luyten, Duriez, & Goossens, 2005).

Empirical findings are thus consistent with our speculations concerning the nature of the social contexts leading to introjection and internally controlling states. In this frame one can view self-critical depression as a chronic and pervasive state of ego-involvement in which one continuously fails to live up to the demands and is thus punished. Unfortunately, self-critical perfectionism appears to get transmitted from the one generation to the other through controlling parenting (Assor et al., 2004; Soenens, Elliot, et al., 2005). Presumably, the contingent love self-critical perfectionists display vis-à-vis their own functioning gets projected onto their children, such that children experience their parents as displaying conditional regard, which subsequently affects their own functioning.

Indeed, such dynamics between parent and child may be mutually problematic. Using a cross-lagged longitudinal design in two samples of middle and late adolescents, Soenens, Luyckx, Vansteenkiste, Duriez, and Goosens (2008) compared three models concerning the role of parental control in depression. Results generally favored a reciprocal model in which controlling parent behaviors contribute to increases in depression, which in turn enhance parents' tendency to control their teenager. This represents a truly maladaptive cycle between parent and child. This bidirectional relationship suggests that more depressive symptoms in an adolescent can elicit less autonomy support from parents over time, even as autonomy support from parents conduces toward fewer depressive symptoms in their adolescents.

Further, Soenens, Park, Vansteenkiste, and Mouratidis (2012) examined whether this association between parental control and depressive symptoms among adolescents might be culture bound as some cultural relativists have argued, versus whether as SDT suggests, the detrimental effects of psychological control and the loss of autonomy generalize across cultures. Soenens et al. (2012) specifically investigated the relevance of two domain-specific expressions of psychological control (i.e., dependence oriented and achievement oriented) in both Belgian and South Korean adolescents. Analyses showed very similar relations between the psychological control, depressive personality, and depressive symptoms across the two samples, thus supporting the notion that the effects of psychological control generalize across cultures.

In short, there are clear relations between control and these internally controlling forms of depression in which self-critical cognition is salient. Although there is substantial evidence that vulnerability to depression varies, the importance of autonomy thwarting in this expression of psychopathology is becoming ever better documented.

Eating Disorders: Anorexia and Bulimia

In her classic book on the topic, Bruch (1973) described eating disorders as pathologies of autonomy. She argued that these eating pathologies typically involve a struggle for control that takes the form of an obsession with eating and body image, with control over one's body dynamically staving off a pervasive sense of ineffectiveness. Bruch saw people with eating disorders as exemplifying the capacity, as a function of harsh introjects, to manipulate bodily states and desires to preserve the illusion of self-sufficiency and to feel a sense of control with respect to oneself and others. In restrictive anorexia, the introjects around eating and weight are more stable and effective in keeping people's eating behaviors in abeyance, whereas in bulimia there is a more open conflict between rigid controls and akratic eating. Bulimics engage in binge eating—in expressive, uncontrolled consumption—only to be plagued by guilt and self-derogation leading to vomiting or abuse of diuretics.

The psychodynamics highlighted by Bruch were empirically supported in an early study by Strauss and Ryan (1987). They found greater self-oppression and self-rejection in both anorexic and bulimic participants than in a matched control group, suggesting internally controlling dynamics, whereas control-group participants displayed more flexible self-management and self-acceptance. Furthermore, Strauss and Ryan documented a particularly heightened impersonal causality orientation (Deci & Ryan, 1985a) among restrictive anorexics, indicative of an impoverished sense of both autonomy and effectiveness.

Internally controlling forms of regulation are readily apparent in the dynamics of many behaviors entailed in eating disorders, especially those involving restrictive self-control. Whether anorexic or bulimic these patients display inordinate concern with how others view them, and hypertrophied public self-consciousness. As Plant and Ryan (1985) argued, such consciousness potentiates an external perceived locus of causality in which people have to conform to the projected views of others. Although a focus on weight is often paramount, eating disordered patients are typically self-conscious, demanding, and self-critical with regard to many aspects of appearance and behavior. And although restrictive anorexics in particular appear to display a high degree of personal control, the regulatory basis of this control is dictatorial.

Applying SDT to anorexia, Vansteenkiste, Soenens, and Vandereycken (2005) described how a focus on thinness represents an attempt to gain a sense of security and worth, yet the thinness, even when attained, fails to supply the anticipated emotional benefits. The anorexic person is never thin enough, yet they continually work with the belief that positive feelings are a few pounds away. The paradox, however, is that achieving their extrinsic goal is satisfying to some degree, so it further anchors them in this pattern of behavior. These patients often strongly assert that they do feel better when losing weight and believe that the pursuit of weight loss is therefore not the source of distress. Indeed, their own experiences seem to confirm that efforts at weight loss are part of the solution. The transitory nature of relief thus fosters an addictive quality to the internally controlling drive for thinness.

Whereas the restrictive anorexics can display a high degree of control with respect to eating, bulimic patients often find their control overwhelmed by an impulse to binge eat. Binges typically occur at times of high psychological need frustration, thus showing how their introjected regulatory structures are not sufficiently stable to keep the impulse in check. The binge impulse is often a reaction to the experience of need frustration rooted in internal criticism, so it represents an attempt to escape from the painful sense of self that carries the burdensome, introjected standards. For example, Verstuyf, Vansteenkiste, and Soenens (2012) researched the connections between need frustrations and binge eating. In a sample of female adolescents, they showed indeed that an investment in appearance-focused motives led to need frustrations, which in turn predicted increased bulimic symptoms. Along similar lines, a diary study in female adolescents (Verstuyf, Vansteenkiste, Soenens, Boone, & Mouratidis, 2013) indicated that daily variation in psychological need frustration covaried with ups and downs in bulimic symptoms, suggesting that binge eating serves to compensate for painful experience of need frustration.

It is interesting to note that, as the psychic threat gets greater for individuals with the bulimic disorder, the people's regulatory capacities becomes weakened, whereas in people with obsessive-compulsive personality the regulatory capacity often becomes even more rigid and dominant. The lack of stability of the regulatory introjects in the people with bulimia thus allows for the akratic action, but the self-evaluative introjects invariably result in self-disparagement and feelings of depression for having lost control. It is therefore interesting to note in this regard that the long-term course for many restrictive anorexics is a shift to bulimic patterns of coping.

Although again there are multiple contributors to the development of bulimia and related eating disorders, the role of familial factors in setting up the dynamics of introjection and internal control are quite salient. Bruch (1979) has vividly depicted the role of parents in catalyzing anorexia by depriving their daughter of autonomy and the "right to live her own life" (p. 38). Minuchin, Rosman, and Baker (1978) similarly reported high levels of enmeshment and intrusive control in families of patients with eating disorders. Strober and Humphrey (1987) reported that both anorexics and bulimics experience parents as blaming, rejecting, and critical. Strauss and Ryan (1988) found less mutuality of autonomy in the object representations of both bulimic and anorexic participants, and lower expressiveness within their families. Another more recent study found that late-adolescent women hospitalized for eating disorders reported having more psychologically controlling fathers than a matched sample of women without the eating disorders (Soenens et al., 2008).

Summary

Each of the disorders we have considered thus far begins with rigid, demanding, and critical introjects. These rigid structures take varied forms and are more or less stable and effective in controlling the people's actions. In some cases, most notably obsessive-compulsive personality and anorexia nervosa, the disordered individuals can feel a strong sense of personal control and self-efficacy—the OCP can keep personal affairs orderly and anorexics can keep body urges under control. But these, like the other disorders involving salient introjects, constitute disturbed autonomy and can terrorize people with such contingent self-esteem. Findings in this area also highlight

the important difference between personal control and autonomy; being self-controlled can sometimes yield desired outcomes yet not be experienced as autonomous or volitional (Muraven, Gagné, & Rosman, 2008).

We turn now to disorders characterized not by the prevalence of introjects, but rather by the relative absence of internalization. These forms of psychopathology involve the lack of adequate regulatory structures that link one effectively to the socializing context.

Impairments of Internalization in Externalizing Disorders

As we argued earlier, the process of internalization is dependent upon certain affordances in the caregiving environment—namely, autonomy support, structure, and involvement—which together facilitate both attachment to caregivers and a readiness to assimilate the values they model. Some caretaking environments, particularly those characterized by coldness and hostility or by neglect conduce toward poor quality of attachments and lessened internalization of social norms and prosocial behaviors (Johnson, Cohen, Chen, Kasen, & Brook, 2006; Joussemet et al., 2008). In addition, those low in autonomy supports, especially the lack of both perspective taking and attunement to needs and interests, are at risk for both low social skills and negative social interactions (Shields et al., 2001). In fact, parenting environments impact on internalization through their effects on need satisfaction (Ryan et al., 2006). Controlling parents not only restrict opportunities for children to develop self-regulatory capacities, they create emotional and need-related frustrations that can fuel negative behaviors.

In the realm of more severe forms of psychopathology, we are also concerned with more extreme forms of need thwarting, including physical, sexual, and emotional maltreatment, which thwart all three basic needs, with irradiating effects across multiple developmental lines. Such parenting conditions may result either in externalizing problems (Gershoff, 2013) such as conduct disorders, or, especially when the thwarting is extreme, in disorders such as dissociative identity.

Illustrating this with respect to externalizing disorders, Shields, Cicchetti, and Ryan (1994) examined the social-competence self-regulation impairments of children who had been maltreated by caregivers. The setting was a summer camp for both maltreated and economically disadvantaged children, allowing for a comparison of these groups. As predicted, children who had endured maltreatment displayed, as rated by observers, less social competence, more emotional dysregulation, and impaired self-regulation reflected in externalizing disorders as well as internalizing disorders. Indeed, self-regulatory deficits mediated the relations between maltreatment status and social competencies.

In a subsequent study, Shields, Ryan, and Cicchetti (2001) further explored this developmental process by assessing maltreated and nonmaltreated children's representations of the parenting they experienced. They found, as expected, that the representations of parents in maltreated children, as accessed through a projective narrative task, were less coherent and integrated, and more negative and constricted than those of nonmaltreated children. These differences in parental representations were in turn related to the externalizing processes of emotional dysregulation, aggression, and peer rejection in the ecologically valid camp setting.

These issues concerning need thwarting conditions and impairments in self-regulation have particular salience with respect to conduct and oppositional disorders, in both of which internalization, self-regulation, and capacities for relatedness are impaired.

Conduct Disorders and Antisocial Personality

Broadly speaking antisocial personality disorder (APD) applies to persons who lie, steal, manifest an impoverished sense of responsibility, are aggressive and manipulative toward others, and show evidence that these patterns are continuations of behavior disorders earlier in life. Children diagnosed with *conduct disorders*, a frequent antecedent of APD, display control problems, lability, a lack of ability to give and receive affection, and delayed or impaired development of conscience. Further, self-aggrandizement and egocentrism typically characterize their behavior, and their lying about accomplishments highlights their excessive need to be recognized or esteemed by others in an immediate way. Like adults with ADP, these children tend to display a lack of conscience, or deep concern with what is good or right. Related to conduct disorders and APD is the behavioral category of reactive or destructive aggression, the developmental routes of which have been related to those associated with these diagnostic categories.

Etiologic theories of APD have clearly implicated biologic or genetic factors such as poor autonomic reactivity (Burnette & Cicchetti, 2012; Raine, 2013). Yet even with this recognition of potential biologic vulnerabilities, it is clear that such vulnerabilities become amplified in nonnurturing environments. Our contention is that APD is a psychopathology entailing *impaired internalization*, and although internalization may have been compromised by biological factors (Jafee, Moffitt, Caspi, & Taylor, 2003),

we maintain that these impairments can also be linked to, and are interactive with, deficits in the social contextual factors associated with the basic psychological need supports that are essential for internalization to develop.

An internalization perspective looks toward the family environment for the relational resources that support the internalization of values of a prosocial nature, resources that are frequently lacking in the families of persons developing APD. For example, the empirical evidence supports the idea that prosocial values are most likely to be acquired (or expressed) when caregiving is characterized by warmth (Maccoby, 1980), low power assertive discipline (Hoffman, 1960), and autonomy support (Ryan & Hawley, in press).

The experience of growing up in a nurturing, caring, and responsive familial environment undoubtedly facilitates prosocial values both directly and indirectly. A person who grows up in a basic need supportive environment will have been exposed to models of caring and concern about others, from figures to whom they are likely to attach and desire to emulate. Support for this comes from many quarters. For example, Ryan and Connell (1989) reported that children who experience a high quality of relatedness to parents were more autonomously motivated in the prosocial domain. Conversely, a variety of clinical and empirical perspectives have suggested that antisocial personality, oriented towards self-serving, manipulative, and hedonically gratifying acts, has its roots, in part, in cold, inconsistent, and controlling family environments (e.g., Benjamin, 2003). A plethora of studies has also shown that the common backdrop to APD and conduct disorders of childhood includes such factors as maternal depression, loss, high family conflict, other parental pathology, and impoverished conditions of life that fragment the family (Coie & Jacobs, 1993; Loeber & Stouthammer-Loeber, 1986). All of these factors potentiate a situation ultimately lacking in the basic nutrients upon which internalization depends—namely autonomy support, adequate structure and guidance, and concerted, caring involvement.

One limitation of these models of value acquisition, and their implications with regard to the development of externalizing disorders such as APD, is that they do not focus on how or why children might develop nonprosocial or nonmoral attitudes, except as a converse or absence of moral internalization. For example, there are probably very few parents who strive to teach their children to be manipulative, materialistic, or Machiavellian, but there are many children who develop such an orientation. Absence of identification does not explain why one proactively seeks to act in *these* ways. Thus, a fuller model of APD requires both explaining why internalization fails, and why hedonic, aggressive, self-gratifying values predominate instead.

Directly informative in this regard is a six-year longitudinal study by Joussemet et al. (2008), who followed children from six to twelve years of age. Specifically, they identified developmental trajectories in childhood aggression in which they applied SDT. They found that over these years children on average engage in a lower frequency of aggressive acts, presumably reflecting socialization and development. Yet the slope of that trajectory differs among children, such that while for most there are declines in aggressive acts, for others there are maintained or escalating frequencies of aggression. After controlling for a number of other risk factors for being aggressive (e.g., being male, having a reactive temperament, parental divorce/separation), Joussemet et al. found, as they hypothesized based on SDT, that having a mother who was autonomy thwarting rather than autonomy supportive reliably increased the odds of a high aggressive trajectory.

In fact, some research within SDT suggests that controlling parenting can result not only in poor internalization, but also oppositional motivations. In line with this, parental prohibition of moral misdeeds perceived to be controlling was found to predict increased oppositional defiance (Vansteenkiste, Soenens, et al., 2014). Other studies have established the explanatory role of need frustration in the relation between controlling parenting and oppositional defiance and associated problem behaviors (Van Petegem, Beyers, Vansteenkiste, & Soenens, in press). Indeed, it seems that much antisocial behavior can be understood as a reaction to controlling, power-assertive strategies in contexts where attachment security and relatedness is low (Kim, Kochanska, Boldt, & Nordling, 2014).

Ryan, Sheldon, Kasser, and Deci (1996) argued that, to the extent that individuals lack autonomy support and caring involvement (and therefore are deficient in the development of self), they often turn toward extrinsic values to gain and sustain some minimal sense of power, narcissistic importance, and worth, and a corresponding lack of concern with doing for others or contributing to society. In line with this, Kasser et al. (1995), analyzing data from a long term longitudinal sample, found that adolescents who were more materialistic came from homes where both they and their mothers reported that there was less autonomy support, warmth, and security. They also found that more impoverished, high-crime neighborhoods, in confluence with these more controlling and hostile parenting environments, were likely to promote children's placing strong importance on these extrinsic values. Most relevant in this context, Kasser et al.'s analysis of clinical interviews with

participants in an at-risk population (defined in terms of maternal psychopathology and low socioeconomic status) revealed that those with greater centrality of materialistic values were more likely to be clinically diagnosed as conduct disordered. One important aspect of this work was its clarification that environments that fail to support autonomy and relatedness promote a compensatory emphasis on alienated or substitute needs, such as material acquisitions and visible trappings of worth. These, in turn, activate the so-called antisocial personality, albeit in ways often seen as self-centered. The research also highlights the continuity of motivational dynamics between nonclinical and clinical populations, as caregiving factors associated with materialism, in more extreme forms are associated with conduct disorders. This general pattern of findings is also consistent with Coie and Jacob's (1993) analysis of conduct disorders.

From the perspective of SDT, the development of conduct disorders and a self-focused goal orientation both stem directly from inadequate attachment and failed internalization resulting from an externally controlling, inconsistent, and affection-impoverished social context as they interact with vulnerabilities to poor self-regulation. To the extent that social values (and the economic conditions that structure them) disable, distract, or fragment the caretaking environment, then children will be more oriented to narcissistic goals to gain a temporary sense of worth and importance. This model is applicable not only to conduct-disordered children but increasingly also to American culture more generally (Kasser, 2002; Twenge et al., 2010). Put succinctly, the more we create conditions that disrupt the quality and stability of familial relationships, the more narcissistically oriented and antisocial our culture as a whole may become.

In sum, conditions of need thwarting, particularly threats to and deprivations of autonomy and relatedness satisfactions in childhood conduce to lowered attachment and interpersonal connectedness, to poorer development of self-regulation and thus impoverished internalization, and to need substitutes in the form of hedonic and materialistic aims, rather than prosocial ones. While such conditions negatively affect wellness in general (e.g., Kasser et al., 1995) when applied to vulnerable individuals the result is often more entrenched antisocial patterns of behavior.

Severe Need Thwarting in Dissociative Identity and Borderline Personality Disorders

We have argued that essential to the formation of integrated experience and behavioral regulation is support for autonomy, competence, and relatedness. Dissociative identity disorders (DID) and borderline personality disorders (BPD) represent, in most cases, disorders befalling individuals whose life experiences were characterized by not only deprivation, but also active intrusive thwarting, of both autonomy and relatedness needs. In fact, they represent disorders where there has been a failure in the average expectable environments needed for psychological development. For example, Johnson et al. (2006), using a longitudinal sample, reported that low affection (low relatedness) and punitive (low autonomy support) parenting practices were associated with elevated risk for borderline and other personality disorders. Steinberg and Schnall (2001) reported extremely high rates of early physical and sexual abuse among patients with DID. In the histories of people with either disorder, important others who should have been loving and kind to them were instead hurtful and maltreating, violating of the minds and bodies of the people who needed their support. The compensatory results of this are less integrated functioning and diminished sense of autonomy and connection.

Borderline Personality Disorder

Borderline personality disorders have become a predominant concern in clinical settings both because of their increasing incidence and thus the personal resources demanded in their treatment. Studies of BPD highlight many issues in character pathology generally, and they represent a prototypic example of structural damage to the self that has been associated with caregiver failures to support autonomy and relatedness in early development (Ryan, 2005).

The core feature of BPD is the lack of a cohesive and stable sense of self. Associated with this lack of a consistent and organized self are highly labile emotions, interpersonal relations, and self-esteem dynamics. Borderline individuals show the externalizing attributes of impulsivity, along with some of the features of internalizing disorders such as susceptibility to depression, anxiety, and fragmentation in the face of self-esteem related losses. A cardinal feature of BPD is anger, both self- and other-directed, which can result in destructive actions and magnify relationship volatility and internal feelings of being overwhelmed and disintegrated. More generally, patients with BPD have difficulty differentiating internal needs from external reality, and they are tremendously dependent on concrete supports from others to maintain a sense of self. They lack the internal regulatory processes to modulate anxiety, which can escalate to panic proportions, particularly when no one is available to contain and comfort them.

Persons with BPD also often lack a stable identity or sense of purpose (Meissner, 1988). Patients with this disorder may, however, latch on to something or someone in an effort to derive a temporary feeling of cohesion, but these choices are often inappropriate or destructive. Commitments are difficult because borderline individuals lack a stable and cohesive self that can form the basis for sharing in committed relationships or endeavors. Connected with the lack of feeling of identity, patients with BPD may feel empty and isolated (Westen, 1991). Clearly, there is a diminution of their true self whereby they lose connection to their interests and feelings. Patients with this disorder often report feelings of boredom and may engage in impulsive acts, such as substance abuse, careless spending, and binge eating, to counteract such feelings. Closely related to this is borderline individuals' lack of capacities for reflective awareness, especially when inner urges are strong (Bleiberg, 2004; Ryan, 2005).

Phenomenologically, patients with BPD often report being both controlled and helpless with respect to their behavior. They often feel like a victim of circumstances without a sense of responsibility for the direction of their own fate. One late adolescent patient, for example, reported that prior to self-mutilation he entered into a lost state, where the overwhelming impulse to cut came on him (impersonal perceived locus of causality), while at the same time he felt he could obtain relief and release only from dysphoric self-hate by engaging in such acts (suggesting external causality). In no sense did he feel autonomous and volitional in these acts, but rather driven, desperate, and helpless.

Although there is some evidence of genetic contributions to BPD, in that many appear to have exhibited a difficult child temperamental profile, much of the etiology appears to be associated with care-giving environments (e.g., Silk, Lee, & Hill, 1995). As we discussed in attachment research, formation of a stable and cohesive sense of self depends on nurturance in the form of autonomy support and positive involvement. Yet as Sperry (2003) noted, those with BPD have typically experienced severely impoverished care-giving during these early years, with parents' (particularly mothers) having difficulty allowing the children to move toward self-sufficiency and autonomy. Through being both controlling and inconsistent, parents of individuals with BPD fail to bolster the children's integrated self that is essential for the tasks of emotion regulation and identity formation. Having been exposed to caregivers who did not provide autonomy support and were unable to take the children's perspectives, the children failed to develop the sense of reflective awareness that would allow them to be in touch with their own internal states or the internal states of others.

Early caregivers of individuals with borderline disorder have often been described as unavailable, inconsistent, and neglectful, with frequent reports of sexual, emotional, and physical abuse (Sperry, 2003; Zanarini, 1997). In one study, 80% of borderline patients were reported to be physically or sexually abused or to have witnessed serious domestic violence (Herman et al., 1989). Explicating more specifically the affect and behavior regulation difficulties of these patients, Linehan (1993) suggested that patients with borderline disorder often come from families that invalidate the affective experience of their children. There is little tolerance for fears or anxieties in their children, and they do not offer soothing or comfort when needed. Without such care, these children have difficulty internalizing the capacity to self-soothe, resulting in emotion regulation difficulties, especially being unable to tolerate feelings of distress.

According to object relations theorists (Masterson, 1985), the disorder has its roots in the mother–child relationship, particularly during the phase of separation-individuation when the child is striving to experience him or herself as separate from the mother. Part of the phase involves a pushing away from the mother. In families of borderline individuals, the mothers are not able to tolerate movement toward self-sufficiency as it brings up their own fears of abandonment. Consequently, the mothers threaten to withdraw nurturance from the children if they move to act as separate autonomous individuals. Given this level of conflict, there is no "good" object that can support the psychological needs underlying a cohesive sense of self.

The problems of borderline patients thus illustrate how lack of empathy and consistent involvement and autonomy support undermine intrinsic interests and tendencies and self-regulatory functions—all aspects of a healthy autonomous functioning (Ryan, 2005). These developmental thwarts are thus critical to the formation of BPD. Sadly patients with BPD thus have ongoing experiences of lack of need satisfaction, as they have difficulty trusting in relationships and often find themselves acting without autonomy, both contributing to inner distress and continuing cycles of dysregualtion.

Dissociative Identity Disorder

Dissociative disorders are a particularly important issue within SDT given the theory's focus on autonomy as integration and synthesis. That is, SDT defines autonomy as the integrated regulation of behavior, and dissociative disorders, by definition represent the absence of such integrated regulation. There are two broad senses in which

dissociative disorders can represent nonintegration. Some dissociative disorders concern a lack of integration between behavior and experience with a sense of self. This is evident in depersonalization symptoms and when there is amnesic or accessibility barrier for certain event or actions. More extreme is the issue of multiplicity, the idea of more than one center of consciousness, expressing distinct motivations, memories, and attributes.

Dissociative disorders thus fundamentally represent a substantial breakdown in self-integration (Ryan et al., 2006). Related by some to an extreme form of BPD, as well as to severe PTSD, most clinicians and researchers also view most dissociative disorders, and particularly dissociative identity disorder (DID) as frequently a product of severe maltreatment or loss (although see Lynn, Lilienfeld, Merckelbach, Giesbrecht, & van der Kloet, (2012) for a contrary perspective.) Dissociation represents a protective or defensive mechanism, originally arising to protect integrity of a self that is beset with trauma. However, when inability to integrate experiences is chronic or severe, fragmentation of self-functioning and increased tendency to use dissociation to cope with threat occur (Carlson, Yates, & Sroufe, 2011).

DID manifests as compartmentalized functioning, in which traumatic experiences are housed in dissociated, often inharmonious, parts of personality. Yet more distinctly, DID symptoms include alterations between distinct identity states, often accompanied by amnesic barriers between them. Given its traumatic origins, symptoms of DID overlap with those of both BPD post-traumatic stress disorder. Yet DID is also commonly related to depression, associated with both developmental deficits and helplessness within the condition. In part this may be related to a common pattern in which, in an attempt to maintain relatedness to an abusing or harsh caregiver, the child internalizes self-critical and self-blaming views (e.g., Westen, 1991). Low self-esteem and depressive affect thus commonly accompany DID and other dissociative disorders.

DID is an autonomy disturbance insofar as autonomy requires cohesiveness and integration, and the violation of self, especially by caregivers, can shatter integrity. The splitting of personality has the function of defensively shielding the core self from pain or harm (van der Hart, Nijenhuis, & Steele, 2006), but the shifts in identity that characterize DID are typically not experienced as within personal control. Indeed, they have an impersonal perceived locus of causality (Ryan et al., 2006). Depersonalization, another symptom associated with DID, also exemplifies this sense of impersonal causality, as if one's body were acting independently of one's will. As autonomy, or self-rule, depends on a sense of self and an internal perceived locus of causality for behavior, it is clear that autonomy is seriously disturbed when behavior occurs without choice or in a dissociated state.

The perceived lack of personal causation is often part of the despondency and depression these patients report. For example, a patient who came to treatment for depression and for concerns for her memory for events had manifest symptoms of DID. She subsequently revealed repeated sexual abuse by her father that she previously had not reported. Images began to surface, often uncontrollably. As memories unfolded it was also clear that she had been repeatedly threatened if she ever told anyone, a command she had internalized. Various parts of her story, and emotional reactions to it, were represented by different personality systems, each with its own age and makeup, and its own capacity to exert executive control under particular circumstances.

As van der Hart and colleagues (2006) pointed out, whereas healthy personality functioning is characterized by synthetic, coordinated functioning, the defensively precipitated identities in DID are often very simple and focused, and not prone toward integration or harmony with other personality subsystems. Van der Hart et al.'s treatment approach focuses on increasing connectivity between split off parts of personality, using a slow process of exposure and dialog in which compassion and understanding are fostered, along with encouragement to move toward feared or avoided opportunities for self-realization, to further promote such connectivity. Clinicians who have worked with DID know the difficulty of the process approach and the required patience and empathy. Often change requires strong supports and anxiety reduction strategies as well. Adaptation and tools for grounded self-regulation rather than full integration is often an appropriate goal. The goal of course is the recovery of more coherent, integrated functioning, and the resumption of self-development to whatever extent possible.

In sum, a fundamental tenet of developmental psychopathology is that the study of both normal and atypical development should inform each other (Cicchetti, 2006; Cicchettti & Toth, 2009). SDT's research into basic psychological needs richly links psychologies of growth with those of pathology. Evidence shows how the psychological nutrients that facilitate optimal development, when neglected or thwarted can have cascading negative effects across development. Moreover, the kind of need thwarting a child experiences can be related to the kind of pathology he or she manifests. We identified three types of disorders reflecting different types of autonomy disturbance:

internalizing disorders, impairments in internalization, and self-fragmentation. Each reflects a varied way the integrated self-regulation and ownership of actions is disrupted, and each also has autonomy thwarting as a featured symptomatic or etiological factor.

Translational Implications: Autonomy and Autonomy Support in Psychotherapy and Intervention Programs

An interesting question concerns the relations between *etiological factors* such as lack of autonomy, relatedness, and competence supports in development to *ameliorative factors* proposed by various treatment approaches to psychological problems. It seems clear that the absence of need-supportive inputs from caregivers can catalyze an array of negative developmental processes, both behavioral and biological, that eventuate in disordered functioning. Reciprocally, in efforts to treat the immediate harms and cascading negative effects of such social etiological factors, SDT suggests that need supportive treatment and intervention contexts are critical.

Ameliorating or treating existing disorders often entails addressing need deficits both *directly*, by providing a need supportive therapeutic context, and *indirectly*, for example by providing people with skills or opportunities to better satisfy needs in their natural environments. In other words, SDT suggests therapy is, in large part, effective through facilitating the individuals' capacities to act with autonomy, and in acting so, to satisfy all three basic psychological needs (Ryan & Deci, 2008).

Autonomy support is of course important to all schools of psychotherapy, especially because volitional motivation is so necessary to therapeutic engagement and success. For example, Ryan, Lynch, Vansteenkiste, and Deci (2011), reviewing approaches to psychotherapy, and behavior change distinguished between outcome and process focused therapies. Outcome focused approaches (e.g., behavioral and cognitive behavioral treatments) tend to promote autonomy through an emphasis on transparency. Patients are told beforehand what is expected and allowed to select in to treatment, or not. Readiness for treatment can also be facilitated through motivational enhancement therapies, such as brief motivational interviewing (MI; Miller & Rollnick, 2002) as adjuncts to outcome-focused interventions to prepare the individual to volitionally engage the therapy. Ryan et al. pointed out that more *process-oriented* schools of therapy (e.g., psychodynamic and existential approaches) conceive of motivation as a focus of treatment itself rather than something that facilitates pre-treatment readiness. Cultivating autonomous engagement and taking interest in resistances is in fact considered an active and ongoing focus of process-oriented therapies.

Zuroff et al. (2007), drawing on SDT, proposed that autonomy should be considered a common factor in all effective psychological treatments. Supporting their proposal, they reported a study of depressed outpatients who were randomly assigned to receive interpersonal therapy, cognitive-behavioral therapy, or pharmacotherapy with clinical management. Assessments of depression severity were taken before and after treatment, and therapeutic alliance, the clients' autonomous motivation, and therapists' autonomy support were measured at the third session within each group. Zuroff et al. found first, as expected by SDT that therapist autonomy support was associated with greater client autonomous motivation. More strikingly, autonomous motivation was a better predictor of improved outcome than therapeutic alliance across all three treatments. The researchers therefore suggested that the promotion of autonomy is an important factor in treatment across modalities and can be distinguished from therapeutic alliance per se.

Given its focus on facilitating autonomous motivation, not surprisingly SDT has increasingly been used as a guiding framework for clinical interventions and randomized clinical trials in behavior change (Ryan, Patrick, Deci, & Williams, 2008). In fact clinical studies applying SDT attest to the positive consequences of autonomy-supportive treatment climates, including higher treatment attendance, less dropout, less relapse, and enhanced well-being over the course of treatment. Such results have been obtained in various domains such as drug and alcohol dependence (Foote et al., 1999; Ryan, Plant, & O'Malley, 1995; Zeldman, Ryan, & Fiscella, 2004), weight loss (Williams, Grow, Freedman, Ryan, & Deci, 1996), smoking cessation (Williams, McGregor, et al., 2006), general medication adherence (Williams, Rodin, Ryan, Grolnick, & Deci, 1998), HIV-related medication adherence (Kennedy, Gogin, & Nollen, 2004), eating disorders (Van der Kaap-Deeder et al., 2014), and other issues.

Beyond the importance of autonomy for behavior change is its importance in restorative self-development and personality growth. These principles are critical both in psychotherapy and in programs that provide support and training for caregivers. Particularly germane to the issue of motivation in growth-focused settings is a focus on *autonomy support*, which conduces exploration, disclosure, and integration (Weinstein, Przybylski, & Ryan, 2012). Specific behaviors associated with autonomy support include (1) taking the child's or adolescent's internal frame

of reference and welcoming negative feelings and resistance; (2) providing a meaningful rationale for requests and activities; (3) minimizing external controls such as contingent rewards and punishments or conditional regard, instead nurturing inner motivational resources (e.g., challenge, curiosity); (4) providing opportunities for participation, input, and choice; and (5) following the child's rhythm of progress and development (Reeve, 2009; Ryan & Deci, 2008). In autonomy-supportive contexts, pressure to engage in specific behaviors or express specific attitudes is minimized, and individuals are encouraged to base their actions on their own reflective considerations and values. Thus, autonomy for behavior is facilitated insofar as actors are helped to identify and own their reasons for changing or not changing behaviors, and do not feel pressured toward specific outcomes. This in turn leads to greater internalization and maintenance of change.

In addition to experiencing autonomy, internalization also requires that a person experience the confidence and competence to change. In SDT, *competence support* is afforded when practitioners provide the effectance-relevant inputs of structure and feedback (Jang, Reeve, & Deci, 2010; Sierens, Vansteenkiste, Goossens, Soenens, & Dochy, 2009). Clients are afforded the skills and tools for change and are empathically supported when efficacy-related barriers emerge. In the SDT model of change, gaining a sense of competence is facilitated by autonomy, in that, once people are volitionally engaged and have a high degree of willingness to act, they are then most apt to learn and apply new strategies and competencies (Markland et al., 2005). At that point providing additional challenges and structure can be especially helpful.

Finally SDT considers *relatedness support* as critical in both growth and internalization processes. Unconditional positive regard and helpful, but not intrusive, involvement facilitate relatedness experiences, which support interest and curiosity, as well as the trust and connectedness important to internalization. However, unconditional regard is not merely a technique, and it must be perceived as authentic or genuine to have the functional significance of relational support (Ryan, 1995).

These general principles can be actively applied in programs to train teachers (e.g., Aelterman, et al., in press; Cheon, Reeve, & Moon, 2012) or parents to adopt a more need-supportive approach, as to enhance developmental outcomes and lessen psychopathology. For example, Joussemet, Mageau, and Koestner (2013) studied an intervention program called the *How-to Parenting Program,* which included components meant to enhance provision of structure, greater relatedness and more support for autonomy. Results indicated the program succeeded in increasing these parenting attributes relative to baseline, and moreover, the level of children's internalizing and externalizing symptoms were significantly decreased, suggesting program effectiveness.

Future translational efforts must also move beyond tertiary efforts at psychotherapy and behavior change, toward more prevention, and this is a goal for which SDT's body of knowledge is uniquely suited. SDT, as an empirically supported framework, points both to general facilitating factors (e.g., psychological need satisfactions), and criteria for testing any specific strategies for enhancing these factors (i.e., measurements of targeted motivational mediating variables). There is thus great promise ahead for both intervention and process studies of behavior change and for creating conditions in families, schools, and communities that build resilience through fostering capacities for autonomy.

SDT AND THE STUDY OF DEVELOPMENT AND PSYCHOPATHOLOGY: CONCLUSIONS AND IMPLICATIONS

Among the central aims of SDT is the explication of the social-contextual conditions that promote optimal development of self. Thus, we have focused considerable attention on specifying the conditions that both facilitate and undermine optimal development. In this way, basic psychological needs are constructs that link SDT's efforts in understanding growth and positive experience, to the study of ill-being and the development of psychopathology. It is our contention that many of the processes that are integral to nonoptimal functioning in normal populations are also central to various psychopathologies. Indeed, we see continuity in the basic psychological needs for autonomy, competence, and relatedness across people's personality differences, developmental epochs, and cultures, suggesting that thwarting of these basic needs, especially when being severe, is a critical component of psychopathology and more normal or transitory maladjustment.

The developmental antecedents of disturbed autonomy are manifold, with genetic, biological, interpersonal, and sociocultural factors all being relevant (Cicchetti & Dawson, 2002; Ryan & Hawley, in press). Genetic and other biological factors enter transactionally into interpersonal relationships, facilitating or forestalling the quality of these social contextual inputs and thus constituting an obstacle or affordance for experienced need satisfaction, and cultural factors both shape and are emergent from patterns of social and familial functioning. Our focus has

been primarily on the social and familial factors, although our aim was not to provide a complete account of the development of autonomy disturbances. Rather, we have attempted to describe the phenomenological significance of autonomy in normal and pathological development and to show empirically and theoretically how interpersonal factors contribute to the etiology of pathologically disturbed autonomy.

Within this approach, we have viewed the development of autonomy as proceeding most effectively in familial and social contexts that provide autonomy support, optimal structure, and interpersonal involvement. In the absence of these necessary social nutrients—in contexts that thwart satisfaction of the needs for autonomy, competence, and relatedness—disturbed self-development is expected, resulting in the emergence of psychopathology. Psychopathology is thus the result of disorganizing influences, of contexts that thwart or forestall personality integration.

We have reviewed a large number of studies indicating that the development of autonomy—that is, the maintenance of intrinsic motivation, the internalization of values and regulatory processes, the integration of emotions, and the formation of identities—is facilitated by the contextual nutrients of caregiver attention and interest, and of encouragement for exploration and self-initiation. Contexts where interpersonal involvement and autonomy support are absent have been found reliably to diminish autonomous regulation and impair the development of self. The contextual elements that have consistently been found in our studies to impair autonomy and development—namely, controlling or uninvolved parenting—have also been emphasized in the clinical literature on the antecedents of disorders that involve either heteronomous introjects or failures of internalization. Thus, there appear to be clear parallels between the results of the empirical explorations of autonomy dynamics in normative development and the conclusions from clinical studies of psychopathology. Indeed, basic psychological needs represent constructs linking our understanding of both growth and pathology in self-development (Vansteenkiste & Ryan, 2013).

Future Directions

SDT focuses on the role of basic psychological needs in both growth and pathology. What is exciting about the convergence between SDT-grounded research results on both healthy populations and those experiencing psychopathology is that it sets the stage for more integrative empirical investigations in which the concepts of autonomy, competence, and relatedness needs figure heavily. For example, the constructs concerning intrinsic motivation, internalization, and autonomy-supportive relationships all bear on clinical phenomena, and they help us see the continuity of human needs in diverse populations. Whereas theories of internalization have been widely discussed in developmental and clinical literatures by such seminal writers as Freud, Mahler, Erikson, Perry, Piaget, and Kohlberg to name a few, there has been a paucity of empirically based studies of the process, and little specific theory about factors that facilitate versus undermine internalization in clinical settings. SDT's empirical focus provides testable hypotheses, amenable to both experimental and field methods, concerning both how to measure internalization, and its antecedents, consequences, and neuropsychological correlates.

More detailed work on the antecedents of specific autonomy disturbances within the various disorders will also be important. It is clear, for example, that the lack of autonomy support and genuine relatedness by caregivers are antecedent to the development of a wide range of pathologies (Ryan et al., 2006). Yet why an individual develops anorexia nervosa rather than pervasive self-critical depression in familial contexts that are demanding and critical is an example of the kinds of questions that are important to tackle empirically, and in coordination with epigenetic and neuroscience findings. Although failures of autonomy support appear to supply a generalized stressor to integrated development, how this differentially impacts and interacts with varied diatheses and vulnerabilities is an area for further inquiry. We know far too little about the specific pathways to specific disorders, leaving the study of factors that conduce to or elicit particular pathologies an important agenda for continued research.

The theoretical framework of SDT specifically distinguishes autonomy from independence, and this distinction is one we see as particularly critical to the field of developmental psychopathology, as well as to theories of parenting, attachment, and development more generally. Noting that both independence and dependence can be either heteronomous or autonomous can help future researchers disentangle what heretofore has been a very mixed and confused literature on dependence across the life span. In our view, dependence should be viewed not only as a potential problem but also as a positive capacity. The willingness to rely on and receive support from others is a basic human propensity that is fostered when autonomy is supported (Ryan et al., 2005). Future research can thus build on this distinction, examining more clearly the pros and cons of dependencies in different developmental epochs and interpersonal contexts. It can also inform

the growing literatures on psychopathology as it relates to gender and culture, where issues of autonomy and independence have too often been melded and confused (Chirkov, Ryan, & Sheldon, 2011).

More generally, we have pointed to the connections between the development and integration of personality and the phenomenological experience of autonomy in the regulation of behavior. In our view, the issue of autonomy is a critical one for organizational perspectives on developmental psychopathology. The experience of autonomy is a defining feature of organization, whereas disturbances of autonomy that correspond to fragmentation and disorganization in psychological development are also manifest as experiences of control and amotivation. We have further pointed to environmental conditions that either thwart or nurture needs for autonomy, competence, and relatedness as influential factors in development either away from or toward greater organization and integrity, respectively. The differentiated study of how these psychological needs, in interaction with the biological and social conditions of development, result in relative integration and healthy self-regulation supplies a broad and important agenda for future clinical research, and for the development of a knowledge base applicable in clinical interventions.

Because of their fundamental importance in psychological development and their pervasive expression in human behaviors, there is clearly more to know about the nature of basic psychological needs, their evolution, and their mechanistic underpinnings. Moreover, research is only nascent regarding their dynamic interaction with physiological or physical needs (Chen, Van Assche, Vansteenkiste, Beyers, & Soenens, in press). Finally, there is much more research needed about micro- and macrosocial contextual factors impacting their satisfaction or frustration. Progress is rapidly being made on the neuropsychological underpinnings of autonomous and controlled forms of motivation, as we have reviewed. However, much of this knowledge is still at the descriptive level and has yet to be coordinated with genetic studies, and the differential expression of human capacities for growth and defense over development. For example, we know that need thwarting impacts more than immediate experience and behavior and can have cascading effects in multiple areas, from social adjustment to executive functioning (e.g., Bernier, Carlson, & Whipple, 2010; Vansteenkiste & Ryan, 2013). Understanding how need frustrations have these arrayed effects is a matter that will require both more refined empirical and theoretical efforts at every level of analysis.

Developmental psychology, in fact, offers windows into our evolved tendencies and their selective advantages (Ryan & Hawley, in press; Tomasello, 2008). The fact that basic psychological needs universally play a role in healthy psychological development and wellness suggests that further studies, both genetic and comparative, will add to our understanding of their role in adaptation and maladaptation. More generally, SDT has grown very rapidly in recent years, and its body of evidence contains studies of persons in every part of the life span. Yet there needs to be much deeper understanding of both how need satisfactions change over time in character and focus and how they support developmental progressions in multiple developmental lines.

As a universalistic, organismic perspective on development and personality functioning SDT is also inherently a cross-cultural psychology. Cultures, by their behavioral norms, environmental affordances, and familial practices differentially impact need satisfactions and frustrations. Although the cross-cultural research in SDT has largely focused to date on showing commonalities in effects of satisfaction and frustration of basic needs across groups, domains and cultures, as a maturing scientific perspective it is also time for SDT to take closer interest in the differences these contexts set in motion. For instance, there may exist some cross-cultural variability in the way the psychological needs get nurtured and satisfied (Soenens, Vansteenkiste, & Van Petegem, in press). Along with this, greater attention is needed on cultural differences that enhance or undermine the adopted and internalization of need supportive tertiary and preventive interventions.

Beyond culture we also need more empirical research on how conditions of impoverishment and oppression at cultural levels impact developmental outcomes as mediated by need supports and thwarts. Both proximal and global conditions affect human psychological need satisfactions, so just as we need to coordinate the study of psychological needs with their mechanistic underpinnings, understanding the more global social conditions that affect human wellness is critical to research that can inform policies on child welfare, education, and the necessary social supports to facilitate optimal development for children of all social backgrounds. Illustratively, two recent studies demonstrate how differences in socioeconomic status and the presence of income inequalities negatively affect people's physical and mental health (Di Domenico & Fournier, 2014; Gonzales, Swanson, Lynch, & Williams, 2014). Insofar as conditions of poverty and deprivation conduce to psychopathology through the frustration of basic needs, global efforts to address such conditions and to establish greater social justice deserve our attention both as clinical scientists and as world citizens.

CHAPTER 10

Roots of Typical Consciousness: Implications for Developmental Psychopathology

PHILIPPE ROCHAT

GENERAL AIM 439
WHAT DOES IT MEAN TO BE CONSCIOUS? 440
Origins of Feeling Experience 440
What Is Representation? 442
EXPERIENTIAL AWARENESS AT BIRTH 443
What Is it Like to Be a Newborn? 444
Experiential Vicariousness at Birth 447
CONSTRAINTS ON EARLY EXPERIENCE 447
Experiential Versus Conceptual Awareness 448
Functional Propensities of Newborns 449
Built-In Motivational and Attention Systems 450
Built-In Sameness Detection System 450
Core Knowledge and Conceptual Primitives 452
Revisiting Infantile Amnesia 453
ROOTS OF INTERSUBJECTIVITY 455
Sociality and Reciprocity in Typical Development 455
Products of Emerging Reciprocation 456
Developing Self- and Social Awareness 457
Social Dependence and Human Symbolic Psychology 459
Unfolding Levels of Sharing and *Conscientiousness* 460
CONCLUSIONS: IMPLICATIONS FOR DEVELOPMENTAL PSYCHOPATHOLOGY 463
Centrality of Mutual Recognition 463
Given Sense of Self-Unity 464
Primordial Possession of the Own Experience 464
REFERENCES 465

Mental illness has to be considered against what supports and might be the roots of typical consciousness: what human consciousness is made of, how it tends to work and develop in the healthy young child. Deviances do exist and are only revealed against what might constitute a typical norm. The etiology, emergence, and evolution of mental ills (main object of developmental psychopathology) do require both a clinical and a normative approach. That is the imperative behind this chapter, attempting to provide some normative look at what appears to constitute typical consciousness in early development.

GENERAL AIM

The tidal wave of infancy data harvested in the past 50 years changed the view of the starting state of typical development, away from strict empiricism (behaviorism) or stage-like, domain general structural constructivism à la Piaget. The discovery of early capacities interpreted as deeply rooted in animal evolution is now part of mainstream theorizing. It is important to remember that such views were demonized for their reductionism only a few decades ago. In recent years, nature did regain some weight in contrast to nurture. The explosion of brain measurement technology contributed to such radical shift in the perennial nature–nurture controversy, a polarized and weight shifting debate. Here, I want to propose a few basic systems and mechanisms accounting for starting state representational development. These systems are supported by a large body of infancy research and tend to be acknowledged by most theorists. General enough, yet falsifiable, these systems and mechanisms cut across and somehow transcend the many theoretical controversies that continue to animate the field of developmental psychology.

First and foremost, I want to describe and discuss a system that allows infants from birth and even in utero, to represent what is of the same, in other words to represent *sameness* of feelings. Sameness detection systems are a necessary pre-condition for the emergence of any forms of consciousness, in other words any forms of awareness of having knowledge about something. Sameness detection is the backbone of the conscious (thinking) mind as William James describes it.

Representations that form the content and format of the conscious mind, is framed here as a dynamic process

of informational transformation that operates at multiple representational levels: analogical sensory representations of what is out there in terms of physical energy (proximal stimulation); more cognitive and conceptual representations capturing what is out there in terms of differentiated objects or entities (distal stimulation); pretend representations of what was there (imagined stimulation); might-be representations of future events (projected stimulation); or could-be representations in terms of conjectures (simulated stimulation).

In the generic sense, representation does capture a transformational process that operates at sensory, perceptual, and conceptual levels. The question is what might be the foundational expression and early development of such process? Ample evidence now suggests that the starting state development of the child is not just sensory and motor, but perceptual and very early on, at least within the first year, also conceptual with a propensity toward essentialism or the default belief that things are made of a set of ontologically deep characteristics (as opposed to surface features). Research shows that from the outset, infants are objective perceivers whose actions are organized around functional goals. They start off from birth being actors and not just complex passive reactors or thermostat-like reflex machines. These action systems have their own motivational components (hunger, comfort, curiosity), tapping into physical and social environmental resources that are indispensible for their survival. This starting state can be viewed as the evolutionary product of prolonged immaturity and hypersocial dependence of human childhood, two uncanny characteristics that are unique to our species.

It is within this general context that we discuss the roots of human consciousness as it typically develops in an attempt to characterize basic prerequisites for its healthy development. The attempt here is to provide some general frame to the perennial reflection in the field of developmental psychopathology regarding what it takes—minimally—to function in an adaptive way and what could go wrong, such as in cases of autism or schizophrenia.

WHAT DOES IT MEAN TO BE CONSCIOUS?

Consciousness comes from the Latin word *conscientia*, meaning "with knowledge" or "knowledge with others" as it was originally meant in ancient Greek philosophy prior to Descartes' ergo sum, his "ego-logy" that announced the modern self-identity of eighteenth-century Enlightenment (Rochat, 2009; Taylor, 1979). In a literal sense, to be without conscious or nonconscious means to exist without knowledge or in the ancient sense, without the potential of sharing knowledge with others (*sine sientia or con-sopio*: literally "stupefied," "benumbed," "put to sleep"). But what does it mean to be minimally conscious and have knowledge, hence not to be benumbed or stupefied?

By definition, consciousness necessarily entails some sensory awareness, some embodied feeling experience corresponding to any affective or emotional experience like pain but also feelings of surprise in the face of the unexpected, comfort in the face of what is expected. In the most generic sense, consciousness would correspond to the process by which sameness among sensations or individuated perceptual events is detected and assembled (synthesized) for further mental processing. Consciousness is the process of meaning creation by linking disparate experiences on the basis of what they share (sameness) and, hence, also necessarily what they don't share (difference). In the most generic sense, consciousness is thus the experience of discrete events (i.e., sensations) that are linked and compared. It is what unifies and gives direction to subjective experience, the primary and necessary root of self-unity and self-agency.

Questions remain as to what are the representations or syntheses that are produced by the typical conscious process? What is the typical content of consciousness early in development? Infancy research has shed new empirical light on the issue and the roots of what might be lacking when psychological development goes astray.

Origins of Feeling Experience

A rich body of neuroanatomical and behavioral evidence points to the fact that implicit feeling awareness—and hence subjective experience—is already present at birth, possibly even in the womb. This is a rather revolutionary idea considering that not so long ago, the idea of feelingless infants (i.e., *infans,* or nonverbal children) was the default assumption.

Until fairly recently, the zeitgeist was to deny infants any form of worthwhile feeling experience (phenomenal awareness). Proof of it is that in the 1940s and 1950s, surgery without anesthesia was routinely performed on infants and young children. Modern surgeons conveniently paralyzed squirming infants injecting Curare or similar paralytic agents. Under such circumstances, adults recalled excruciating pain during surgery; however, patients were not believed, and the practice went on for 20 years. As Dennett (1981) pointed out, "The fact that most of the patients were infants and small children may explain this

credibility gap" (p. 201). Even today, local anesthetics are not routine in painful procedures on newborns such as heel prick and circumcision, even by pediatricians practicing in state-of-the-art maternity hospitals. The zeitgeist continues to be that infants have either no feelings or less feelings or that feeling experience at this early stage might not be as consequential for lack of memory (infantile amnesia; see later section on the topic). Such rationale raises questions when looking at the brain as well as behavior in pre- and postnatal development.

Looking at brain development during the prenatal and postnatal period suggests that the necessary neurological prerequisites for feeling experience might already be in place by *8 weeks* after conception, meaning when the sperm meets the egg! Here is in a nutshell what we know today about the emergence of the brain and neural growth from conception to birth. This emergence is humbling for its pace and complexity, considering that the brain is probably the most complex system in the universe. It reminds us of the great biological forces behind development. It takes only 4 weeks from conception for the neural tube to be formed from layers of cells on the embryonic disc (Hepper, 2002). Only one extra week is needed for the basic five-part structure of the brain (i.e., telecephalon and diencephalon of the forebrain, midbrain, hindbrain, and the spinal cord) to be anatomically differentiated and clearly visible. By 11 weeks of gestation (not 3 months after conception), the medulla, cerebellum, inferior and superior colliculus, and both cerebral hemispheres covering the diencephalon are also clearly visible (Carlson, 1994).

From then on and for a few years, both hemispheres grow in surface areas via folding grooves and convolutions. This growth reflects rapid and exponential connection network among synapses and myelination of axons that provide insulation (fatty white matter) for better transmission of electrochemical nerve impulses. By 2 years of age, the child's brain already weighs 80% of its lifetime maximum (Kretschmann, Kammradt, Krauthausen, Sauer, & Wingert, 1986).

In terms of neural growth, between 10 and 26 weeks gestational age, neurons are produced at a rate of 250,000 a minute, leading to overproduction. Beyond 26 weeks, more than half of the produced nerve cells are selectively pruned and die. The surviving 100 billions will eventually form the adult brain (Oppenheim, 1991). All of this development is indeed humbling. We should always keep it in the back of our mind when thinking about what it means to be present, alive, and having experience in this world.

Regarding connection between cells, an overproduction of synapses also continues beyond birth, with peaking periods that vary across brain regions (Rakic, 1972). Synaptogenesis continuing after birth is not homogeneous and synchronous across brain regions. For example, postmortem data indicate that synaptic density peaks earlier in the auditory cortex (3 months) compared with the middle frontal gyrus (15 months; Huttenlocher & Dabholkar, 1997). This kind of growth asynchrony is reflected, for example, in the sequential development of sense modalities in the womb and beyond (i.e., vision lag).

In short, these facts remind us that brain emergence and the neural (sensory) machinery that necessarily underlies implicit feeling experience are fast, remarkably precise, and predictable in their unfolding. To the naked eye or through the lens of the microscope, it is an explosive and amazingly well-programmed growth. In relation to putative first feeling experience, brain development puts in place within 8 weeks the potential for fetuses to sense the world and hence the necessary prerequisite to eventually feel it: the potential for first minimal, obviously implicit, and very rudimentary feeling experience. Let us not forget, however, that feeling experience rests on the prerequisite of an ability to sense the world, as machine do. In humans, such necessary sensory machinery matures within weeks of conception and long before birth. In its development and within the confine of the maternal womb, fetal research show that it actually recapitulates the emergence order of the main sensory systems in the course of species evolution. The sensory machinery (sense modalities) of fetuses matures in the same sequential order than our ancestral species (Gottlieb, 1971; Lecanuet & Schaal, 1996). Somesthetic sensitivity (skin and body feelings) matures first. This sensitivity corresponds to tactile (skin pressure), vestibular (posture and balance), and pain stimulation (tissue damage). It is followed by the maturation of chemosensory sensitivity that combines olfaction and gustation (i.e., smell and taste), followed by audition (pitch, amplitude, and phrasing of sounds) and finally by vision (light and optic array). From this, we can conclude that the necessary sensory prerequisites of first feeling experience are in place at least by the third semester of gestation. But when can we say that first feeling experiences actually emerge in development? New ways of observing fetuses (three- and four-dimensional sonic echography and image scanning) suggest that already by the last trimester fetuses express emotions such as *happiness* via smiling and *sadness* via frowning of the eye brows and lowering of the corner of the lips in the same way newborns express such mental states at birth and beyond (Hata, Dai, & Marumo, 2010). More intriguing is the fact that nociceptive (pain) receptors appear first in and around the mouth area at

around 7 weeks postconception. They rapidly extend to the palmar surface of the hands by 11 weeks, and the rest of the skin and mucosal surfaces by 20 weeks (Brusseau & Mashour, 2007; Smith, 1996).

In all, this suggests that in trying to find the roots of feeling experience, above and beyond sensing, we should probably look in the womb for its embryonic stage. But what about representation? Does feeling experience entail representational ability? Next, we turn to this question, but first it is necessary to clarify what lies behind the concept of representation and its multiple meanings at various levels of analysis.

What Is Representation?

The term *representation* is widely used across all sciences—from engineering to brain science and cognitive psychology. It is among the most polysemous and mixed-bag concept of all, the meaning of which lies in the eyes and uses of the beholder. Do brain scientists, roboticists, cognitive psychologists, or computer scientists talk about the same thing when using the term representation in their respective fields? It appears that they might refer to one basic process after all—but a process that is happening at incommensurable and irreducible scales, from groups of neurons or electronic chips storing nondescript information to semantic networks forming bodies of knowledge and the creation of meanings about the larger environment. Like philosophers or anthropologists, it is to the latter that developmental psychologists typically refer to when talking about representation.

In the most literal sense, representation means re-presenting or *presenting again*. Etymologically, it thus refers to a transformation from one state of being to another. It is fundamentally a transformative process and its product, for example, the transformation of a physical event (light stimulation in the environment) to a subjective or psychic state that is embodied and stored for further mental processing (sensation of the light hitting the retina).

Representation is thus essentially a process. It is not a thing in itself but a transformation. By analogy, a cloud in the sky is the symptom of an ongoing atmospheric condensation and air mass exchanges, not a thing. Representation (presenting again) captures the transformative process by which information is translated from one system to another, whatever the translation code might be: analog, digital, or symbolic.

Representational process is pervasive in nature, present at all levels of functioning in living organisms: from the transduction of light energy at the cellular level on the retina, giving rise to its sensation; to the mental generation of spatial maps, the emotional expression of mental states; to the macro level of collective habitus or group ways. The process of representation is also present and what characterizes any information processing machines, minus the feeling experience and subjectivity that are exclusive to living and sentient animals like us.

From this perspective, the transformative process of representation exists at all levels of description, from the neurological to the psychological, moral, and societal—each level requiring a different language to account for them. At the low neurological level, the language of mechanical causality applies. The process can be analyzed and accounted for on the basis of highly specific neurochemical factors causing the transduction process underlying any sensory awareness that is the object of psychophysics. Vision neuroscientists can trace precisely the successive representational transformations in the visual cortex leading to higher levels perception and consciousness that is the object of perception theories. From such causal description, neuroscientists capture the necessary transformative, meaning-making process of perception. An example of such representational process at a cellular level is captured by pioneer neuroscientist Donald O. Hebb in his seminal 1949 book on the *Organization of Behavior*: "...A repeated stimulation of specific receptors will lead slowly to the formation of an 'assembly' of association-area cells which can act briefly as a closed system after stimulation has ceased; this prolongs the time during which the structural changes of learning can occur and constitutes the simplest instance of a representative process (image or idea)" (p. 64).

At the psychological, sociocognitive, and interpersonal level, any causal account of representation is much more elusive as they depend on an intricacy of complex interacting factors such as age, individual, and group (cultural) differences. As social scientists, the best we can do is to capture representational patterns. These patterns are documented in the same way natural scientists document varieties of species, eventually coming up with some accounts as to what might be some of the underlying causes of the observed diversity.

At the macro level, the developmental approach has the distinct advantage of allowing for the description of representation not only for what they are at various ages but also for how they systematically unfold in ontogeny. The credo behind the developmental approach is that the constitutive elements of human representational systems are best revealed in their change and as new forms come about in ontogeny. However, for representational systems

to become organized around concepts that unify and give direction to subjective experience, some prerequisites are necessary. It includes—as we will consider in subsequent sections—built-in action attractors and sameness detection systems supporting the basic ability to pay attention and register what remains invariant in the midst of what otherwise would be mental chaos and confusion, meaningless, and maladaptive experience.

Three General Levels of Mental Synthesis

Philosopher Immanuel Kant's (1724–1804) views on the mind continue to be valid and helpful today when dealing with the issue of trying to distinguish levels of representation as a transformative cognitive process. Following Kant (see Brook, 1994), sensory inputs from the world need to be unified to become conscious experiences about something. In other words, for the sense datum to become knowledge about the world, it needs to be synthesized within a temporal and spatial structure at three levels: (1) the transformation of sensory apprehension into intuitions or percepts; (2) the coordination of intuitions or percepts in reproductive imagination (what would correspond to mental simulation in today's neuroscientific jargon); and (3) the recognition of concepts in coordinated intuitions (conceptualization of a priori categories).

Kant proposes that the unity of our conscious experience rests on these three kinds of synthesis, an idea that still prevails in current cognitive sciences. Within the Kantian framework, one can argue that newborns do engage in the synthesizing of sense data, certainly at the first level proposed by Kant and probably also at the second level. The third level seems to be evident only in a few months down the road, possibly before the first birthday as suggested by Jean Mandler (1988, 1992). Mandler and now many other researchers provide numerous empirical evidence that at least by 9–12 months infants manifest object categorization that is based on ontological concepts such as containment, agency, continuity, or nonobvious inferred property like weight, animacy as opposed to inanimacy, self-propulsion as opposed to driven by passive movement, even intentional as opposed to accidental or random actions (see also Wellman & Gelman, 1992, for further detailed discussion). Core knowledge and essentialist interpretations of infant cognition are continuously challenged by researchers within a more empiricist (Humean) tradition that emphasizes perceptual learning over ad hoc representational capacities in the young child (see, e.g., Rakison & Poulin-Dubois, 2001).

However, there is unquestionably a trend toward an ever growing body of research suggesting that in the first year, infants are already engaging in a perceptual analysis expressing the three kinds of syntheses proposed by Kant, presumably the foundation of unity in consciousness. But what about newborns, and what about infants at birth? Do they show signs of unity in their experience? The most probable answer is yes.

EXPERIENTIAL AWARENESS AT BIRTH

Based on empirical facts accumulated over the past 50 years in the booming field of infancy research, we now have more empirical ammunition to speculate about what it might be like to encounter the world by seeing, feeling, or hearing at the origins of life. We better understand not only how newborns experience the world from the perspective of psychophysics (what range of stimulus thresholds infants detect across the various sense modalities) but also what attracts them in their exploration of objects in the environment and what information they appear to pick up, store, and eventually retrieve as newborns and even as fetuses during the last two trimesters of gestation. We know that newborns see colors and use dynamic information, preferring moving rather than static things (Rochat, 2001). We also know that infants are innately attracted to particular configurations like moving faces, regions of high contrast on a visual display, high-pitch sounds, and human voices with particular contours (i.e., motherese). We know why they crave sugar, why they appear to innately savor sweet tastes, and why they show repulsion and strong rejection of bitter tastes.

Topping all of these well-established empirical facts, there is now a vast amount of habituation and other operant conditioning studies with newborns showing that infants from birth are fully attuned to novel as opposed to familiar experiences. Probably one of the greatest and most striking discoveries in developmental psychology over the past few decades is that most of what is demonstrated in newborns is also shown in healthy fetuses during the last trimester of gestation: they habituate, learn, store experiential information, and demonstrate comparable threshold across sensory modalities. Furthermore, what they learn in the womb is readily transferable ex utero. Facts show that few-hours-old newborns prefer to suck in certain ways on a pacifier and to hear the voice of their mother over the voice of a female stranger (De Casper & Fifer, 1980). They orient significantly more, showing preference in smelling a gauze impregnated with the mother's amniotic fluid over the fluid of a stranger that just gave birth (Marlier, Schaal, & Soussignan, 1998a, 1998b).

What can be safely inferred from these now well recognized and numerous facts (see Rochat, 2001) is that not only are newborns sophisticated learners, perceivers and even knowers, but more importantly that they have from the start a very rich affective and emotional life. We are not born affectively "neutral" but on the contrary alive with forces pushing and pulling us around: born with strong desires and untamed affective needs as Freud speculated in a highly controversial book over a century ago (Freud, 1905). This rich and untamed affective life cannot, however, be reduced to an early sensory experience that would be undifferentiated and disorganized. What newborns experience of the world is not a blob of chaotic multimodal sensations befalling onto the senses as "a blooming, buzzing, confusion," confusion taken to mean "chaos" and not the literal sense of con-fusion or *fusion with* that suggests some harmony of experience.

We now know that newborn experience is anything but chaos. Healthy neonates are quick to learn, they attend and respond to specific physical events felt in and out of the body, manifest emotions (in the literal sense of moving out feelings via scream and other clearly readable basic facial expressions that are innate). In all, this experience is not an affectively neutral experience that would be mainly attached to the functioning of automatic reflexes. This is not the case since learning is involved from the start, infants acting rather than responding in a world that has values: comfort, pain, relief, and an intense orientation toward particular affective states linked to satiety, specific odors and tastes, dim lights, contrasted visual contours or high-pitch speech sounds. This experience rests on an embodied semantics of approach and avoidance, dangers and strong attractors or pulls.

Because of learning, newborns' experience is not repetitive but rather cumulative: a present experience is influenced by what happened prior. It can be therefore assumed that if successive experiences might be homologous, they are never absolutely the same. This inference simply means that newborn experience does not rest on the feelings that might accompany automatic reflexes as for example the feeling of something hitting my knee and the proprioceptive sensation of my knee automatically jerking forward. Such machine-like experience does exist in newborns, in the same way it persists in adults with the feeling experience that accompanies nonvolitional responses like a knee jerk or the obligatory chill one feels running down the spine while stepping on what was thought to be a snake but in fact is a piece of dead wood laying around.

However, what it is like to be a neonate cannot be reduced to the sensations that arise from such responses. Infants at birth are more than reflex machines: from the outset they desire. They are fast to learn, showing unmistakable orientation toward specific and meaningful experiences: food, comfort, and an optimum level of stimulation (e.g., not too loud, not too bright, but with a lot of contrast and movement).

What Is it Like to Be a Newborn?

Daniel Stern (1991), in an unusual book titled *Diary of a Baby: What Your Child Sees, Feels, and Experiences*, took on the task to imagine what it is like to be a young child from 6 weeks to 4 years. Stern writes from the perspective of the child and reconstructs what it must feel like to be hungry, to wake up, or to stare at a moving spot of light. Stern infers the world of sensations of a fictive newborn (named Joey), based on what we now know about perception, learning, and affect regulation in infancy. The world of Joey at 6 weeks is for Stern a world of sensations. Although this world is nameless and nonobjectified, not yet explicit or conceptualized, it is a world rich of motion and moving impressions, where pieces of space are contrasted, detached, move, meet, overlap, vanish. It is a world made of rhythms and changes of pace in which the infant detects forces expressed in movements: acceleration, deceleration, shrinking, and looming of forms and shapes that are more or less capturing the attention of the child-like magnets of various forces that wax and wane. The world that Stern describes has phenomenal *qualities*. It is experienced from a particular embodied point of view, the first-person perspective that Stern tries to capture. It is a world of sensations, but a world with a point of experiential origin that is the body, the referential point in space where sensations arise while the infant experiences being awake and alive in the world via multiple sensory channels that are *all open at the same time*, either actively when the infant is on his own or more passively while cared and manipulated by others. This in-unison working of the senses does not however entail chaos but rather a pull toward a primitive harmonious order (of phenomenal awareness) that will become eventually objectified, brought to explicit cognitive coherence and scrutiny (consciousness proper), a phenomenal consciousness that has, in addition, cognitive accessibility. (See the discussion and distinction proposed by philosopher Ned Block [2007]).

Stern's assumption, in his speculation, is that the world of sensations of the newborn is not just undifferentiated or diffuse. It is a world of experiences with distinct qualities and values that are anchored in the body, lived from within and therefore carrying with them a subjective perspective.

Such speculation regarding what it must be like to be a newborn finds support in numerous research studies pointing to a minimal *self-awareness* at birth, therefore evidence that even neonates have subjectivity and the propensity to experience the world from their own embodied perspective.

Among all the existing speculations on what might animate the psychic life of newborns, assuming that there is one prior to language, which was not easily accepted until fairly recently, ideas emerging from Freud's psychoanalytical approach have been the most prolific as well as the most controversial. Freud (1905) was the first to place desire in the instinctive behaviors expressed by newborns, and the first to identify early embodied sensory experience as being the cradle of the person, with its often, debilitating characteristics emerging in development. To introduce the notion of infantile sexuality was a revolutionary act of courage at the time and still is to a large extent.

Freud's pulsion theory of psychosexual development outlined in *Three Essays on the Theory of Sexuality* (Freud, 1905/2000) was a paradigm shift. With it he took on the taboo idea that infants from birth might be driven by erotic desires that quickly extend and transcend survival instincts evolved by the species. In the history of ideas, de facto, Freud offered with his pulsion theory the most comprehensive account of what might drive behavior at birth, aside from conditioning.

Obviously, Freud's theory was not the first published account on the questions of early experience and what it might be like to be an infant, but Freud's account was the most thorough and inquisitive to be proposed on what might constitute the psychoaffective forces driving behavior at birth. This account opened a whole new vista on what might be the constitutive elements of subjective life.

Although Freud's pulsion theory and the theoretical concepts inferred continue to be criticized, it was the first to ground subjective life, from the outset, in the experience of the body as we perceive and act in the world, an embodiment of psychic life, its somatic grounding that is now routinely vindicated by current research in the cognitive and affective neurosciences (see Barsalou, 2008; Damasio, 1995; Gallese, 2007; Gazzaniga, Ivry, et al., 1998, for a review).

The important contribution of Freud's pulsion theory is that it grounds psychic life in the feeling of the body, particularly certain bodily regions (oral, anal, genital) invested successively by the young child in his or her development. At the core of this theory, there is the pleasurable quest for bodily feelings (excitability) and its control (search and suppression): a drive-reduction account that remains a powerful causal account of what might motivate psychic life at the outset. There is also the general, rightful intuition that at birth, the body is the primordial locus of exploration and meaning making.

However, the concepts of *autoeroticism* and primary narcissism expressed by the infant, both at the core of Freud's (1905) pulsion theory, need serious revision in light of recent progress in infancy research. The Freudian idea of a first drive toward autoeroticism and the view that early psychic life is primarily revolving around a basic form of narcissism are now problematic. Autoeroticism as a primary drive reduces early experience of being in the world to some sort of blind, circular, nonobjectified, and autistic quest toward bodily excitation and suppression. We now know that there is much more than blind autoeroticism in the life of newborns.

Starting State Synesthesia

Throughout our lives we try to establish what can be counted on and relied upon to survive and make sense of being alive in this world. This quest is already embodied in the neonate, and that is the built-in focus on what can be expected and trusted in a world that is by definition constantly changing, associated to a subjective experience that is fundamentally dynamic, the stream of consciousness William James writes about.

The question is what mechanisms might jumpstart the sense of sameness expressed by infants at birth? What might drive newborns to focus their attention and learning on what remains the same in the midst of constant changes? Based on recent discoveries in behavioral neurosciences, some basic mechanisms might jumpstart the innate sense of sameness expressed by newborns: in particular what would amount to a starting experiential state of acute *synesthesia*.

Synesthesia corresponds to the spontaneous, implicit metaphorical experience of a sensation or percept in one modality that is simultaneously experienced in another. For example, one might experience the particular timber or pitch of a sound with the vivid experience of a specific color, the experience of time duration corresponding to the obligatory experience of a particular spatial layout or form (Simner et al., 2006). Neuroscientists have now established the embodied (neurobiological) reality of such synesthesic experiences that, according to existing surveys, are part of the life of approximately 5% of all adults (Hubbard, Arman, Ramachandran, & Boynton, 2005; Spector & Maurer, 2009).

What is of interest to us here is the idea proposed and tentatively documented with infancy research by Spector and Maurer (2009)—that adult cases of synesthesia

might in fact be remnant and magnifying cases of intersensory connections that are present at birth, pruned, and somehow inhibited in the course of typical perceptual development. But these connections are expressed in muted forms in *all adults,* as Spector and Maurer put it. Accordingly, synesthesia could be the natural starting state of our subjective sensory experience. We would indeed start off with a conflation of all sensory modalities as suggested by William James (1890) in his statement about blooming, buzzing, confusion. Here is what James had to say:

> The physiological condition of (the) first sensible experience is probably nerve-currents coming in from many peripheral organs at once. .... In a new-born brain, this gives rise to an absolutely pure sensation. But the experience leaves its "unimaginable touch" on the matter of the convolutions, and the next impression which a sense organ transmits, produces a cerebral reaction in which the awakened vestige of the last impression plays its part. Another sort of feeling and a higher grade of cognition are the consequences; and the complication goes on increasing till the end of life, no two successive impressions falling on an identical brain, and no two successive thoughts being exactly the same. (pp. 7–8)

This experiential conflation or pure sensory experience elegantly described by James is possibly the symptom of a major competence and not an incompetence as it has been taken by most infancy researchers over the past 50 years.

Infants are born with the ready-made opportunity to link experiences from the various sense modalities, experiences that co-occur and tend to be qualitatively linked, corresponding to particular feeling tones and profiles.

From the start, intermodal systems might exist that allow these sensory experiences to coalesce into the affective core of subjective experience that ultimately gives it *values*: values in rudimentary polarized terms such as pleasure or displeasure, stress or calm, soothing or enhancing, attunement or disharmony, bonding or estrangement. All these represent affective meanings (good or bad feelings) that are at the core of subjective experience, particularly in early development.

This affective core cannot be simply dissociated from subjective experience, as abstract and rational such experience might be later in development: as for example in the epistemic pleasures and satisfactions in discovering a theorem, in the building of a coherent argument, or in the reaching of an agreement with others.

But what kind of empirical evidence is there that supports the assertion of a rich primitive sensory conflation, a conflation that would harmonize rather than confuse early experience?

In relation to *synesthesia*, there is an abundance of empirical evidence showing that infants from birth are readily able to process information across sensory modalities. One-month-old infants are reported to discriminate an object they see projected on a screen based on the previous experience of an analogous object explored with their mouth only (i.e., a smooth spherical pacifier or a bumpy spherical pacifier with a knobee texture; Meltzoff & Moore, 1979). In another series of highly controlled, careful psychophysical studies on newborns in the early 1980s, Lewkowiz and Turkewitz (1980) demonstrated that neonates transfer learning from the auditory to the visual modality. Following visual habituation to either a bright or a dimmed light, they responded differently to corresponding soft or intense sounds in the auditory domain.

In support of such unitary or common functioning of the senses at the outset, an even older neurobehavioral study by Wolff and collaborators (Wolff, Matsumiya, Abrohms, van Velzer, & Lombroso, 1974) shows that if the tactile stimulation of the newborn's wrist evokes activation of the somatosensory cortex, this activity is significantly enhanced when the infant hears also a white noise. Such auditory-tactile interaction is not found in adults, a phenomenon that appears to be specific to the perceptual experience of newborns.

As additional developmental evidence on an early unitary functioning of the senses, let me mention the work of Neville and collaborators showing that if infants respond to spoken language with, as expected, enhanced activity in the auditory cortex, unlike adults and children, they also respond with enhanced activity in the visual cortex (Neville, 1995).

Finally, in support of the natural primacy of synesthetic experience, Mondloch and Maurer (2004) show in a series of studies that 2–3-year-old children tend to be naturally inclined to perceive the same pitch–lightness, color–letters, or sound–shape correspondences typically expressed by synesthetic adults (but also to some extent by nonsynesthetic adults). Young toddlers tend, for example, to systematically perceive that a higher pitch sound goes with a brighter color; a nonsense word made of rounded vowels goes with a jagged shape (e.g., te-ta-ke goes with a sharp-edged form), or that the letter A goes with the color red).

In all, these few empirical examples taken from the developmental literature on synesthesia, and there are many other, support the idea of a highly organized intermodal and resonating experience at birth. Early perceptual experience is made of rich sensory correspondences and implicit "a-modal" representations that can be said to be

metaphorical because they transcend the particularities of the sense modalities as singular perceptual systems. It is, and this is important, an experience that carries rich conflation and correspondences, not the cognitive confusion that has been assumed by many infancy researchers, including myself, since James's misconstrued blooming, buzzing confusion.

Experiential Vicariousness at Birth

In addition to starting state synesthesia, there is also abundant empirical evidence and even precise animal models substantiating the possibility of an innate capacity for vicariously experiencing self-produced and other-produced action: the experiential (phenomenological) equivalence between the observation and the execution of the same action. As a quick reminder, in the original experiments, Rizzolatti and his team from Parma found that the responses of single nerve cells recorded in area F5 of the premotor frontal cortex of the macaque monkey discharge equally when the monkey itself performs a specific action (e.g., reaching for a peanut) or when the same monkey observes another monkey (or another person) perform the same action (Rizzolati, Fadiga, Gallese, & Fogassi, 1996). These cells are thus multimodal by nature and are activated when a particular action is performed by the individual or seen performed by another.

This discovery has had much resonance as it might provide some biological validation to the idea that there might be a deeply rooted system matching self and others' representations, a mirroring system that could be the constitutive element of higher order phenomena like empathy, language learning, and basic embodied intersubjectivity. Note, however, that these ideas remain highly controversial (see Hickok, 2014). Plausible yet indirect behavioral evidence of mirror systems functional at birth is provided by the numerous research on facial imitation in neonates, the matching reproduction of facial expression, tongue gestures or emotional displays, actions that are seen repetitively being performed by an adult model at close visible range and that are systematically reproduced by the infant (e.g., Meltzoff & Moore, 1977, 1997). Such imitative responses in neonates suggest that typical infants are born with the necessary mechanism that would allow for the experience of an equivalence between the perception and the execution of actions (Lepage & Théoret, 2007). In James's terminology, infants would be born with the opportunity to experience the *sameness* of what is done by the self or what is seen done by somebody else or vice versa. Rather than in a state of cognitive confusion, infants would therefore be able from the start to experience and exploit in future learning, the *analogical link* between the products of two different agents: something self-generated and the same thing generated by others, in the same way that they would be able to experience the analogical link between the varieties of sensory experiences in their incipient *synesthesia*.

It is worth noting that the importance placed here on an innate sense of sameness expressed by neonates is also at the root of analogical reasoning and processing, the mechanism by which novel situations are understood in reference to what is familiar (the same) and that developmental psychologists view as a core mechanism of cognitive development (see Gentner, Holyoak, & Kokinov, 2001). The analog format of early representations that would allow for sameness detection across domains is demonstrated in multiple infancy works documenting the existence of a general system supporting the comparison and determination of relative magnitude in terms of number but also spatial extent, frequency, and duration (see Lourenco & Longo, 2011, for a thorough review of exiting infancy research and lively debate around the issue). Such general magnitude system, presumed to be innate, would cut across numerical, spatial, and temporal domains, therefore entailing some starting state analogical and synesthetic abstraction. As suggested by Walsh (2003, p. 486):

> Given the utility of relational inferences on quantities and the power of a statistical picture of the physical world that would extract co-variance of time, space and quantity, it would perhaps be as maladaptive for the infant brain not to use a common metric as it is difficult for an older child to unbind these three elements when learning mathematics.

CONSTRAINTS ON EARLY EXPERIENCE

In the short history of modern developmental psychology, theoretical controversies have revolved primarily around the relative role of innate biology (i.e., nature expressed in maturational and evolutionary factors) and the relative role of experience and learning factors (i.e., nurture). Progress in infancy research during the last 40 years strongly supports a marked theoretical shift from either strict empiricism (behaviorism) or constructivism à la Piaget (1967/1971) and toward a third solution to the nature–nurture controversy, not unlike the *diathesis–stress* model found in recent theories of developmental psychopathology (see Cummings et al., 2000).

Truthfully, 50 years of infancy research certainly debunk the myth of the tabula rasa and reinforce the major role played by evolved propensities to experience and construe

the world in specific ways, what philosopher Jerry Fodor coined *modularity of mind* in a highly influential book of the early 1980s (Fodor, 1983). However, these propensities change and are transformed in the course of the first weeks, when infants swiftly manifest new fluencies in innate propensities and also develop new capacities that are qualitatively different and more powerful to resolve problems, adapt to new situations, construe what is going to happen next. They also rapidly become better at picking up invariants over change, parsing such invariants to be memorized for further inferences.

Admittedly, when the tabula rasa was debunked (e.g., Pinker, 2002), it created blind spots on the actual process of learning and the mechanisms underlying developmental changes. The particular focus of dissident infancy researchers then was inspired by dynamic system theories and the self-organizing emergences of new forms in physics (Thelen & Smith, 1996) or epigenetic phenomena in the realm of biology by which experience crucially determines the phenotypic expression of genes (Gottlieb, 1971; Oyama, 2000).

In spite of such neglect, the majority of infancy researchers have focused on accounting for innate or precocious competencies in acting, perceiving, and representing objects, people, and the self.

Experiential Versus Conceptual Awareness

Newborns' experience of the world is rich from the start—within the polarity of pleasure and pain, restfulness and agitation, approach and avoidance. Newborns cry and fuss when hungry or tired. They show irrepressible smiles with eyes rolling to the back of their head after a good feed. They feel something, expressing unmistakable pleasure and pains. These expressions have adaptive functions, forming crucial signals for caregivers on whom newborns rely to survive. But how much unity and embodied self-awareness can be ascribed to such emotional, obviously not yet objectified experience of being alive in the world?

To address this question, it is necessary to distinguish two basic forms of being in the world: the *experiential* and the *conceptual*. This is not a new approach, supported and proposed by recent research and theories in cognitive neuroscience, in the footsteps of James proposing a distinction between the I or experiential self and the Me or conceptual (objectified) self. Damasio (1999) emphasized the fundamental difference between core consciousness and extended consciousness about the self and events that are construed over time and emerging with language. Similarly, Edelman and Tononi (2000) called for a distinction between primary- and symbolic- (language- and narrative-) driven consciousness. A large body of research in neuroscience supports the experiential diversity of being aware in the world, including blind-sight, hypnotic dissociation of pain, and other highly relativist (as opposed to real or core) perceptual phenomena (see Gazzaniga, Ivry, & Mangun, 1998). There are different kinds of awareness, not all necessarily requiring re-cognition, language, or the capacity to represent representations as in meta-cognition. It is justified to talk about infra- or prelinguistic awareness. There are indeed markedly different ways of being aware and conscious, as opposed to nonconscious or unconscious (Rochat, 2009).

Newborns are not yet conceptually aware of being themselves alive in the world, obviously. However, they are *experientially* aware. Newborns, when not sleeping, are not merely in a wakeful state of confusion between what they feel and what causes them to feel. If they see a face or are struck by an object, they do not become this face or this object. Although not yet conceptualizing them as objects of reflection, they do not confound them with their own subjective feeling or sensory experience. This can be assumed to the extent that newborns feelings and behaviors cannot be simply reduced to automatic reflex responses, like the mechanical adjustments of a thermostat or any kind of automata.

Infants are born predisposed to act with purpose, oriented toward indispensable resources in the environment, be it food, comfort, or protection. These innate functional action systems are what unify the experiential awareness of newborns. It is also what justifies the ascription of selfhood from the outset of development.

Although babies are born with poor contrast sensitivity and grating acuity (Banks & Shannon, 1993), infancy researchers investigating newborn vision demonstrate that despite the obvious developmental lag of the modality, active perceptual processing does take place at birth. For example—and relevant to our discussion—using habituation and novelty preference paradigms researchers have established that newborn infants, only a few hours old, when awake and alert, perceive the real (distal) size of objects, not the varying (proximal) sizes projected onto the retina. Newborns perceive size constancy of objects (Granrud, 1987), most likely via visuo-proprioceptive convergence cues from both eyes as they line their gazes and focus onto the distal object (Kellman & Aterberry, 2006). In all, this kind of empirical evidence suggests that newborn infants have feeling experience and are not just limited to sensing what is recorded at the proximal level of the receptors (i.e., the retina). Early perceptual competency

of perceiving a world that is distal and objectified in relation to the self forms the necessary core for the perception and control of self-produced action in relation to nonself things in the world.

Functional Propensities of Newborns

Newborns are born actors and not just passive "reactors" to stimulations (any stimulations) as pioneer child psychologists tended to describe the starting state of development: reflex montages or systems following Piaget, pure autoeroticism according to Freud, or random reactions as suggested by James. In addition to automatic reflex responses, that are clearly part of the child's survival kit and innate endowment, newborns also act in certain organized and oriented ways that are not merely automatic in nature. Thumbs are brought to the mouth for sucking, eyes are moved to track objects selectively, and leg movements are organized in coordinated stepping or kicking patterns. Even in the womb, fetuses manifest actions with some invariant patterns and a compression of degrees of freedom that is oriented outward, toward the environment, making movements of the infant and related perceptions more than merely random or disorganized.

In recent years, research based on the ultrasonic observations of fetuses demonstrates the remarkable continuity between prenatal and postnatal behaviors (Prechtl, 1984). Fetuses and newborns show the same rich repertoire of organized patterns of movements that are not simply random, but rather preadapted to tap into vital environmental resources such as food or comfort. These movements are not of a solipsistic and endogenous nature like tics or twitches. Rather, they are outward oriented, coming to closure with particular external consequences (e.g., food or thumb in mouth; skin or eye contact with particular objects in the environment). Such movements are actions, not mere reflexes.

Reflexes and action systems correspond to two radically different control systems and hence to two radically different psychologies. The beating of the heart, the movements of the lungs in breathing, the shaking of the whole body under a cold spell, the knee-jerk response, or the blinking of eyelids in response to an air puff all belong to the first kind of bodily movements. They are autonomic and reflex responses of the organism. The control of such movements is endogenous and self-contained. These movements consist in highly predictable stimulus–response loops. They are in essence automatic, *triggered* by particular stimulations.

Following physiologist Sherrington's (1906) first account of this kind of bodily movements, the control is encapsulated and rigidly prescribed within the organism as reflex arcs. It clearly involves subcortical neural networks as surgically decorticated animals continue to express such movements. The control of such movements can be described as closed feedback systems like thermostats controlling for constant temperature inside a house. Closed control systems are simple when considered in isolation, but they are complex when considered in interaction with each other. Each is calibrated to respond to particular ranges of stimulation from the environment that are internal and external to the body. Each system controlling for a particular autonomic/reflex response is also adapted to interact with myriad other similar systems that, in concert, maintain the integrity of the organism as a whole living and adapting system.

In brief, autonomic and reflex movements are controlled by closed-loop feedback systems that ensure basic physiological functioning. They keep the individual organism alive, but such movements do not involve any perception or any particular higher order treatment of basic physiological signals or sensations. In a way, this kind of bodily movement is sensitive but psychologically blind to its responding environment. The movements are triggered by nonspecified circumstances.

The second kind of innate bodily movement is *action systems*. They are more than autonomic or reflex responses, also expressed from birth and prominent during the first six weeks of life. Such movements are distinct from the first kind on two basic grounds. First, they are movement systems consisting of actions that are oriented toward particular functional goals. These systems are by definition adapted to tap into available resources that exist outside the individual organism, in the surrounding environment: food, surfaces, objects, or people. Second, these movements are organized into systems that are flexible, capable of changing based on previous experiences, and adjusting to novel circumstances. They allow room for learning, controlled by open-loop feedback systems. Although still unintentional, this second kind of movement entails perception and learning, some psychology, and presumably higher order cortical involvement.

Infants at birth show more than autonomic/reflex arcs (Rochat, 2001 for a general review). Sucking, grasping, stepping, rooting, or head turning are too often construed as reflexes or automatic responses triggered by non-specific stimulations. Multiple studies show in fact that such movements need to be construed as actions rather than reflexes, actions that are already oriented toward particular features and resources in the environment: for example, faces or objects with a certain shape, texture, consistency, or smell.

Above and beyond the search for optimum visual stimulation and in particular toward maximum light contrast, immediately after birth newborns track with their eyes objects that move close by in their field of view. More impressive is the fact that they do so preferentially when the objects consist of face-like displays. Research shows that they tend to track more canonical face-like displays (two adjacent dots for eyes above vertically aligned two dots for nose and mouth) compared with noncanonical face-like displays with the same but scrambled features (Morton & Johnson, 1991). Similarly, newborns tend to suck differentially on pacifiers that are more or less mimicking the biological nipple of the mother. They suck less and increase oral exploration as a function of the eccentricity of a pacifier compared with the biological nipple in terms of texture and consistency (Rochat, 1983; Rochat & Senders, 1991). We found the same kind of results when recording newborns' grasping of objects varying in texture and consistency that are placed in one of their palms (Rochat, 1987). Researchers have even established that newborn infants are significantly more inclined to orient their face toward gauze impregnated with their own mother's amniotic fluid or breast milk compared with gauze impregnated with the amniotic fluid or the breast milk of another woman who just gave birth (Marlier et al., 1998a, 1998b).

If newborns orient and root to smells or face-like displays, if they suck and grasp at objects introduced in their mouth or in their hands, they do so with discrimination and preference. This kind of movement is not made of autonomic, reflex responses triggered by nonspecific stimulation. It is under the control of previous experiences (learning) and intrinsically oriented toward particular environmental resources. It calls for some psychology engaging more than subcortical structures. However, such control is not yet intentional proper. It arises in the context of adaptive actions generated by the single individual in relation to physical objects and the physical aspects of people. It does not depend on reciprocal communication and shared experience with others or intersubjectivity.

Built-In Motivational and Attention Systems

Born in a world of values, from the start infants experience the basic affective polarity of approach and avoidance, events that are either qualitatively attractive or repulsive. It is well documented, for example, that from birth infants are attracted to sweet tastes and avoid bitter or sour tastes (Steiner, 1979). This built-in motivational system is linked to automatic positively rewarding or negatively rewarding mechanisms. Reward mechanisms via endogenously triggered opioid (endorphin) pathways are now well supported by numerous animal models (see, e.g., Barr, Paredes, Erikson, & Zukin, 1986; Blass, Fitzgerald, & Kehoe, 1987). In other words, infants are born prepared to be reinforced in certain ways in their learning and channeled in their experience and to be drawn to a particular carving of attractive objects in the environment, including their mother's smell and the taste of maternal amniotic fluid or the colostrum laced with sweetness, a reward needed for newborns to survive (see Marlier et al., 1998a, 1998b).

At a more epistemic level, infants are also born with typical ways of attending the visual world. Visual activity of the newborn is endogenously organized and not simply reflex-like, not just triggered by light stimulations.

In a seminal book, Marshall Haith (1980) systematically documented via an eye tracker the visual behavior of neonates in the dark, looking at a homogeneous ambient light environment, and when presented with various contrasted contours (e.g., solid horizontal, vertical or oblique black and white bars). Haith reveals the "systematic rules that babies look by"—the title of his book. His research shows that infants are oriented toward maximum information in the environment guided or rewarded toward maximum rate of cortical firing, which corresponds to the zeroing the fovea and scanning where there is maximum contrast in the environment. Newborns eyes are attracted by the defining edges of a contour. Once located, these edges are systematically scanned back and forth to generate maximum cortical firing rate. From his series of studies, Haith concludes that newborn function visually according to precise rules driven by specific reward contingencies (maximum cortical firing rate, or high firing rate principle according to Haith). These innate rules constrain infants from the start to carve meaningful perceptual information, hence specific representations about their environment, an interesting alternative to either radical tabula rasa (nurture) or nativist (nature) perspective. As Haith (1980) pointed out:

> Perceptual theorists agree that homogeneous surfaces are uninformative, it is the edges and boundaries of stimuli that carry the important information. One could imagine a sequence in which babies first scan areas of high contour density for their firing potential. Such activity would facilitate neural growth and, as associative areas and memory capabilities develop, these same stimulus regions would provide information for synthesizing objects and placing them in a spatial-temporal perspective. (p. 124)

Built-In Sameness Detection System

If we have learned one thing in recent years from studying babies—and there has been a huge wave of interest in

studying infants in the past 40 years—it is that from birth, and even prior to that based on the numerous evidence of fetal learning (Lecanuet & Schaal, 1996), infants are active in processing invariant information over changes. In their inclination to scrutinize novelty hides a deep look for sameness. They avidly look for regularities in the environment, and this is the name of the game from the outset: we are born and built in a way that what we are primarily preoccupied with is the detection of what remains the same in the midst of constant changes.

Throughout our lives we try to establish what can be counted on and relied upon, building trust and coherence. This quest is already embodied in the neonate, and that is the built-in focus on what can be expected and trusted in a world that is by definition constantly changing, associated to a subjective experience that is fundamentally dynamic.

But prior to developing these ideas, it is important to insist that the focus on *sameness* in the environment, which seems to be the core aspect of infant behavior and development, remains a core aspect of the human mind all through the life span. It might even be thought to be at the root of morality and the conception of justice and equity across human cultures. As James wrote over a century ago: "The mind can always intend, and know when it intends, to think of the Same . . . . This sense of sameness is the very keel and backbone of our thinking" (James, 1890, p. 459).

The past 40 years of booming infancy research did certainly debunk a great deal of strong-held common assumptions: that babies were born cognitively helpless and passive, their behavior disorganized. Prior to this research, it was not uncommon to construe infants as born blind and oblivious of the world surrounding them, a blank slate in need of fundamental growth and learning, often thought to be born in a vegetative state that kept them alive and tentatively able to receive indispensable care and protection from others. These views have certainly changed, but the fact that human children are pretty helpless at birth should not be overlooked, particularly when comparing them to the infants of other species. These ancient views were not that counterintuitive after all.

Compared with other species, humans are indeed born too soon, greatly immature and markedly dependent on others to survive. This is due to the combination of the proportionally larger brains we evolved as a species, together with the narrowing of the female's birth canal associated with bipedal locomotion, a posture uniquely evolved by our species and linked to protracted external gestation, namely, that we are born much sooner compared with other primate species (Montague, 1961; Trevarthan,1987). We start standing and roaming the world on our own by 12 months, and it takes many, many long childhood years to separate from our own original niche and to become autonomous to reproduce this cycle of development with new progenies.

The premature human birth leads to a state of protracted dependence during approximately one-fifth of our life. This remarkable dependence shapes our psychology from the outset. It is a simple, straightforward fact yet is probably the major determinant of what makes us psychologically unique in the animal kingdom.

The new wave of infancy research shows not that infants are born much more mature than previously thought but that infants are born much better equipped to tap into and exploit the prolonged state of dependence in which they are born. As Bruner (1972) wrote years ago, there are "uses of immaturity" (p. 1) by the young child. Numerous research tapping into preferential looking, and sucking, visual familiarization; violation of expectations; and other clever habituation and dishabituation paradigms show that infants from birth and even prior in the confine of the womb are remarkably quick to learn (see Rochat, 2001, for a review).

The most solid and reliable finding is indeed that healthy young infants get easily bored and are particularly inclined to seek novel information. From birth on, infants expect particular outcomes to occur based on past experiences and show a natural inclination to build up on new expectations.

Two-month-olds are attuned to complex probabilistic algorithms or conditional probability that one particular event will be followed by another, for example, in their ability to discriminate among strings of speech sounds they hear successively or the frequency of lights flashing at different locations in the environment (Haith et al., 1997; Saffran et al., 1996).

Infants show all this remarkable learning ability while not having to worry about being fed, getting enough cuddling, or living in wet diapers. Their protests are typically heard, and they are able to explore and encounter the world around them in playful ways. Childhood is, for the most part, a prolonged immaturity that translates into a prolonged, socially secured, and assisted opportunity for a free license to learn and to explore, to fantasize, and to realize these fantasies in the unbridled works of children's imagination. But children's free license to explore and to play is not just free and self-organized; it is also highly constrained by early core representations of objects, self, and others and by innate propensities to imitate and mirror the mental states of those interacting with the self.

Between birth and 2 months, noticeable changes occur, particularly in the social domain. By 6 weeks, infants universally begin to respond to faces with smiles that are not just automatic or linked to feeding or satiety but that are socially elicited, taking place in face-to-face

exchanges and active emotional coregulation. This is what is generally recognized as unmistakable demonstration of primary intersubjectivity or first sign of an infant's active sense of shared experience with others. These face-to-face exchanges are, in the broad sense, aimed at coregulating feelings and at creating mutual affective attunement, a *sameness of feelings* with others in a mutually affective proto-dialog and emotional entrainment that has been extensively documented in the past 30 years.

This mutual affective entrainment is typically geared toward the maintenance and coregulation of a shared happy, often exuberant, state first initiated by the adult but also increasingly initiated by the infant, particularly from approximately 7 months (Rochat, 2001; Striano & Rochat, 1999). Note, however, that such coregulation around a shared state does not require the context of face-to-face exchanges particularly nurtured in Western industrial cultures. It also occurs via different sensory channels when babies are tied to the back of an adult, days in and days out, or being carried on the hips of older siblings.

In the realm of social exchanges and intersubjectivity with a focus on shared feelings, the name of the social game is again about sameness detection. It is about the mutual monitoring of *sameness* in reciprocal affects and emotional expression, including the timing of such expression that specifies mutuality: whether, for example, the mother is more or less responsive to changes in the emotional expression of the infant and vice versa or whether the infant is more or less responsive to the mother (Bigelow & Rochat, 2006).

We now know that by 2 months infants become very much attuned to this relative mutuality of emotional responses, showing reliable negative responses when their expectation is violated, as in the case of the famous still-face situation (Tronick, Als, Adamson, Wise, & Brazelton, 1978). From at least 2 months, infants detect and overtly react to the violation of mutuality expectation; in other words, they react to the fact that others are not responding with *equivalent* emotional responses. What developmental research shows is that possibly from 2 months, and certainly by 7 months, infants create and promote similarities, hence sameness in feelings. They express the active propensity to create equivalent experiences with others.

What is intriguing is that this propensity becomes what is often identified as the central piece of cognitive and symbolic development, in particular language development. This central piece is the emergence by 9 months of *secondary intersubjectivity* with the active sharing of attention in reference to objects in the environment (i.e., joint attention; see Tomasello, 1995). Once again, this important development rests on the new active sense and monitoring by the child of equivalence (thus sameness) in the focus of visual attention between self and others. The name of the game remains essentially the same.

The sense of sameness is the broad concept used here to capture the natural inclination already expressed at birth to bridge experiences and draw analogies between things that are intrinsically distinct, between physical objects, but also between self and others. The sense of sameness not only pertains to linking physical objects, self, and people because they phenomenally look alike or share the same qualities but also to spatial-temporal relations among things and probabilistic co-occurrences of events: that something entering one end of a tunnel typically tends to reappear some time later from the other end; or that if I smile and coo toward someone I expect this person to somehow respond in comparable ways.

As mentioned previously, research demonstrates that these latter aspects (contingency and conditional probability detection) are expressed very early on. They are other expressions of infants' propensity to sense a link between things as belonging to a same set, a same chunk, or category of experiences.

It appears to be all part of the embodied propensity to sense sameness or equivalence (i.e., same value, same meaning). It is part of the analogous sense that is at the origins of concepts, symbols, and other representational signs that *stand* for something that exists in the world as separate entities: my own reflection in the mirror that I recognize and identify as the same as my embodied self. What is peculiar in human development, however, is that from around 2 years of age typical children start explicitly to recognize and identify themselves not just in mirrors but also through the evaluative eyes of others. They become *self-conscious*, what can be viewed as one of the major trademarks of our species around which developmental psychopathologies could revolve and be triggered (Rochat, 2009, 2014). But what might be the experiential (phenomenal) and representational (cognitive) origins of such development? As a preliminary discussion, we want to posit what is meant by representation, which we framed earlier as content and format of consciousness. It is a concept that can have multiple meanings across domains, including physics, engineering, neurobiology to psychology, and the cognitive sciences.

Core Knowledge and Conceptual Primitives

If from birth infants are motivated objective perceivers and actors, questions remain as to what they might construe

and represent about the world at a more conceptual level. Beyond mere sensory awareness, we now know that neonates are perceptually engaged as they feed, orient, control their posture, reach toward things, and explore objects and events, including their own body and how it affects the world. But what might they abstract and eventually memorize of what they sense and perceive of the world?

By 6 months, an abundant literature demonstrate that the typically developing infant has highly specific expectations about the world, in particular what pertains to the self, physical objects, and people (see Rochat, 2001). If those expectations are learned from experience, they are learned very fast, so fast that such learning has to be channeled by what could amount to core knowledge or some of conceptual primitives that are the evolutionary product of natural selection. Such cognitive primitives would strongly scaffold early experience, and there is now an abundance of empirical evidence pointing to such innate conceptual constraints, although the nature of such constraints remains highly controversial and source of various theories that continue to animate the field of infancy research (Carey & Gelman, 1991; Haith, 1998; Wellman & Gelman, 1992).

In relation to physical objects, numerous studies demonstrate that from at least 5 months of age, and sometime even earlier, infants construe objects as persisting in their existence when disappearing from sight (Clifton, Rochat, Litovsky, & Perris, 1991), expecting midsize objects to be substantial (i.e., to occupy space, to be spatially continuous, subject to gravity, and not existing at two different places at the same time— Baillargeon, 2004; Kellman, Spelke & Short, 1986; Spelke, Breinlinger, Macomber, & Jacobson, 1992). Infants detect who is agent and patient of an event action, inferring causality above and beyond mere associative learning (Leslie, 1982), even when the protagonists act at a distance, as in the case of chase scene between predator and prey (Rochat et al., 2004). In the first year, infants are already construing the goals and intentions of others who are acting on objects (Woodward, 2009), and by the middle of the second year they appear to anticipate the actions of others holding false beliefs about where things are in the environment (Onishi & Baillargeon, 2005). False belief understanding, hence theories of mind, typically reported as emerging across cultures between the age of 3 and 5 years (Callaghan et al., 2005), would actually project much deeper roots at an implicit level and in the context of nonverbal tasks.

The new wave of cognitive science in infancy has now established that within a few months and certainly prior to the emergence of syntactic, symbolic-based language, infants infer and hence represent a great deal of nonobvious aspects of the world. The products of such inference are what infancy researchers present and discuss as core knowledge (Kinzler & Spelke, 2007) or conceptual primitives (Carey, 2010; Mandler, 2004), infants inclined from the outset to make sense of reality with the default assumption that the world is made of entities that have hidden essence corresponding to defining (essential) ontological or constitutive characters (Gelman, 2003; Gelman & Bloom, 2000). Theoretically, what comes out of this new cognitive science of the budding child is that we might have evolved, as a species, the unique propensity to see and construe of the world in essentialist terms, constrained and guided from at least 2 months of age by what would amount to innate core knowledge or representations in the physical as well as the social domains, including the self. Traces of essentialism and core representation are now documented in infants as young as 5–6 months of age who appear to discriminate and prefer animated puppets or abstract protagonists wearing googly eyes that behave prosocially (e.g., help) rather than antisocially (e.g., hinder) (Hamlin et al., 2007). Six-month-old infants show surprise when an animated large cube backs out and shows deference to a smaller triangle, both wearing animal-like googly eyes (Thomson et al., 2011). They appear to infer social hierarchy and norms in terms of relative physical power. Same-age infants are even shown to recognize essential characteristics of social group formation by inferring that in-group members are supposed to act in similar ways (Powell & Spelke, 2013).

In relation to affectivity, recent findings uphold Bowlby's original idea that by the end of the first year and with the emergence of various forms of attachment to the primary caretaker, infants construct a representational, hence implicitly conceptual working model of their social and affective environment. One-year-olds who are either securely or insecurely attached to their mother based on the Ainsworth Stranger Situation manifest opposite expectations when viewing an animation movie with a large oval figure representing the mother was either helping or ignoring a smaller oval figure representing a baby. Securely attached infants looked longer and hence presumably are more surprised when the mother ignored the baby as insecurely attached infants showed the reverse: more surprise when the mother helped and nurture the baby (Johnson, Dweck, & Chen, 2007).

Revisiting Infantile Amnesia

First coined by Freud, the phenomenon of infantile amnesia invites to speculate that there might be a radically different mental organization at birth, or even *none*

whatsoever, newborns simply driven by unrepressed and chaotic pleasure orientation. It does indeed leave open the possibility of a different and incomparable experience to what older children and we as adults experience and represent of the world.

The memory black hole of the first months outside of the womb and in the world has naturally enticed philosophers to think of a primary representational incompetence, the incompetence of infants to create memories, even memories stored for later retrieval. This absence of conscious recollection from our life prior to the third birthday is universal. It is pervasive despite the claims of highly speculative therapies and other rather unscrupulous psychoanalysts reconstructing from patient hearsay what young infants might feel and what might be meaningful events for them.

If we consider infantile amnesia as the symptom of an original incompetence, their inability to store and represent sensory information, it is also presumably the symptom of an original incapacity to synthesize sensory impressions into the concepts that give the mind its conscious unity. Children, prior to 2–3 years of age, would be incapable of giving sensory experience its unified mindfulness. Translated in Kantian terms, infantile amnesia would be symptomatic of mental blindness. Babies' intuitions of the world and of their own body arising from sensory experience would be blind, not yet transcended into concepts and representations, not yet synthesized into bodies of knowledge that can be consciously retrieved. Historically, this is also what the founders of modern psychology assumed. Wilhelm Wundt, who established the first experimental psychology laboratory in Leipzig in the late nineteenth century, considered that infants could not help in the scientific understanding and conceptualizing of the adult mind. He writes in his *Outline of Psychology* (1897): "The results of experiments which have been tried on very young children must be regarded as purely chance results, wholly untrustworthy on account of the great number of sources of error. For this reason, it is an error to hold, as is sometimes held, that the mental life of adults can never be fully understood except through the analysis of the child's mind" (translated into English in 1907; cited in Kessen, 1965).

Progress in neuroscience might also have reinforced this intuition as we now have ample evidence that the brain of the young child continues to develop in marked ways during the first two to three years of life, particularly in the prefrontal regions of the neocortex, which are involved in the higher order synthesis of neural information as in advanced executive function, inhibition in problem solving, and intentional actions (e.g., Zelazo, 2004). Furthermore—and this is what delimits infancy from childhood—by the second year children become symbolic, increasingly proficient with language, and beginning to manifest an unambiguous conceptual sense of who they are (Bates, 1990). Their vocabulary becomes full of personal pronouns and adjectives like *I, me,* and *mine*. All these mental changes occur by the second to third year of life and correlate also to what is typically reported as our earliest, reliable memories.

From this point on, the veil of amnesia appears to be lifted. Memories are stored to become potentially retrievable and communicable in narrative forms (Dennett, 1992; Nelson & Fivush, 2004). From then on only, it would therefore be legitimate to postulate that the child possesses a mind that is explicitly conceptual, showing unity in the Kantian sense. This unity also implies a conceptual sense of who the child is as an entity among other entities, a person among other persons in the world. From the time they speak, children identify (recognize) themselves in mirrors and show embarrassment. They start to show off, begin to lie if necessary, and to engage in pretense. Arguably, the child's experience rises to mindfulness proper. It is unified over time and space. Representations of representations are synthesized and organized into abstract concepts that can be mentally manipulated at will to generate new truths and true previsions about future states of the world.

In short, historically, there has been a natural inclination, albeit with good reason, for many thinkers of the mind to believe that there might be a lack of representational unity at birth. The lack of unity would persist until children develop the ability to synthesize representations of the world that are memorable and organized along the continuum of time and space. If a concept of self is an a priori condition of unity in consciousness—as was suggested by Kant—it would be erroneous to speak of any notion of self prior to language, prior to the explicit ability to remember, conceptualize, and recognize the world symbolically, in particular within symbolic conventions. This, of course, would extend to any other non-symbolic animals, that do not possess language, namely creatures that are not capable of representing representations, not capable of organizing thoughts around a priori truths and within a continuous timeline that gives hindsight to the direct sensory experience of the world.

There are marked qualitative shifts in how and what the mind processes between birth and the onset of language, particularly when the child starts to remember an increasing number of past events in the explicit narrative formats of autobiographical memories (Nelson & Fivush, 2004). However, much research shows now that the phenomenon

of infantile amnesia is not due to a lack of unity or sense of self, as alluded to by the founders of modern psychology. In fact, infantile amnesia is becoming increasingly a misnomer given the flow of empirical evidence that demonstrates long-term procedural memory in infants of only a few months, infants who presumably should be deep into our memory black hole period (e.g., Bauer, 1996; Meltzoff, 1995; Rovee-Collier & Hayne, 2000). In addition, numerous studies show that the timing of first explicit memories (typically between 2 and 4 years) can vary greatly among individuals depending on memory content, gender, family structure, and culture (Nelson & Fivush, 2004).

It thus appears that children develop autobiographical memory progressively, incrementally, and parallel with language development. It does not emerge abruptly as if children were overcoming the obstacle of a generalized amnesia, hence a disorganized mind incapable of having organized representations of representation, not functioning rationally on the basis of a priori concepts, only finding unity and selfhood by their third birthday.

ROOTS OF INTERSUBJECTIVITY

By the second month, there is a behavioral revolution. Typical infants open up to the world in unmistakable ways. When not sleeping or crying, they spend markedly more time in a wakeful state, actively and spontaneously tracking and exploring objects, particularly faces in the environment (Wolff, 1987). When attending to faces, they begin to spend significantly more time exploring internal features, namely, eyes and mouth, compared with outside features such as forehead contours and hairline, which are preferentially attended to by infants less than 1 month of age (Haith, Bergman, & Moore, 1977). More significant is the fact that by 6 weeks of age, in a face-to-face situation infants begin to manifest smiling. Such smiling expression is elicited by the social engagement of others as they typically try to create a shared positive emotional experience with the infant.

From this point on, infants enter the give and take of interpersonal conversation—a privileged context in which they can differentiate their first-person perspective from the third-person perspective of the social partner with whom they converse. They develop a sense of shared experience or primary intersubjectivity, which in face-to-face exchanges is a first form of triadic exchanges that is turned toward the self of the infant, the infant being the prime topic of the communicative exchanges with the adult. From 2 months on and until approximately 9 months, the main topic of communication is the infant himself and not yet the objects that surround the infant and the adult (secondary intersubjectivity; see Tomasello, 1995; Trevarthen, 1979).

Sociality and Reciprocity in Typical Development

The sense of reciprocity is expressed very early in the life of the healthy child. By two months, infants start to engage in face-to-face proto-conversations, first manifesting signs of socially elicited smiles toward others (Rochat, 2001; Sroufe, 1996; Wolff, 1987). Such emotional coregulation and affective attunement are more than the mirroring process underlying neonatal imitation and emotional contagion evident immediately after birth (Meltzoff & Moore, 1977; Sagi & Hoffman, 1976; Simner, 1971). From this point on, infants express a new sense of shared experience with others in the context of interactive, typically face-to-face plays, what Trevarthen (1979) first labeled as *primary intersubjectivity*.

When infants start to engage in proto-conversation, they are quick to pick up cues regarding what to be expected next from the social partner. In general they are quick to expect that following an emotional bid on their part, be it via a smile, a gaze, or a frown, the other will respond in return. Interestingly, adult caretakers in their response are typically inclined to reproduce, even exaggerate the bid of the child. If the child smiles or frowns, we are inclined to smile or frown back at her with amplification and additional sound effects. There is some kind of irrepressible affective mirroring on the part of the adult (Gergely & Watson, 1999).

The complex mirror game underlying social cognition does manifest itself from approximately 2 months of age and from then on, infants develop expectations and representations as to what should happen next in this context. The still-face experimental paradigm that has been extensively used by infancy researchers for over 30 years provides good support for this assertion (see the original study by Tronick et al., 1978). Infants are disturbed when the interactive partner suddenly freezes while staring at them (Rochat & Striano, 1999). They manifest unmistakable negative affects, frowning, suppressing bouts of smiling, looking away, and sometimes even starting to cry. In general, they become avoidant of the other person, presumably expecting them to behave in a different, more attuned way toward them.

This reliable phenomenon is not just due to the sudden stillness of the adult, as the infant's degree of negative responses varies depending on the kind of facial expression (i.e., happy, neutral, or fearful) adopted by the adult while suddenly still (Rochat, Striano, & Blatt, 2002). Also, it appears that beyond 7 months old, infants become

increasingly active rather than avoidant and unhappy, showing initiative in trying to reengage the still-face adult. Typically, they touch her, tap her, or clap hands to bring the still-face adult back into the play, with an intense gaze toward her (Striano & Rochat, 1999).

Numerous studies based on this still-face paradigm and studies using the double video paradigm, in which the infants interact with their mother, whom they see on a TV, either live or in replay (Murray & Trevarthen, 1985; Nadel, Carchon, Kervella, Marcelli, & Réserbat-Plantey, 1999; Rochat, Neisser, & Marian, 1998), all show that early on infants develop social expectations as to what should happen next or what should happen while interacting with others. The difficult question is what do these expectations actually mean psychologically for the child? What does it mean for 2-month-olds to understand that if they smile toward an individual this individual should "normally" smile back at them? What does it mean that they pick up the fact that amplified and synchronized mirroring from the adult is an invitation for more bouts of interaction?

One could interpret these expectations as basic, possibly subpersonal, and automatic. Accordingly, face-to-face interactions are information-rich events for which infants are innately wired to pick up information, attuned and prepared from birth to attend to and eventually recognize familiar voices and faces (e.g., De Casper & Fifer, 1980; Morton & Johnson, 1991). From birth, infants would be attuned to perceptual regularities and perceptual consequences of their own actions, wired to prefer faces, human voices, and contingent events as opposed to any other objects, any other noises, or any other random events. Accordingly, this would be enough for young infants to build social expectations and manifest apparent eagerness to be socially connected as shown by studies using the still-face experimental paradigm or the double video system. But there is more than what meets the eyes of an engineering look at the phenomenon (Rochat, 2009). It is more than just mechanical and requires another, richer look to capture its full psychological meaning.

This proposal is based on evidence of major developmental changes in the ways that children appear to connect with others and reciprocate. Infants rapidly go beyond mirroring and imitation to reciprocate with others in increasingly complex ways, adding the explicit social negotiation of *values* to the process. This development corresponds to the unfolding of primary and secondary (i.e., triadic exchanges of the infant with people in reference to objects in the environment by 7–9 months), and also a *tertiary* level of intersubjectivity from at least 3 years of age. Table 10.1 summarizes the road map of various levels of intersubjectivity unfolding in typical development between birth and approximately 4 years of age.

Each transition represents a major extension. The extension from primary to secondary intersubjectivity is well accounted for in the literature (Bruner, 1983; Trevarthen, 1979; Trevarthen & Hubley, 1978; Tomasello, 1995; see Table 10.1). At the tertiary level of intersubjectivity, objects and situations in the environment are not just jointly attended to (secondary intersubjectivity) but also become *jointly evaluated* via negotiation, until eventually some kind of a mutual agreement is reached, also a crucial progress in the development of sociality and morality as we will see next.

Products of Emerging Reciprocation

When infants begin to open up to their social environment by reciprocating via smiling and cooing toward others interacting with them, and because of the obligatory propensity of others to mimic or *reproduce* with marked exaggeration what infants express (i.e., affective mirroring; Gergely & Watson, 1999), infants have the

TABLE 10.1 Levels of Intersubjectivity Unfolding in Typical Development

	Type	Context	Behavioral index	Process	Age
I	Mirroring	Face-to-face engagement	Imitation	Automatic simulation	Birth
II	Primary intersubjectivity	Reciprocal dyadic exchanges	Proto-conversation, social expectations	Emotional coregulation	2 months
III	Secondary intersubjectivity	Triadic exchanges about things	Joint attention; social referencing	Intentional communication and intentional coexperience	9 months
IV	Tertiary intersubjectivity	Triadic exchanges about the value of things	Self-recognition and embarrassment, use of possessives, claim of ownership, prosocial behaviors	Projection and identification of self onto others	20 months
V	Ethical stance	Decision regarding the value of things, what is right vs. wrong	Claim of ownership, sharing, distributive justice, theories of mind	Value negotiation with others, narration, meta-representation of reputation	From 4 years

Source: This table is based on the table included in Rochat & Passos-Ferreira, 2008.

unique opportunity to *objectify* themselves in relation to others. Face-to-face exchanges, turn taking, and the proto-conversations dominated by affective mirroring allow for self-objectification and the objectification of first vs. third person perspective. All this forms a privileged context in which infants can learn to distinguish their own and others' perspectives on the self, the basic prerequisite of intentional and referential communication. This context is the template for the intentionality expressed in relation to physical objects, intentionality that starts to be manifested by infants by the time they begin to smile in the context of reciprocal social exchanges (Rochat & Striano, 1999).

Infants might learn also to objectify themselves in the exploration of their own dynamic traces in objects they acted upon: a mobile they kicked or a ball they pushed (Piaget, 1952; Rochat, 1995, 2002; Watson, 1995). The effect of self-generated actions on the object does indeed reflect the dynamic and the amount of energy produced by the infant who can pause and contemplate traces of himself in such effects. However, in this context, the differentiation between the first- and third-person (object) perspective is possible only on a trial-and-error basis. Interactions with physical objects do not carry the bidirectionality of attention, the mutuality and tutoring guidance that a reciprocating adult typically offers to the child. Reciprocal exchanges are intrinsically referential in relation to each of the protagonists (infant and adult). They specify on-line, in a unique way, the alternating perspectives of each protagonist because of the give and take, reciprocal, and coconstructed format of conversational exchanges.

The learning of a differentiation between the first- and third-person perspective is facilitated by reciprocal exchanges. Infants can eventually generalize what they learn in interaction with others to their interaction with physical objects, rather than the reverse. It is reasonable to postulate the precedence of one format of exchange (social interaction) over the other (action on physical objects) to explain the emergence of intentionality in development, assuming of course that we do not postulate innate module for such stance.

Social partners (e.g., caretakers) work hard from the outset to reveal themselves intentional in communication and are quickly perceived as such by the infants. Children will eventually also perceive others as intentional *outside* of face-to-face communicative contexts, when observing them interacting and acting on physical objects. The generalization of an understanding of others as intentional with both objects and other people aside from the self opens up new, crucial opportunities for observational and imitative learning. These are often identified as basic mechanisms of cultural transmission that are considered, by some, to be unique to our species (Tomasello, 1999; Tomasello, Kruger, & Ratner, 1993).

Developing Self- and Social Awareness

For decades now, the mirror mark test has been used as an acid test of conceptualized self-awareness from both a developmental and comparative perspective (Amsterdam, 1968, 1972; Gallup, 1970). Self-directed behaviors toward a mark surreptitiously put on the face and discovered in the mirror would attest of self-concept, in other words an objectified sense of the self (but see also Mitchell, 1993; Rochat & Zahavi, 2011 for alternative views on the mirror mark test). What the individual sees in the mirror is Me, not another person, a feat that is not unique to humans since chimpanzees, orangutans, dolphins (Parker, Mitchell, & Boccia, 1995), and now magpies as well as elephants are also reported to pass the test (Plotnick & DeWaal, 2006; Prior, Schwarz, & Güntürkün, 2008).

The majority of children pass the mirror mark test by 21 months (Bertenthal & Fisher, 1978), although it depends on culture (Broesch, Callaghan, Henrich, & Rochat, 2011). But beyond the mirror mark test and what its passing might actually mean in terms of emerging self-concept, there is an early and universal reaction to mirrors that, in my view, is most revealing of human psychology. This reaction is the typical expression of an apparent uneasiness and social discomfort associated with mirror self-experience. The same is true for seeing photographs of one's self, or hearing the recording of one's own voice. Across cultures, mirror self-experience is *uncanny*, an expression of deep puzzlement. This is evident even by adults growing up with no mirrors and who manifest terror when confronted for the first time with their own specular image (see Carpenter, 1976). Looking at the self in a mirror puts people, young and old, in some sort of arrested attention and puzzlement. Mirror self-experience is indeed an uncanny experience (Rochat & Zahavi, 2011).

In general, aside from the landmark passing by a majority of children of the mirror mark test from around the second birthday, mirror self-experience develops to become incrementally troubling and unsettling for the healthy child. Such development is not observed by young autistic children, impaired in their reading of others' mind (Baron-Cohen, 1995), but passing the mirror mark test (Neuman & Hill, 1978). They will remove the mark from their faces when they perceive it but do not show the signs of coyness and embarrassment so typical of nonautistic children (Hobson 2002, p. 89). It appears that for autistic

children there is a different meaning attached to the mark they discover on their faces that they eventually touch and remove. This meaning would not entail the same kind of self-evaluation or self-critical stance in reference to the evaluative gaze of others expressed in typical children via self-conscious emotions. Autistic children's passing of the mirror test is not self-conscious proper and does not appear to entail any sense of reputation as defined earlier.

In her pioneer research on children's reactions to mirror and establishing (in parallel with Gallup, 1970) the mirror mark test, Amsterdam (1968, 1972) describes four main developmental periods unfolding between 3 and 24 months. In the *first period* of mainly sociable behaviors toward the specular image, infants between 3 and 12 months tend to treat their own image as a playmate. A *second period* is accounted for by the end of the first year, in which infants appear to show enhanced curiosity regarding the nature of the specular image, touching the mirror or looking behind it. By 13 months a *third period* begins, during which infants show marked increase in *withdrawal behaviors* by crying, hiding from, or avoiding looking at the mirror. Finally, Amsterdam accounts for a *fourth period* starting at around 14 months but peaking by 20 months when the majority of tested children demonstrate embarrassment and coy glances toward the specular image as well as clowning. These changes index the self-reflective and ultimately the unique self-conscious psychology unfolding in human ontogeny. Such psychology is the product of a complex interplay of cognitive and affective progress that take place during this early period of child development (Amsterdam & Lewitt, 1980), something that Charles Darwin inferred observing his own child long before the recent wave of experimental works around the mirror mark test.

In his book on the expression of the emotions in man and animals, Darwin (1872/1965) was struck by the unique and selective human crimsoning of the face, a region of the body that is most conspicuous to others: "Blushing is the most peculiar and the most human of all expressions" (p. 309).

Observing blushing in his son from approximately 3 years of age and not prior, Darwin highlighted the mental states that seem to induce human blushing:

> It is not the simple act of reflecting on our own appearance, but the thinking what others think of us, which excites a blush. In absolute solitude the most sensitive person would be quite indifferent about his appearance. We feel blame or disapprobation more acutely than approbation; and consequently depreciatory remarks or ridicule, whether of our appearance or conduct, causes us to blush much more readily than does praise. (p. 325)

These observations capture something fundamental and distinctive about humans, a unique motivation behind their social cognition: the exacerbated quest for approbation and affiliation with others, the unmatched fear of being rejected by others (see Rochat, 2009).

The expression of embarrassment in front of mirrors by 2 to 3 years is associated with the child's growing metacognitive abilities, in particular the child's growing ability to hold multiple representations and perspectives on the same thing, including the self. The recognition of self in the mirror is also for the child the recognition of how the self is publicly perceived.

From the point of view of neurophysiology, there is an apparent link between the emergence of metacognitive abilities around 2–3 years and the documented orderly maturation of the rostrolateral region of the prefrontal cortex. The growth of this prefrontal cortical region would correlate with the development of new levels of consciousness, in particular the transition from minimal to metacognitive levels of self-consciousness (Bunge & Zelazo, 2006; Zelazo, Gao, & Todd, 2007).

Elsewhere (Rochat, 2009), I interpreted the negative affective connotation of mirror self-experience (e.g., embarrassment and self-conscious emotions as opposed to positive jubilation) as expression of a universal tendency to hold an overestimated representation about the self that is at odds with what is actually seen by others, the latter truly revealed in the mirror. First-person (private) perspective on the self is generally overestimated compared with third-person (public) perspective. This interpretation is supported by the well-documented illusory superiority phenomenon found in adults (Ames & Kammrath, 2004; Beer & Hughes, 2010; Hoorens, 1993).

Arguably, such overestimation would bring about the experience of a generalized gap between private (first-person) and public (third-person) self-representations, a gap that is the source of basic psychic tension and anxiety, the expression of a generalized social phobia, and universal syndrome expressed from 2–3 years of age (Rochat, 2009).

An alternative interpretation would be that young children shy away from their reflection in the mirror, not because they are self-conscious but rather because they wrongly construe the presence of another child staring at them with some kind of a persistent still face, hence to be avoided. But this is doubtful considering, as we have seen, that very early on infants discriminate between seeing themselves or seeing someone else in a video (Bahrick, Moss, & Fadil, 1996; Rochat & Striano, 2002).

By showing embarrassment and other so-called secondary emotions (Lewis, 1992), young children demonstrate

a propensity toward an evaluation of the self in relation to the social world (the looking-glass self first proposed by Cooley, 1902). They begin to have others in mind, existing through in addition to with others.

Children begin to express secondary emotions such as shame or pride in parallel by 2 to 3 years of age and these are probably linked to the emergence of symbolic and pretend play. Such play entails, if not at the beginning but at least by 3 to 4 years of age, some ability to simulate events and roles, to take and elaborate on the perspective of others (Harris, 1991; Striano, Tomasello, & Rochat, 2001; Tomasello, 1999; Tomasello, Striano, & Rochat, 1999).

The process of imagining what others might perceive or judge about the self, whether this imagination is implicitly or explicitly expressed, is linked to the cognitive ability of running a simulation of others' minds as they encounter the self. There are fantasies and phantasms involved, the stuff that feeds the self-conscious mind and characterizes a metacognitive level of self-awareness (i.e., the construal and projection of what others might see and evaluate of us).

Social Dependence and Human Symbolic Psychology

For centuries the question of the origins and development of consciousness intrigued philosophers, moralists, educators, biologists, and more recently psychologists and neuroscientists: from Augustine, Rabelais, Rousseau, and Darwin to Freud and Piaget. All speculated how the experience of being in the world comes into place and is shaped in the early days of psychic life, from the moment infants come out from the obligatory, in appearance lethargic and silent 9 months gestation in the womb. Over 16 centuries ago, for example, in what is often considered the first self-narrative in the history of Western thought, Augustine in his *Confessions* expressed the idea that the origins of what one knows about the self is primarily social. Self-knowledge would be learned from others, particularly women because of the primal maternal bond:

> I give thanks to you, lord of heaven and earth .... For you have granted to man that he should come to self-knowledge through the knowledge of others, and that he should believe many things about himself on the authority of the womenfolk. Now, clearly, I had life and being; and, as my infancy closed, I was already learning signs by which my feelings could be communicated to others. (Augustine, 398 AD/2007. Confessions, 1.6.10.).

Augustine's intuition that we first learn about ourselves through contact with *the womenfolk* reflects a basic fact to which any speculation on early subjective experience should indeed refer to: that infants rely on others to live and survive. Necessary submission to the cares of others, the mother in particular, is the point of psychic origin. If neonates do their share to survive—breathing, eating, as well as orienting, approaching and avoiding—they are nonetheless born is a profound state of helplessness and dependence. This is the bottom line, particularly pronounced in the human infant who is born too soon after nine months of slow gestation (Rochat, 2001).

As already mentioned, the human birth creates a unique ecology of behavioral growth compared with other animal species, an ecology of protracted *exterogestation*, hence a particularly long and marked dependence due to immaturity (Bruner, 1972; Montagu, 1961). It is an ecology that has been constrained, among other contingent and cascading factors, by the evolution of bipedal locomotion. After nine months in the womb, the head circumference of the normally developing fetus becomes dangerously large for the mother and for itself.

Disproportionately big compared with other primate species, it also reaches a growth limit in relation to the birth canal of humans that evolved to be narrower with changes in pelvic bone configuration, reflecting itself the bipedal locomotion evolved by the *Homo* genus (Gould, 1977; Montagu, 1961; Trevarthan, 1987).

Human protracted exterogestation creates a unique case of altriciality in the animal kingdom, an unusual need for care from others and an exacerbated dependence on others to survive beyond the third year (when most children of all cultures today expand the circle of close caretakers to socialize on their own with peers in the more formal circle of school).

This state of protracted dependence is the specific context in which human consciousness and the human psyche take roots in their development. That is the original bath that we need to consider if we want to figure what it is like to be a newborn: it is first and foremost the experience of relying on generous caregivers, themselves conscious and reflective, willing to give freely and abundantly attention and care. It defines human experience at the outset. Attachment and dependence are evident in other animals. However, what is unique compared with any other mammalian species, is that human dependence is (1) protracted and (2) engages explicitly conscious (as opposed to just minimally conscious) others that have beliefs and communicate symbolically with one another.

In this primary context, how might it feel to be a newborn? What kind of sensuous experience might arise is such a great state of immaturity and dependence?

In *The Family Idiot*, Sartre's (1971/1981) biography of nineteenth-century writer Gustave Flaubert, he ponders this question at length and in remarkable depth. In the first part of this long essay ("The Constitution"), Sartre describes in detail the initial experiential state of total abandon to the cares of others. Sartre speculates that it is in this early submission to specific maternal gestures, attitudes and attention that one can find the roots of Flaubert's apparent passivity as a child and subjective disconnection as an adult, possibly also the source of his genius as inventor of the modern novel: "Gustave as a child, is not *made* to act; what he feels is dizzying submission to this constitutive nature experienced within him as the product of *others*" (p. 48; author's translation from French). He goes on a few pages later:

> The newborn, molded everyday by dispensed cares, internalizes the maternal activity of his own passive "being there", in other words the infant internalizes the maternal care activity as the passivity that conditions all the pulsions, and all the internal rhythms of desires, speeds, accumulated storms, schemas that reveal at the same time organic constancies and unspeakable wishes – in brief that his own mother, buried deep into that body, becomes the *pathetic* structure of affectivity. (p. 58)

Sartre (1971/1981) insists on the inescapable determinant of the mother as a whole person that determines the affective core experience of cared newborns. Maternal constitution, relative sensitivity, and life story is inescapably reflected in the kind of care, attention, and gestures mothers are able to dispense to their infant. Indeed, in the experiential life of newborns that revolves primarily in the passive reception of cares molded by others, there is more than the serving of basic survival needs such as food, warmth, and hygiene. There is also, as Sartre points out, the transmission of unique trans-generational idiosyncrasies or family truth:

> ... When the mother breastfeeds or clean her infant, she expresses herself, like anybody else, in her personal truth, which, naturally, sums up in it all her life, from her own birth; in the meantime, she realizes a rapport that changes depending on circumstances and people – for which she is the *subject* and that we can call maternal love. .... But, at the same time, by this love and through it, by that person, skillful or unskillful, rough or tender, the way her history made her, the child is manifested to himself. (p. 57)

In summary, Sartre (1971/1981) proposes astutely that experiential awareness of what it might be like to be a newborn is highly dependent on the subjective experience of others. It would be, in large part, socially determined and intersubjective to start with, in the context of dispensed cares. In other words, it would depend primarily on the interaction of a mother–infant experiential point of view, from which each partner would extract their own mutually defining meanings, not unlike the dialectic of master and slave: the newborn would extract a sense of imposed passivity and submission, the mother would extract a sense of duty and fulfillment in the instinctive call for maternal love and protection: a constitutive rapport of force.

Unfolding Levels of Sharing and *Conscientiousness*

With the intentional communication about objects that emerges by 9 months of age via social initiatives and explicit bouts of joint attention (secondary intersubjectivity), infants break away from the primary context of face-to-face exchanges. They become referential beyond the dyadic exchanges to include objects that surround the relationship. Social exchanges also include conversations about things outside of the relationship, becoming triadic in addition to being dyadic. Exchanges become object oriented or objectified, in addition to being the expression of a process of emotional coregulation. Infants now willfully try to capture and control the attention of others in relation to themselves via objects in the environment. At this point, however, the name of the game is limited to the sharing of attention just for the sake of it. Children measure the extent to which others are paying attention to them and what they are doing. They begin to check back and forth between the person and the object they are playing with (Tomasello, 1995), or they begin to bring an event to the attention of others by pointing or calling for attention to share the experience with them. However, such initiative ends there, and is typically not followed through in further conversation or coregulation. For infants, secondary intersubjectivity in triadic exchanges is a new means to control their social environment, in particular the proximity of others as they gain new degrees of freedom in roaming about the environment (Rochat, 2001). By becoming referential, infants also open the gate of symbolic development. They develop a capacity for dual representation whereby communicative gestures stand for and become the sign of something else (e.g., a pointing gesture as standing for a thing out there to be shared with others). Communication becomes intentional, transcending the process of emotional coregulation and affective attunement that characterizes early face-to-face, proto-conversational exchanges (i.e. primary inter-subjectivity). Yet it remains restricted to the monitoring of whether others are, or are not, co-experiencing with the child.

Nevertheless, with the emergence of intentional communication and the drive to co-experience events and things in the environment, infants learn and begin to develop shared meanings about things. To some extent, they also begin to develop shared values about what they experience of the world, but this development remains limited. For example, when facing dangers or encountering new situations in the environment, they are now inclined to refer to the facial expressions of others that are paying attention to the same events (Campos & Sternberg, 1981; Striano & Rochat, 2000). The meaning of a perceived event (e.g., whether something is dangerous or threatening) is now referred to others' emotional responses, to some extent evaluated in relation to others, but it ends there. The process does not yet entail any kind of negotiation regarding the value of what is experienced. The world is essentially divided into either good (approach) or bad (avoidance) things and events. Such basic social referencing emerges at around 9 months, in parallel to the propensity of infants to share attention with others and to communicate with them intentionally (Rochat & Striano, 1999; Tomasello, 1999).

By the middle of the second year of life, triadic exchanges develop beyond basic social referencing and the sense of co-experience with others that is the trademark of secondary intersubjectivity. The child now begins to engage in active negotiation regarding the values of things co-experienced with others. They manifest *tertiary intersubjectivity*, a sense of shared experience that rests on complex ongoing exchanges unfolding over time: things that happened in the past, are manifest in the present and are projected by the child into the future. The prototypical expression of this new level of inter-subjectivity is the expression of secondary emotions such as embarrassment or guilt.

In relation to the self, by 20 months, children begin to represent what others perceive of themselves and gauge this representation in relation to values that are negotiated. If they see themselves in a mirror and notice a mark surreptitiously put on their face, they will be quick to remove it and often display coy behaviors or acting out (Amsterdam, 1972; Rochat, 2003). They begin to pretend and mask their emotions (Lewis, 1992). In general, they become self-conscious, negotiating and actively manipulating what others might perceive and evaluate of themselves (Lewis, 1992; Rochat, 2009). From this point on (18–20 months of age), children project and manipulate a public self-image, the image they now identify and recognize in the mirror. It is an image that is objectified and shared with others, a represented public self-image that from now on will be constantly updated and negotiated in relation to others. Interestingly, by 20 months, children's linguistic expressions begin also to include the systematic use of possessives, children starting to claim ownership over things with imperative expressions such as "Mine!" (Bates, 1990; Tomasello, 1998). Such expressions demarcate the value of things that are jointly attended in terms of what belongs to the self and what belongs to others. This value begins to be negotiated in the context of potential exchanges, bartering, or donations. With the explicit claim and demarcation of property, the child develops a new sense of reciprocity in the context of negotiated exchanges of property, whether objects, feelings, or ideas. At around the same age, children also begin to demonstrate prosocial behaviors, engaging in acts of giving and apparent benevolence by providing help or spontaneously consoling distressed others (Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). Self-concept, ownership claim, and a new concern for others bring the child to the threshold of moral development and the progressive construction of an explicit sense of justice (Damon, 1994). What follows in development is a new level of social reciprocity that is increasingly organized around an ethical stance taken by the child. But this ethical level of reciprocity develops between 3 and 5 years of age and beyond as shown by our recent investigation of young children's sense of fairness in sharing across cultures.

There is a developmental trend from a reluctance to share to subtle, more reciprocal exchanges. For example, children between 3 and 5 years of age become significantly more flexible and systematic in adjusting their successive bids while engaged in bartering exchanges of stickers or toys. They are increasingly inclined to up their bids until an agreement is reached. This developmental trend is also associated with an increased understanding by the child of others' mental states, a trend that appears to cut across cultures (Callaghan et al., 2005).

As children start to claim explicit ownership and invest affects into objects of devotion, they do so by first manifesting unmistakable exclusivity in their possession, a blunt reluctance to exchange. They show overwhelming egocentrism. When the child begins to say "Mine!" she not only implies that "It is not yours," but also is explicitly stating defensive exclusivity, a reluctance to even contemplate sharing and an unmistakable claim that she wants to keep it for herself.

In cross-cultural observations (Rochat et al., 2009), we confirmed that this egocentric trend is a universal trend. We found it in 3-year-olds and to a lesser extent in 5-year-olds from all over the world, who are growing up in highly contrasted physical, social, economical, and

cultural environments. It happens in children living in rich or poor neighborhoods and in cultures fostering radically different values regarding private property. We observed this trend in children in small, highly collectivist villages of rural Peru or in small isolated fishing communities in Fiji. This same trend occurs in children growing up in violent and lawless as well as affluent neighborhoods of Rio de Janeiro; unschooled kids begging and living on the streets of Recife in Brazil; young children attending a Communist Party–controlled preschool in Shanghai, China; and in middle-class North America (Atlanta, Georgia).

In general, we found that across cultures, between 3 and 5 years, there is a robust developmental trend toward more equity in sharing. In conditions where the child was one of the two recipients, 3-year-olds tended to distribute overwhelmingly more candies to themselves, whether equity was possible or not. By 5 years, however, this trend was still evident but significantly tamed. Children continued to favor themselves and are selfish but markedly less. Interestingly this trend was the same in children from all cultures but was reduced in children growing up in small rural and collective communities (i.e., Peru and Fiji in our sample). In development, there is thus a universal drift in active sharing from massive to reduced selfishness between 3 and 5 years of age, a trend moderated by the cultural environment of the child. Despite the significance of cultural factors, the trend toward increased altruism/prosociality in sharing is remarkably robust from the time children begin to be explicit in claiming ownership.

Culture appears to play a role in the developmental pace at which the child becomes inclined to share with greater equity, but the general trend is there regardless of marked variations. In China, children were tested in a preschool that emphasized primarily group activities and sharing. Children always play, sing, and learn as members of a group, rarely as individuals isolated from the group. Such attempts are much less frequent in middle-class North American preschools, such as those of the children we tested in Atlanta. In Fiji or in Peru, the tested children lived in small, close-knit communities where public and shared properties dominate over ostentatious private ownership. When they exist, preschools in these regions are known to emphasize synchronized group activities in children.

The stability of this developmental trend is particularly striking when considering the three groups of Brazilian children. Each group grows in highly contrasted economical and social circumstances within the same national and cultural borders. A group of children lived in the poor and insecure environment of a favela in Rio de Janeiro, an environment dominated by young drug lords that terrorize and dictate law and order. Another group was composed of privileged children, of the same age, from an affluent private preschool situated just a few miles away from the favela. The third group of Brazilian children was composed of 3- and 5-year-old unschooled street kids from the city of Recife, a few hundred miles northeast of Rio. These children spent their days unsupervised by adults, begging on the street, collecting refuse, and typically spending the night with an extended family living in precarious, unsanitary slums close to public dumps.

One could easily presume that the drive to own, and not to share, in the young children of the favela, and particularly the street kids of Recife, might be different compared with the privileged children of Rio. Our research shows that it is not the case. All of these children demonstrate the same developmental trend toward a significant decrease in selfishness and increase in more equitable sharing between 3 and 5 years.

In typical development, young children become more equitable in their sharing, regardless of their economical and cultural circumstances because they enter the culture of their species (*Homo Negotiatus*), a culture that is fundamentally based on reciprocal exchanges. Hoarding and coercion are antithetical to this culture. If it exists, it is an anomaly, due to particularly stressful circumstances (war, disaster, rebellion, madness). It is not cardinal to the culture of *Homo Negotiatus*, unlike any other animal species that are not designed to have others in mind in their social exchanges and their sharing of resources.

We construct equity as well as agree on values by an active process of approximation and mutual monitoring. This process takes form within reciprocal exchanges. We do so by negotiation and ultimately by caring about reputation, namely our relative proximity with others. What happens between 3 and 5 years, is a marked progress in this process that channels children away from greed and immediate gratification. The product of this development is the emergence of a moral space in which children begin to care about reputation.

Children between 3 and 5 develop an understanding that they are potentially liable and that they build a history of transactions with others. Needless to say, parents and educators foster this development in all cultures, but this fostering is essentially the enforcement of the basic rules of reciprocity, the constitutive elements of human exchanges. Children are channeled to adapt to these rules they depend on to maintain proximity with others. From this, they begin to build a moral space in relation to others, a moral space that is essentially based on the basic rules of reciprocity. It is a moral space that is constantly in the

making, constantly revised, and in which equity is endlessly approximated by way of negotiation. Philosopher Charles Taylor (1989) notes in his book on the *Sources of the Self*: "What we are constantly losing from sight is that being a self is inseparable from existing in a space of moral issues, to do with identity and how one ought to be. It is being able to find one's standpoint in this space, being able to occupy a perspective in it" (p. 112). Consciousness and conscientiousness are indeed inseparable in typical development.

CONCLUSIONS: IMPLICATIONS FOR DEVELOPMENTAL PSYCHOPATHOLOGY

In this chapter and based on current progress in infancy research, we considered what seems to constitute the roots of typical consciousness. A large body of recent works indicate that healthy infants are born equipped to represent categorical features of the environment that are relevant for their survival such as faces (i.e., face-like displays); food (i.e., associated with particular taste or smell); but also less pragmatically, things that are of the same (i.e., selective process of sameness detection). Infants are born in a world of values. These values are represented in terms of specific attractor forces. There is a predetermined approach–avoidance polarity that channels the infant's attention and give direction to perception and action from the outset. As we have seen, newborns do not just sense the world but perceive it in terms of what it affords in for action: food, contact, novel vs. familiar experience, what should be avoided or approached. More than reflex machines limited in experiencing automatically proximal stimulations, research shows that they are perceivers of distal objects. As objective (distal) perceivers of the world, they are born implicitly aware of themselves as differentiated entities among other entities. Contrary to what was assumed by pioneer developmental psychologists like Piaget or Freud, newborns are now shown to have minimal self-awareness, not born is an initial state of fusion with the environment. In fact, one could argue that much of developmental psychopathologies and their deleterious effects affect what appears to be a given starting state of human development. Some aspects of this starting state, topic of this chapter, can have particularly deleterious consequences with the onset of neurodevelopmental disorders like schizophrenia or autism. Such instances can be viewed as the *undoing* of the typical propensity displayed very early on to engage in mutual recognition, experience self-unity as well to have a deep sense of possessing (i.e., controlling) one's own experience.

As illustration, and to conclude, we review next some of these deleterious undoing of typical consciousness. The intent is to emphasize aspects that are naturally a given from a very young age and too often taken for granted by the healthy individual. The importance of such aspects is clearly revealed in instances autism and schizophrenia where foundations of typical consciousness are undermined.

Centrality of Mutual Recognition

Kanner (1943), in his description of infantile autism, noted that these children appear to have "an innate inability to form the usual biologically provided affective contact with people, just as other children come into the world with innate physical and intellectual handicaps" (p. 23). Kanner went on to insist on what he sees as the extreme autistic aloneness of these children, their social isolation. Interestingly, for novice yet well-intended healthy adults who might try to engage a child diagnosed with autism, there is always a great deal of discomfort, frustration, and sense of being thwarted, of becoming unsettled and unsure of themselves (Greenspan & Wieder, 2006; Sigman & Capps, 1997). These children are difficult to figure out, removed, unpredictable, unreachable. Looking through or beside you, they behave as if you were transparent, *invisible*, nonexistent, *nonconsequential,* an experience that is a typical source of great discomfort for the well-intended parent or caretaker, and presumably a permanent discomfort for the autistic child withdrawn into his world.

The symptomatic trademark of autistic children is the depleted sociality experience by anybody trying to engage them and connect with them. The social current and cocreation of meanings that normally arise among communicating individuals are either hindered or plainly absent. It takes a great deal of expertise and exercises from parents, educators and therapists to contact these children, a difficult and courageous enterprise that requires sometimes infinite patience (e.g., Greenspan & Wieder, 2006).

What makes the raising of an autistic child so much more difficult and exhausting compared with raising a healthy, even hyperactive child is the fact that there is no room for mutual recognition, no room for reciprocal acknowledgment. The love parents of autistic children might express, often inexhaustibly, remains unmatched in its return. In this context, parents have difficulties recognizing themselves in the impact they have on their child. Inversely, the child is impaired in recognizing himself in what he does to his parents. Autism causes *mutual* blind mindedness, mutual invisibility, and it is a source of great

discomfort, obviously for the trying parents, but also for the disconnected child.

Given Sense of Self-Unity

At some basic level, feeling experience carries with it a fundamental sense of unity or *self-evidence*. It is that my feelings experiences of the world are mine, can only be mine, and nobody else. This is true no matter what, and to the extent that one doesn't take drugs or shows symptoms of schizophrenic autism or any other kinds of psychosis.

As continental phenomenological philosophers in the tradition of Husserl, Merleau-Ponty, Sartre, and many others but more recently Gallagher and Zahavi (2009) would claim, this self-evidence comes for free with any kinds of feeling experience. It is an implicit given. In the same way, James Gibson (1979) in his ecological approach to perception proposes that perceiving the world always necessarily entails *coperceiving* oneself as perceiver and actor in the world. One implies the other, no matter what, like the two sides of the same coin. This is a simple yet powerful intuition that is theoretically helpful, accounts for much of what we see in the development of children and in devastating instances of psychopathology like schizophrenia. For these empirical reasons, there are good reasons to endorse such implicit self-evidence that feeling would necessarily entail. However, one should acknowledge other philosophical and psychological perspectives adopting radically different epistemological starting points. These views are that the mine-ness of experience is more likely an illusion and a cognitive reconstruction rather than a necessary given. Accordingly, self-perception would be more the product of an inference and a mental representation rather than an implicit direct counterpart of any acts or direct perception, as Gibson suggested. Cognitive reconstruction views, however, appear untenable when considering very young infants as well as adults suffering mental and other self-disorders found particularly in schizophrenia but also other psychotic symptoms.

Research show that we are born with the basic intuition of what belongs to our own feeling experience and what is not. Few hour-olds infants do show unambiguous discrimination between self- and non–self-touch. For example, newborns root significantly more in the direction of another person's finger that touches one of their cheeks compared to when one of their own finger of hand comes spontaneously in contact to the same cheek. They discriminate between self-produced double touch of simultaneous cheek and finger touching and the single touch of a non–self-finger (Rochat & Hespos, 1997). This simple observation tells us, among other empirical evidence found in neonates that we are born with the potential for the implicit sense of exclusive mine-ness of experience, something that is probably the necessary phenomenal prerequisite of psychological development, its necessary subjective seed. That my feelings are mine is self-evident and does not have to be an indirect representational reconstruction. If that were the case, it is doubtful that neonates would show discrimination between double and single touch experience. Such empirical evidence would imply that there is from birth the potential self-evidence property of feeling experience.

Primordial Possession of the Own Experience

A look at the anomalous experience of psychotic adults who suffer from great cognitive disorganization and uncontrollable hallucinations within the schizophrenia spectrum, demonstrates how fundamental and actually basic self-evident mine-ness experience is, the sine qua non condition of our sanity. It shows clearly that self-evident *mine-ness* of feeling experience is the cornerstone of the ways we create meanings and bring coherence to our experience of being alive in this world: something that is ineffable (hard to put words on) and pre-reflective (implicit) by nature.

Loss of self-evident mine-ness of experience can be pathological and long lasting, as it can be temporary and provoked by drugs and other trance inducing rituals that are so pervasive across religions and cultures. Speaking tongues and other possessed states are symptomatic of self-evident feeling experience transmuted (mentally delegated) to a fictive entity that intrudes individual consciousness, be it the devil or a dead ancestor. Trance states can transform the implicit self-evidence typically accompanying feeling experience into the embodied *allo*-evidence of another. Possessed individuals are literally invaded and under the spell of another. There is experiential loss of self-control, until the individual snaps out of their trance state. Aside from religious rituals, hypnosis is a good, more secular example of trance-like state. It continues to be successfully exploited in psychotherapy and psychoanalysis, in the footsteps of Charcot (1825–1893) in his pioneer research on hysteria and other neurotic symptoms shown to be of psychological origin, as well as Freud in his early practice of psychoanalysis (Breuer & Freud, 1895/2000). Such induced temporary disturbance and loss of subjectivity is similar in some fundamental ways to chronic psychosis like schizophrenia.

Refined examination of the subjective, first person perspective accounts of hundreds of schizophrenic individuals reveals that first and foremost, schizophrenia and allied

symptoms are disorders of minimal self-experience including at its core, self-evident *mine-ness experience (*Parnas et al., 2005). It is typical for individuals suffering the atrocious ills of schizophrenia to report that although they rationally, thus explicitly know that their thoughts originate from within them and are not hallucinations proper, these thoughts are nonetheless *not* felt as generated by them. There is no implicit sense of self-agency in thinking or generating thoughts, they are thus somehow possessed rather than in possession as discussed above. It is a loss of thought *ipseity* (from the Latin word *ipse*, self), in other words the loss in the mine-ness of thinking one's own thoughts. Losing this basic and implicit sense of self is devastating, of almost unimaginable horror magnitude as probably best conveyed by Elyn Saks's (2007) vivid account of her own, very personal and detailed journey into schizophrenia:

> This experience is much harder, and weirder, to describe than extreme fear or terror. Most people know what it is like to be seriously afraid. If they haven't felt it themselves, they've at least seen a movie, or read a book, or talked to a frightened friend—they can at least imagine it. But explaining what I've come to call "disorganization" is a different challenge altogether. Consciousness gradually loses its coherence. One's center gives way. The center cannot hold. The "me" becomes a haze, and the solid center from which one experiences reality breaks up like a bad radio signal. There is no longer a sturdy vantage point from which to look out, take things in, assess what's happening. No core holds things together, providing the lens through which to see the world, to make judgments and comprehend risk. Random moments of time follow on another. Sights, sounds, thoughts, and feelings don't go together. No organizing principle takes successive moments in time and puts them together in a coherent way from which sense can be made. And it's all taking place in slow motion (p. 13)

Delusions and hallucinations are an intrinsic part of the diagnosis of schizophrenia and the self-disorganization, including voices as running commentaries on the person's behavior or thoughts, some sort of inescapable hyper-reflectivity but from a third-party perspective that invades the individual who lost basic self-evidence, the loss of an implicit trust that subjective experience *belongs* to oneself, a feeling experience that is not self-specifying anymore but rather diffused and confused with a world that is chaotic: the forceful, uncontrollable voices and intrusive thoughts that have no overarching narrative structure, no meaningful organization.

Such psychopathologies point to the fact that to function and experience the world normally, self-evidence and the basic feeling experience that one's thoughts and perceptions belong to oneself are a necessity—these are indispensible, absolute prerequisites to avoid mental invasion and the loss of minimal self-reference. How easy it is for us to take for granted the fact that these gestures, this voice, such vision *belong* to no one else and no other source than *me*. Without this basic self-evident feeling experience, we are at a loss. Losing it is indeed devastating: it is the primordial prerequisite of a healthy psychological development that starts in the womb.

REFERENCES 518

INTRODUCTION

I was incredulous when a bright 2-year-old with whom I was once conversing looked at me quizzically and asked, with tremendous earnestness: "Am I me?" Was this budding young philosopher wrestling with a distinction that William James (1892) introduced over 120 years ago, namely, the I-self versus the me-self? I was tempted to think so. Of course at his age, he was more likely struggling to sort out the linguistic conventions governing the use of the pronouns I and me. Nevertheless, I found his query quite profound. It set the stage for examining how I-self and me-self processes change with age, from a developmental perspective.

James (1890, 1892) himself wrestled with the distinction between the I-self and the me-self in adults and never arrived at an explanation that was, to him, intellectually satisfying. He concluded that the I-self was an incorrigible construct, an elusive concept that defied clear explication. Many scholars to follow retained this distinction in their own theorizing, where the I-self has been afforded such characteristics as a sense of *agency*, as the *observer,* one's intellectual pulse and window on the world and as the cognitive engine that drives the creation of the me-self (see reviews in Harter, 1999, 2012). However, too many theorists have paid only lip service to the role of the I-self, failing to translate this concept into researchable or applied formulations that document its specific functions.

Moreover, the I-self has been overshadowed by the me-self, which took center stage in the self literature (see Harter, 2012; Wylie, 1979, 1989), particularly with regard to measurement issues. The *me-self* reflects one's image in the psychological mirror, the self as *observed* and personally described, namely, one's *concept* of self at both domain-specific levels (e.g., perceptions of one's competence, physical appearance, social acceptability) as well as more global self-esteem. Unfortunately, the me-self in the mirror became an entity over which the individual myopically preened, a self that demanded enhancement, promotion, and protection, often reflected in self-serving biases and self-deception (see Harter, 2012; Leary, 2004). As the self literature evolved, the I-self was increasingly given short shrift, particularly from a developmental perspective.

It is the intent of this chapter contribution to resurrect the I-self, to restore the I-self to its rightful place as a critical cognitive-developmental process, with implications for both normative and pathological development. Critical to this endeavor is the premise that we must adopt a neo-Piagetian perspective (see Fischer, 1980; Fischer & Bidell, 2006; Harter, 1999, 2012), charting how changing cognitive-developmental processes define the I-self. These processes, in turn, dictate how the content and structure of me-self evaluations will correspondingly change with age. However, it will be argued that we need to broaden and revitalize the I-self's job description, beyond that of the mere architect of the me-self, beyond efforts to package, protect, enhance, and distort the me-self. This is the dark side of the I-self's preoccupation that leads to pathological conditions. This job definition will be reviewed. However, momentarily fast-forwarding, I will also address how there are better ways for the I-self to spend its precious time that can contribute to mental health.

As a backdrop, I first review how developing I-self processes contribute to the construction of the me-self. I will address these processes across six levels of development, very early childhood, early to middle childhood, and late childhood as well as early adolescence, middle adolescence, and late adolescence. Those positive Jamesian (1892) I-self functions, *self-awareness*, a sense of *agency*, as well as the *continuity* and *coherence* of the self will be included in this developmental analysis. In first describing self-development across these six substages, the focus will be on (1) normative development as well as what will be labeled (2) normative-developmental *liabilities,* psychological speed bumps along the road that are typical for many children and adolescents but do *not* represent minefields that are signals of psychopathology. Typically, with appropriate support and good-enough child rearing, children and adolescents will healthily proceed, lurching toward normative development as emerging adults and beyond. However, not all are so blessed.

Research supported by grants to the author by NICHD and the W.T. Grant Foundation.

What might go awry? I will conceptualize psychopathology as various *deficiencies in me-self* development where anomalies and clinical symptoms are primarily manifest. Yet the I-self is a coconspirator, as we explore the dark side of the contribution of the I-self. One can ask whether this less than admirable preoccupation has been forced upon the I-self by societal and cultural demands as well as certain socialization practices, for example, less than optimal parental child-rearing practices, including various forms of abuse in the extreme.

Thus, next, the dark side of the I-self's job description will be discussed, namely, how from a Western perspective the I-self should be gainfully employed in protecting and enhancing the me-self, deceptively packaging it as a valued commodity in the psychological market place. For example, conditional support from parents—behave according to my agenda for you if you want my love and support—can lead to false self manifestations that compromise the more positive I-self functions (Harter, Marold, Whitesell, & Cobbs, 1996). Moreover, severe and chronic abuse can seriously interfere with other I-self roles such as self-awareness, a sense of agency, as well as the continuity and coherence of the I-self (see Harter, 1999).

I will then review how the dark side of self-development can also include how the I-self conspires to keep the me-self at the heart of those developmental psychopathologies that intimately involve self-evaluations. Five such pathological conditions that involve these self processes will be examined: (1) self-aggrandizement, self-serving biases, self-deception, and narcissism; (2) negative self-evaluations in the form of low self-esteem and poor self-concept; (3) depressive reactions, syndromes, and suicidal behaviors; (4) eating-disordered behaviors; and (5) the role of negative self-processes that can lead to violent revenge in the face of bullying.

1. Self-Aggrandizement, Self-Serving Biases, Self-Deception, and Narcissism

There is a contemporary belief that the self is cause for concern in our culture, among certain self-theorists (see Harter, 2012; Leary, 2004). Many adults in our society seem transfixed by the need for self-enhancement, self-serving biases, falsely inflating their self-esteem for personal gain. These manifestations on the psychological landscape shade into increasing *narcissism,* a psychological condition that takes on different manifestations at different developmental levels, as will be traced in this chapter. Similarly, the cognitive *skills* to engage in self-aggrandizement and the *motives* for so doing will differ across developmental levels, an issue that will be tracked across the six stages.

2. Negative Self-Evaluations in the Form of Low Self-Esteem and Poor Self-Concept

Normatively, these evolve in a predictable developmental sequence, but at each stage there is the potential for derailment. Thus, we will evaluate what factors can interfere with healthy or optimal self-esteem, leading to precariously low self-esteem. In addition, very negative self-evaluations are revealed in particular domain-specific self-concepts. We will deal with those socialization practices that interfere with optimal self-esteem development, including such parental practices as *conditional support*, which involves behavioral demands of the child if he/she wishes to insure parental love. However, children do not perceive conditional parental behavior to be genuine love. In addition, abuse by caretakers can interfere with both I-self and me-self processes, provoking negative self-evaluations (Harter et al., 1996).

3. Depressive Reactions, Syndromes, and Suicidal Behaviors

There has been considerable research (see reviews in Harter, 1999, 2012) revealing that depressive reactions are intimately related to negative self-concept and low self-esteem. In the most severe cases, these can lead to suicidal gestures, which for some, meet with tragic outcomes that result in the termination of one's life. Taking its toll is abuse by caregivers, insensitive responses by peers, and most recently bullying, including cyberabuse, which has become the new look in cruelty, destroying children's and adolescent's sense of worth. In extreme cases, victims are driven to engage in previously unthinkable acts of self-destruction. We will bring this literature up to date.

4. Eating-Disordered Behaviors

Although there are many different theories and approaches to this serious problem among our youth, much of the research reveals that self-processes are highly implicated. Negative perceptions of one's body image, relative to the punishing and impossible cultural standards that are touted and blasted on TV, movies, and social media, contribute. These seriously erode the bodily self-images of our children and adolescents, and not just for females. Males are now held to higher standard of physical attractiveness. Our own research, as well as that of others, reveals that these negative self-perceptions of appearance lead directly to low self-esteem or self-worth, which in turn result in eating-disordered behavior (see Harter, 2012). These reactions, in turn, can lead to active suicidal attempts or more passive behavior such as lack of intake in food that can stunt biological growth processes and in some cases result in death.

5. The Role of Negative Self-Processes Leading to Violent Revenge in the Face of Bullying

The previous decade has seen a flurry of activity and interest in bullying and prevention programs within the schools that are certainly welcome, to stem the tide of this type of abuse. Our own approach has been to view these phenomena as intimately related to the self and our own model of the causes and consequences of self-esteem identifies several various self and social processes (Harter, 1999, 2012). Clearly, the victims of abuse and harassment have displayed low self-esteem and related attributes that we have identified in our model (for example, inadequacy in domains valued by peers) that make them targets of harassment. But why, one might ask, has it been the *victims* that have emerged, in the 12 high-profile cases of school shootings, who are the perpetrators of such violence? Why did they, in particular, seek revenge? Our own scrutiny of the most widely publicized cases has revealed that in every case these White, middle-class, suburban, or rural boys had not only been harassed and physically abused but had been *publicly humiliated*. At a broader level, we have argued that there is not a simple, direct link between being bullied and revenge. Rather, it has to be mediated by an *emotional reaction*, which we have identified as *humiliation,* with correlates of anger, frustration, shame, and depression (Harter, 2012). However, humiliation seems to be the primary trigger that eventually evokes the rage of revenge. These, and other models that implicate the self, will be explored.

Summary

There are many contributions to psychopathological behaviors in children and adolescents, as this entire handbook will illuminate. This particular chapter will focus on those factors that involve the *self*, more specifically the interface of the I-self and the me-self, an approach that may be complementary to other perspectives. The field needs those that are adept at integrating such approaches, which hopefully this volume will do.

As a developmentalist, I will approach the topic by first introducing a framework in which I distinguish between Jamesian I-self processes and me-self processes. I argue that the self has not received its rightful due as an active construct or that too much of the self-literature has focused on the me-self, providing an unbalanced view of self processes. Thus, next I identify six stages of developmental, three within childhood and three within adolescence, since there are rapid changes within childhood and adolescence in both I-self and me-self processes; we can no longer treat childhood and adolescence as two broad, general stages. Both normative self-representations and potential normative liabilities will be highlighted. Finally, I will argue that certain forms of developmental psychopathology are largely manifest in me-self aberrations but that the I-self plays a role, dictated by societal and cultural values including conventions and expectations.

Thus, I first briefly trace how the I-self contributes to me-self development, normatively, including some predictable *liabilities* that are *not* pathological and usably abate under normal, child-rearing conditions. Unlike certain purely descriptive treatments of mere me-self changes, I indicate how changes in I-self development contribute to the manifestations of the me-self at different stages. Furthermore, unlike other treatments, I honor the role of the Jamesian specific I-self processes that he so brilliantly identified.

The chapter then turns to the dark side of the I-self's job description in having to package the me-self in a manner that would be acceptable to societal dictates about what the me-self should look like, behave like, how it should display itself, sometimes falsely, against the wishes of one's authentic self. This is most evident in the mandate to package the self, to falsify the self, to engage in self-aggrandizement that can lead to self-serving behaviors that border on and include narcissism.

Against this background, we visit the six stages of childhood and adolescence, applying this developmental thinking to five different areas of developmental psychopathology, which are manifest differently at each of the six stages. To review, these forms of developmental psychopathology that intimately involve the *self,* are listed as follows:

1. Self-aggrandizement, self-serving biases, and self-deception, that can evolve into narcissism
2. Negative self-evaluations in the form of low self-esteem and poor self-concepts
3. Depressive reactions, syndromes, and suicidal behaviors
4. Eating-disordered behaviors
5. The role of negative self-processes, including humiliation, which can lead to violent revenge in the face of bullying

How the I-Self Can Contribute to Mental Health and Well-Being

The chapter will end with an emphasis on how I-self processes can spearhead more mentally healthy preoccupations that temper some of the negative pathological effects of the me-self and can supplant such processes

in order to allow the I-self its rightful due as a positive force in development. We will enlarge and broaden upon this vision, casting the I-self in a more positive light, as a key player in promoting psychological health. Links to contemporary theorizing that provides an antidote to some of these disruptions in adaptive I-self functioning will be discussed. This new and more optimistic focus on human behavior suggests that we devote more energy to appreciating and fostering a number of such processes that can be cast in I-self/me-self parlance. These include self-awareness, self-efficacy, sense of agency, mastery motivation, the concept of flow, self-continuity and self-coherence, mindfulness, from a Buddhist perspective, which includes a focus on egolessness, the quiet ego, humility, and compassion. From a Buddhist perspective, far more fringe benefits will accrue if the I-self averts its myopic gaze away from protecting the me-self through a distorted lens of self-aggrandizement. Consistent with the premises of the field of positive psychology (see Lopez & Snyder, 2009; Snyder & Lopez, 2002) more beneficial outcomes will ensue from an exploration of the I-self's role in promoting *authenticity*, which, in today's Western world, unfortunately seems to be in short supply.

From this relatively new field of positive psychology (see Lopez & Snyder, 2009), other constructs will be selected that can be interpreted within an I-self/me-self perspective, highlighting the role of the I-self in promoting mental health and well-being. These include the role of self-acceptance, the role of positive emotions, positive affectivity, emotional intelligence, emotional competence, emotional creativity, cognitive creativity, sense of control, self-determination, optimism, hope, and curiosity.

HOW THE I-SELF CONTRIBUTES POSITIVELY TO THE DEVELOPMENTAL CONSTRUCTION OF THE ME-SELF, INCLUDING JAMESIAN I-SELF FUNCTIONS

Developmental approaches to the self have primarily focused on age-related changes in the *me-self*, although they have not been theoretically driven. For example, Montemayor and Eisen (1977) provided compelling examples of the changes in self-descriptions across three broad developmental periods: early childhood, later childhood, and adolescence. Young children's descriptions were very concrete, focusing on observable behaviors (e.g., I can run fast, I live in a big house); those in later childhood were more likely to include socially relevant traits or attributes (e.g., I am popular, I am nice), whereas adolescents were more likely to refer to more general, abstract personality characteristics (e.g., I am intelligent, I am moody) (see Damon & Hart, 1988; Harter, 1999, 2012; Rosenberg, 1979). Age-related differences in the me-self were primarily described as developmental changes in the *content* of self-representations.

The cognitive revolution within the field of psychology in the 1980s and 1990s brought with it the premise that the self was primarily a cognitive construction, namely, a *theory* about the self (see Epstein, 1991; Markus, 1980; Sarbin, 1980). These scholars addressed this contention for adults, forcefully arguing that our species has been designed to cognitively create *theories* about our world, including the construction of a *theory of self*, which makes meaning of our personal experiences.

With the advent of neo-Piagetian formulations of cognitive development (Case, 1991, 1992; Fischer, 1980; Fischer & Bidell, 2006), attention turned to how changing cognitive structures determined the very nature of the self theory that children and adolescents construct at different periods of development (see Harter, 1999). As cognitive processes undergo normative-developmental change, so will the *content* and very *structure* or organization of self undergo alterations. That is, the particular cognitive limitations and advances at each developmental period will dictate the emerging features of the self-portrait. I first suggested (Harter, 1999) a new conceptual framework, arguing that the influential cognitive-developmental processes be thought of as *I-self* processes. These, in turn, are central to corresponding changes in the content and structure of the *me-self*, namely, the resulting self-descriptions as the product, the image in the mirror, as it were. I have subsequently (Harter, 2012) expanded upon this conceptualization and will share some of that thinking here. I have distinguished between three levels of childhood (early, middle, and late) as well as three levels of adolescence (early, middle, and late). The reader interested in illustrative cameos of representative self-description at each of these six stages is referred to Harter (2012).

James's I-Self Functions: Self-Awareness, Self-Agency, Self-Continuity, and Self-Coherence

Although James (1892) struggled with the concept of the I-self, he nevertheless afforded it certain functional properties, certain positive characteristics. However, he did not speak to how these functions might be defined differently, or change, as a result of development. Thus, these will also briefly be addressed over the six periods of development that have been our focus. For the most part, this will cast the I-self in a more favorable light, with a job description more promising than the negative portrayal of the dark side

of the I-self's more odious duties. A developmental analysis of these positive functions, as well as how the I-self's role contributes to both normative descriptive characteristics of the me-self, including transient liabilities, will now be addressed.

Very Early Childhood (Ages 2–4)

During very early childhood, the I-self can craft only very concrete cognitive representations of the me-self, observable features of the self (e.g., I am a boy, I have a TV in my room, I have a kitty that is orange). Damon and Hart (1988) refer to these as categorical identifications, reflecting the fact that the young child understands the self only as separate, taxonomic attributes that may be *physical* (e.g., I have blue eyes), *active* (e.g., I can run real fast), *social* (e.g., My mommy and daddy love me), and *psychological* (I am happy). As Rosenberg (1979) cogently observed, the young child acts as a demographer or radical behaviorist in that his or her self-descriptions are limited to characteristics that are observable.

From a cognitive-developmental perspective, the me-self representations of this period are highly differentiated or isolated from one another; that is, the I-self of the young child is incapable of integrating these compartmentalized representations of self and thus self-descriptive accounts appear quite disjointed. This lack of coherence is a general cognitive-characteristic that pervades the young child's thinking across a variety of domains. As Piaget (1960) observed, young's children thinking is transductive, in that they reason from particular to particular, in no logical order. From the perspective of self-development, the I-self cognitive processes are unable to coordinate the attributes of the me-self.

Neo-Piagetians have elaborated on these processes. For example, Case (1992) refers to this level as *interrelational*, in that young children can forge rudimentary links in the form of discrete event-sequence structures that are defined in terms of physical dimensions, behavioral events, or habitual activities. However, they cannot integrate two such structures, in part because of working memory constraints that prevent young children from holding several features of the self in mind simultaneously (see also Griffin, 1992). Fischer's (1980) formulation is very similar. He labels these initial structures *single representations*. Such structures are highly differentiated from one another because the child is incapable of integrating single representations into a coherent self-portrait. Thus, the I-self processes of this period allow for little coherence in the self-descriptive narrative, which constitutes piecemeal and seemingly random, unrelated features of the me-self.

However, those characteristics that might be considered normative limitations are not really liabilities in any serious sense of the term. In fact, as has been argued elsewhere (Harter, 1999, 2012) they may serve motivational functions that propel young children to develop new skills in the absence of subjective cognitive scrutiny.

Jamesian I-Self Functions

Very young children (ages 2–4) have emerged from an earlier stage in which they mastered bodily self-awareness, they know what they look like as the *self-recognition* mirror paradigm has documented (see Berthenthal & Fischer, 1978; Lewis & Brooks-Gunn, 1979; Rochat, 2003). Subsequently, during very early childhood, self-awareness takes on more psychological manifestations, namely, the verbalization of self-referential attributes and behaviors. That is, linguistically the young child can now *describe* the self.

One feature of self-awareness at this substage of early childhood is the labeling of *internal states*, primarily basic emotions. By age 3, most children are able to describe their experiences of being happy, mad, sad, and scared (Bretherton & Beeghley, 1982; Harter & Whitesell, 1989; Kring, 2008).

A second manifestation of the I-self is a sense of *agency*, the conviction that one has control over one's actions and thoughts (see Lewis, 2008; Thomson, 2006). As a causal agent, one's actions have a predictable impact on others or the environment. Thus, a prototypical young child might describe how he can kick a ball really far and can count up to 100 if there is an audience to listen.

A third rudimentary I-self function at this age level is the sense of *continuity* or physical *permanence* over time (Nelson, 2003; Rochat, 2003). There is the realization that the self is invariant over time, even given changes in outward appearance (e.g., wearing different clothes, changing their hair). There is considerable agreement (Fivush & Haden, 2003) that *autobiographical memory* is critical to a sense of continuity. Creating self-*narratives* represents a primary mechanism by which a sense of continuity is established. Finally, the I-self must construct a sense of *self-coherence*, meaning that the different parts of the self are unified. This I-self function is less at issue at this developmental level because the self is highly differentiated, if not fragmented. Self-coherence will, however, because an important issue in mid- to late adolescence, as our own work has documented (Harter, 2012).

Early to Middle Childhood (Ages 5–7)

The hallmarks of me-self descriptions at this age level include competencies (e.g., I am good at my schoolwork),

physical skills (I can climb high on the jungle gym), and social skills (I have a lot of friends). However, the self-portrait is one of total virtuosity (e.g., I can do lots of stuff, real good! If you are good at things you can't be bad at things. Maybe *other* kids can't do certain things, but not me!). Thus, all-or-nothing thinking is still pervasive.

With regard to the cognitive-developmental advances of this period, what I am labeling as *I-self processes*, children at this age begin to display a rudimentary ability to inter-coordinate concepts that were previously compartmentalized (see Case, 1985; Fischer, 1980). For example, they can form a category or representational set that combines a number of their competencies (for example, good at running, jumping, climbing and throwing, or knowing their numbers, letters, and words). However, all-or-none thinking persists. In Case's (1985) model and its application to the self (Griffin, 1992), this stage is labeled *unidimensional* thinking. At this age, such black and white thinking is supported by another new cognitive process that emerges. The novel acquisition is the child's ability to link or relate representational sets to one another, to map representations onto one another, to use Fischer's terminology. However, of particular interest, with implications for self-development, is one type of representational mapping that is extremely common in the thinking of young children, namely, a link in the form of *opposites*. For example, in the domain of physical concepts, young children can oppose up versus down, tall versus short, thin versus fat or wide, although they cannot yet meaningfully coordinate these representations.

The ability to construct opposites, an I-self process, can also be observed within the descriptions of self and others, where the child's ability to oppose *good* and *bad* is especially salient. The child develops a rudimentary concept of the self as good at many skills. Because good is defined as the opposite of bad, this cognitive construction precludes the young child from being bad. Thus, an oppositional mapping (Fischer's term) takes the necessary form of "I'm good and therefore I can't be bad." However, others can be bad. Thus, this I-self structure leads the child to over-differentiate favorable and unfavorable attributes. These limitations extend to the inability to integrate such attributes as *nice* and *mean* (Fischer & Biddell, 2006), *smart* and *dumb* (Harter, 1986), or emotions such as *happy* and *sad* (Harter & Buddin, 1987). This mapping structure leads to the persistence of me-self descriptions laden with virtuosity.

Thus, the inability to acknowledge that one can possess both positive and negative attributes or emotions represents a normative cognitive liability that is a hallmark of this period of development. Moreover, due to greater linguistic abilities, the child is now able to verbally express his or her staunch conviction that one cannot possess both positive and negative characteristics, simultaneously. As one 5-year-old interviewee vehemently asserted: "Nope, there's no way you could be both smart and dumb, you only have one mind!" An interesting 5-year-old's insight, from the perspective of how the me-self is dependent upon I-self processes!

What might be considered to be the limitations of this period, for example, all-or-none thinking, the inability to coordinate positive and negative attributes (e.g., being both nice and mean) do *not* appear to be major normative liabilities in terms of the functioning of young children. Parents and teachers, who know children well, who have seen them pass through these phases normatively are not troubled by these manifestations. Toward the end of this period, parents or teachers may engage in dialogue with children to begin the exploration into how one can be both nice and mean, happy and sad, providing age-appropriate relevant examples that may facilitate the child's development to the next normative stage. As always, cognitive development can be enhanced with appropriate social interventions.

Jamesian I-Self Functions During Early to Middle Childhood

Self-awareness, self-agency, and self-continuity I-self processes undergo several developmental advances at this next level, ages 5 to 7, that Rochat (2003) described as one of *metacognitive self-awareness*. Children become more cognizant of how they are viewed in the public eye, attempting to simulate how the minds of others are constructing an image of them. Improved, but still limited, perspective-taking skills allow children to observe others evaluating the self (Selman, 1980, 2003).

This awareness is consistent with Nelson's (2003) concept of a *cultural self* that emerges during this period. The child's autobiographical self-history, codified in narratives, comes to be crafted in accordance with a cultural framework that dictates roles, institutions, and values. For example, these may include occupational choices that are likely to reflect gender stereotypes such as fireman, doctor, and professional athlete (for boys) and teacher, nurse, and mother (for girls). Behavioral norms are also salient (e.g., I'm learning why it is important for girls and boys to act differently). Bem (1985) observed that gender schemas not only dictate the *content* of stereotypes but also highlight that it is initially important to adhere to these cultural directives.

In the construction of *narratives*, children take an increasingly active role in telling their autobiographical

story, displaying a greater sense of *self-agency*. They incorporate their own personal experiences and mastery efforts and their successes. In addition, children, as architects of their narratives, are more likely to underscore *intentions* and future plans. These promote a greater sense of *self-continuity*, as children project their narratives into the future.

Middle-to-Late Childhood (Ages 8–10)

In contrast to the more concrete behavioral representations of younger children, older children are much more likely to describe the me-self in terms of generalizations such as *popular, helpful, nice*, *smart*, *mean*, and *dumb*. Children at this age level can now acknowledge that they can possess both positive and negative attributes. In addition to making reference to cognitive competencies *and* limitations, self-attributes become increasingly *interpersonal*, as relations with others become more salient dimensions of the self (see Damon & Hart, 1988; Harter, 2006).

From the standpoint of emerging cognitive-developmental processes that define the I-self, atttributes represent traits in the form of generalizations, based upon the integration of more specific behavioral features of the self (see Fischer, 1980; Siegler, 1991). For example, a generalization that one is smart, can be based upon the integration of scholastic success in both language arts and social studies. One may also feel dumb based on a generalization combining poor performance in both math and science. Popular may also combine several behaviors such as being nice, helpful, and good at keeping secrets.

A second I-self cognitive advance is the realization that one's self-attributes can be both positive and negative, in contrast to the all-or-none thinking that dominated the two earlier periods of childhood. As one 9-year-old thoughtfully observed, "I now realize that I can be both smart and dumb, you aren't just one or the other." Thus, what were formerly contradictory opposing attributes that could not co-exist in one's self-portrait can now be acknowledged by the I-self as realistic me-self descriptions that can simultaneously be integrated. These processes also apply to *emotion* concepts in that children can now also appreciate the fact that they can experience both a positive emotion (e.g., happy) and a negative emotion (e.g., sad) simultaneously (Harter & Buddin, 1987).

Children at this age can, for the first time, construct a higher order concept of their global self-worth or self-esteem. This construction involves, as James (1892) contended for adults, an evaluation of their competence or adequacy across those domains of their life in which success is *important*. Our own research has provided considerable documentation that this theory of the causes of self-esteem is alive and well, beginning at about age 8 (see Harter, 1999).

Also central to the construction of a concept of one's global self-worth is the contribution of Charles Horton Cooley (2002), who argued that a different process guided the formation of such a global concept. In his formulation of the looking-glass self, he argued that significant others function as psychological mirrors into which we gaze, to attempt to determine what *others* think of the self. These perceptions are then integrated into one's personal construction of their perceived worth as a person. Our own findings document Cooley's contention, at this period of development, not as an alternative theory competing with James' formulation, but one that complements it (Harter, 1999). Thus, advances in the I-self's cognitive ability to integrate diverse information about the me-self's competence as well as the importance of success in different domains (bolstering James' formulation) as well to take the perspective of another's evaluation of one's self and integrate it in one's global sense of worth of esteem (Cooley's contention) each emerge at this period of development.

Liabilities at this stage may ensue, if certain perceptions are less than accurate. For example, a child may overestimate or underestimate the level of one's competence in a given domain, given lack of experience in coordinating objective evidence of success (in the classroom, on the playing field, in social situations) into realistic subjective self-perceptions. Similarly, a child may not yet be sufficiently skilled at reading the perspectives of others who may be judging the self. Perspective-taking undergoes developmental change, as Selman's work (1980, 2003) has clearly demonstrated. Thus, there are subsequent skills to master in order to arrive at a realistic evaluation of the self, particularly one's authentic self, a topic to which we shall return, as we move into the stages of adolescence. However, there is definite improvement in perspective taking during later childhood, as we next address, in identifying James's I-self functions.

Jamesian I-Self Functions During Middle to Late Childhood

Perspective-taking skills improve dramatically between the ages of 8 and 10, facilitating increasing *self-awareness* (see Selman, 1980, 2003) and decreasing egocentrism. The standards and opinions of others become more internalized because the child can more clearly determine whether external expectations are met.

Narratives reflect a more mature sense of *agency* and *self-continuity*. Autobiographical memory is primarily dictated by personal experiences as the child becomes the major author of his or her life story, not merely the

narrator, previously incorporating input from parents. Agency is also observed in perceptions of both academic and social *self-efficacy*, expectations about what one can achieve in challenging circumstances (Bandura, 1977, 2006; Maddox & Gosselin, 2003). For example, a child may know how she can do well in certain school subjects and understands what it takes to be liked. The personal ownership of narratives, in consort with greater memory capacities, increased linguistic abilities, and a sense of self-efficacy all provide an increasing sense of *self-continuity*. Moreover, the child's *cultural self* (Nelson, 2003) expands during these years, as the child further adopts the standards and values of the larger society.

Interlude: Limitations of Piaget's Theory of Adolescent Cognitive Development, Applied to the Self

Adolescence represents a dramatic developmental transition, with pubertal and related physical changes as well as cognitive-developmental advances. With these new I-self cognitive acquisitions, adolescent development introduces the ability to think abstractly (Case, 1985; Fischer, 1980; Fischer & Bidell, 2006; Flavell, 1985; Harter, 1999, 2012; Higgins, 1991; Piaget, 1960). From a Piagetian perspective, the capacity to form abstractions emerges with the stage of Formal Operations in early adolescence. These newfound acquisitions, according to Piaget, should equip the adolescent with the hypothetico-deductive skills to create a formal theory. This observation is critical to the topic of self-development, given the claims of many earlier scholars (e.g., Epstein, 1973, 1981; Greenwald, 1980; Kelly, 1955; Markus, 1980; Sarbin, 1962) that the self is a personal epistemology, a cognitive construction, a theory that should possess the characteristics of any formal theory. Therefore, a self-theory should meet those criteria by which any good theory is evaluated. These criteria include the degree to which a theory is parsimonious, empirically valid, internally consistent, coherently organized, testable, and useful. Given Piaget's formulation, entry into the period of formal operations should make the construction of such a theory possible, be it a theory about entities in the world or a theory about the self.

As will become apparent, however, the self-representations constructed by the I-self during early and middle adolescence fall far short of these criteria. Self-representations are not coherently organized, nor are the postulates of the self-portrait internally consistent. Moreover, many self-attributes fail to be subjected to tests of empirical validity; as a result, they can be extremely unrealistic. Nor are self-representations particularly parsimonious, quite the contrary. There is little self-coherence. Thus, the Piagetian framework fails to provide an adequate explanation for the dramatic developmental changes in the me-self that can be observed across the substages of adolescence. Nor does it account for why the self does not meet the requisite criteria to qualify as a formal theory. A *neo*-Piagetian approach is needed to understand how changes in cognitive-developmental I-self processes result in both the organization and content of a very different me-self, at three levels: early adolescence, middle adolescence, and late adolescence. Each of these periods is next addressed, beginning with early adolescence.

Early Adolescence (Ages 11–13)

Many of the me-self descriptions to emerge in early adolescence represent *abstractions* about the self, based on newfound I-self cognitive abilities that integrate trait labels into higher order self-concepts (see Case, 1985; Fischer, 1980; Fischer & Bidell, 2006: Flavell, 1985; Harter, 1999; Higgins, 1991). For example, the young adolescent can construct an abstraction of the self as intelligent, by combining such traits as smart, curious, and creative. Alternatively, one may create an abstraction that the self is an airhead, given situations in which one feels dumb, scholastically inadequate, or just downright stupid. Similarly, an adolescent could construct an abstraction that he or she is an extrovert (integrating the traits of talkative, cheerful, and funny in social situations) as well as that he or she is also an introvert in certain interpersonal situations (where one is shy, uncomfortable, and nervous). Thus abstractions represent advances in the form of more cognitively complex representations now constructed by the I-self, whereby trait labels can now be appropriately integrated into even higher order generalizations that apply to the me-self.

Although the ability of the I-self to construct such abstractions represents a cognitive advance, these representations are highly compartmentalized; that is, they are quite distinct from one another (Case, 1985; Fischer, 1980; Fischer & Bidell, 2006; Harter, 1999; Higgins, 1991). For Fischer, these single abstractions are therefore over-differentiated, and therefore the young adolescent can only think about each abstraction as an isolated self-attribute. According to Fischer, structures that were initially observed in childhood reappear, but at a new abstract level. Thus, just as single representations were compartmentalized during early childhood, Fischer argues that when the adolescent first moves to the level of abstract thought, the I-self lacks the ability to integrate the many single abstractions that are constructed to define the me-self in different relational contexts. As a result, young adolescents will engage in all-or-none thinking at an

abstract level. For Fischer, movement to a qualitatively new level of thought brings with it lack of cognitive control on the part of the I-self. Therefore, adolescents at the level of single abstractions can only think about compartmentalized self-attributes, one at a time, but not simultaneously. Thus, contrary to earlier models of mind (Piaget, 1960), in which formal operations supposedly usher in newfound cognitive-developmental abilities that should allow one to create an integrated theory of self, fragmentation of self-representations during early adolescence is more the rule than the exception (Fischer & Ayoub, 1994; Harter, 1999, 2012; Harter & Monsour, 1992).

Compartmentalization of these abstract attributes can also be observed in the tendency for the young adolescent to be *unconcerned* about how certain postulates appear inconsistent across different roles and relationships. Thus, the fact that the self-portrait lacks consistency or coherence at this stage of early adolescence is not distressing. However, the inability to integrate seemingly contradictory characteristics of the self (e.g., intelligent vs. airhead, extrovert vs. introvert, cheerful vs. depressed) has the psychological advantage of sparing the young adolescent potential *conflict* over opposing attributes in his or her self theory (Harter, 1999; Harter & Monsour, 1992).

Moreover, as Higgins (1991) observes, the increased differentiation functions as a cognitive buffer, reducing the possibility that negative attributes in one sphere may spread or generalize to other spheres (see also Linville, 1987; Simmons & Blyth, 1987). Thus, although the construction of multiple selves across roles and relationships sets the stage for attributes to be contradictory, most young adolescents do not identify potential inconsistencies or experience conflict within their self-portrait, given the compartmentalized structure of their self-representations. However, the inability to integrate one's various attributes at this stage has liabilities for important Jamesian I-self functions to next be discussed.

Jamesian I-Self Functions During Early Adolescence (Ages 11–13)

Early adolescence marks the beginning of intense self-consciouness, a heightened concern with the reflected appraisals of others (Harter, 1999, 2012; Lerner, 2002; Rosenberg, 1986). S*ocial awareness* increases dramatically, leading to a greater self-awareness of how one's attributes are viewed by others, particularly because different significant others hold varying opinions of the young adolescent. This preoccupation and uncertainty contributes to the beginning of introspection, self-reflection, and rumination (see Selman, 1980, 2003), particularly about one's negative characteristics. Thus, self-awareness is a mixed blessing.

Moreover, the compartmentalization of role-related attributes, as multiple selves abound, also represents a double-edged sword. It spares young adolescents the psychic pain of acknowledging contradictory attributes in their self-portrait. However, it interferes with the I-self functions of agency, and self-continuity, particularly its corollary of self-coherence. There is no integrated sense of self with which one can imbue intention and future directions.

Middle Adolescence (Ages 14–16)

New cognitive I-self processes emerge during middle adolescence, giving the self-portrait a very new look (Fischer & Bidell, 2006; Harter, 1999, 2012). Whereas in the previous stage single abstractions were psychologically isolated from each other, during middle adolescence the I-self acquires the ability to make *comparisons* between single abstractions. Fischer labels these new structures abstract mappings; the adolescent can now map constructs about the self onto one another, that is, directly compare them. Such mappings force the individual to compare and contrast different attributes as they become increasingly salient. It should be noted that abstract mappings have features in common with the representational mappings of children, in that the cognitive links that are initially forged take the form of *opposites*. During adolescence, these opposites reflect contradictory *abstractions* about the self (e.g., extrovert vs. introvert, tolerant vs. intolerant, responsible vs. irresponsible, good-looking vs. unattractive).

Noteworthy is the fact that the abstract mapping structure that the I-self imposes on the me-self has serious limitations as a means of relating two concepts of self to one another. The ability to merely compare attributes simultaneously forces the individual to recognize troublesome inconsistencies within the self. However, the individual cannot yet truly integrate such self-representations in a manner that would resolve apparent contradictions. As a result, the awareness of these opposites causes considerable intra-psychic conflict, confusion, and distress (Harter, 1999; Harter & Monsour, 1992) given the inability to coordinate these seemingly contradictor self-attributes. For example, one adolescent interviewee agonized over whether she is an extrovert or an introvert (Am I just acting like an extrovert, am I just trying to impress them, when really I am an introvert?). Another adolescent expressed consternation over a different contradiction (So which am I, responsible or irresponsible, how can the same person be both?). Thus, the cognitive-developmental limitations of the I-self during middle adolescence contribute to the emergence of what James (1892) identified as the conflict

of the different me's, leading to major normative liabilities, to be overcome at the subsequent level.

Jamesian I-Self Functions During Middle Adolescence (Ages 14–16)

Development is not necessarily a linear progression toward some teleological end point. There is clearly a blip on the psychological radar screen at midadolescence. This point is often missed in classic treatments of development. *Self-awareness*, a Jamesian I-self function, previously manifest as the unreflective self-acceptance of one's attributes during earlier periods of development vanishes. What were previously unexamined self-truths, the basis for a durable self-image, now become troublesome self-hypotheses. The tortuous search for the self is made more difficult given the painful proliferation of multiple me-selves that now crowd the self-landscape (Harter, 1999). Self-awareness becomes quite intense, yet the images are not stable or enduring. It is much like a lighthouse beacon that flits from buoy to buoy, providing only fleeting glimpses of potentially troubled waters. By analogy, awareness quickly shifts from role to role where one's image of self is defined quite differently. Thus, a kaleidoscopic self emerges (Harter, 2012).

Another related I-self function, a sense of *self-coherence*, is compromised given the contradictory multiple selves that cannot be integrated. The self as a *causal agent* can also be problematic, given that the construction of multiple selves that do not speak with one voice. Thus, there is no efficacious self at the helm, precluding the perception that one is a causal agent in control. As such, it is difficult for adolescents in this period to project a clear sense of themselves into the future, and as a result, the search for *self-continuity*, links between one's past, present, and future selves, must be put on hold. For many adolescents, our own daughter included, one manifestation is the ever changing swirl of potential occupational choices, many of which seem contradictory. While it is healthy to consider options, it is difficult for those in midadolescence to logically think through how to make meaningful decisions. Nonjudgmental listening on the part of parents and other significant adults is critical, scaffolding a consideration of the pro's and con's supporting their own thinking, without heavy-handed suggestions or adult decisions.

Late Adolescence (Ages 17–19)

In contrast to middle adolescence, in late adolescence the many potentially contradictory attributes are no longer described as characteristics in opposition to one another. Thus, one can be both an extrovert as well as an introvert, responsible as well as irresponsible, both depressed and cheerful as well as conscientious as a student but also lackadaisical. With regard to the last of these attribute pairs, one of our interviewees explained: "That's normal, I mean you can't just be a total 'grind,' you'd be pretty boring if you were. You have to be *flexible*." He further explicated why introversion doesn't conflict with extroverted behaviors: "You have to be *different* around other people. It would be weird to be the same kind of person on a date or with my friends at a football game or with my mother!"

Some important I-self cognitive acquisitions allow the older adolescent to overcome some of the liabilities of the previous period, where opposing attributes were viewed as contradictory and a cause of internal conflict. The general I-self cognitive advances during late adolescence involve the construction of *higher order-abstractions* that allow for the meaningful intercoordination of single abstractions (see Case, 1985; Fischer, 1980; Fischer & Bidell, 2006; Harter, 1999, 2012). For example, the fact that one is both introverted and extroverted can be integrated through the construction of a higher order abstraction in which the self is adaptive. The observation that one is both depressed and cheerful can be integrated under the personal rubric of moody. Similarly, flexible can allow one to coordinate conscientiousness with the tendency to be lackadaisical. Thus, what were formerly troublesome inconsistencies in the me-self can now comfortably coexist.

In the English language we actually have particular linguistic terms that codify the integration of concepts that might appear to be contradictory. One of our older teenage interviewees utilized two such words in his description of his feelings about going off to college. "I want to be independent of my family but still want to remain connected to my parents, so I guess you could say that I am *ambivalent*. I am excited about going to college but sad over leaving my parents; it's rather *bittersweet*." Such higher order abstractions provide self-labels that bring meaning and therefore legitimacy to what formerly appeared as troublesome contradictions within the self. They allow the older adolescent to *normalize* potentially inconsistent attributes within their personality. Thus, we have observed how at every developmental level, the I-self is at the helm, in creating an age-appropriate portrait of the me-self.

Jamesian I-Self Functions During Late Adolescence (Ages 17–19)

Limitations of the preceding period are overcome as a result of cognitive-developmental acquisitions during late adolescence (Case, 1985; Fischer, 1980). One critical cognitive advance is the ability to construct higher order

abstractions that provide a meaningful integration of single abstractions that previously represented contradictions (e.g., depressed and cheerful no longer conflict because they are combined into the higher order abstraction of moody). The older adolescent can also resolve potentially contradictory attributes (e.g., studious versus lackadaisical) by asserting that one is flexible or adaptive, thereby subsuming apparent inconsistencies under more generalized abstractions about oneself. Each of these new acquisitions sharpens the accuracy of the I-self's *self-awareness,* a Jamesian I-self function. Through these mechanisms, conflict over previous contradictions in one's self-portrait abates (Harter & Monsour, 1992). Thus, self-awareness is also reflected in the older adolescent's recognition of these cognitive strategies and their effectiveness.

Characteristics reflecting personal beliefs, values, and standards become even more internalized. The focus on future or possible selves (see Markus & Nurious, 1986) also gives the older adolescent some sense of direction, albeit often idealistic. Thus, compared to midadolescence, the teenager at this stage demonstrates a greater sense of *agency* as well as self-continuity. In addition, the ability to construct higher order abstractions that resolve the many contradictions of the previous period allows for a much more integrated and *coherent* self-portrait. In addition, older adolescents can now construct a self with a greater sense of *self-continuity* that can aid in plans and projections for the future. Theoretically, this would be the ideal; however, there are impediments given cultural dictates and demands that can lead to pathologies, to which we next turn.

SELF-ENHANCEMENT AND SELF-SERVING BIASES: THE I-SELF/ME-SELF CONSPIRACY

We have observed how the I-self, defined as age-appropriate cognitive processes, constructs a changing me-self at different stages during childhood and adolescence, a worthy goal. However, there is a downside to this endeavor. The I-self is also required to devote time and energy in efforts to enhance and package the me-self in a way that meets with societal expectations. However, this protective preoccupation with the self is a contemporary cause for concern.

There is not unequivocal support for such a position. Some (see Alicke & Sedikes, 2009) make a case for how self-enhancement is *normative*, in describing optimistic cognitive illusions, viewing the self as having more personal control than might be warranted, and better life circumstances, than others would describe about them. In so doing, they emphasize the many positive, self-protective strategies. Those not engaging in such biases are more likely to experience depressive reactions.

However, we concur with Leary (2004) that there are costs of self-enhancing strategies, self-serving biases, unrealistically inflated self-perceptions, self-aggrandizement, narcissistic fantasies of omnipotence, and other illusions about the self that have been amply documented among adults, leading Leary (2004) to refer to the *curse of the self*. Adults engage in downward social comparisons to make themselves look better, they claim to be better than average, they take more responsibility for their successes than failures (blaming external factors for one's personal misfortunes), and they believe that they are special or have unique talents (the false uniqueness effect). Finally, they are unaware of these biases, acknowledging them in others but not in themselves. These self-serving behaviors threaten relationships with others and have personal costs, one of which is they jeopardize *authenticity*. The true self can become seriously compromised for adults by narcissistic tendencies to inflate, becloud, and distort the real inner self, in desperately seeking social approval, admiration and associated gain (see Harter, 2012). In sum, the I-self is at the helm, actively packaging the me-self, in the service of meeting these potentially destructive goals.

However, just what are the *developmental prerequisites* necessary to engage in these processes? At each of the same six developmental levels, three in childhood and three in adolescence, we can ask three questions:

1. What determines the need or *motive* to pursue various self-enhancement goals at a given substage? Why might one be driven to enhance and protect the self?
2. At each developmental level, what cognitive *skills* or *mechanisms* are available to the I-self to engage in such self-serving strategies? We cannot assume that the mature I-self processes accessible to adults are operative during the developmental stages of childhood and adolescence. At what point, therefore, do self-serving biases merge into narcissism and become more pathological?
3. What are the *consequences* of engaging in developmentally determined self-enhancement strategies or self-serving biases, and when do they become truly compromising?

Self-Enhancement Strategies During Very Early Childhood

Critical to this assessment is the observation that very young children's self-reports are overly positive and inaccurate, for several reasons that involve the developmental limitations of the I-self. First, young children lack the

cognitive ability to engage in *social comparison for the purpose of self-evaluation*. From a cognitive-developmental perspective (Piaget, 1960), social comparison requires that one be able to hold two dimensions in mind simultaneously, actively comparing an evaluation of one's own characteristics to another's. This exceeds the cognitive capacity of the very young child's I-self.

Second, one can observe the rudimentary use of *temporal comparison*, an awareness that one's current skills greatly exceed those of the not-so-distant past (see Harter, 2012), leading to an overestimation of young children's abilities, by social-comparative standards. For example, young children may boast that they can run faster than when they were younger, which is true. Temporal comparisons are particularly salient and gratifying given that skill levels change rapidly during this age period and thus improvement is quite noticeable. An appreciation for these advancements contributes to the overestimation of one's competencies.

A third limitation of the I-self processes in young children is their inability to distinguish between their *actual* self-attributes and their *ideal* self-attributes. As a result, self-evaluations are unrealistically positive since the fusion or confusion of the two judgments favors idealization. These overly positive evaluations reflect the cognitive limitations of the I-self rather than purposeful deceit (Harter, 2012).

Fourth, very young children lack the *perspective-taking* ability to understand and therefore incorporate the perceived opinions held by significant others (Harter, 2006; Selman, 1980, 2003; Thompson, 2006). Thus, the inability to fully comprehend that adults may be critical of them leads very young children to persist in overly positive self-evaluations. The I-self's cognitive prerequisites for Cooley's (1902) looking-glass self formulation, in which the opinions of others are recognized and incorporated into the me-self, are lacking in very young children.

Fifth, cognitive limitations also lead to young children's inability to acknowledge that they can possess both positive and negative self-attributes (Case, 1985; Fischer, 1980; Fischer & Bidell, 2006; Harter, 1999, 2012). That is, the all-or-none thinking characteristic of this age level extends to children's evaluations of themselves. They must be unilaterally positive in most young children.

For all of these reasons, very young children's self reports will naturally be overly positive and inaccurate. However, do they constitute the conscious self-enhancement efforts that have been described for adults? While some (see Trzesniewski, Kinal, & Donnellan, 2010) view these normative self-biases as similar to the types of self-enhancing strategies observed in adults, my own developmental perspective suggests a different interpretation. First, young children do not need to tactically enhance perceptions of competence because their self-evaluations are already normatively inflated! Thus, they do not possess the *motives* that propel adults' tendency to enhance themselves, namely, to protect or conceal fragile or negative self-images. Second, the *mechanisms* employed by adults are not yet in place (e.g., downward social comparisons, false uniqueness processes, attempts to reduce ideal-real self-image disparities, social perspective taking). Third, the consequences are quite different. The normative exhibitionistic displays of young children are typically endearing and meet with social adult approval. In contrast, the self-centered grandiosity among adults, evoked to protect a damaged self, blinds narcissists to their shortcomings and does not elicit support from others; rather it provokes rebuffs or rebukes.

The very young child's desire to be the center of attention, *normative narcissism*, is age appropriate compared with pathological forms of narcissism where these concerns are excessive (see Kernberg, 1975, who has articulated the distinction between normative and pathological narcissism). The exhibitionism among healthy children is typically warm and engaging, whereas in pathological narcissism, the demands for constant admiration are defensive and generally not socially welcome.

One can also observe the seeds of the construction of a false me-self, by the I-self, given processes that build upon unrealistic self-perceptions, compromising one's sense of authenticity. The emergence of *language*, another I-self function, represents a double-edged psychological sword in this regard. Language clearly promotes heightened levels of relatedness and allows for the creation of a personal narrative. Stern (1985), however, also alerted us to the liabilities of language, which can drive a wedge between two simultaneous forms of interpersonal experience, as it is lived and as it is verbally represented. The young child can distort his or her immediate experience and create a fantasized or falsified construction of the self. Such distortions may contribute to the rudimentary formation of an inauthentic self, if the child accepts the falsified version of experience.

Self-Enhancement During Early to Middle Childhood (Ages 5–7)

Because the I-self of young children is not yet cognitively equipped to develop a general concept of one's worth as a person (see Harter, 2012), there is no global

self-esteem to enhance! The normative overestimation of competencies described for the previous period continues, for the most part, to persist, including: (1) the inability of the I-self to engage in *social comparison* for the purpose of self-evaluation; (2) the use of *temporal comparison* highlighting greater skill levels compared with previous competencies; (3) the inability to differentiate one's *actual* self attributes from one's *ideal* attributes; (4) the *lack of perspective-taking,* which precludes an appreciation for the evaluations of significant others; and (5) the inability to acknowledge that the me-self is composed of both positive and negative characteristics. As such, self-perceptions continue to be inaccurate. These I-self limitations obviate the need to protect the me-self; there is no obvious *motive*. These unrealistically positive perceptions of competence are reinforced by all-or-none thinking. However, basically, young children do not possess the skills to engage in defensive or protective strategies. They may lie or blame a sibling in an attempt to conceal a transgression (Wilson, Smith, & Ross, 2003). However, their efforts are usually quite transparent and thus not that effective as self-protective strategies.

I-self processes identified in very early childhood will continue to set the stage for the development of false self-behavior. As noted for the previous stage, language provides the linguistic vehicle through which the child can falsify his or her experiences. As language becomes more proficient, and as the child plays an increasingly active role in constructing his or her autobiographical narrative, the development of a falsified self becomes increasingly possible. As one of our young interviewees revealed in describing his life story, "Some parts are make-believe but mostly they're true!" Thus, the child has a basic notion that the content can be distorted. Wolf (1990) has described several mechanisms such as deceit and fantasy, whereby the child at this age, as author of his or her self narrative, can select, edit, or change the facts in the service of personal goals, hopes, or wishes (see also Dunn, 1988). This linguistic-cognitive backdrop of I-self processes can pave the way for a lack of authenticity.

Narcissism continues to be *normative* at this age level. This includes fantasies of success, wealth, power, and fame that are probably less than realistic. These include positive autobiographical stories, peppered with fanciful projections into the future, grandiose aspirations and wishes about who or what one will become when one grows up. The normative narcissism at this age level is associated with more conscious exhibitionism; there is more awareness of the impact on one's audience, as the child shows some budding showmanship. Nevertheless, these behaviors are still within the normative bounds of age-appropriate narcissism.

Self-Enhancement During Middle to Late Childhood (Ages 8–10)

Advances heralded as hallmarks of development usher in the potential for various self-protective strategies to emerge. First and foremost, the newfound I-self capacity to forge a concept of one's global self-esteem, unavailable to younger children (see Harter, 2012) raises the psychological specter that feelings of worth may need to be protected or defended. Greater perspective-taking skills allow the older child to realize that there is a wider, observing audience whose members are also evaluating the self. This, in turn, can provoke self-consciousness and the need to develop strategies to ensure the I-self's positive self-evaluations of the me-self. The increased ability to engage in social comparison also makes one's self-appraisals more vulnerable. Thus, advances during this period paradoxically may produce new *needs,* demanding that new I-self skills be devoted to the protection and enhancement of the me-self. What new skills might promote such strategies?

First, sensitivity to social comparison allows one to capitalize on this awareness and to submit others to *downward social comparison*. Thus, the I-self can implicitly or explicitly compare oneself with peers considered inferior, thereby enhancing the me-self. Older children can now adopt the *better-than-average* strategy as well as make attributions that one is more successful than others in areas of greatest social importance, thereby elevating their self-esteem.

Thus, increased perspective-taking skills emerge, but they are not necessarily utilized toward the greater good of peers. They might also be employed in the service of *impression management*, playing to the prevailing peer standards of what is cool or awesome. Newfound perspective-taking skills can also be used to one's advantage, by manipulating peers to meet one's own needs and desires (Selman, 1980, 2003). The older child can engage in psychological attempts at persuasion, convincing others to view things from his or her own perspective. One is reminded of Tom Sawyer, who conned his peers into believing that his job of painting the fence was a desirable enterprise.

Older children can also engage in a practice first identified by James (1892), who viewed self-esteem as a balance between perceptions of domain-specific competencies and the *importance* of success attached to these domains. The I-self can *discount* the importance of domains in which one is not meeting one's expectations, thereby preserving and protecting the me-self.

Therefore, the period of middle to late childhood ushers in new critical acquisitions that forecast the need to engage in self-enhancement strategies. First, there is the emergence of the concept of one's global self-esteem and second, the acknowledgement of negative self-appraisals, present new *motives* for self-protection and enhancement. Third, new cognitive-developmental skills (e.g., social comparison abilities, enhanced perspective-taking skills and discounting) equip the older child with the *capacity* to engage in self-protection, self-enhancement, and self-presentation.

Another potential negative is that true-self behavior may become eroded, as the older child can better evaluate the self unfavorably, with the realization that significant others, particularly peers, may also have unfavorable views of one's me-self. This vulnerability may alter the self that is presented to the social world, leading to frantic efforts to regain favor in the eyes of others. Thus, false-self behavior may become more prevalent, given increasing I-self management skills designed to protect a potentially fragile me-self.

Earlier *normative* narcissistic features begin to fade in middle to late childhood, as children become better able to accept their flaws, adopting a more balanced perspective on their strengths and weaknesses (Bardenstein, 2009). However, new *pathological* manifestations of narcissism emerge (Bleiberg, 1994). The older narcissistic child lacks empathy for others' feelings and intentions. Grandiosity, an inflated sense of self coupled with impulsivity, precludes a tolerance for outcomes that are not immediately successful. Others are blamed for one's personal deficits, compromising relationships (see Bardenstein, 2009; Kernberg, 1998). The narcissist's sense of superiority and entitlement leads to the exploitation and manipulation of peers. Preoccupied with protecting a fragile sense of self, narcissistic children devalue others and if criticized, display rage. Narcissists may self-select relationships with weaker peers who will reinforce their grandiose self views (Carlson & Gjerde, 2009). They seek to dominate social interactions, to impress others and to gain admiration rather than to establish genuine friendships or close relationships (Thomaes, Bushman, Stegge, Olthof, & Denissen (2008).

Self-Enhancement During Early Adolescence (Ages 11–13)

Normative strategies on the part of the I-self to protect and enhance the me-self are evident in early adolescence. The heightened preoccupation with others' perceptions of oneself, coupled with a focus on the discrepancy between the real and ideal self, conspire to produce an escalation in the *need* to protect and enhance the self. As one young adolescent told us, "It's important to act as if you really like yourself." Thus, there is an appreciation of the powerful motives for self-protection and self-enhancement. Moreover, young adolescents have certain requisite skills.

The increasing emphasis on *social comparison* provides a psychological stimulus for the strategy of *downward* social comparison. Although overt comparisons are frowned upon, successful students have the information to conclude that they are more scholastically competent than others, thereby protecting or enhancing the self. The criteria for social acceptance are quite clearly communicated by peers, leading the more popular young teenagers to conclude, through downward social comparison, that they are higher on the totem pole of popularity. Since only a few can rise to the top of the scholastic and social ladders, most young adolescents are vulnerable, fueling their motivation to enhance, or at least protect, their self-images.

Cognitive I-self skills to engage in certain adult attributional biases become available to the young adolescent. For example, successes can be attributed to internal, stable characteristics such as intelligence whereas failures are due to external factors such as an excessively difficult test. As a young adolescent interviewee recounted, "If I do well on tests, I tell myself it's because I'm smart. If I don't do well, it's because the test was too hard or the teacher didn't teach us what we needed to know." Another attributional bias for lack of success is the claim that one simply didn't study hard enough, implying that one could have done better, with increased personal effort.

Young adolescents also make use of Greenwald's (1980) concept of beneffectance, a self-protective strategy in which one's central or important attributes are touted as positive, whereas negative characteristics are relegated to the periphery of one's concept of self. However, these tactics can coexist with an I-self who may become preoccupied with protecting a me-self that is becoming increasingly false or phony.

Early adolescence brings with it (1) a greater appreciation of the meaning of false self behavior, (2) its greater salience in one's vocabulary, and (3) a preoccupation with its detection. Not until about age of 12 or 13 can young adolescents clearly define false self-behavior (Harter, 2012). Definitions focus on concealing what you really think or feel and saying things that you don't really believe. One adolescent participant struggled consciously with this issue: "I try to tell myself that what *I* think is the most important, that I should just be my true self. I shouldn't be phony and act like I'm somebody else. Except I *do*!" Young adolescents are sleuths and appear driven to detect hypocrisy. While they acknowledge some false

self behavior in themselves, they are far more likely to observe it in others (e.g., parents and peers). Anthony (1982) has described a new vocabulary that emerges at this stage. Young adolescents subject others' beliefs to scrutiny and criticism, attempting to expose the contradictions in parental arguments, values, and behavior. Thus, parents, in particular, are accused of hypocrisy, deflecting blame from the adolescent, which, in turn, should supposedly protect the me-self.

However, the young adolescent's self-perceptions are not necessarily *accurate*.

During the preceding period of late childhood, a number of cognitive-developmental advances promoted more realistic self-evaluations. However, the progression toward more accurate judgments is not necessarily linear. As noted earlier in the chapter, there are *liabilities* of advances to new levels of cognitive development, in this case, early adolescence (Harter, 2012). The young adolescent can now begin to construct abstractions about the self, for example, extravert and introvert. However, the more abstract the representation, the farther removed it is from concrete behavioral evidence. As a result, self-evaluations can lack convincing documentation, thereby leading to inaccurate self-evaluations.

Moreover, narcissism becomes a potential danger to the self at this age. The features of narcissistic personality disorders begin to emerge and can crystallize during early adolescence (Bleiberg, 1994) and become more stable (Bukowski, Schwartzman, Santo, Bagwell, & Adams, 2009). These include an omnipotent sense of self, refusal to acknowledge one's shortcomings, and unrealistic demands for public affirmation. Narcissistic disturbances invariably stem from concerns that one is ignored or not given sufficient attention, often coupled by doubts about one's ability to evoke positive responses from others.

Another source of narcissistic vulnerability is the realization that one's actual self does not conform to one's lofty aspirations (Joffe & Sander, 1967). Joffe and Sander observe that narcissistic vulnerability evokes *shame* given the deflation that accompanies the inability to measure up to one's ideal. Those with pathological forms of narcissism defensively deny any signs that they are failing to achieve self ideals. Their self-narrative contains illusions of power, omnipotence, control, perfection, and invulnerability resulting in a highly distorted sense of self. They cannot see past their own reflection. These self-aggrandizing fantasies conceal very fragile and unstable self-esteem, requiring high-maintenance personal efforts to obtain compensatory attention and admiration (Rhodewalt, 2006), efforts that may be doomed to failure.

Self-Enhancement During Middle Adolescence (Ages 14–16)

Our developmental analysis has focused on several themes, including the needs or motives fueling attempts to protect and enhance the self and, second, the skills to enact the various strategies that have been identified in adulthood. Although certain skills are in place (e.g., the ability to engage in downward social comparisons) contradictions between multiple selves may preclude a thoughtful consideration of just which selves should be protected or enhanced. The adolescent may be overwhelmed with the enormity of the challenge. Given that the adolescent at this stage is ill equipped to resolve the various contradictions in his or her self-portrait, he or she will be very ineffective in employing self-protective or self-enhancing strategies. One adolescent expressed this distress as follows. When she puts on her extraverted face, she asks, "Am I just trying to impress the other kids, when I am really an introvert?" Thus, there would appear to be a motive to engage in self-enhancement, although efforts are not particularly successful. The desire to enhance the self is powerful, although the skills may not be accessible.

Moreover, what may pass as normative narcissistic attempt to protect the self must be distinguished from more pathological forms of narcissism (Bleiberg, 1994; Lapsley & Stey, 2012). These theorists discuss this distinction within the context of a major developmental challenge during midadolescence, namely, the need to begin the process of separating from parents, to individuate, while at the same time remaining appropriately connected. In healthy adolescent development, teenagers maintain basically good relationships with parents, despite the squabbles and normative conflicts (Bleiberg, 1994). They build, and strive toward, an ideal self as they explore their expanding world. They struggle with the construction of realistic self-images in their pursuit of future goals, and in the process create their own personal fable. At this age, their narratives contain moderate feelings of *omnipotence*, a perception of *uniqueness*, and a sense of *invulnerability*, features of *adolescent egocentrism*, as initially described by Elkind (1967), further examined by Harter (2012). How, then, do these presumed normative characteristics differ from pathological manifestations of narcissism?

Lapsley and Stey (2012) offered several contrasts. Normative narcissism reflects (1) grandiosity without the exploitation of others, (2) illusions without a sense of entitlement, (3) expressions of invulnerability without shame, (4) a sense of omnipotence that doesn't risk the isolation from others, (5) the desire for realistic admiration versus the unrealistic demands for attention and preening

self-preoccupation, and (6) positive affect and warm relationships with others versus derision, lack of empathy, and envy. Thus, these distinctions mark the boundaries between normal and dysfunctional narcissism. Dysfunctional narcissism represents failed attempts at self-enhancement. Extreme grandiosity provokes desperate maneuvers on the part of the I-self to protect the me-self's very precarious self-esteem and illusory control. They display relentless addiction-like strivings to continually assert their superiority (Morf, Horvath, & Torchetti, 2001). However, such efforts are eventually unsuccessful, leading to consequences such as peer rejection because such an inflated self-portrait reflects unrealistic bravado. This, in turn, provokes negative social feedback. In addition, dysfunctional narcissism also leads to the alienation from one's authentic self (see Given-Wilson, McIlwain, & Warvurton, 2010; Nicholls & Stukas, 2012), particularly if they broadcast supposed evidence for their self-glorification (Wallace, 2011).

These processes also interface with the potential for the construction, by the I-self, of a false, me-self, which can become more pathological. The proliferation of multiple selves at this developmental juncture, coupled with the ability to detect potential contradictions between self-attributes displayed in different roles, naturally ushers in concern over which attributes define the true self (Harter, Bresnick, et al., 1997). Many of our participants have spontaneously agonized over which was their true self, the real me. An illustration of this preoccupation can be seen in the confessions of one 15-year-old girl. When she switches from being cheerful with friends to being nasty with parents, she asks, "Which one is the real me?" In obsessing over being both an extrovert and an introvert, she laments, "I don't know who I really am!" In admitting that she is both irresponsible with friends but responsible on the job, she queries: "So which am I, responsible or irresponsible, how can the same person be both?" She ends her self-reflection disclosing that she thinks a lot about "who is the real me, and I try to figure it out when I write in my diary, but I can't resolve it." Thus, from a normative perspective, the adolescent at this age level is ill equipped to solve these dilemmas. If the adolescent *ruminates* excessively about these contradictions, then more pathological thinking ensues. That is, the frantic I-self seems unable to protect the kaleidoscopic me-self (Harter, 2012).

Self-Enhancement During Late Adolescence (Ages 17–19)

Clearly, in late adolescence, cognitive advances in the form of higher order abstractions and efforts to *normalize* potential contradictions serve to reduce the distressing conflict and negative self-appraisals. In addition, efforts to discount lack of success in domains that are deemed unimportant are increasingly utilized as strategic attempts to maintain high self-esteem. As one older adolescent put it to us: "Let's face it, I'm not that popular, you have to be a jock in our high school to be really popular, but I have never been into sports, they just aren't important to me, that isn't where I put my energies. I have my own circle of friends, so being popular doesn't really appeal to me." Discounting the importance of athletic competence and popularity, domains in which one is not that successful is but one of many self-protective strategies.

However, other strategies, identified in the adult literature, become even more available to older adolescents, as their repertoire expands, allowing them to engage in self-enhancement, self-serving biases, and narcissistic tendencies. For example, the *better-than-average effect* can be observed in another adolescent's declaration that "I am more moral than the average person my age," a stance that also requires downward social comparison. Thus, most of the self-protective and self-enhancing strategies exhibited by adults are available to older adolescents. In addition, older adolescents, no longer as overwhelmed with the contradictions and confusion experienced in midadolescence, may be in a better position to facilely or skillfully execute and combine strategies, as the I-self attempts to better protect the me-self.

The issue of authenticity remains on the personal radar screen of older adolescents, although they are less likely to agonize about whether they, or their parents, are phony or hypocritical. That said, it remains a cultural preoccupation that one cannot avoid. The English language is rife with terms that speak to our societal concern with false self-behavior. As Lerner (1993) pointed out in her intriguing book *The Dance of Deception,* we have a vast vocabulary that signifies deceit. Verb forms refer to *fabricating, withholding, concealing, distorting, falsifying, pulling the wool over someone's eyes, posturing, charading, faking*, and *hiding behind a façade*. Adjectives include *evasive, elusive, wily, phony, fake, artificial, two-faced, hypocritical, manipulative, calculating, pretentious, crafty, conniving, duplicitous, deceitful*, and *dishonest*. Noun forms include *charlatan, chameleon, impostor, hypocrite, a fake*, and a *fraud*.

Given the cognitive and linguistic advances of older adolescents, their own vocabulary is likely to expand, as they become increasingly aware of how society chooses to verbally frame such deceitful activities and personal characteristics. Many manifestations primarily refer to verbal expression in which one's true belief and attitudes are suppressed and in their place, false opinions are endorsed.

However, as a strategy to gain or maintain approval, from both peers and parents, opting into this dance of deception may ultimately backfire. Our own findings reveal that those who display higher levels of false-self behavior within a given relational context (suppressing their voice, supplanting it with false assertions) report less peer approval and lower self-esteem (Harter, Waters, & Whitesell, 1997). Greater true self behavior is associated with higher self-esteem. Thus, those admitting to false self behavior devalue their worth as a person, raising a causal question for future research: Namely, which comes first? Does true versus false self behavior *precede* the corresponding high versus low self-esteem? Alternatively, does one's evaluation of his or her overall worth as a person dictate the perceived authenticity of the self?

Concerns about the prevalence of false-self behavior shade into links to *narcissistic* tendencies during the period of late adolescence. Characteristics of both normative and pathological narcissism emerged as salient during the previous period of midadolescence (Bleiberg, 1994; Lapsley & Stey, 2012) when a major developmental challenge is to begin, in earnest, namely, to separate from the family, to individuate. This theme can be activated or exacerbated for those in *late* adolescence when the end of high school looms large and separation issues come to the forefront if one is college-bound or moving out of the home due to job or new age-appropriate relationship demands. Leaving home can trigger excessive separation anxiety that, for those whose upbringing has put them on a path to maladaptive narcissism, can provoke rage at parents who are perceived as the perpetrators.

These reactions can be exacerbated in future adulthood when narcissistic individuals present themselves as grandiose and arrogant, creating an inflated impression of their self-worth; the motive is to avoid internalized feelings of inadequacy (LeCours, Briand-Malenfant, & Torchetti, 2011; Ruggiero, Veronese, Castiglioni, & Sassaroli, 2011). The causal role of pathological narcissism also has been found to result in aggressive behavior (Bushman & Thomaes, 2001; Thomaes, Bushman, Segge, Olthof, & Denissen, 2008). As Bushman and Thomas (2001) observe, when the narcissistic ego deflates, narcissistic aggression inflates. Others focus on the self-conscious emotions, namely, hubris (excessive pride), which becomes deflated and can be replaced by shame (Tracy, Cheng, Martense, & Robins, 2012). As Campbell and Buffard (2008) point out, while there are immediate benefits to narcissistic behaviors (feel-good temporary affective experiences), these backfire in that they are not well received by others, in most social circles.

Those who fit what Bleiberg (1994) has described as *histrionic exhibitionism* may become especially troubled over separation issues provoked by impending adulthood. Their excessive dependency upon parents, and their inordinate need for admiration that may not be forthcoming in their new environment, will not bode well at this developmental juncture. A healthier reaction to these new demands (see Bleiberg, 1994; Lapsley & Stey, 2012) can be observed among our own study participants in normative samples. For example, one older adolescent admitted to being ambivalent about going off to college and that leaving home will be bittersweet. Although he was looking forward to leaving home and going to college, he acknowledged, "It's a little nervous," and, "I'll probably always be somewhat dependent on my parents." He tries to reassure himself that "my parents will always be there for me."

Healthy reactions notwithstanding, Twenge, Konrath, Foster, Campbell, and Bushman (2008) reviewed convincing evidence that narcissism has clearly been on the rise over the past few decades in the United States. Other findings reveal that contemporary youth in this country display narcissistic over-confidence. Campbell, Goodie, and Foster (2004) reported findings indicating that today's students have markedly higher and more unrealistic educational expectations and aspirations for success. By way of illustration, slightly more than half of recent high school students predicted that they would earn graduate or professional degrees, even though only 9% of 25- to 34-year-old high school graduates actually obtain such credentials.

Thus, narcissism has become a societal cause for concern. Cultural pundits observe that a sense of *entitlement* among our youth is on the rise. Furthermore, it would seem that increasingly greater numbers of parents and educators are co-conspirators in bolstering unrealistically positive perceptions of the competencies and the overall self-worth of their children and adolescents. For example, the national frenzy to enhance the self-esteem of our youth is apparent within schools systems as well as around the family dinner table. (See Harter, 2012, for an extensive treatment and critique of the *self-esteem movement*.)

Recently (Harter, 2012), I shared my concern over the costs of the contemporary preoccupation with enhancing if not aggrandizing the self among adults in our culture (see Leary, 2004), which is descending the developmental ladder. Self-enhancement strategies, self-serving biases, the inflation of self-esteem, unrealistic self-appraisals, and narcissistic illusions of omnipotence are all pernicious processes that compromise personal authenticity and jeopardize interpersonal relationships. In the present chapter,

I have addressed three developmental questions for each stage. First, what *needs* or motives, if any, are there to engage in self-protective and self-enhancing strategies? Second, what *skills* exist that allow one to execute such biases? Third, what are the consequences? Several needs and skills emerge in late childhood and proliferate during adolescence. Thus, there is cause for concern, not only for adults but also for older children and teenagers who may be driven to engage in self-serving strategies that compromise personal authenticity and relationships with others. Unfortunately, this only taxes the already harried I-self to keep pace in its efforts to falsely package the me-self so that it will be socially acceptable and presentable to the world at large.

SOCIALIZATION PRACTICES THAT CAN COMPROMISE JAMESIAN I-SELF FUNCTIONS

I-self cognitive processes do not develop in a vacuum. Benevolent parents, positive childrearing practices can certainly facilitate the developmental trajectory that has been identified. However, negative socialization practices, such as conditional support, where children are instructed in the psychological hoops they must jump through to win parental approval and love, backfire. Instead, they instill false self behavior in children who try to please parents and meet *their* agenda. Moreover, severe neglect and abuse, can compromise the emergence of these positive I-self functions at each developmental level.

Chronic and severe abuse typically provokes a variety of *dissociative* symptoms in which there is a massive attempt to protect the psyche by efforts to eliminate the abusive events from consciousness. These psychological efforts serve to numb the pain and anxiety leading to psychogenic *amnesia* that interferes with the victim's lack of *awareness* of self (Brier, 1992; Cicchetti & Toth, 2006). The defensive structures driven by abuse will also compromise the victim's sense of *agency* (Putnam, 1993; Westen, 1993). The dissociative symptomatology that is defensively mobilized by the abuse victim seriously interferes with a *sense of coherence*, the consolidation of features of oneself that would be experienced as integrated (Briere, 1992; Fischer & Ayoub, 1994; Putnam, 1993; Westen, 1993). Thus, all of the Jamesian I-self functions are compromised by negative socialization practices, the most severe of which is chronic abuse. A comprehensive treatment of this topic, including an extensive review of the extant literature on the effects of abuse, with illustrative examples, can be found in Harter (1999, 2012).

CROSS-CULTURAL DIFFERENCES IN SELF-ENHANCEMENT

The self-enhancement strategies and self-serving biases, while not unique to Americans have been found to be more prevalent among North Americans, compared to those in Eastern, Asian cultures. Americans are notorious for not only viewing themselves positively but also making *unrealistic* evaluations of their positive attributes (Cross & Gore, 2003; Heine, 2007; Heine, Lehman, Markus, & Kitayama, 1999). This self-enhancing style takes other forms, as described earlier. For example, Americans take credit for their successes but attribute failures to external or situational factors. Another tactic is to make downward social comparisons, highlighting the less adequate performance of others, thereby looking more competent. A meta-analysis by Mezulis, Abramson, Hyde, and Hankin (2004) reveals strong tendencies for Americans to demonstrate a self-serving, attributional bias, namely, making more internal, stable, and global attributions for positive, compared with negative, personal outcomes. Asian samples, in contrast, did not show such biases. The authors concluded that there is no *universal* attribution positivity bias.

These self-enhancement strategies more common in Western cultures can be contrasted with the *self-effacing* tendencies among Eastern cultures that involve *modesty* and *self-criticism* toward the goal of *self-improvement*. Heine (2003) defined self-enhancement as the tendency to dwell on, elaborate, and exaggerate positive aspects of the self, relative to personal weaknesses. In contrast, self-effacing tendencies and self-improvement involve the tendency to dwell on, elaborate, and exaggerate *negative* aspects of the self, relative to personal strengths, in an effort to correct perceived shortcomings (see also Kanagawa, Cross, & Markus, 2001).

In another meta-analysis of published cross-cultural studies on self-enhancement (Heine & Hamamura, 2007), pervasive and pronounced differences between East Asians and Westerners were revealed. Westerners demonstrated a clear self-serving bias whereas East Asians did not (with Asian Americans falling in between). This evidence converges with other findings indicating East Asians typically do not self-enhance.

The vast majority of cross-cultural analyses have focused on the Japanese culture. However, others have addressed these issues in South Korea and China. Kim, Kim, Kam, and Shin (2003) examined self-enhancing versus self-effacing tendencies among Koreans. College students were read two scenarios, one in which the protagonist

was bragging about positive accomplishments and a second in which the main character emphasized negative self-perceptions. The results revealed that the negative self-presentation was judged more favorably than the positive self-presentation, suggesting the role of self-effacement.

Wang and Ollendick (2001) have reviewed literature revealing self-effacing tendencies observed in Chinese culture. Their findings highlight the value that Chinese society places on modesty and harmonious social relationships. They argue that self-effacing behavior will be more likely to obtain favorable social responses from others that, in turn, will serve to maintain harmony. In contrast, the self-enhancing tendencies observed among European Americans function to support an elevated sense of self-esteem.

Wirtz and Chiu (2008) offered an interesting perspective on the type of *ego* that differentiates those in Western and Eastern cultures. They describe the self-enhancing strategies and self-serving biases among Westerners in terms of Greenwald's (1980) concept of the *totalitarian ego*. Greenwald has likened these self-protective and self-promotional tendencies to a controlling political state. Just as a totalitarian state exercises control of the media, relies on propaganda, and regulates political life, the self devotes effort toward information control and self-serving personal propaganda through a variety of self-enhancing cognitive biases. According to Greenwald, egocentrism, illusions of control, self-serving biases, and the manipulation of personal memory all operate to glorify the self. They review literature suggesting that the self in Eastern cultures is more restrained or subdued. These suggest that the Eastern self, in contrast to the totalitarian ego, constitutes a more reserved representation that has been labeled the *quiet ego*. This theme is revisited in a concluding section of this chapter.

Cross-cultural differences in *autobiographical memory* parallel the distinctions raised above. For Americans, the content of memory focuses on distinction and personal accomplishment, whereas autobiographical memory in Eastern cultures emphasizes connectedness and interpersonal relationships. Leichtman, Wang, and Pillemer (2003) summarized findings that adults who have grown up in individualistic, Western cultures recount earlier, lengthier, and more detailed childhood memories than do adults who have grown up in more collectivist cultures. American parents support their children's autobiographical narrative accounts that underscore personal preferences, needs, judgments, opinions, successes, and personal control compared to those of children from Korea and China (see also Wang & Leichtman, 2000). These researchers further documented, in the stories of Chinese children, the greater orientation toward social engagement, concern with moral correctness, respect for authority, and themes of responsibility. Thus, there is considerable evidence for cross cultural differences in what can broadly be characterized as self-enhancing tendencies displayed by Westerners in contrast to the self-effacing strategies manifest in Easterners leading to different behavioral stances. Westerners, on average, emphasize the individualistic goals of personal success whereas Easterners, on average, adopt a stance toward harmonious social relationships.

Interestingly, despite these cross-cultural differences, a recent study reveals that narcissism is on the rise among Chinese youth (Cai, Kwan, & Sedikides, 2012), just as in the United States, though it is still higher in this country. More specifically, those from higher socioeconomic classes, those from one-child-only families (given the political edict, a generation ago), and those reporting individualistic values scored higher on measures of narcissism. Social-cultural changes (e.g., the influence of capitalistic economic practices, the one child per family legislation) have contributed to the rise of narcissism among certain Chinese, according to the authors. Other observers have pointed to how four doting Chinese grandparents vie for the attention of a single grandchild, which may lead to children's greater sense of exaggerated self-esteem and entitlement.

SELF-EVALUATIONS IN GLOBAL SELF-ESTEEM AND SELF-CONCEPT: I-SELF AND ME-SELF FUNCTIONS

The I-self is also responsible for another me-self construction in the form of an overall evaluation of one's worth as a person, typically referred to as global self-esteem or self-worth. Unfortunately, many children and adolescents report distressingly low levels of self-esteem. However, from a cognitive-developmental perspective, such a representation is not within the child's repertoire until approximately age 8. That is, it cannot be verbalized in young children.

Young children do exude self-esteem in their behavior, what we have labeled *behaviorally presented self-esteem* (see Haltiwanger, 1989; Harter, 1999). Teachers report that preschoolers who have high self-esteem display confidence, curiosity, initiative, and independence. In addition, they react adaptively to stress, adjusting to changes and transitions, they tolerate frustration, they persevere, and they are able to handle criticism and teasing. Those children who manifest low self-esteem in their behavior rarely display these positive features and have difficulty in reacting to

change, stress, and frustration. An interesting question is whether young children with low behaviorally presented self-esteem also report low self-esteem when they are older and can verbalize their worth as a person. If the negative parenting practices leading to low self-esteem *persist*, for example, lack of affection, conditional support, neglect, excessively punitive discipline, and abuse (see Harter, 1999), then one would expect continuity over time. That is, an individual who displayed low self-esteem in his or her behavior as a young child would also, as an older child report negative feelings of worth on self-esteem questionnaires.

This ability to form a linguistic concept of global self-esteem does not emerge until about the age of 8 (see Harter, 1999). Two historical scholars originally addressed the potential causes of verbalized self-esteem in adults. James's (1892) formulation focused on the cognitive prerequisites in that perceived success in domains deemed important is weighed against perceptions of actual accomplishments. If perceived successes are congruent with one's pretensions, then high self-esteem will ensue. In contrast, if perceptions of success fall short of one's aspirations, then low self-esteem will be experienced. For Cooley (2002), who proposed a looking-glass self model of self-esteem, the internalization of the opinions of significant others, as social mirrors, dictated the level of global self-esteem. However, these processes do not emerge until middle childhood.

Our own research (see Harter, 1999, 2012) finds strong support for the formulations of both James (1892) and Cooley (2002). We first identified age-appropriate domains, namely, scholastic competence, athletic competence, social competence, physical appearance, and behavioral conduct, assessing older children perceptions of competence or adequacy in each domain. To examine James's theory, we also asked older children to report on the *importance of success* in each domain. In this manner, we could determine if there was a discrepancy between perceived competence or adequacy and the importance of success in each domain. The high self-esteem child is not necessarily a super-star in all domains. Rather, the I-self is able, as James hypothesized, to *discount* the importance of success for domains in which one does not feel competent or adequate. In contrast, the low self-esteem child is unable to discount the importance of success for domains in which he or she feels inadequate. We will return to why the I-self is unable to engage in this discounting process, leading to very negative and debilitating self-evaluations for some individuals.

We have also documented the fact that Cooley's (1902) looking-glass self model of self-esteem is alive and well, in the lives of older children and adolescents. Self-reports of approval from parents, as well as classmates, are highly predictive of global self-esteem (Harter, 1999). Older children with high self-esteem provide favorable accounts of the positive support and approval they receive. Of more importance to this chapter are the self-reports of low self-esteem children who experience lack of social support from parents and peers, reporting low approval as well as overt rejection. Moreover, those who report *conditional* support from parents and peers also suffer in terms of low self-esteem. Thus, if parents make their love contingent upon unrealistic demands on their children, this practice will erode the child's self-esteem, as our findings have documented (Harter, 1999).

Self-esteem becomes more nuanced in early adolescence, with implications for those who evaluate their sense of worth unfavorably. The term *self-esteem* becomes salient in the young adolescent's vocabulary. As one adolescent participant concluded, "It's a big deal to show that you have high self-esteem." Moreover, young teenagers begin to form meta-theories about the causal nature of constructs that involve themselves and others. For example, they form meta-theories about the directionality of their perceived attractiveness and self-esteem and about the causal links between peer approval and self-esteem.

From a Jamesian (1892) perspective, perceived adequacy in domains of importance strongly predicts self-esteem, as young adolescents come to appreciate (Harter, 1999). A preoccupation with the congruence or discrepancy between ideal and real self-representations intensifies during early adolescence. Moreover, perceptions of physical appearance are particularly salient in predicting overall worth (see Harter, 2012). The majority of young adolescents admit that they are basing their self-esteem on their perceived appearance. Those whose self-esteem is dependent on meeting the punishing societal standards report lower perceptions of their appearance, lower global self-esteem, and greater feelings of depression (see Harter, 1999). As one young adolescent admitted, "How much I like myself as a person depends on how I look. I'd like to be good looking, like the models and the TV and movie stars, but that's impossible. I'm too short and I weigh too much."

Although perceived approval is an important determinant of one's level of self-esteem, young adolescents who are *preoccupied* with the importance of the opinions of peers are also at risk (Harter, Stocker, & Robinson, 1996). They admit to greater *fluctuations* in both approval and self-esteem, lower *levels* of approval and self-esteem, and are more distracted in the classroom. As one adolescent described it, "How much I like myself really depends on

what other kids think about me, I have to admit it. One day, like if I get invited to a party, I'll feel great about myself. But then the next day, if somebody I know ignores me in the hall or doesn't say something nice, then I feel terrible about myself. Sometimes I think too much about this during my classes and I don't concentrate on what the teacher is saying." These adolescents, drawn like magnets to the social mirror, are also more likely to report that their lack of support leads to their being depressed, a topic to which we shall return. Fast-forwarding to adulthood, Cambron, Acitelie, and Petit (2008) reported that women who base their self-esteem on interpersonal relationships (friendships, romantic involvement) are more at risk for depression.

Those in middle-to-late adolescence face different potential assaults to their self-esteem that become more differentiated in terms of the various social sources of approval that impact one's sense of personal worth. Contradictory messages from different significant others can lead to self-esteem volatility, what Rosenberg (1979) called the *barometric self*. Differential approval across roles will also lead to different levels of role-specific self-esteem in each context, what we termed *relational self-esteem* (Harter, Waters, & Whitesell, 1998). As one adolescent interviewee explained, "How much I like myself as a person goes back and forth, my self-esteem is higher with kids who know me than with my parents," a pattern that our findings have documented. Rosenberg's concept of the barometric self refers to volatility in the overall *level* of *global* self-esteem. Because adolescents report that their self-attributes, as well as their self-esteem, vary across relationships, we have coined the term the *kaleidoscopic self* to capture this greater complexity.

Relational self-esteem with *classmates* is the most predictive of global self-esteem (Harter, Waters, & Whitesell, 1998). As one adolescent observed, "What all of the other kids think of you is so important to how much you like yourself as a person." As reported elsewhere (Harter, 1999), the approval of close friends is not as highly related to self-esteem where there is less variability (scores are uniformly high given that, by definition, a close friend likes you). The perceived approval from classmates presumably reflects a more objective or credible index of validation from those whom Mead (1934) referred to as *the generalized other*. Those who cannot garner the support of this general body of peers will suffer greatly, in terms of low relational self-esteem with peers as well as global self-esteem.

Normatively, global self-esteem declines between early to midadolescence (see Harter, 1999). The increased penchant for *introspection*, an I-self function, can contribute to lowered self-esteem by facilitating the contrast between one's *real* and *ideal* self-concepts. This produces a heightened awareness of the *discrepancy* between the real self (e.g., I can get pretty obnoxious and intolerant) and one's ideal (e.g., I'd like to be friendly and tolerant all of the time, that's the kind of person I *want* to be, and I'm disappointed in myself when I'm not). Thus, consistent with James's (1892) formulation, the more one's aspirations or ideals outstrip perceptions of one's actual capabilities across different domains, the lower one's self-esteem.

The realm of physical appearance is particularly critical (see Harter, 1999, 2012). Perceived attractiveness looms large in importance, yet most cannot meet the punishing societal standards so salient in our culture. The I-self, as cognizer, also looks outward and is well aware of the cultural preoccupation with attractiveness, as well as its criteria. The demand that females be excessively thin, tall, long-legged, with ample breasts and a pretty face, framed in flattering hair, is an ideal that 95% of females in this culture cannot attain (Kilbourne, 1999). As a result, aspirations far outweigh perceived appearance, contributing to lower self-esteem (see Harter, 2012). One female adolescent participant admitted that she wants to look like Beyonce but knows she doesn't and never could, and this sets up a painful discrepancy. In reality, she falls far short of the cultural standards for beauty. Similar dynamics are emerging for males who attempt to emulate the cultural criteria of male attractiveness that now include height, muscularity, rippled abs, and great hair (see Harter, 2012; Kiang & Harter, 2006). These issues continue into late adolescence and beyond, given our societal cultural obsession with attractiveness and the impossible criteria to which both females and males are subjected. We will return to the implications of this cultural preoccupation, in the subsequent section on eating disorders.

WHY CAN'T THOSE WITH LOW SELF-ESTEEM ALTER THE PERCEPTIONS OF THEIR OVERALL LACK OF WORTH?

Our model of the determinants of global self-esteem documents the fact that both the Jamesian (1892) formulation, emphasizing the discrepancy or congruence between perceptions of success in domains deemed important, and Cooley's (1902) looking-glass self theory of the role of approval from significant others, both contribute to self-esteem. Thus, there seem to be two clear pathways to increasing the self-esteem of those who suffer from

negative self-evaluations of their worth. First, one needs to reduce pernicious discrepancies. Second, one needs to find niches in which to garner support. These strategies have broader implications for those engaged in intervention efforts to enhance self-esteem, and I have suggested some possible pathways toward such a goal (Harter, 1999). Yet there are reasons to realistically question even my own former optimism.

James (1892), a brilliant theorist, was quite sanguine about how one might increase one's self-esteem. He postulated two potential routes to self-esteem enhancement. One could lower one's aspirations by discounting the importance of success in areas where one was deficient. Alternatively, one could raise one's level or actual competence or personal adequacy (e.g., through skills training or other efforts to overcome one's limitations). Both of these strategies will serve to reduce the discrepancy between perceived competency or adequacy and the importance of success; decreasing this discrepancy should, in turn, increase one's level of self-esteem.

Although such interventions are theoretically appealing, they may not be that plausible given the realities of the lives of children and adolescents in our contemporary culture. There are two psychological roadblocks to discounting the importance of the specific domains we have selected, in the face of perceived deficiencies. First and foremost, these domains were initially chosen because most children and adolescents, in interviews, identified these arenas as extremely important. That is, we are living in a society where scholastic competence, athletic competence, social competence, physical attractiveness, and appropriate behavioral conduct are highly valued and are sought after by the majority of youth in the cultural mainstream. Thus, personal aspirations and standards in these domains are typically quite high, making it difficult for those feeling inadequate to discount their importance. The domain of physical appearance is particularly hard to discount.

Second, these domains are highly valued by significant others, notably parents and peers. Our own findings reveal that children and adolescents report that scholastic competence and behavioral conduct are extremely important to parents. In contrast, social competence, physical appearance, and athletic competence are judged to be particularly important to peers. Moreover, importance to others is highly correlated with importance to the self; competence/adequacy in domains important to others is just as highly correlated with self-worth as is competence in domains important to the self. Thus, it would appear to be extremely difficult for children and adolescents to discount the importance that represents standards set by significant others whom they wish to please (see also Baumeister, 1993). The inability to discount these aspirations is particularly debilitating for those who acknowledge deficiencies in these areas. Moreover, limitations in these domains will also make it difficult to garner the support of parents and peers, also so critical to maintaining positive self-esteem.

Increasing one's competence and corresponding self-evaluations as an alternative strategy for decreasing the discrepancy between competence/adequacy and the importance of success would also appear to be problematic for many youth. First, there are undoubtedly natural limits to the extent to which children and adolescents can increase their actual competence or adequacy. Although a given individual may be highly motivated to improve his or her scholastic performance, athletic ability, or physical appearance, there may be little that one can realistically do, given certain ceilings on intellectual and physical potential.

Moreover, there may also be limitations placed on perceptions of competence/adequacy given the standards imposed by social comparison, an I-self process by which the me-self is compared with others. The process of comparing the self to others begins in middle childhood and increases with development, as most children adopt the cultural preoccupation with how individuals differ from one another, with competition, with who is the best, and who ascends to the top of ladder. Thus, how one measures up to peers and societal standards becomes the filter through which judgments about the self pass. Thus, even if motivated, most individuals will fall short, relative to the punishing peer standards that provide the metric for self-evaluation. As a result, it is difficult for many to reduce the discrepancy between perceived competence/adequacy and the importance of success, hampering the desire to enhance one's self-esteem (see Harter, 1993). Thus, debilitating low self-esteem persists.

Baumeister (1993), in his book *Self-Esteem: The Puzzle of Low Regard*, presents other explanations for why low self-esteem is so resistant to change. Moreover, Swann's (1996) *Self-Verification Theory* provides an alternative interpretation for why negative self-evaluations are so intractable. People, Swann argues, are powerfully motivated to retain their self-perceptions, even if negative, because they provide a road map for what to expect from others and how to behave. Feedback to the contrary, even if positive, is psychologically distressing and disruptive because it derails people from their life's agenda. Thus, low self-esteem is likely to persist because the I-self has come to consistently define the me-self. This discussion has focused on the determinants or antecedents of self-esteem, addressing the causes of low self-esteem. We next turn to

cross-cultural differences in self-esteem. Following this topic, we address correlates and consequences of low self-esteem, including depression, suicidal behaviors, eating disordered behaviors and humiliation, in the face of severe peer harassment, leading to violent revenge.

CROSS-CULTURAL DIFFERENCES IN SELF-ESTEEM

There are clear differences between Western and Eastern conceptions of self-esteem that are critical to recognize, before Westerners encourage Eastern cultures to adopt their frameworks, paradigms, and instruments. Clearly, self-esteem is a value touted by Americans, as witnessed by the many attempts to protect and enhance it, as has been demonstrated. However, high self-esteem, based on individual accomplishments, is not revered as a psychological commodity in most Eastern cultures. Rather, harmonious relationships represent the primary sources of self-respect (Diener & Diener, 2009; Kang, Shaver, Sue, Min, & Zing, 2003). Kang et al. further reported that high self-esteem predicted *life satisfaction* for European Americans but not for Koreans and the Chinese. Rather, *relationship quality* was found to be the path to life satisfaction for these Asian groups (but was not highly predictive for Americans).

These findings relate to an interesting linguistic cultural observation by Wang and Ollendick (2001), who studied self processes in China. In the Chinese language, there is no equivalent term for self-esteem! The same is true for Japanese. This would appear to reflect the point above, namely, that self-esteem is not a core value and therefore is not represented or codified in their respective languages.

Yet this has not deterred American psychologists from subjecting Asian children, adolescents, and adults to instruments designed for US culture, assuming that such measures are useful and can be meaningfully interpreted. We cannot make such assumptions (Harter, 2012). Wang and Ollendick (2001) concurred, arguing that this approach is problematic because investigators assume that the construct of self-esteem has the same meaning in China, compared with the United States, leading to findings that are potentially misleading and inaccurate.

This conclusion was borne out by a colleague, Professor Lee C. Lee (personal communication, April 15, 1987) who employed our global self-esteem subscale with first-generation Chinese immigrant children who came to New York. Lee indicated to me that these items lacked meaning for her sample, concluding that the concept of global self-esteem, as defined in American culture, was not appropriate to include on an instrument administered to Chinese children.

Others have found the psychometric properties of our Self-Perception measures to be inadequate. Meredith, Abbott, and Zheng (1991) reported that only 20 of the 36 items (almost half) on our Self-Perception Profile for Children (Harter, 1985) factored appropriately in a Chinese sample. Similarly, in both this and another Chinese sample employed by Stigler, Smith, and Mao (1985), the reliabilities were unacceptably low. Moreover, in both studies, the Global Self-Esteem was particularly problematic. Culturally, inappropriate *content* on a given instrument will invariably contribute to an inadequate scale *structure* and to unacceptable psychometric properties.

A further concern inheres in the fact that for the Chinese (Meredith et al., 1991; Stigler et al., 1985) and for Japanese (Maeda, 1997; Sakura, 1983) and for Koreans (Rhee, 1993), the mean domain-specific self-concept scores and the Global Self-Esteem ratings were considerably lower than scores in the United States, Canada, Australia, and Western Europe samples. There are several interpretations for this pattern. First, the Eastern Asian penchant for modesty and self-criticism, part of their self-effacing orientation, would predictably lead to lower scores. The contrasting American style of self-enhancement with its positive bias would ensure relatively high scores.

Another explanation for the more negative self-evaluations of Asian samples can be traced to our structured-alternative question format (Harter, 1985). This particular question format (see Harter, 2012) invites if not requires some degree of social comparison with one's peers. Stigler et al. (1985) indicate that overt social comparison is frowned upon in Chinese culture, where individual differences in competence or ability are downplayed, in the service of social harmony. Thus, Chinese children's unwillingness to report that they may be superior to others should lead to a pattern of scores that may not reveal their private perceptions of personal competence.

Thus, the inappropriate content of a Western instrument, the lack of meaningful items, a problematic question format (with our own measures that pull for social comparison), self-effacing or self-critical response tendencies, and inadequate psychometric properties all conspire to make these measures methodologically inappropriate and culturally insensitive. Other thoughtful investigators (e.g., McCrae, 2001; Tsui, Nifadkar, & Ou, 2009) have pointed to problems in translation, including the typical back-translation procedure. See Harter (2012), where these different issues are reviewed in more detail and where it is urged that those in different cultures take stock of these

problems and perhaps initially design interview questions to address their specific research questions and hypotheses. Responses may then evolve into a culturally sensitive measure that would directly bear on their an appreciation of their own cultural values and yield more meaningful results. Using cultural standards, establishing cutoff scores for what constitutes pathology, would be preferable for normative and applied research.

A final criticism of much cross-cultural research is that too many studies are conducted with samples of convenience, namely, university students. Such students, albeit in their culture of origin, are not representative community samples. As McCrae (2001) thoughtfully pointed out, undergraduates may not be accurate proxies for more nationally appropriate samples that are representative of age, socioeconomic status (SES), education, and experience in a given culture. Watkins, Mortazavi, and Trofimova (2000) echoed this concern. The dangers of generalizing from a single group such as college students became evident in their own research. Moreover, they make another important point: University students around the globe have been westernized in many respects, they may be wrestling with or rejecting the cultural values of their family of origin and are a poor choice for cross-cultural research, because they are not representative of their culture at large.

Thus, there are clear challenges in the assessment of self-constructs across cultures. The field must attend to these critiques and seek solutions to the problems plaguing assessment procedures as well as the selection of representative cultural participants. Solving these dilemmas is critical to provide a window through which we can observe cultural differences that are both accurate and meaningful. However, more important to this chapter is a focus on what self-esteem processes might be pathological, leading to low self-esteem, and related symptoms of depression and eating disorders, if not other manifestations. We, they, need to employ culturally sensitive definitions for both normative, including transient liabilities, and pathological conditions that may involve the self, culturally defined.

DEPRESSION AND SUICIDAL BEHAVIORS

In the previous section, we reviewed the causes or antecedents of global self-esteem, which focused on perceptions of competence/adequacy in domains deemed important, as well as approval from significant others. However, if the I-self's evaluations of the me-self do not directly impact an individual's day-to-day functioning, then an understanding of such representations will contribute little to our comprehension of the behavior of children and adolescents. Why should we care about self-esteem unless we can demonstrate that it plays a vital role in individuals' lives? The efforts of self theorists and researchers may be misguided if self-research reduces to a cognitive epiphenomenon that has little impact on everyday functioning.

Considerable research now demonstrates the powerful link between self-esteem and depression (Harter, 1999). There is clear historical precedent for including negative self-evaluations as one of a constellation of symptoms experienced in depression, beginning with Freud's (1952) observations of the low self-esteem displayed by adults suffering from depressive disorders. Others within the psychoanalytic tradition have continued to afford low self-esteem a central role in depression (Bibring, 1953; Blatt, 1974).

Numerous theorists and researchers to follow have addressed the manifestations of depression in children, adolescents, and adults, focusing heavily on cognitive components involving the self (see Abramson, Metaksky, & Alloy, 1989; Baumeister, 1990; Beck, 1975; Hammen & Goodman-Brown, 1990; Higgins, 1989; Kovacs & Beck, 1986; Nolen-Hoeksema, Girus, & Seligman, 1986; Pyszczynski & Greenberg, 1987; Seligman & Peterson, 1986). In our own studies (see Harter, 1999) we have consistently found that among older children and adolescents, self-esteem is highly related to affect along a continuum of cheerful to depressed (with correlations ranging from .72 to .80). These findings are consistent with those of other investigators (Battle, 1987; Beck, 1975; Kaslow, Rehm, & Siegel, 1984).

More recent findings confirm the strong relationship between negative self-evaluations, low self-esteem, and depression (Berg & Klinger, 2009: Lee-Flynn, Pomaki, DeLongis, Biesanz, & Piterman, 2011: Robles-Pina, DeFrance, & Cox, 2008; Montague, Enders, Dietz, & Canendish, 2008: Sadhwani, 2012; Schwartz, Klimstra, Luyckx, Hale, & Meeus, 2012; Sturman, Flett, Hewitt, & Rudolph, 2009). Among clinic samples of inpatient adolescents with psychiatric diagnoses of depression, we have also documented a powerful link between self-esteem and self-reported depressed affect (Harter, Marold, & Whitesell, 1992). Moreover, these effects are exacerbated in those who have been the victims of sexual abuse (see Turner, Finkelhor, & Omrad, 2010).

Our own findings, consistent with those of others, led to the development of a model of the causes (competence/adequacy in domains of importance in addition to peer and parental support), correlates, and consequences

of self-esteem (Harter, 1999; Harter, Marold, & Whitesell, 1992). Initially we postulated that self-esteem served as a mediator between the causes of global feelings of worth and depression. However, it became apparent that the exceedingly high correlation between self-esteem and depressed affect did not permit a clear interpretation of the directionality of these two constructs. Moreover, when we added *hopelessness* to our battery of measures, following the lead of Kovacs & Beck (1986), we found it to be equally correlated, at high levels, to both depression and self-esteem. Thus, for the purpose of statistical modeling, we combined self-esteem, depression, and hopelessness into what we labeled the Depression/Adjustment Composite. This composite, in turn, was predictive of *suicidal ideation,* as an outcome. Baumeister (1990) has postulated that many suffering from depression and its correlates are driven to consider suicide as a solution, as a form of escape from the painful cognitions and affects about the self and the disapproving reactions and rejection by significant others.

More recent studies have also documented the strong link between depression and suicidal behaviors (see Au, Lau, & Lee, 2012; Santos, Saraiva, & DeSousa, 2009). Others have examined the specific components or symptoms of depression and their relationship to suicidal behaviors. For example, core mood disturbance symptoms (i.e., depressed affect) and self-punitive thinking have been found to be the major predictors of suicidal ideation (Keilp et al., 2012).

The incidence of suicide among adolescents has tripled in recent decades, leading to efforts to identify the determinants of this major mental health threat to our youth (see Noam & Borst, 1994; Pfeffer, 1988). Several broad classes of risk factors implicated in depression and suicidal behavior have captured the attention of researchers, including biological precursors, epidemiological correlates, and social/psychological stressors. Our own model has focused on an examination of this third class of risk factors, consistent with the emphasis and urging of others (see Spirato, Brown, Overholser, & Fritz, 1989).

The following poignant self-disclosure by one of the adolescents in our studies provides a personal cameo of the model that has evolved in our research:

> I look in the mirror and most days I don't like what I see, I don't like how I look. I don't like myself as a person. So I get depressed, bummed out. Plus, my family has rejected me and that makes me feel pretty lousy about myself. My mother is really on my case because I'm not living up to what she wants me to be. If I get A's in school, she's nice and is proud of me but if I don't she doesn't approve of me. You could say that how she treats me is conditional on how I do. Mostly she tells me I am a failure and I am beginning to believe it. Doing well in school has always been important to me, but now I feel like I'll never amount to anything. There's no way I am ever going to be able to please her, it's pretty hopeless. I don't get much support from other kids, either. I probably never will because I'm an introvert. I don't even try to make friends. So a lot of the time I get depressed. When I am depressed I feel very sad because other people have hurt me, but I'm also angry at them, for not caring and for rejecting me. I feel so depressed that I often think about just killing myself. Life is worthless, but so is death. So what's the use?

Different Pathways to Depression

Although most of the components of our model appear in this adolescent's personal vignette, not all depressed adolescents report all of the precursors of depression we have identified. Inspection of hundreds of profiles has revealed six different routes to the depression composite (see Harter, 1999; Harter & Whitesell, 1996). A central tenet for those studying psychopathology is that there are multiple pathways to a given disorder (Cicchetti & Rogosh, 1996; DeKlyen & Greenberg, 2008). We first identified six subgroups, all of whom reported low self-esteem, depressed affect, and hopelessness. One subgroup does report all of the predictors in the model, reporting incompetence/inadequacy in domains that are viewed as important to peers (physical appearance, social competence, and athletic competence) and important to adults (scholastic competence and behavioral conduct). They also reveal corresponding lack of approval from both peers and parents.

A second subgroup reported inadequacy in the domains judged important to both peers and parents, as well as lack of parent support. Children from this group that we interviewed seemed to be in denial about the lack of acceptance from peers, for a variety of reasons (see Harter, 1999). A third group acknowledged lack of competence/inadequacy in the domains deemed important to peers and parents, as well as low peer support. However, they did *not* report lack of parent support, presumably, interview data revealed, because they had benevolent parents who provided unconditional love, accepting their child's deficiencies; in some cases, they were congenitally caused.

A fourth pathway to the depression composite (low self-esteem, depressed affect, and hopelessness) was characterized by negative perceptions in domains important to peers only, with accompanying lack of peer support. These individuals reported positive self-evaluations in the domains of scholastic competence and behavioral conduct and appeared to garner the approval of parents.

However, interviews revealed the greater importance of the peer culture and the need to meet with the approval of classmates, which they were not garnering because of their perceived inadequacies, and this overshadowed success in the domains that were rewarded by parents.

A fifth pattern was manifest by those who did report success in the peer-important domains, accompanied by peer support, but who were nevertheless more focused on their lack of adequacy in the domains important to parents, scholastic competence and behavioral conduct, leading to depression. Interviews indicated that for some, placement in special education classes because of either scholastic or behavioral difficulties, accompanied by lack of approval from parents, were largely responsible. The sixth and last pattern was initially puzzling. These depressed youth reported low levels of success in both the domains important to peers and parents, yet surprisingly they felt the approval of both peers and parents. Interviews revealed that these individuals were extremely self-critical, with very high and unrealistic standards for their own behavior, and did not feel that the approval of others was credible (see Blatt's, 1995, discussion of self-critical depression). The identification of these six patterns has implications for those involved in intervention efforts to ameliorate low-self esteem, depression, and hopelessness. Given that there is not one pathway to these manifestations, it behooves us to identify individual differences in the specific causes leading to depressive behaviors.

Depression as a Combination of Sadness and Anger

Another line of our research has examined the phenomenological experience of depression as a combination of sadness and anger, consistent with the clinical literature, which points to the *comorbity* of internalizing and externalizing symptoms (e.g., Rutter, 1989). Moreover, it is also congruent with our own research on mixed or multiple emotions (reviewed in Harter, 1999). Our studies reveal that the vast majority of adolescents (80%) report that depression involves the co-occurrence of sadness and anger. However, a key question became anger at whom? The classic Freudian interpretation is that depression involves anger turned *inward* against the self (Freud, 1968). However, our own research has revealed that most of the causes that adolescents cite for being depressed involve actions of the others against the self. Correspondingly, they report that they are angry at *others* when they feel depressed. We have speculated that adolescents may not yet have developed the inhibitions or defenses that would prevent them from expressing their feelings toward the significant others whom they perceive to be the cause of their depression-related anger.

The Perceived Directionality of Low Self-Esteem and Depressed Affect

As described earlier, statistical modeling could not determine the directionality of self-esteem and affect, given that they were so highly correlated. This issue is reminiscent of the debate, in the 1980's, about the primacy of cognitions versus emotions (Izard, 1984; Lazarus, 1984; Zajonc, 1984). Our own solution was to go to the font of wisdom itself, the adolescent who experiences both low self-esteem and depression. We simply asked them: Which comes first? Do you first feel depressed and then don't like yourself as a person, or is it that you don't like yourself as a person and this makes you feel depressed? Our findings revealed two groups, one of which endorsed the first directionality orientation and another that endorsed the second orientation (see Harter, 1999).

Those for whom depression preceded low self-esteem described actions of *others* against self, revealing three categories of examples: (1) perceived rejection by others; (2) conflict with others; and (3) the experience of the *loss* of another (through their death or the termination of a relationship). Those for whom low self-esteem preceded feelings of depression cited dissatisfaction with particular *self-attributes* for three primary reasons: (1) negative evaluations of their appearance; (2) lack of competence (scholastic or athletic); and (3) dissatisfaction with their behavior or conduct in social interactions. In Harter (1999) we give many examples of the explanations of adolescents, for each of these orientations. For those working directly with depressed adolescents, we suggest, based on these findings, that it would be important to assess their perceptions of the directionality between self-esteem and depressed affect, since this will have implications for intervention. In conclusion, it is clear that there is a powerful, but complex link, between self-esteem and depression, indicating how the me-self is involved in this form of psychopathology.

EATING-DISORDERED BEHAVIOR

Our own research has identified one-self-concept domain that robustly affects global self-esteem across the life span, namely, perceived physical appearance. The I-self harshly judges the appearance of the me-self, which, in turn, negatively affects the evaluation of one's overall sense of esteem.

This link is profoundly impacted by cultural standards of appearance for each gender, given that the culture clearly touts physical attractiveness as the measure of one's worth as a person (see Harter, 1999, 2012). The empirical findings have revealed that the correlations between perceived attractiveness and global self-esteem range from the .60s to .80s, in our own studies. Moreover, investigators have demonstrated that these relationships are not merely statistical but are very much embedded in the consciousness of individuals well aware of this link.

In our own research (Kiang & Harter, 2006), we have found strong support for a model in which contemporary cultural values are highly endorsed. These values include the perceptions that being attractive will lead to higher self-esteem, that meeting societal standards of appearance will make people more popular, and that people who are overweight are discriminated against. However, there is enough variability in these scores to determine that such awareness predicts perceptions of one's own appearance, which in turn predicts level of self-esteem, depression, and eating-disordered behavior. Specifically, those endorsing these cultural values reported more negative views of their appearance, lower self-esteem, more psychological correlates of eating disorders, and more eating-disordered behaviors (see also Smith, 2010). Other studies with undergraduate females have indicated that when self-worth is based upon perceptions of physical appearance, particularly among those displaying vulnerable narcissism, such individuals are at risk for eating disorders (Gordon & Domback, 2010; Vartanian, 2009; Welch & Ghaderi, 2013).

Our own study (Kiang & Harter, 2006) was conducted with college students. However, the seeds of such a model are sown in childhood and adolescence. Children and teenagers of both genders are well aware of the prevailing norms for desirable appearance. For adult females in the 2000s, one must be tall, very thin, weigh very little (ideally around 110–115 pounds), and have ample breasts and of course a pretty face and stunning hair, an unattainable combination for more than 90% of the female population. The average American woman is 5 feet, 4 inches, tall and weighs 140 pounds. Standards have been extremely punishing for females across the decades.

Kim and Sundar (2012) concurred, observing that the discrepancy between one's bodily ideal and perceptions of one's actual bodily self is associated with both depression and eating-disordered behavior. They attribute the cause to intensified exposure to unrealistic images of others, for example, celebrities and media models (see also Bergstrom, Neighbors, & Malheim, 2009, on the media's impact on body image disturbance). Important to these dynamics is whether females *internalize* the thin ideal now so prominent in contemporary culture (Dittmar, Halliwell, & Stirling, 2009). Processes involving a *feared* body image, based on ideal-real discrepancies, also contribute (Woodman & Hemings, 2008).

Other recent research cites the role of *self-criticism* in eating disordered behaviors. In a study of adolescent females in Israel, self-derogation emerged as a strong predictor of eating-disordered symptoms (Fenning, Hadas, Itzhaky, Roe, Apter, & Shahar, 2008). In another investigation, bulimic symptoms in females were associated with a history of emotional and sexual abuse, leading to depressive symptoms and self-criticism, in the form of expressed bodily dissatisfaction (Dunkley, Masheb, & Grilo, 2010).

These standards are not lost on our children and adolescents. Children succumb to the same discouragement of not being able to emulate the looks of models, singers, and movie stars in the limelight. Meeting these exacting standards becomes particularly critical during early adolescence as teenagers face inevitable pubertal changes that signal their impending adulthood. Thus, they adopt adult standards as the physical markers for what defines attractiveness, appeal, and social acceptability, all of which determine one's self-esteem.

What is new, within the last two decades, is the fact that the bar has been raised for males in our society. No longer is appeal to be judged primarily by status, wealth, position, and power but by physical standards of attractiveness, as well. Muscular build, abs, biceps, physique, and hair on the head as well as face have all come to define the new ideals for men (see Harter, 2012; McFarland & Kaminski, 2009).

The genetic throw of the dice leads some young adolescent males and females to fare better than others on the competitive battleground, a minefield on the road to winning the attractiveness war. For example, early-maturing girls are at a distinct disadvantage given the current emphasis on thinness and height because on average they are typically heavier and shorter compared with later-maturing girls, who tend to be thinner and taller. The pattern is just the opposite for adolescent males. Early-maturing boys tend to be taller and more muscular, which gives them a physical edge. Thus, beginning in earnest at this age, evaluations of one's appearance take on critical implications for one's global self-esteem. The I-self is attentive to the cultural standards of attractiveness comparing the me-self to the ideal, which in turn determines one's level of self-esteem. Thus, those not meeting the gold standard are at serious risk for pathological forms of low self-esteem, depression, and possible suicide, as well

as for eating disorders that can be life threatening. While this preoccupation initially becomes quite salient in early adolescence, it continues throughout the life span.

Although the etiology of various eating disorders is quite complex and beyond the scope of this chapter, it is clear that appearance-related issues, body dissatisfaction, low self-esteem, and depression are implicated in eating disordered behaviors (see also Wertheim, Paxton, & Blaney, 2009). Moreover, others continue to emphasize the negative impact of cultural messages about appearance and body ideals (Smith, 2012). Woodruff-Burton (2012) provided a particularly interesting perspective on the cultural ideology of the consumer's image of the ideal or more desirable body. *Postmoderism* has supposedly offered the consumer freedom to choose from a wide range of cultural identities in self-expression. However, particularly for women, paradoxically, there is *little* flexibility or latitude in the contemporary ideals for feminine beauty. Malson (2009) expressed a similar concern, suggesting that the world would be a better place without mass-media saturation of ideals that dictate the pernicious effects of such images. She cites the hyperconformity to a culturally dominant, media-promulgated idealization of female slenderness and the culture's culpability in the production of eating disorders.

Our understanding of these processes is informed by the cognitive-behavioral therapy (CBT) model as it applies to eating disorders (Pike, Devlin, & Loeb, 2004). According to one CBT principle, the self-esteem of an individual with an eating disorder is overly determined by perceptions of body weight, shape, and appearance. In fact, one of the psychiatric diagnostic criteria for anorexia and bulimia is a disturbance in body image. Individuals with eating disorders imbue body weight, shape, and appearance with intense meaning and extreme importance and are acutely sensitive to minute changes in these dimensions, according to Pike et al., in their review of the literature. Weight fluctuations imperceptible to others can dominate the experience of those with eating disorders, having a significant effect on self-esteem and depressed mood.

In their studies of those with extreme eating disorders, Levine and Harrison (2004) found that the importance of weight and shape is significantly correlated with eating-disordered symptomatology. They, and others, argue that this pattern reflects the internalization of society values concerning appearance and the beauty ideal of thinness (Geller, Srikameswaran, Cockell, & Zaitsoff, 2000). Moreover, the overemphasis on weight and shape is motivated by the attempt to compensate for feelings of low self-esteem. Thus, for the individual with an eating disorder, the pursuit of thinness is the only pathway to enhancing self-esteem (see also Showers & Larson, 1999).

As Pike et al. (2004) observed, the societal values that make thinness a holy virtue, and beauty a ticket to happiness, are fundamental to the maintenance of an eating disorder. Achieving the cultural standards of attractiveness is thought to remediate the detrimental experience of low self-esteem. Thus, the fragile victims of eating disorders cling with tenacity to the hope that attainment of the ideal bodily self will enhance their flagging self-esteem. Anderson-Fye and Becker (2004) further observed a link between (desired) upward mobility and eating disorders, given the belief that social status will be enhanced by adhering to societal standards of beauty.

Concerns over weight and body shape continue to dominate more recent studies of eating disorders. For example, Serpell, Neiderman, Roberts, and Lask (2007) documented the fact that adolescent girls with eating disorders reported more negative evaluations of their weight and shape than those without such disorders. Geller et al. (2002) broadened their approach. In addition to shape and weight, they found that those adolescent females who based their self-esteem on intimate relationships displayed more eating-disordered symptoms and reported greater body dissatisfaction and more negative self-esteem. In a related study by Sanchez and Kwang (2007), females who derived their self-esteem from romantic relationships acknowledged their greater body shame that, in turn, predicted bulimic symptoms. In summary, there is clear evidence that appearance-related dissatisfactions and associated low self-esteem contribute heavily to the dynamics of eating-disordered behaviors in normative as well as clinical populations.

THE ROLE OF SELF PROCESSES, HUMILIATION, AND VIOLENT REVENGE

On a gloomy day, April 20, 1999, I turned on the afternoon news and was appalled to learn that 15 minutes from my Colorado mountain home, at Columbine High School, terrified students were being rushed out of the building, as 11 students lay dead, one teacher was dying, and many others teenagers were wounded. This was one of 12 high-profile school shootings between 1996 and 2005. The immediacy, the proximity, of this event spurred my own interest, as a psychologist, in the motives for such mass killings and caused me to study the histories of these several all-male, all-White, suburban or rural older children and teens; what would lead them to such atrocities? These were not

the acts of inner-city gang members from big cities or of identified conduct-disordered youth. Just what might be the dynamics of their behavior, many of us asked? Puzzling was the fact that the shootings seem to be indiscriminantly aimed at random targets, rather than specified individuals. Once the horror of it passed, we began to piece together a picture of what might be the psychological precursors of such tragic and desperate actions.

An examination of the media accounts of the school shooters made it obvious that many of the determinants of our model of self-esteem, and its consequences, could be found in the lives of these adolescents (see Harter, Low, et al., 2003). These youth had been the victims of peer rejection, harassment, taunting, and physical abuse. They did not display the attributes that would garner peer acceptance or parental support. Many reported rejection by parents, as well by peers. They seemed to suffer from low self-esteem, by the accounts of those adults who knew them, as well as depression. And they certainly did not appear to be hopeful about the future. Some were suicidal, three actually suicided, and a few others were prevented from suicidal attempts by police on the scene. It thus seemed to us that many of the dynamics in our model of the causes and consequences of self-esteem could be identified in the lives of these youth (see Harter, 2012). Others have documented that victims of bullying present more negative self-concepts than a control group (Houbre,Targuinio, & Lanfranchi, 2010). These authors also observed that victims experience low self-esteem, depression, and difficulty making friends.

Although our model addressed only *lack* of peer support, it became apparent that it was more serious—these young males actively experienced severe peer rejection. Other investigators (see Bellmore & Gillessen, 2006) also reported that adolescents perceived as victims of bullying and acute harassment came to view themselves as disliked by peers, perceived themselves as socially inadequate, and reported negative social self-concepts and low self-esteem (see also Ferrell-Smith, 2012; Jenkins & Denaray, 2012). Others (see McGee & DeBernardo, 1999; Leary, Kowalski, Smith, & Phillips, 2003) also described these same features; boys who were regarded as unattractive, socially inadequate, were loners, were cruelly bullied, teased, rejected, and ostracized, as a result.

Moreover, it has been documented that *ostracism* not only leads to depression but also causes individuals to lose their willingness to control their impulses (Crescioni & Baumeister, 2009; DeWall, Gilman, Sharif, & Rice, 2012). Other research (Denson, Dewall, & Finkel, 2012; Denson, Pederson, Friese, Hahn, & Roberts, 2011) also documented a link between lack of self-control and aggression. Similarly, Winstok (2009) reported that reactive violence among adolescent males is linked to low self-control capabilities. Recent findings also reveal that when faced with acute peer rejection, victims often aggress against the very peers from who they desire acceptance, leading to further rejection (Rejinjes et al., 2011).

Thus, as a first attempt at unraveling these dynamics, we expanded our model to include peer rejection, angry feelings of aggression, as well as violent ideation, in addition to suicidal ideation (Harter, Low, et al., 2003). Consistent with the clinical literature on the comorbidity of internalizing and externalizing symptoms, we found a correlation of $r = .55$, between suicidal and violent ideation toward others. Thus, the determinants and correlates in our model of self-esteem put adolescents at risk for endangering their own, as well as others' lives. The I-self, attentive to the social reactions of others to the me-self, incorporates these reactions and shapes the me-self accordingly. Thus, our most recent model of the causes and consequences of self-esteem and its correlates now includes peer rejection (not just lack of approval), anger (not just depression), and violent ideation (not just suicidal ideation). The model is displayed in Figure 11.1.

The Role of Humiliation

However, the story of the revenge that those who experience such victimization at the hands of peers who reject them does not stop there. The picture of the role of self processes also includes self-conscious *emotions*. One, in particular, was clear in the media accounts of the school shooters: as victims of bullying and harassment, they were all *humiliated*. Humiliation is an emotion that involves the debasement of the self by others, as a cause, and if the attacks against the self become chronic, the victim reacts with angry revenge (Elison & Harter, 2007). In the extreme, as has been revealed in our own society where access to guns is rampant, chronically bullied male youth, whose self-esteem has been compromised and who have, in response, felt humiliated, ultimately responded angrily and desperately, killing others. Our own approach to the issue of the effects of bullying, on the victims, differs somewhat from other conceptualizations in postulating that the emotion of humiliation is a key *mediator* of the violent revenge that the victims ultimately act upon. Chronic bullying leads to low self-esteem and related humiliation, which, in turn, fuels attempts at retribution, and sadly, acts of attempted mass killing. Emotions are powerfully implicated in human behavior, as many thoughtful emotion

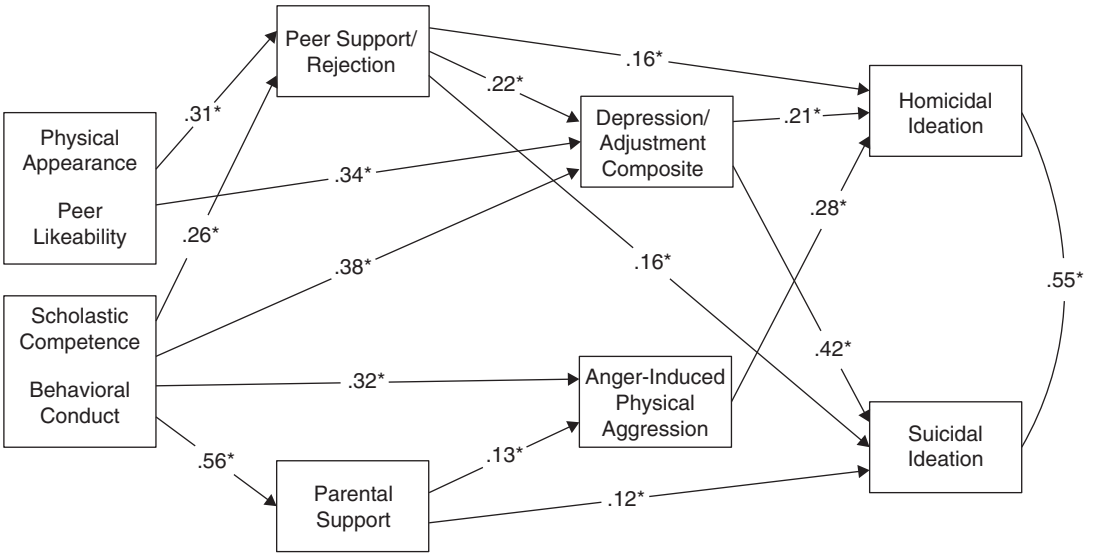

Figure 11.1 Path-Analytical Model for Predictors of Homicidal Ideation and Suicidal Ideation

theorists and researchers have documented (e.g., Fridja, 1986; Lewis & Haviland-Jones, & Barrett, 2008; Saarni, Campos, Camras, & Witherton, 2006), and we are simply echoing a similar framework.

Interestingly, humiliation, as one of a family of *self-conscious* emotions (see Tracy, Robins, & Tangney, 2007) that includes shame, guilt, and embarrassment, has been given short shrift. This, despite the fact that many children and adolescents are humiliated, in schools, playgrounds, and neighborhoods, every day of their lives. Yet there has been surprisingly little empirical research on this critical emotion (Harter, 2012). This is true not only in the research literature but also in the clinical literature. Negrao, Bonanno, Noll, Putnam, and Trickett (2005) noted that attention to humiliation has also be conspicuously absent in the childhood sexual abuse literature, where shame and anger have been the primary focus.

Thus, we have embarked on a program of research over the past decade to document the many critical features of humiliation. For example, we have found that it is critical that there is an *audience* that witnesses acts to demean the victim, psychologically, threatens their sense of self-esteem, that engages in hostile laughter, mocking the victims. In addressing humiliation, it is critical to distinguish it from other self-conscious emotions, shame, guilt, and embarrassment. There are similarities but also differences (see Elison & Harter, 1906; Harter, 2012; Tracy & Robins, 2004). We will summarize these, with a focus on humiliation, addressing the *causes,* implications for the *self,* role of the *other*, *emotional* correlates, and *behavioral consequences* (see also Torres & Bergner, 2012).

The Dimensions of Humiliation

One dimension addresses the *causes* of humiliation. Clearly, bullying, taunting, harassment, mocking, and torture, in the extreme, at the hands of *others* have been identified as powerful, prototypical antecedents (see Elison & Harter, 2007; Gilbert, 1997; Harter, 2012). Ostracism has also been implicated (Hartling, 2007). These causes differ from the antecedents of *shame*, which typically involves a *moral transgression* where, in the parlance of this chapter, the I-self is ashamed of the me-self, for the violation of cultural and personal standards of behavior (Lewis, 1987). Several theorists have argued that humiliation is more *other-focused,* whereas shame is more *self-focused* (Gilbert, 1997; Klein, 1991; Miller, 1988; Sarpharie, 1993). Humiliation can also be distinguished from embarrassment in that it involves the *hostile intent* of others who deliberately engage in overt acts designed to denigrate the victim, to demean them in a manner that lowers their social status (Lacey, 2011). Moreover, the derogation of the victim is judged to be *unfair* or undeserved (Combs, Campbell, Jackson, & Smith, 2010; Gilbert, 1997; Hartling & Luchetta, 1999; Klein, 1991; Statman, 2000; Torres & Bergner, 2010).

Humiliation has definite implications for the self. If the self is seriously devalued in the eyes of others, one loses one's dignity and experiences a major loss of self-esteem, leading to humiliation as a very intense, painful emotional reaction. Klein (1991) described the experience as loss of face, an invasion of the self, at the hands of others. This experience is exacerbated if the personal attack is directed

at one's perceived weaknesses. For example, if the self is viewed as a klutz, then spilling food in a restaurant, and then tripping in an attempt to recover the food on the floor, will reinforce one's trait attributions of clumsiness, intensifying the experience of humiliation. Moreover, in a dissertation by McCarley (2009), we found evidence that the lower the global *self-esteem* that one brings to a potentially humiliating experience, what Tangney and Dearing (2002) referred to as *trait* self-esteem, the more intense the emotional reaction. However, Tangney and Dearing also pointed out that a drop in more transitory or *state* will also be experienced as a *result* of being humiliated.

The specific role of the *other* is also critical in that an *audience* is a prerequisite for the experience of humiliation (Harter, Low, et al., 2003; Harter, Kiang, et al., 2003). Our findings have revealed that humiliation is intensified if the observing others laugh or join in the mockery by the perpetrators. In addition, we have documented the fact that the larger the audience, the more intense are the feelings of humiliation. This feature differentiates humiliation from shame or guilt in that the latter emotions can be personally experienced in the absence of an audience.

There are also clear *emotional correlates* of humiliation. It is likely that embarrassment will be experienced. However, as Elison and Harter (2007) pointed out, the humiliated person will probably first be embarrassed; yet if one merely feels embarrassed by an event of their own doing, for example, walking out of a restroom with toilet paper on his or her shoe, one may feel embarrassed, but not necessarily humiliated. People would only feel humiliated if there was a witnessing audience who began to laugh at them and mock them cruely. However, the emotional correlates that accompany humiliation extend beyond embarrassment. The victim also feels anger toward the perpetrator, if not rage (see Leidner, Sheikh, & Ginges, 2012). The entire constellation of associated emotions also includes sadness and depression, as well as anxiety and fear over future humiliation and attacks against the self.

Intense emotional correlates provide causal links to the *behaviors* that can be provoked. Humiliation and the associated emotion of anger are highly likely to fuel acts of revenge or retaliation, as in the case of the school shooters who were driven to violence given a chronic history of victimization (Combs et al., 2010; Elison & Harter, 2007; Harter, Low, et al., 2003; Hartling, 2007; Jackson, 2000); Leary, Kowalski, Smith, & Phillips, 2003; Smith, 2008; Trumbull, 2008; Walker & Knauer, 2011). Scheff (2011) went so far as to claim that the humiliation–revenge cycle is the most dangerous element in human history. Smith, Webster, Parrott, and Eyre (2002) reported that humiliation, more so than shame, was strongly correlated with hostility (see also Garbarino, 1999). In contrast, shame is more likely to cause the individual to want to escape, hide, or disappear (Harter, Kiang, et al., 2003).

Humiliation and Violence Within the School System

In our own research (Harter, Low, et al., 2003), we have explored young adolescents' reactions to hypothetical events that simulated the types of harassment experienced by the school shooters, albeit it somewhat milder forms, through the creation of vignettes. Two features of these vignettes were noteworthy. First, there is a peer audience that laughs at the victim in a mocking fashion. Second, each vignette ends with a statement to the effect that this was not the first time something like this had happened, implying a history of insult and ridicule, given that being chronically harassed was a feature of the experience of the actual school shooters. We first determined the mean level of rated humiliation, which was 3.4 on a 4-point scale (1 to 4), clearly indicating that the vignettes we created did, as intended, evoke feelings of humiliation. Young adolescents in this normative sample were asked to indicate how likely they would be to react violently, in retaliation or revenge and to rate each of the variables in our revised model. We first divided the sample into violent and nonviolent ideators and then examined their ratings on each of the variables in the model.

Violent ideators, compared with the nonviolent ideators, reported greater anger and blame toward the perpetrators and, interestingly, greater difficulty in getting a humiliating event out of their mind, suggesting the role of rumination. Violent ideators also acknowledged more depressed affect, lower self-esteem, and greater hopelessness. In examining the antecedents of self-esteem and its correlates, violent ideators reported significantly lower feelings of peer likability and physical attractiveness, along with lower feelings of peer approval and higher peer rejection. Parent approval also differentiated the two groups. Violent ideators also report a greater preoccupation with violent media (e.g., movies, TV, video games) as well as more interest in, and access to, weapons and bombs.

Finally, in this same study, we sought to determine whether teachers could identify those students at risk for violence. Thus, teachers were asked to independently rate violent tendencies in their own students. A comparison of teacher ratings with students' own ratings of violent ideation revealed that teachers were largely unaware that a significant number of adolescents in their own classes would harbor thoughts of revenge or retaliation, should they be humiliated. This is not to indict teachers, given that

their job description does not include such detection. The point is that there may be self-report strategies that can help to identify such individuals who are at risk, not only for harmful acts toward others but also toward themselves.

Within the last decade, others have turned their attention to the role of humiliation and violence within the school setting. Phillips (2007) described the dynamics of bullying and verbally and physically attacking victims. The behaviors on the part of bullies are purposeful strategies to affirm masculine norms of toughness, strength, dominance, and control (also see Pollack's, 1998, description of the boy code). Olweus (2008) described bullying as one of the biggest social problems affecting children in our schools today (see also Jenkins & Demaray, 2012; Tenenbaum, Varjas, Meyers, & Parris, 2011). Mattaini (2008) also addressed this concern, observing that rates of harassment, bullying, threats, coercions, and humiliation, and the intentional and hostile exclusion in the peer environment are much higher that even most adults realize (see also Williams & Nida, 2009).

Employing a daily report methodology, Nishina (2012) found that humiliation increased on school days on which adolescent students reported public peer victimization. Meltzer, Vostonis, Bebbington, & Dennis (2011) studied retrospective reports of being bullied in schools during childhood, in a psychiatric sample of adults. Being the victim of bullying led to the experience of suffering defeat and humiliation, which in turn provoked feelings of entrapment, hopelessness, depression, and suicidal ideation or attempts in adulthood. Miller (2012) also pointed to self-destructive behavior, including suicide.

These dynamics extend to our college campus environments, where bullying, in the form of hazing, has become institutionalized (Denmark, Klara, & Baron, 2008). Moreover, it is not merely peers who engage in humiliation tactics; adults in positions of authority (e.g., sports coaches) also use practices such as belittling, rejecting, and emotional abuse to command respect and demand higher levels of performance.

Of course, school officials and parents have become painfully aware of bullying and humiliation within the schools, as it has risen in the consciousness of today's culture, in part due to much greater media coverage. Post-Columbine, there have been several copycat school rampage shootings, which rightfully should be distinguished from other forms of violence (e.g., inner-city gang members targeting single victims in drive-by shootings), as I have also argued (Harter, 2012). Larsin (2009) made a related point, namely, that rampage shootings are to be distinguished from other forms of school violence, for example, a targeted assault on a single individual and gang-related vendettas.

Sadly, awareness of retaliatory violence in the form of mass public shootings has been enhanced by the subsequent murderous actions of a previous university student at Georgia Tech.

Most recently (in 2012), society has witnessed the attempted mass killing of innocent shoppers at a mall in Oregon, the murderous intent of the shooter to kill as many as possible in a movie theater in Aurora, Colorado, and the senseless shooting of 20 young children and six adults in an elementary school in Newtown, Connecticut. We know less, at this point, about the psychological makeup of these shooters, particularly since two of the three killed themselves, attesting to the link between violent acts toward others as well as toward the self. Whether low self-esteem or a history of humiliation was part of their own personal story has yet to be determined; we can only speculate.

These events have provoked an intense new political agenda on the part of the Obama administration, toward enacting tougher gun control legislation, at odds with the powerful National Rifle Association. Others argue for more mental health services to identify potentially deranged individuals as well as preventative measures in terms of support systems and interventions to support people who may well be at risk. Toward this goal, our own studies, as well as the efforts of others, have identified a number of psychological factors within the self-system that contribute to violent and suicidal ideation among our youth.

Cyberbullying

In recent years, a new trend has emerged, both in this country and abroad, namely, *cyberbullying*. This type of harassment is defined as sending demeaning messages on the internet (e.g., Facebook, twitter), email, or texting that involve public or private derogatory comments directed at negative characteristics about the self that are intended to ruin one's reputation (Menesini, Calussi, & Nocentinie, 2012). Pyzalski (2012) operationalized it as a form of bullying understood as peer aggression whereby a bully or perpetrator attacks someone perceived to have lower status, where there is an imbalance of power between the victim and the perpetrators. Whereas children and adolescents, at the end of the school day, can escape the direct form of bullying, be it physical or verbal, they cannot avoid cyber bullying if they are connected to social media, emails, or texting. Thus, it becomes a particularly pernicious form of persecution, all the more so because

it can be done anonymously and oppressively, with little space for escape. One's own room is no longer safe if one is connected to the Internet and these other forms of social media communication.

There is a small, but growing, literature on the topic, although most authors acknowledge that there has been little solid empirical research on the topic. Admittedly, this is a difficult topic to research. That said, there are a few articles that focus on the characteristics of the *bullies*: that they lack the moral values that would prevent such acts by either traditional or cyberbullies (see Menesini, Nocentinin, & Camodeca, 2013), researchers from Italy. Perren and Gutzwiller-Helfenfiner (2012), from Switzerland, also report that a lack of moral emotions and moral values predicted cyberbullying. Another study from Portugal (Almeida, Correia, Marinho, & Garcaia, 2012) documented the role of moral disengagement and lack of empathy. Some investigators cite the need for *self-enhancement* among cyberbullies (Menesini et al., 2012).

Other studies focus on the characteristics of the *victims* of bullying through cyberspace tactics. Some have pointed to the victim's *low self-esteem* (Brighi et al., 2012; Holfeld & Grabe, 2012), *social anxiety* (Holffeld & Grabe, 2012), and *loneliness* (Brighi et al., 2012). While there are similarities between the traditional bullying victim dynamics and cyberbullying, there has not yet been a focus on the humiliation experiences by victims. One report from Luxenberg investigators (Konig, Gollwitzer, & Steffgen, 2010) suggests that some forms of cyberbullying are conducted by victims of bullying who are seeking vengefulness and justice. However, there has yet to be empirical research on the importance of *humiliation* as a mediator between the experience on the part of cyberbullied victims and their acts of revenge and just through what media or behaviors it might be enacted. Thus, much more attention needs to be directed toward these issues, both in this country and abroad.

SUMMARY, THUS FAR

This contemporary excursion into James's (1892) insightful recognition of the I-self, for too long put on the intellectual shelf, has been something of a roller-coaster ride. It began with a developmental perspective, describing how the I-self, defined as changing cognitive abilities, shapes the me-self across three stages of childhood and three stages of adolescence. This discussion also addressed those positive I-self functions identified by James, which included self-awareness, a sense of agency, the continuity of the self and its companion, self-coherence. Although James intended these terms to reflect the adult self, their origins were traced across the six developmental levels.

Next ensued a discussion of the dark side of the demands put upon the I-self in contemporary culture, tracing at each of these same developmental levels, whether and how the I-self had the motives and skills to engage in the self-enhancement tactics and self-serving biases that are observed in adults. Next, we examined how the conspiracy between the I-self and the me-self contributed to five different, though related, forms of developmental psychopathology in which the self was intimately related: (1) narcissism; (2) low and debilitating global self-esteem; (3) depression reactions including suicidal ideation; (4) eating-disordered behaviors; and (5) violence in the form of victims' actions of revenge in the face of harassment and bullying.

However, the point was made that I-self and me-self processes do not develop in a vacuum, the child's socialization experiences impact how these processes unfold. Many benevolent parents support the development of adaptive healthy I-self functioning. In contrast, conditional parent support, where the parental agenda is intrusively foist upon the child, can suppress the child's true self, leading to false self-manifestations. The severe and chronic abuse of children at the hands of caretakers can derail healthy development, compromising such I-self functions as self-awareness, a sense of agency, of self-continuity and of self-coherence. While we have seated certain forms of developmental psychopathology at the interface of what has been labeled a co-conspiracy between the I-self and the me-self, the I-self also has the potential to provoke positive, mental *health*. I would be remiss to not flip the coin given that, as students of developmental psychopathology, our ultimate goal is to understand and ensure healthy functioning. Thus, we turn next to this topic, affording the I-self its rightful position in promoting mental health.

The I-Self's Role in Promoting Mental Health Among our Children and Adolescents

As noted, James (1892) identified several I-self functions, self-awareness, sense of agency, sense of self-continuity, and self-coherence. However, he did not map out how these might be manifest at different developmental levels, nor did he thoughtfully explore the implications for either psychopathology or mental health, to which I now turn. That has been the goal of this chapter.

Awareness

Awareness involves not only self-awareness but also an appreciation for the outer world. Admittedly, one I-self job definition is to scrutinize the inner world of the me-self. But the I-self also directs its awareness, its gaze, to the outer world of reality. It is literally the eye that perceives the world beyond the self with the potential to make many interesting observations, such as sunsets and rainbows and the beauty of nature. It becomes aware of others and the gratification of meaningful relationships. It looks for opportunities to improve one's capabilities, it looks for challenge at an appropriate level. This may occur in one's work situation leading to greater job satisfaction. It may involve leisure activities, reading, writing, gardening, sports, travel, new educational ventures, wonderment, and falling in love. It involves getting a life. Whatever one's choice, such activities can only be pursued if the I-self is unencumbered by its stultifying demands to defensively package and protect a potentially fragile Me-Self.

Sense of Agency

The positive and natural desire to be a causal agent can be captured in many manifestations, including (1) self-efficacy, (2) mastery attempts, (3) intrinsic motivation, and (4) the concept of flow. We will address each of these and then turn to the issues of self-consistency and self-coherence.

Self-Efficacy as an I-Self Process

James's (1892) identification of a sense of agency as a critical I-self function has much in common with a more recent construct in the field, that of *self-efficacy* (Bandura, 1977, 2006). Self-efficacy is actually a belief on the part of the I-self that one can successfully make things happen, it is an I-self observation about one's sense of agency, projected into the future, both near and far. I repeatedly find that self-efficacy is often confused with *self-concept*. (I encounter this confusion when people interested in our own instruments indicate that they are looking for a measure of self-efficacy, whereas our self-perception profiles tap present domain-specific self-concepts and self-esteem, *not* self-efficacy.) So what is the difference? Perceptions of competence or adequacy are *me-self* constructions, namely, the *product* of the self-evaluation process, the *observed* self in the psychological mirror. Self-efficacy is an I-self cognitive belief about one's ability to be successful in the future.

Self-efficacy, since Bandura (1977) first introduced the concept, has permeated the field of psychology as well as many related disciplines. It obviously spoke volumes to many who welcomed the introduction of a construct that captured this dynamic force in human nature. Static self-perceptions did not reflect this vibrant process, the belief that one held the personal power to be efficacious. What are the implications of conceptualizing self-efficacy as an I-self process? How might it be relevant to the goals of this chapter, namely, to identify how I-self and me-self processes contribute, not only to developmental psychopathology but to conceptions of mental health?

Bandura (2006) recently gave us some clues. He embedded this construct within the general debate about psychological *traits* that transcend context versus attributes that are situation-specific, that are very much bound by context. His conclusion is that self-efficacy is best conceptualized as context-specific. One may feel efficacious in one domain but not necessarily in others or all domains. To take a contemporary example, a bright computer nerd may feel that he can contribute brilliantly to the latest social media frenzy but feels far less efficacious in the realms of romantic pursuits or reality TV. Whether one conceives of self-efficacy as trait-like or more situation-specific, however, is not really germane to the issue of pathology versus mental health. The point is that self-efficacy is really a characteristic of the I-self, an active force, be it cognitive or physical activity in which one acts on the world, with the belief that one can achieve an effect in the immediate or distant future. It is one embodiment of James's I-self function of *agency*. It is the I-can force that makes us move confidently forward.

Mastery Motivation

The concept of mastery motivation appears in the work of many scholars and is most frequently invoked in dealing with manifestations in children and adolescents. Originally, it appeared in the writings of Robert White (1959), who described the concept of effectance motivation, a driving force beginning in infancy that propelled the child toward curiosity, exploration, and mastery attempts that were designed to have an effect on one's world. Whether this is kicking one's foot to make the mobile above one's head, attached to a string, jiggle or move, or attempt to master linguistic utterances in order to have an effect on one's caregivers, this is the I-self in action. Among young children, it might amount to kicking a soccer ball to score a goal or using language to impact the significant others in one's world, through communication, where there is

definitely a goal in mind. Thus, mastery attempts became intimately related to *motivational goals* that propel healthy development, very definitely an I-self function.

We see the concept of mastery in Deci and Ryan's self-determination theory (Deci & Ryan, 2000; Ryan & Deci, 2000, 2009), who documented children's strivings for both competence and autonomy. These natural strivings are contrasted to a preoccupation with meeting the external goals established by significant others, captured in contingent reward systems and conditional approval (Harter, 1999), which can compromise these normative and necessary I-self functions. Socializing agents and caregivers, are, therefore, quite relevant.

In a recent creative integration of attachment theory and goal orientation theory, Rusk and Rothman (2010) pursued these themes. From each of their respective perspectives, they argued that caretakers can endanger the pursuit of self-validation goals in contrast to facilitating the I-self functions of cognitive openness, curiosity, mastery, exploration, learning, and effective problem solving for its own sake. They drew upon the attachment theorizing of Mikulincer (1997, 1998), describing how certain caregivers' attachment styles can interfere with these functions. From Mikulincer's perspective, those who are compromised by negative attachment styles (e.g, anxious-ambivalent or -avoidant) that stem from lack of parental responsiveness or attunement will turn to an underlying concern with approval to falsely enhance self-worth rather than a focus on mastery and learning goals. For goal-oriented theories, a major distinction is drawn between *self-validation* and *learning or mastery goals* (see Dweck, 1999; Dweck & Master, 2009; Kaplan & Maehr, 2007; Mikulincer & Shaver, 2007).

Dweck's (1999) work can readily be brought to bear upon this distinction and can be cast into I-self versus me-self terms. Dweck has identified those children who adopt an *entity* theory of characteristics (such as intelligence, social skills) who view such attributes as fixed and immutable. They cannot be altered. She contrasts these individuals to those who adopt who she labels as *incremental* theorists, who see the promise of improvement and change, due to their own personal efforts. The relevance to the me-self versus I-self processes is that those who adopt an entity perspective have much in common with self-validation tendencies; these are individuals who are desperately trying to protect and falsely enhance the me-self. Those who adopt an *incremental* perspective are much more aligned with I-self mastery goals. Thus, the message is that the incremental perspective serves an important I-self function in the service of mental health.

Intrinsic Versus Extrinsic Motivation

Intrinsic motivation, defined by such dimensions as curiosity, exploration, preference for challenge, and the joy of learning for its own sake (Harter, 1981; White, 1959) can be intimately linked to the two aforementioned themes, self-efficacy and mastery motivation. As such, we view them as I-self processes where the energy is directed outward toward interesting pursuits that are rewarding for their own sakes, versus a preoccupation with the fragile me-self, preening nervously in the mirror. Over the years, my own research group has directed a great deal of attention to the distinction between intrinsic versus extrinsic motivation, trying to unravel the correlates and consequences of both orientations. In this chapter, I have revisited this distinction linking intrinsic motivation, as an I-self function to mental health, whereas extrinsic motivation seems more aligned with an orientation toward seeking extrinsic rewards from significant others that focus on protecting the self. This latter perspective, in turn, interferes with true mastery goals and the potential intrinsic joy of competence. But do the consequences of these two orientations really matter?

Our own findings reveal a very high, positive correlation between intrinsic motivation and perceived competence scholastically, including greater pleasure in such accomplishments. These seem more consistent with the I-self functions of mastery and intrinsic motivation. Those who report an extrinsic orientation, more akin to Dweck's students who report an entity interpretation, seem more intent on self-validation goals, a more me-self focus with its compromising features.

However, our findings (Harter, 1981, 1999) reveal, sadly, that intrinsic motivation systematically declines as children move through the school system. We and Eccles (see Eccles & Roeser, 2009) have given trenchant analyses of how the decline in intrinsic motivation is a function of certain educational practices within school systems (see review in Harter, 2012). The purpose of this chapter is not to review these debates. However, there is a subplot here. As a review of the self-esteem movement (Harter, 2012) indicates, the emphasis on falsely enhancing students' views of their skills, competence, and value, places the focus on the me-self and its negative consequences, compromising the I-self functions that can lead to mental health.

The Concept of Flow

Closely aligned to concepts of intrinsic motivation is the construct of flow, introduced initially by Csikszentmialyi (1997). Flow is characterized by a complete absorption in what one is doing, a pleasurable, optimal state of being that seems akin to a Jamesian definition of the I-self. There are links to intrinsic motivation in that one is engaged in rewarding activities, in and of their own sakes, without consideration of extrinsic rewards. Whether these are leisure pursuits or related to aspects of one's profession, typically the dynamics involve perceived challenges that stretch existing skills beyond, but not exceeding, one's capabilities. There are clear proximal goals that allow one to make this determination. Moreover, the process is very pleasurable.

Particularly critical to this chapter is that the flow experience is relatively free of self-consciousness; there is the loss of awareness that one is a social actor. Rather, there is the perception that the activity is intrinsically rewarding, there is no extrinsic goal in sight. Intense concentration is one of the defining features of flow, it is clearly an in the moment experience. There is a loss of a definition of self, of the self-consciousness that so defines the me-self. Flow marks the fading of the me from self-awareness as attention is taken up entirely by the challenges in which one is engaged (Nakamura & Csikszentihalyi, 2002). The ultimate goal is the growth of the individual, as the optimal level of challenge stretches one's existing skills and who one is as a person. The flow experience is thus a force of expansion, consistent with James' intended goal of the I-self.

Self-Continuity

Self-continuity, for James (1892), referred to an I-self function in which there was a sense of continuity or the permanence of the self over time. For young children, this involves the realization that the self is invariant over time, even given changes in outward appearance, for example, wearing different clothes, changing one's hair style, growing taller (Nelson, 2003; Rochat, 2003). Very young children have not yet acquired such a concept. As Piaget (1960) documented, when questioned about whether their gender could change, young boys will acknowledge that they could become a girl, and could grow up to be a mommy, and young girls similarly believe that becoming a boy is a possibility, and they could grow up to be a daddy. Thus, very young children do not display self-continuity; they lack a sense of even physical *self-conservation* (Harter, 1983).

However, by age 5 or 6, children do develop a sense of the permanence of their physical self. There is considerable agreement that *autobiographical memory* is critical to a sense of continuity (Fivush & Haden, 2003). Creating *self-narratives* represents a primary mechanism through which a sense of the continuity of the self is established. Initially, narratives are highly scaffolded by parents, who dictate and reinforce aspects of the child's experience that they feel are important to codify and remember (Fivush & Hudson, 1990; Haden, 2003: Nelson, 2003; Nelson & Fivush, 2004). Increasingly, these autobiographical accounts are *coconstructed* by parent and child, in that the child takes on a greater role in their construction. By mid to late childhood, the child takes the major responsibility for the content and structure of his or her narrative, one's budding life story. Interestingly, there is no demand for total accuracy or completeness. Certain experiences can be omitted, others embellished, at the whim of the narrator. However, when the narrator takes charge of the construction of his or her autobiographical story, then a sense of continuity permeates the continuing narrative.

The I-self function of *agency* contributes to a sense of self-continuity. The perception that the self is continuous provides the individual with a sense of purpose and the direction that one's life will take. It allows one to appreciate who I am and will continue to be. There is a core and enduring self at the helm, in the face of more superficial change. As such, it contributes to a mentally healthy and adaptive approach to the future.

Clinicians have become aware of the importance of a sense of self-continuity when dealing with adult clients who have been severely and chronically abused as children or adolescents. Such individuals typically display forms of pathology where there is the loss of significant chunks of their autobiographical memory and some may never have had the opportunity to create such narratives (see Putnam, 1993). These amnesic gaps in memories, the loss of significant phases of their lives can be extremely derailing, when there is no sense of self-continuity to provide direction in the form of who one is as a person.

For some, this takes the form of low self-esteem, depression, and in some cases suicidal ideation. For others, a different condition may arise, what we have labeled an impoverished self (Harter and Marold, reported in Harter, 1999, 2012). I first encountered such a phenomenon when, in a seminar on the self for experienced clinicians, one astute woman asked me, "But what do you do with a child who *has no self*?" This struck me as a very profound question, for which I did not have a good answer, but it provoked me, in collaboration with clinician Donna Marold, to flesh out what such a developmental history might look like.

The Impoverished Self

The history of what we labeled as an *impoverished self* has it roots in the early socialization practices of caregivers who fail to assist the child in the co-construction of a positive, personally rich, and coherent self-narrative. This typically happens given parents, who because of their own dysfunction (e.g., depression, borderline pathology) and other inadequacies do little in the way of fostering the child's self-narrative (see discussion in Harter, 2012). Marold, in her clinical practice, observes that children with an impoverished self come to therapy with the lack of a descriptive, evaluative vocabulary to define the self and there is little in the way of autobiographical memory or a personally meaningful narrative. The liability is that they have few personal referents or self-concepts around which to organize present experiences. As a result, the behavior of such children will often appear to be disorganized, without purpose. Moreover, to the extent that a richly defined self promotes motivational functions in terms of guides to regulate behavior and to set future goals, such children may appear aimless, with no clear pursuits.

Marold has astutely observed that these children do not have dreams for the future, whereas most children do have future aspirations, as naïve as they may appear to be. They want to be a hero on a professional sports team, or a firefighter, an astronaut, a doctor, or a teacher, a nurse, a veterinarian. However, the parents of children with an impoverished self do not foster goals, nor do they engage in such simple acts as posting the child's artwork or school papers on the refrigerator door. They do not have family rituals such as cooking the child's favorite food or reading (and rereading!) cherished bedtime stories. Marold (see Harter, 2012) has suggested several interventions for working with such children to basically recreate a sense of self-continuity that has been neglected or lost, or create one that has never been established. By observing the consequences of those socialization factors that can interfere with the development of the I-self's sense of continuity over time, we can appreciate its contribution to the healthy adaptation of individuals.

Chandler et al. (2003) addressed the role of a lack of self-continuity among adolescents. They provide findings that those adolescents who fail to develop a strategic justification for the continuity of the self are more prone to suicidal behavior. They lack earlier developmental solutions and cannot create a new workable rationale, which brings with it a lack of personal connectedness to one's past, current, or future self, leading to a sense of futility. Thus, those who "lose the thread of their own personal persistence are at special risk for suicide" (p. 116).

The value of establishing a sense of self-continuity, through the continued construction of autobiographical narratives, carries over into adulthood (McAdams, 1997). In developing and embellishing a self-narrative, the individual creates a sense of continuity over time as well as coherent connections among self-relevant life events. In constructing such a life story, the I-self is assigned an important agentic role as author, temporally sequencing the Me-selves into a coherent self-narrative that provides personal meaning and a sense of future direction. Moreover, as these psychologists argue, narrative construction is a continuous process, as we not only craft but also revise the story or our lives, creating new blueprints that facilitate further architectural development of the self. As such, this cognitive reframing can serve to promote healthier self-development.

The I-Self Function of Self-Coherence

Self-coherence, for James (1892), referred to how, at a given point in time, the various facets of one's personality form a unified, coherent whole. Personal characteristics are consistent with one another and make for a sense of the integrity of one's self-portrait. However, in contrast, in other discussions of the self, James (1890) pointed to the different Me-selves that the I-self constructs. He observed: "Many a youth who is demure enough before his parents and teachers, swears and swaggers like a pirate among his tough young friends" (p. 169). Often, James conceded, these different selves could be discordant, if not contradictory. He labeled this experience *the conflict of the different me's* and described how the incompatibility of potential roles continues into adulthood. As he observed, "A man has as many social selves as there are individuals who recognize him and carry an image of him in their mind" (p. 190).

So how can this conceptual conundrum be resolved, how can there be a *coherent* self in the face of the conflict of the multiple me's? Surprisingly, for this intellectual giant, James had no ready answer. He seemed to emphasize the troublesome contradictions between disparate selves rather than the I-self function of insuring compatibility or coherence. In fact, he accused the I-self of being an elusive if not incorrigible construct, and eventually abandoned his interest in the I-self, never really wrestling with this dilemma. The subsequent discussion will attempt a contemporary explanation that might resolve this apparent contradiction.

It should first be acknowledged that theorists in the first half of the twentieth century did not embrace

James's (1890) pluralistic contentions. There was historical resistance to the notion of discordant selves. Rather, most endorsed a self-consistency ethic. Scholars seemed more enamored with the view that the self was integrated, unified, and rational (Allport, 1961; Horney, 1950; Jung, 1928; Lecky, 1945; Maslow, 1954; Rogers, 1951). For example, Allport emphasized the importance of a sense of *inward unity*. Lecky highlighted the theme of self-consistency and the need to maintain the integrity of the self. Later in the century, Epstein (1973; 1981) argued that one's self-theory must meet the criterion of *internal consistency*, which he formalized as the unity principle, arguing that there is a basic need to ensure the unity and coherence of the conceptual system that defines the self.

However, these formulations, emphasizing the supposed coherence of the self then met with new resistance toward the end of the twentieth century that continued into the twenty-first century, on two fronts: one was empirical, the other sociocultural. The empirical challenge came in the form of findings such as our own, described earlier, revealing a normative liability of adolescent development, more consistent with James's view of the *conflict of the multiple me's* (see Harter, Bouchey, et al., 1997). Our findings demonstrated that beginning in middle adolescence, the different me-selves that the I-self constructs in various roles (with parents, teachers, classmates, close friends, romantic partners, on a part-time job) can be quite inconsistent, if not totally contradictory, causing intra-psychic conflict and emotional distress.

The second challenge came in the philosophical shift from an era viewed as *modernism*, where the emphasis was on the consistency, coherence, and the rationality of human behavior to the current period of *postmodernism* (see Gergen, 1991; Lifton, 1993). Postmodernism initially not only stressed the reality of the multiple selves that contemporary society thrusts upon the self, but focused on the perils of such multiplicity, describing the landscape as cluttered with potentially treacherous minefields. Individuals were described as psychologically compromised by their inability to navigate the contradictory psychological pathway that represented a segmented self.

However, on both fronts, the empirical and the sociocultural, the pendulum has once again shifted. Our own findings (Harter, Bouchey, et al., 1997) have revealed, as described earlier, that the normative *liability* of perceived contradictions between one's multiple selves during midadolescence undergoes a transformation in later adolescence and beyond. Two processes have been documented (Harter, 2012). First, cognitive-developmental advances in the form of higher-order abstractions (Fischer, 1980) can be constructed by the I-self, allowing the older adolescent or adult to integrate what were previously viewed as inconsistencies. For example, the earlier perceptions that one was depressed with parents but cheerful with peers can be integrated into the conclusion that one is *moody* or flexible, thereby precluding the perception of conflict.

The second process involves the *normalization* of previous conflicts within the self. Thus, the older adolescent comes to the conclusion that it is normal and socially acceptable to be different in different roles or social contexts, that it would be weird, in the words of one young man, to be the same self (see Harter, 2012). Moreover, normalization will be more likely if the older adolescent receives the reassuring support of significant adults (see Fischer and Bidell, 2006, on the importance of social support at higher developmental levels during adolescence). As observed earlier in this chapter, most *normative liabilities* are transient as cognitive-developmental and socialization factors come to the rescue. From the perspective of transformational interventions, parents and other significant adults (e.g., counselors or therapists) can provide support for an understanding that it is normal to maintain different selves, providing examples from the teenager's own life situations.

The post-modern era also witnessed a compatible shift in thinking about the multiplicity of the self. The construction of multiple selves was now viewed as a realistic and adaptive stance to the demands of modern life. Thus, it became appropriate to display different selves in different life contexts, shifting one's psychological stances accordingly. Paulhus and Marin (1988) are among those who have endorsed the *functional flexibility* of multiple selves that can be called upon, confidently and adaptively, across different relational contexts.

How do these considerations bear upon the issue of the *coherence* of the self and the I-self's contribution to the mental health of the individual? Our own research and thinking suggests that this requires a redefinition of coherence. No longer do perceived *unity*, consistency, and total integration seem to be the appropriate consideration. That is, the I-self is no longer required to integrate one's diverse role-related attributes into one big happy sense of unity. However, the I-self is not off the hook by this declaration. It must come to the rescue by providing some solution as to how the different facets of the self can comfortably co-exist, and in the process achieve a new sense of coherence.

Our own research also provides some clues, consistent with the observations of Paulus and Marin (1988), in examining certain features of *acculturation* and *bicultural*

adaptation. Tara Mehta, who came to our graduate program from India, was interested in the adaptation of youth from India and other Eastern Asian countries, to the United States, to Chicago, specifically. We became interested in the claims of Berry (2005), a much respected researcher who described the phenomena of acculturation and bicultural adaptation.

Berry (2005) challenged the prevailing uni-dimensional models in which individuals were supposedly required to either retain and vigorously defend the values of their culture of origin, or reject those values and totally embrace American values and traditions. He argued that there were different *combinations* of the endorsement of these two sets of values, for example, (1) rejecting the values of one's culture of origin and embracing American values (which he labeled rejection), (2) retaining the values of one's own culture and rejecting American values (labeled assimilation,) or (3) both retaining one's native cultural values while also adopting American values and traditions (which he labeled integration).

Although we respect his reformulation, Mehta and I challenged his assumption that those endorsing both sets of values truly felt integrated. Such individuals are clearly dealing with the issue of different selves from a more complex multicultural perspective. Our framework was more consistent with the position of Hong, Morris, Chiu, and Benet-Martinez (2000) who observed that two cultural forms of self-appraisal may alternatively be triggered in everyday life, leading to what they labeled cultural frame switching. Thus, such individuals would appear to reflect a bicultural form of adaptation rather than feeling that their different self-appraisals are experienced as a unified, coherent, whole. However, we felt that research was necessary.

To examine this hypothesis empirically, Mehta and I (see Mehta, 2005, described in Harter, 2012) provided young adult respondents (most originally from India) four written options, each of which was accompanied by a puzzle-like drawing that visually depicted each choice (Figure 11.2). We sought to tap four different orientations toward those who fell in the bicultural quadrant, displaying the values of both their culture of origin and American values: (1) true *integration* (first drawing at the top); (2) *unhealthy fragmentation* (second drawing); (3) *healthy differentiation* (third drawing); and (4) *no interest/reflection* on these issues.

Mehta (2005) and I predicted that the majority of these East Asian Indian participants would select the healthy differentiation option and that relatively few would endorse the integrated choice. These predictions were supported in that 70% did select the healthy differentiation option,

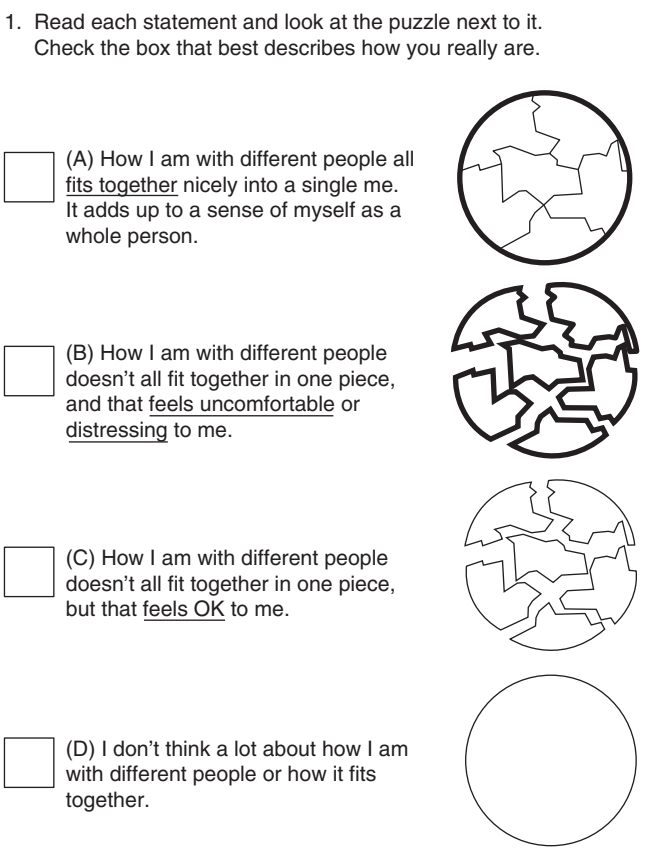

Figure 11.2 Measure to Assess Integration or Differentiation of Multiple Selves

whereas only 13% opted for the integrated choice. Another 13% chose the unhealthy fragmentation description, with only 4% selecting the no interest/reflection choice.

Based on this pattern of findings, we suggested that those who endorse both sets of values should not be conceptualized as displaying the integration of their self attributes, given that this is not their subjective experience, based on our data. Rather, bicultural appears to be the more appropriate designation. Our conclusion is consistent with the perspective of Friedman and Liu (2009), who define biculturalism as the ability to *comfortably understand and act in accordance* with the norms, ways of thinking, and attitudes of two cultural systems. The bicultural individual also has the ability to *shift* between these two systems appropriately, as the situation demands, as Hong et al. (2000) argued.

The findings from this study bear upon the definition of self-coherence as we complete our discussion of the I-self's role in promoting psychological health, beginning with James' contentions about unity of the self. At the same time, he insightfully described the conflict of the different me's, a contradiction that he never really confronted or

resolved. Our own solution is to redefine *self-coherence*, in that different self attributes can *cohere*, stick together (which is the dictionary definition), but not meld. This is the essence of our own conceptualization, operationally defined as healthy differentiation. This is the I-self's task, which will contribute to psychological adaptation for all who realistically experience different self attributes in different social contexts.

For those counseling individuals who are struggling with issues about how to reconcile values of a non-American culture of origin with the values and expectations of American society, the promotion of *healthy differentiation* should be the goal. In terms of transformational interventions, it may also be helpful to employ our visual depiction of the orientations we have studied empirical. That is, research and clinical goals can be integrated. By visually presenting and explaining the different options, one could dissuade the adolescent from thinking that their various selves should feel totally unified. They should be encouraged *not* to feel guilty, ashamed, or conflicted if they honor the values of their country of origin, with family or peers of their original ethnicity but also display American values with their American peers, be they students or coworkers. These roles can comfortably coexist. Counselors or therapists who have done so in their own life would be particularly valuable.

Next, there will be a discussion of cross-cultural differences in how self-coherence is conceptualized and experienced. As the countries of the world become less isolated, and as mobility increases, as in the world of business, there are more demands to think biculturally. However, we must all respect long-standing basic cross-cultural differences in views about self-consistency and self-coherence and how such differences can affect interpersonal relationships, across cultures. Then the stage shifts to broader challenges for the I-self, in the service of mental health.

CROSS-CULTURAL DIFFERENCES IN SELF-COHERENCE

American scholars over the decades have wrestled with the issue of whether the self was experienced as a unified construct versus differentiated, leading to further controversy about whether disparate selves were adaptive versus problematic if not pathological. However, eastern Asian views have remained relatively constant on this issue. Eastern perspectives have espoused a different conceptualization, in that they are more tolerant of inconsistency, ambiguity, and contradiction (Nisbett, Peng, Choi, & Norenzayan, 2001), what these authors refer to as *naïve dialecticism*. When confronted with a potential inconsistency, Chinese participants will attempt to resolve the dilemma through compromise, reasoning that most positions have merit. This type of thinking can be traced to Eastern philosophical notions of Yin and Yan, which are opposing but also integrated forces in the world.

There has been considerable documentation of this cultural distinction within the past decade. Spencer-Rodgers, Peng, Wang, and Hou (2004) examined cultural differences in reasoning about psychological contradictions and the effects of naïve dialecticism on self-evaluations. Their research reveals differences between residents of mainland China and Westerners in their spontaneous self-descriptions. Chinese participants reported more evaluative contradictions. Spencer-Rodgers and colleagues more recently replicated their findings with the Chinese and extended them to the Japanese who also display naïve dialecticism, demonstrating the contradictory, changeable nature of the East Asian concept of self (Spencer-Rogers, Boucher, Mori, Wang, & Peng, 2009). Others (see Hamamura, Heine, & Paulus, 2008) also documented the East Asian tendency toward dialectical thinking, manifest in a tolerance for contradictory beliefs.

Other treatments also focus on the situational specificity that is valued in Eastern cultures, where multiple selves are the norm. Suh (2002) makes explicit reference to such multiplicity that East Asian cultures endorse, which are experienced as comfortably coexisting realities. Suh's research questions the classic thesis in Western psychology that identifies *consistency* as a prerequisite for psychological well-being. Koreans, in his study, viewed themselves as more flexible across interpersonal contexts, which predicted well-being and positive social evaluations, whereas perceptions of identity consistency was a better predictor for North Americans. Spencer-Rodgers et al. (2009) further researched the naïve dialecticism that defines East Asian's tolerance for contradiction and the expectation of situational change in the self.

A similar theme was addressed by Nezlek, Sorrentino, Yasunaga, Otsubo, Allen, and Kouhara (2008), who demonstrated that the self-esteem of Japanese participants changed more in reaction to daily social events (be they positive or negative) than it did for North Americans. Their findings highlight the greater sensitivity of the Japanese to social context in contrast to North Americans. A related study (Tafarodi, Lo, Yamaguchi, Lees, & Katsura, 2004) revealed that East Asian cultures place more emphasis on the contextual adjustment of a person's behavior. Such an adjustment translates into greater variation in the outwardly presented self across contexts. These differences were manifest in comparisons of Canadian adults with Chinese and Japanese participants.

In summary, self-coherence takes on a somewhat different look in East Asian cultures than our revised definition for Americans, where we referred to *healthy differentiation* of one's attributes (Harter, 2012). A commonality involves the notion that the self is differentiated along various culturally appropriate roles, that there is situation specificity in the display of one's attributes. However, East Asians have more tolerance for inconsistency, ambiguity, and contradiction. In contrast, Western thought is fashioned after models of Aristotelian logic that are linear and analytic. Clarity is emphasized with little tolerance for ambiguity. Western formal reasoning requires that contradictions be resolved, only one argument can be logically correct (Nisbett et al., 2001). Although in American culture, adolescents struggle with inconsistency and contradictions in their self-portraits, the ultimate developmental goal is for these inconsistencies and contradictions to be resolved through the logical normalization of such inconsistencies, aided by more mature cognitive processes in the form of higher order abstractions.

MINDFULNESS AS AN I-SELF PROCESS: A BUDDHIST PERSPECTIVE

A central thesis of Buddhism is the cultivation of *egolessness*, which involves the denial of those ego-enhancing strategies that dominate the Western preoccupation with the self. We shall see how mindfulness comes to be a handmaiden for how this can be accomplished. According to one Buddhist scholar, Trungpa Rinpoche (1976), "We build up an idea, a preconception, that self and other are solid and continuous, and once we have this idea, we manipulate our thoughts to confirm it and are afraid of any contrary evidence" (p. 13). According to Rinpoche, we create an intense *watcher,* which is actually a very complicated bureaucracy that we construct to hopefully protect and enhance the self. In I-self, me-self terminology, the watcher represents the rather frenetic, encumbered, and at times, desperate I-self, preoccupied with strategies for managing the impression that the me-self is making on the world.

However, from a Buddhist perspective, one must go beyond this form of self-observation, one must dismantle the complicated bureaucracy that has been created to preserve the falsified illusion of the me-self. The I-self should not be burdened with the impossible task of packaging the me-self so as to be an acceptable psychological commodity in the social marketplace. Rather, the I-self should be directing its energies *outward*, exercising its capacity to enjoy and share life experiences, as opposed to turning inward in its preoccupation with the fabrication of a me-self fitfully designed and distorted to be acceptable to society at large.

How, from a Buddhist perspective, should the I-self achieve these lofty goals? A major answer lies in the cultivation of *mindfulness* that requires a thoughtful awareness of who and where one is in the moment. Here, it is important to contrast the goal of living *in* the moment from living *for* the moment. Living *in* the moment may not always be idyllic, it might call up an awareness that one has to wash the dishes or pay the bills. However, it can be contrasted with living *for* the moment (e.g., let's just get drunk tonight and blow off what we need to prepare for tomorrow). Contemporary psychologists, bridging Eastern and Western perspectives, concur. Langer (2009) describes mindfulness as a flexible state of mind that sensitizes us to our context in the present and opens us up to novel ways of thinking. It is to be aware and attentive in the here and now; this is the essence of being mindful.

Buddhism also encourages us to drop the elaborate fabrication that represents an embellished storyline of our life. Too often we create a Cecile B. DeMille production in which we are simultaneously the director, the producer, and the heroic protagonist: This is my life, the second greatest story ever told! Interestingly, our self dramas typically focus on the past and the future, but not the present. We rarely stop to ask the more critical question: What is going on *right now*? This question is at the core of mindfulness. The goal of mindfulness is the awareness of one's present surroundings, including an accurate perception of oneself.

How, from a Buddhist perspective, can one achieve such mindfulness? In the Buddhist tradition, meditation becomes the pathway to such realizations. A discussion of the essence of meditation practice is beyond the scope of this chapter. However, it begins with the very meaning of the name Buddha, which derives from the word meaning to be awake. A major goal of meditation is to promote mindfulness by reducing our constant mental chatter. We typically engage in considerable cluttered thinking that is reflected in our self-absorbed internal monologues as well as dialogues between our multiple selves. Such thinking diverts our attention from a more mindful focus on the present, which both Eastern and certain Western scholars agree is more adaptive. There have been thoughtful treatments of the meditation process by American psychologists (e.g., Benson, 1975, 1985; Leary, 2004; Langer, 2009; Shapiro, 2009), exploring its benefits, many of which correspond to the Buddhist perspective.

The goals of meditation and the concept of mindfulness, designed to remedy the excesses of the Western self, have much in common with a relatively new emphasis on *quieting the ego* (Wayment & Bauer, 2008). As observed,

in reviewing the many self-enhancement techniques, the Western ego is quite noisy, excessively so in the case of narcissism. Thus, the quiet ego has been contrasted to the noisy, self-aggrandizing ego that requires a self-serving megaphone aimed at audiences whom one hopes will be attentive. However, often the self-promoting proclamations eventually fall on deaf ears.

One feature of the quiet ego is particularly relevant to I-self processes, namely, *detached awareness* (Wayment & Bauer, 2008). Detached awareness refers to the person's awareness of self and situation that is nondefensively detached from egoistic appraisals. In I-self, me-self parlance, the I-self is relieved of its duties to protect and enhance the me-self. Wayment and Bauer also emphasize the role of *humility*, which they view as self-awareness tempered by self-compassion (see also Neff, 2008). In the same vein, Tangney (2009) offered a thoughtful treatment of humility, highlighting one feature that is directly related to the quiet ego. She describes humility as a forgetting of the self, which is *not* a denial of the self. Rather, it requires the recognition that one is but part of the larger universe, putting the self in perspective as a small cog in a much larger world wheel. That said, Tangney is quick to assert that humility is not self-deprecation. It involves the acceptance of one's limitations, as well as strengths, humility respects that while one has a certain degree of personal power, one is not omnipotent. One becomes unselved, in Tangney's view, analogous to the quiet ego.

FURTHER IMPLICATIONS FOR MENTAL HEALTH: THE ROLE OF THE POSITIVE PSYCHOLOGY MOVEMENT

A major goal of this chapter has been to cast developmental psychopathology into a framework of the Jamesian I-self and me-self, arguing that certain I-self/me-self interactions can result in psychopathology. However, it behooves us to translate this framework into our ultimate goals, which are mental health and well-being. Toward this objective, many positive I-self functions have been illuminated. Similar processes have been highlighted in the recent positive psychology movement (see Lopez & Snyder, 2009; Seligman & Csikszentmihalyi, 2000; Snyder & Lopez, 2002). These will briefly be reviewed in keeping with the goals of this chapter.

Keyes (2009), in outlining the criteria for mental health, identified a number of features, including the role of self-acceptance. In the terminology of this chapter, the I-self accepts the me-self, exuding confidence and appreciation for the me-self, without shading into narcissism. The I-self is happy with the me-self, proud of the me-self, although conversely, angry at, or disappointed with, the me-self. In the extreme, such negativity can lead to several forms of psychopathology that have been identified.

Historically, the field of psychopathology has been devoted to a consideration of dysfunctional, negative emotions (see Freud, 1905; Saarni et al., 2006). Emotions such as depression, anxiety, guilt, and shame have been viewed as debilitating. Thus, efforts, initially through psychotherapy but more recently through various prescription drugs, have been designed to reduce negative emotions, as the pathway to mental health. There are two limitations to this approach. From a medical perspective, often pills are not the answer. We do need to respect the fact that negative emotions do have an evolutionary function. Fear alerts us to danger, anger, at an appropriate level, can mobilize us to productive action, and yes, depression, in some circumstances such as grief, can help us to cope with losses.

I am reminded of a compelling popular magazine story (not a research study but a worthy topic.) A mother had lost her 10-year-old son in an unfortunate traffic accident. She went to see a psychiatrist for help in dealing with the tragedy. He proscribed Prozac (the popular drug at the time), and she indeed did feel less depression. Ultimately she resented the medication because it robbed her of the opportunity to appropriately grieve the loss of her son. So we should not be so eager to blot out the negative emotions as the focus of a translational intervention or treatment.

More recently, there has been a shift toward the functional role of *positive* emotions, long ignored as frivolous or irrelevant reactions. Scholars have taken seriously their function. Solid research is proliferating. This is not, in the words of a song some years ago: Don't worry, be happy. Nor is it a girlfriend's advice to just go shopping, buy new shoes, and you'll feel better. I next turn to this new literature, which thoughtfully addresses and researches the functional role of positive emotions.

The Role of Positive Emotions

Frederickson and colleagues, in identifying key components of mental health, from the perspective of self psychology, focus on the role of positive emotions (see Cohn & Frederickson, 2009; Frederickson, 1998). They put forth what is labeled a Broaden-and-Build Theory of positive emotions.

The *broadening* function, an I-self process, refers to the claim that positive feelings serve to widen the array

of thoughts and actions available to the individual, they produce more flexible response tendencies and solutions to life's challenges. As a result of a broadened mind set, one has access to more personal coping resources, which, in turn, enhance the likelihood of success in the future. This broadening function makes the individual more receptive or open to new information and promotes enhanced creativity (see also Isen's, 2000, discussion of the role of positive affect).

According to the *build* function of this theory, once positive emotions broaden the range of potential solutions then the individual's I-self can build upon these options in order to construct enduring personal resources. This building process provides a source of agency for achieving important life goals. Findings from Cohn and Fredericksson (2009) reveal that positive emotions are associated with the ability to develop a more long-range perspective that facilitates the purposeful development of plans and aspirations for the future. Thus, positive emotions can assist the individual in facing and coping with life stressors and thus in promoting mental health.

Positive Affectivity

In a similar vein, Watson and Naragon (2009) invoked the concept of *positive affectivity*, a relatively stable trait that also facilitates well-being. These theorists relate positive affectivity to what has been labeled the big five factor model of personality (see Watson & Clark, 1992). Of particular relevance to a treatment of positive I-self functions is the dimension of *openness to experience*. That is, the I-self not only directs attention to the me-self but to the outer world. It observes a beautiful sunset, it appreciates the beauty to be found in other people. Those high on positive affectivity are more likely to be open to such experiences, furthering a sense of subjective well-being.

Emotional Intelligence

The role of affect in promoting mental health can also be observed in the construct of emotional intelligence (Salovey, Mayer, Caruso, & Yoo, 2009), another theme within the positive self psychology movement. Four processes are key to this formulation that are consistent with additional functions of the I-self:

1. *Perceiving emotions* (e.g., the ability to accurately identify emotions in the self and others)
2. *Understanding emotions* (e.g., the ability to identify the causes and consequences of emotions)
3. *Employing emotions to facilitate problem solving* (e.g., applying creative solutions)
4. *Managing emotions* (e.g., the ability to be open to feelings, both pleasant and unpleasant and utilize them productively)

Emotional Competence

Emotional intelligence bears a close resemblance to the construct of *emotional competence* (Saarni, 1999). The difference is that emotional competencies are graded along a developmental continuum from the most basic to the more mature and complex abilities. Eight levels are identified. At *level 1*, the capacities involve an awareness of one's emotional states, including the possibility that one may experience multiple emotions (see also Harter, 2012). At *level 2,* the individual must develop skills to discern others' emotions based upon situational and expressive clues upon situational and expressive clues that require some degree of cultural consensus as to their emotional meaning. At *level 3,* an important component to emotional competence is the mastery of a culturally relevant vocabulary of emotion labels, namely, verbal facility with commonly employed emotion terminology. At *level 4*, emotional competence also makes reference to the capacity for empathic and sympathetic involvement in another's emotional experiences. At *level 5,* one must further develop skills in understanding that one's inner emotional state need not correspond to its outer expression, both in oneself and others. At *level 6,* emotional competence also refers to the development of skills to cope adaptively with aversive emotions and distressing circumstances by using self-regulatory strategies that weaken the intensity, frequency, or temporal duration of negative emotional states that are destructive. At *level 7*, individuals must come to realize that the nature of a relationship is largely defined by how emotions are communicated within that relationship, where ideally one displays genuineness and authenticity in the expressive display of emotions. At *level 8*, the highest level of emotional competence, *emotional efficacy* is the designated goal. The individual at this level of maturity is very much in touch with his or her emotions and can understand, accept, and respect his or her emotional experiences. Moreover, a person at this level develops a moral belief system about what constitutes the desirable emotional balance in a relationship and strives to meet that goal.

All of these skills, which I would argue demand the attention of the I-self, evolve over time, just as our initial cognitive-developmental analysis described how I-self

functions develop with age as cognitive-developmental skills build upon one another over the six stages that were identified in the overall sequential framework. The developmental acquisition of these emotional competencies, like the mastery of the skills identified under *emotional intelligence*, are viewed as essential components that support mental health and subjective well-being.

These levels have profound implications for translational or clinical interventions. They provide a blueprint for a sequence of states through which one must be guided, somewhat independent of age. One must first assess where an individual is on this progression of stages. Here, it will be important to determine, empirically, how just to assess one's position on this hierarchy, a challenging research task. Is it a developmental hierarchy, first, and how does one investigate this claim? This is the first challenge. It is an appealing notion, particularly because of its translational or clinical implications. But how can such a sequence be empirically validated, across developmental levels? A talented psychologist or psychiatrist might be able, in a clinical interview, to estimate at what level an individual may be, in terms of their emotional skill level. However, in order for this framework to be more useful to many, there must be a thoughtful research program to justify these interesting claims that truly broaden our developmental thinking.

Another new direction might be whether an individual's level along this hierarchy is associated with particular forms of developmental psychopathology. This would represent an invaluable connection between developmental thinking and individual differences that are captured in our categorization of psychopathological disorders. For example, are sociopathic individuals arrested at a particular developmental level? Are borderline pathologies associated with a given level of emotional understanding? This type of union would be welcome in integrating developmental approaches with the developmental psychopathological identification of specific syndromes. Treatment implications might follow.

Emotional Creativity

A related construct put forth by Averill (2009), in support of the tenets of positive psychology, is emotional creativity. There are features in common with emotional intelligence and emotional competence, although there are some nuances that include a focus on creativity as applied to emotions. Two of the components share features in common with these other perspectives. For example, one dimension is labeled Preparation where sample items on an assessment instrument include: When I have strong emotional reactions, I search for the reasons for my feelings; I pay attention to other people's emotions so that I can better understand my own. A second dimension is labeled Effectiveness/Authenticity, where sample items include: My emotions help me achieve my goals in life; The way I experience and express my emotions helps me in my relationships with others; My outward emotional reactions accurately reflect my inner feelings. The third dimension is labeled Novelty and seems to distinguish it from the other frameworks in bringing in the issue of *creativity*. Sample items here include: My emotional reactions are different and unique; I have felt combinations of emotions that other people probably have never experienced: I sometimes experience feelings and emotions that cannot be easily described in ordinary language; I like to imagine situations that call for unusual, uncommon, or unconventional emotional reactions.

The application of this formulation, particularly the dimension involving creativity and novelty sets this framework apart from the previous conceptualizations that related emotional skills and competencies to greater mental health. Averill (2009) discussed these issues in the context of some pathological conditions where the components have been analyzed, and delved into the links between dimensions of spirituality and mysticism, a fascinating direction. The pattern of findings is mixed, although those identifying themselves as mystics score higher on the novelty dimension of emotional experience. The picture is less clear for the one neurotic complex condition selected. However, this work vaults us into the next topic on the issue of whether creativity, outside of the emotional domain, contributes to mental health or its opposite. These arguments will next be reviewed, including how some have seemed to resolve the controversies in a meaningful manner.

Creativity

The more general issue of creativity is relevant to the field of positive psychology as well as to the framework of this chapter, in terms of I-self and me-self functions. It would seem that the I-self is the creative engine, looking inward, looking to the outer world, being open to experience, and trying to balance these observational perspectives. However, as Simonton (2009) cogently argued, there are some controversies in the domain of creativity that must be resolved, where I think the ensuing discussion is reasonably successful.

From a historical perspective, Guilford (1967) was one of thoughtful intellects who made the distinction between

divergent thinking and *convergent* thinking. Divergent thinking was the ability to generate many alternative ides of considerable variety and originality. These were cognitive spewed out, put on the intellectual table, as it were, to later be sifted through for merit and logic and selecting accordingly, the latter convergent process. However, divergent thinking was equated with creativity. (This was the expansive first draft phase as it were, of ideas, drawings, musical notes, and the list goes on, though it depended upon the quality of what was generated! And who was doing the judging, the self or others, and just which others?)

Simonton (2009) first came up with a general observation that creative people tend to have a wide range of interests, greater openness to new experiences, seek more such opportunities, and display more cognitive flexibility and boldness. However, here comes the controversy. Does creativity facilitate mental health? Or, alternatively does it represent that fine line between genius and insanity that puts many so-called creative geniuses over the edge into the land of pathology?

Simonton (2009) attempted to solve the dilemma by postulating two forms of creativity. There is what is termed a *small-c* version of creativity in which those of us have creative flashes that facilitate our problem-solving activities at home, in school, in our work, and are sources of pleasure and pride. (I wasn't thrilled with the terminology because for those of us who can generate such creative flashes in our own home or school or work, it can feel like a big "ahha" experience that is very gratifying. It is no small feat. But I understand the point.) And these experiences may well contribute to subjective well-being and mental health.

The contrast is Big-C creativity, which is demonstrated by those few who make grand creative contributions in their given field (art, literature, music, intellectual endeavors, inventions), contributions to culture, to history, to their own posterity. We will know their names (they have not known ours!). Yet so often, these contributors, the Mozart, Bethoven, many artists, DaVinci, Van Gogh, intellectual giants, Copercnious, Einstein, Darwin, etc. there looms this fine-line argument, were they geniuses, yes, were they also mentally unstable, perhaps. Did the genius contribute to pathology, or did the pathology contribute to the genius? The age-old problem of directionality in psychology where it still difficult to tease about just which caused which?

But this distinction between small-c and Big-C creativity partially separates those for whom creativity can be in the service of mental health (small-c processes) from those in the Big-C category striving to take their art to the big worldwide stage where they want to make a major mark in terms of cultural and historical contributions. And mentally suffer the consequences. If I could be so bold as to make a suggestion, within the humble framework I have tried to develop, I would conjecture that those wanting to be on the big stage of life and culture and the world, making an impact, have had an I-self that eventually becomes overwhelmed, first trying to open the artist to experiences that facilitate his or her craft but then must be totally devoted to packaging the me-self in a manner that will be received favorably by larger and larger audiences on the world's stage. And that contributes to their undoing, ultimately. Obviously, there are trait-like temperamental variables that they bring to their enterprises, as well as socialization experiences, child-rearing, but ultimately when the me-self looks so large that the I-self can no longer protect it, then narcissism and other pathologies creep in.

As an example, I draw upon a marvelous opportunity we in Denver had at the Denver Art Museum this fall and winter. They brought in a most exquisite display of van Gogh's works, dozens of original works brought in from all over the world, filling several rooms, with an excellent audio description of the exhibit where the works were arranged chronologically. Kudos to Christoph Heinrich, the director of the Denver Art Museum, Kira van Lil, an art history professor, and Timothy Standring, the show's curator, and their staff, for a superb and stunning exhibit.

Although the text of the various paintings did not attempt to intentionally pathologize van Gogh, I attended the event with a colleague who is an astute clinician, Shauna Ries, and brought my own psychological lens—it is hard not to in our professions. Van Gogh has certainly been the object of speculation as to his mental health for various reasons, the very nature of his paintings, his bouts of anxiety, his cutting off an ear, his very ungratifying social and intimate life, and his early, untimely, death. My colleague, by the end of the exhibit, studying the various paintings with this background knowledge, came to a possible speculation that he suffered from a pretty severe case of obsessive-compulsive disorder that might have contributed to his reported distress; she felt it in his paintings. We also found it interesting that his many self-portraits, which occurred during the three years preceding his death, might have portended his own prediction of his death, by a self-inflicted gun shot to the chest that was either a suicidal gesture or an accident, as some biographers claim. We speculated that he wanted to leave or preserve a visual memory of his visage for centuries to come, to personalize his legacy, in perpetuity. Biographers say he painted them looking into the mirror, the ultimate me-self obsession.

The point of this excursion into van Gogh was just to bring to life the issue of various forms of creativity some of which might support mental health or alternatively might be more associated with forms of psychopathology that, combined with genius, led to distress for these individuals. Yet we reap the benefits of many of their artistic and other works. The bottom line is that we must value the creativity in our own lives, using it to our greatest advantage to solve intellectual, work-related, and relational challenges toward the goal of subjective well-being and mental health. This will not preclude our fascination with those whose creativity took them over the top, ultimately, for our own cultural, historical, and artistic enjoyment, but at what price to these creators? It would seem that we need both forms of creativity for cultures to successfully survive. And emotional constructs must head the list in terms of these considerations.

POSITIVE PSYCHOLOGY'S EMPHASIS ON ISSUES RELATED TO PERCEPTIONS OF CONTROL: COGNITIVE PLUS EMOTIONAL COMPONENTS

Several themes in the most recent treatments of positive psychology (see Lopez & Snyder, 2009) would appear to echo earlier treatments in this chapter about bringing the I-self's role into mental health considerations. Thus, just the overlap will be briefly presented.

Sense of Control

Thompson (2009) has written about the concept of personal control, which is closely related to self-efficacy (Bandura, 2006). The definition of a sense of control is the judgment that one has the means to obtain desired outcomes and to avoid undesirable outcomes. Thompson wrote that the beneficial features of a sense of control have evolved through evolution, linking it to positive emotions. People who experience positive emotions and a sense of well-being when they had control were more likely to manipulate the environment in ways that increased the chances that their offspring would survive. Those with a drive for control were morel likely to survive and pass on their genes, resulting in an innate desire for control. As such, with the I-self at the helm, control can be a positive force for mental health outcomes and should be fostered through formal and informal interventions, in the therapy room and the classroom.

Self-Determination

Another related construct is self-determination, which is rooted in concepts about self-agency, a Jamesian I-self function (see chapter on self-determination by Wehmeyer, Little, & Sergent, 2009). Little, Hawley, Henrich, and Marsland (2002) defined human agency as "... the sense of personal empowerment which involves both knowing and having with it takes to achieve one's goal" (p. 390). These concepts merge with Deci and Ryan's (2002) focus on the human needs for competence, autonomy, and relatedness. For Deci and Ryan, the socializing environment (e.g., child rearing, schooling) can thwart or contribute to displays of self-determination. People who are causal agents, exhibiting I-self functions, can direct their energies toward achieving or maintaining desired outcomes. As such, the construct of self-determination has much in common with the next topics to be discussed, hope and optimism, more characterized as cognition-emotion hybrids that will contribute to positive mental health.

Optimism

Carver, Scheier, Miller, and Fulford (2009) put a potentially more emotional face on issues of efficacy and control. Still, there is a cognitive focus on expectations for the future, reflecting the pursuit of goals, including desired states and actions. There is an associated expectancy or confidence that the goal can be obtained. Realistic optimism is associated with subjective well-being and enhanced coping skills, both predictive of positive mental health. Pollyanna visions of success, and excessive spin, as we see from politicians, will, in the long run, undermine adaptive outcomes.

Hope

Hope (Rand & Cheavens, 2009) is another construct that is closely aligned with optimism and a sense of agency (Snyder, 1994). An important principle of Snyder's thinking requires the perceived ability to first generate routes to a goal and then execute the determination to successfully bring about that outcome. To the extent that there is a hopeful outcome that is achieved, it will contribute to feelings of well-being. Hope theory shares in common many of the features expressed in the treatment of positive emotions, and thus I will not attempt to be redundant.)

Curiosity

Curiosity qualifies as another I-self function that can impact well-being, and is cited in treatments of the positive

psychology movement. The curious person is open to new experiences and seeks novelty and challenge. As such, theorists have likened it to dimensions of flow, as earlier discussed, and viewed it as another dimension of intrinsic motivation (see Harter, 1981, 2012; Kashdan & Silva, 2009). Curiosity evokes interests and behaviors that are pleasurable, in and of themselves, often stretching the person to new heights. Upon seeking and investing efforts in novel and challenging activities, people with greater curiosity expand their knowledge, skills, goal-directed efforts, and self-awareness (Ainley, Hidi, & Berndorff, 2002). As such, it contributes to well-being.

A complete review of all of the processes that define the emerging emphasis on positive psychology is beyond the scope of this chapter. However, the interested reader is directed toward Lopez and Snyder (2009), where other topics such as forgiveness, gratitude, resilience, and love are also explored.

CONCLUSIONS

This contemporary excursion into James's (1892) insightful recognition of the I-self, for too long put on the intellectual shelf, has been something of a roller-coaster ride. It began with a developmental perspective, describing how the I-self, defined as changing cognitive abilities, shapes the me-self across three stages of childhood and three stages of adolescence. More positive thinking then addressed those positive I-self functions identified by James, which included self-awareness, a sense of agency, the continuity of the self, and its companion self-coherence. Although James intended these terms to reflect the adult self, their origins in this chapter are traced across developmental level. However, the point was made that I-self processes do not develop in a vacuum; the child's socialization experiences impact how these processes unfold. Because the I-self has been neglected, particularly from a developmental perspective, considerably more research needs to be conducted to unravel just how the I-self is constructed. Moreover, its various functions require further investigation because it is the cognitive engine that drives the construction of the me-self (see Harter, 2012).

Next, ensued a discussion of the dark side of the demands put upon the I-self in contemporary culture, tracing at each of these same developmental level whether and how the I self had the motives and skills to engage in the self-enhancement tactics and self-serving biases that are observed to exist in adults. Beginning in midadolescence, teenagers do begin to develop the adult-like capabilities, often exaggerated, which can shade into narcissism, including other pathological forms. This provided a segue into an application of self-processes to severe forms of developmental psychopathology, invoking I-self/me-self functions. Five different applications were presented, taking a developmental approach across three stages of childhood and three stages of adolescence: (1) self-aggrandizement, self-serving biases, self-deception, and narcissism; (2) negative self-evaluations in the form of low self-esteem and poor self-concept; (3) depressive reactions, syndromes, and suicidal behaviors; (4) eating-disordered behaviors; and (5) the role of negative self-processes that can lead to violent revenge in the face of bullying. However, these will require further empirical work, moving beyond mere speculation.

Yet a resurrection of the I-self can end on a note of hope, as I have demonstrated. For this reason, discussion turned to many positive functions that the I-self can perform in the service of mental health and well-being: self-awareness, self-efficacy, sense of agency, mastery motivation, the concept of flow, self-continuity and self-coherence, and mindfulness, from a Buddhist perspective, which includes a focus on egolessness, the quiet ego, humility, and compassion. From a Buddhist perspective, far more fringe benefits will accrue if the I-self averts its myopic gaze away from protecting the me-self through a distorted lens of self-aggrandizement. Consistent with the premises of the field of positive psychology (see Lopez & Snyder, 2009; Snyder & Lopez, 2002) more beneficial outcomes will ensue from an exploration of the I-self's role in promoting *authenticity*, which, in today's Western world, unfortunately seems to be in short supply. These topics, as well, require empirical verification rather than philosophical speculation.

From this relatively new field of positive psychology (see Lopez & Snyder, 2009), other constructs were selected that can be interpreted within an I-self/me-self perspective, highlighting the role of the I-self in promoting mental health and well-being: self-acceptance, the role of positive emotions, positive affectivity, emotional intelligence, emotional competence, emotional creativity, cognitive creativity, sense of control, self-determination, optimism, hope, and curiosity.

Obviously, a comprehensive review of the many features that define the positive psychology literature is beyond the scope of this chapter, as this comes to a close. However, it is noteworthy that these contemporary antidotes to the negative characterization of the self-serving ego represent a

breath of fresh air in terms of resurrecting the I-self. They provide a needed sense of balance, including the search for authenticity, themes that should guide further inquiry and soften our indictment of the me-self, which has become victimized and held hostage by contemporary society, casting the I-self as a potential villain. However, further research is needed before the I-self can be vindicated.

Coda: Putting the I-Self in Perspective

I have asked myself, in crafting this chapter, whether I am reinventing an historical wheel, namely, the age-old homunculous that those in my generation were warned against in Psychology 101. Originally invoked in the practice of Alchemy, scholars conjured up the concept of a little internal man who was infused with the power of directing our thoughts, perceptions, feelings, and behaviors. This notion engendered some appeal in early 1800 theories of psychology, prior to more sophisticated theories of mind. Serious debate ensued in the literature and the notion was eventually defeated, the arguments were deemed fallacious and circular, by the intellectuals who later confronted these issues more empirically (see Ryle, 1949).

I bring this up because in resurrecting the I-self, I do not believe that I am regressing to such earlier thoughts. However, I do tend to personalize the I-self in my writing, because I believe that it is a phenomenological experience in people's lives. As such, it tells a compelling story. Too many psychologists have paid lip service to James's (1892) dichotomy, as some sort of academic reverence, but finding little usefulness in their own work. Forgive me for trying to make it relevant, but it is very useful distinction from a developmental perspective. It has clinical implications, for example, asking clients to reflect on why the I-self is constructing negative me-self self-evaluations. There is also much research needed in terms of further investigating the processes underlying the construction of the me-self, if we truly give the I-self its due.

Moreover, I think we can relate to this distinction given our own personal experiences. I would ask the reader to think about the following: Have you ever said to yourself: I'm so mad at myself, I am so disappointed in myself, I am really proud of myself, I am so happy with myself for what I just accomplished. Or, on a really pleasant social or intimate occasion, we fleetingly observe, I really felt like myself. So let us ask ourselves, Just who is the I doing the talking here? And just who is the object of this reflection? I rest my case! I hope James is smiling in his grave. Or perhaps he and his thinking, in the eyes of contemporary scholars, have been resurrected.

INTRODUCTION

Few youth likely would report that their experiences with peers are irrelevant to their emotional and behavioral development. A majority of children, in fact, spend considerable time with peers; many infants and young children spend more time engaged in peer interactions than with adults, including their parents (Ellis, Rogoff, & Cromer, 1981). Many school-age children indicate that their interactions with peers are a significant source of distress or enjoyment. Children readily can identify specific peers with whom they have friendships, and without whom they feel particularly lonely. By adolescence, youth are more likely to engage in emotional disclosure with peers than with adults, and most utilize feedback from peers as a major determinant for their own developing values, behaviors, and sense of self (Furman & Buhrmester, 1992). Theorists too have highlighted the unique role of *horizontal relationships* with peers in the formation of basic developmental competencies (e.g., Piaget, 1932; Vygotsky, 1981), and diagnosticians have noted difficulties in sustaining adaptive interactions with peers as criteria for major psychiatric disorder (e.g., American Psychological Association [APA], 2013). There is little doubt that peer experiences represent highly salient and developmentally meaningful constructs in understanding youths' maladaptive emotional and behavioral trajectories.

However, peer experiences have been a focus of behavioral scientists' empirical work for a relatively brief period of time. Following decades of a psychoanalytically oriented conceptualization of psychopathology that strongly emphasized early parent–child relations and unresolved libidinal impulses as well as a mid-twentieth-century postwar focus on psychological symptoms among adults (particularly veterans), the study of peer experiences was fairly dormant. Moreover, an understanding of psychopathology more broadly among youth remained elusive.

Studies of young adults experiencing a range of maladaptive outcomes (e.g., significant distress, psychopathology, criminal behavior) brought renewed attention to the study of peers. Roff (1961) revealed that dishonorably discharged military servicemen were more likely than others to have early persistent and severe peer difficulties noted within their early childhood school records. Cowen, Pederson, Babigian, Isso, & Trost (1973) similarly noted that adults receiving psychiatric treatment were more likely than others to have had negative reputations among their peers over a decade earlier; in fact, peer status and reputations discriminated treatment-seeking adults from others more effectively than did a variety of other known predictors of psychopathology (e.g., intellectual ability, physical health, self-esteem, and teacher-reported psychological adjustment). Results such as these unwittingly set an agenda for peer research for decades to come. For the remainder of the twentieth century, dozens of empirical studies were conducted to examine the putative effects of early peer status and reputations on later psychological adjustment. Studies used a host of measures to operationalize peer status and reputations, and examined a wide range of outcomes representing broad and narrow indices of psychopathology. Like some of these early studies, the field also became skewed toward the study of males. In

1987, Parker and Asher published a seminal qualitative review indicating that children who possessed negative status and reputations among their peers were at greatest risk for school dropout, criminal behavior, and other broad indices of psychopathology. This review, and the dozens of studies that were used to support its conclusions, instantiated the peer context as a critical domain for examination among developmental psychopathologists. Few empiricists would deny that peer experiences significantly contribute to youths' development, and may have an etiological role in the development of psychopathology.

It has been almost 30 years since the publication of Parker and Asher's (1987) review. Research on peer experiences currently is abundant and has yielded at least two critical contributions. First, based on a large body of descriptive work, a wide range of peer experiences now has been articulated and operationalized. Although initial work on peer experiences focused almost exclusively on peer status and reputations, and on the construct of peer acceptance–rejection in particular, contemporary work now recognizes that youths' peer relationships, social behaviors, as well as youths' preferences and reputations within the peer milieu each represent related, but distinct peer constructs, varying in form or function across development. Importantly, there remains much work to do in this regard. Although many discrete constructs have been identified, it is clear that youth have developed sophisticated ways of interacting with one another, and regrettably, even more peer behaviors that can cause significant distress among youth. With the advent of more sophisticated technologically mediated forms of peer interaction and a growing awareness of multicultural differences in behaviors among peers, researchers remain challenged to keep abreast of the rapidly changing peer experiences that are so salient and meaningful to youth themselves.

A second substantial contribution offered by recent peer relations research has been the elucidation of cross-sectional and longitudinal correlations among each of many peer relations constructs and indices of maladjustment or psychopathology. Consistent with the tradition set by the groundbreaking work briefly reviewed already, most of this work has focused on peer predictors of psychopathology, rather than vice versa. Most work has focused on externalizing symptom outcomes and health risk behaviors; relatively little research has examined associations among peer relations constructs and internalizing psychopathology. Research has focused on the psychological risks of normative youth who have experienced peer difficulties more than on the peer experiences of clinically referred youth who already have been diagnosed with disorders. Extant data also have offered surprisingly little predictive specificity, and the field of peer relations research often has been critiqued for lacking theoretical frameworks that may organize and guide studies on the putative role of peer experiences on youths' maladjustment. Nevertheless, prior work has offered an excellent foundation for understanding whether peer experiences may be relevant predictors of psychopathology. Much of this work has used robust, follow-forward (sometimes long-term) longitudinal designs to demonstrate the distal effects of peer dysfunction on later maladjustment, often above and beyond competing predictors.

A Developmental Psychopathology Framework

Although the study of peer relations constructs, and associations between peer relations and psychopathology have been remarkably active areas of inquiry, much work is needed to help understand the putative role of peers in youths' development. It is clear that peers provide a context in which development occurs. However, it may be less clear whether peer experiences merely reflect existing developmental incompetence, or whether these experiences may contribute to new deficits. Alternatively, peer experiences may compound existing vulnerabilities, conjointly altering developmental trajectories. Much of this dialectic regarding risk factor models has been discussed for years. In earlier editions of this volume, for instance, researchers articulated several possibilities (Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006). Suggesting that difficulties among peers may be a manifestation of areas of underlying developmental incompetence, or symptoms of psychopathology, an *incidental model* was proposed to explain apparent but not etiological links between peer difficulties and psychopathology. Incidental models are based an assumption of developmental continuities in psychological difficulties. For instance, aggressive behavior in early childhood manifests as disruptive behavior disorders symptoms later in development. Associations between early aggressive behavior and rejection by peers may reveal the social consequences of childhood aggression, but this model suggests no incremental contribution of peer rejection on the prediction of later disruptive behavior symptoms after considering heterotypic continuity in externalizing symptom presentations. In contrast, a "causal model" suggests an association between peer experiences and later psychological symptoms, even after accounting for prior levels of maladjustment. The causal model suggests a direct and independent association between peer difficulties and later psychopathology.

Developmental psychopathology theories and recent research increasingly suggest more sophisticated and necessarily complex models to understand associations between environmental experiences, including peer experiences, and individual development. Developmental psychopathology approaches emphasize multiple levels in which developmental occurs, and the inextricable co-evolution of developmental processes at biological, psychological, social, and cultural levels (Cicchetti & Lynch, 1993). Two tenets of developmental psychopathology theory are especially relevant.

First, transactional models of development suggest that individuals' transactions within the environment are mutually reciprocal and evolve over time (Sameroff, 2000). Linear risk factor models have been most amenable to empirical examination but do not reflect the process by which theorists believe psychopathology develops. Rare is the instance in which a single environmental experience acts in isolation as a predictor of an individual's maladaptive behavior. Rather, an ongoing exchange between an individual youth's behavior, the environmental response to this behavior, and the youth's subsequent reaction to this response (and so on) is most likely to promote the development of psychopathology through modification of developmental competence trajectories.

Theories of contextualism stress the reciprocal influences between an individual's continual development and the evolving social context in which an individual is embedded (Cicchetti & Aber, 1998). Individuals' own characteristics and vulnerabilities affect the social environment just as social experiences can alter the development of individuals' characteristics (Sroufe, 1997). Such transactions are not limited to psychological factors; social experiences can exert effects on myriad biological processes, even including genetic expression (Slavich & Cole, 2013).

Time is an especially important factor within transactional models but further can confound efforts at empirical measurement and testing. Cyclical iterations (i.e., person–environment transactions) may occur within microseconds or over the course of years. Because it is unknown when the observable effects of a specific stimulus may become evident, and the duration of this lag in itself likely is due to factors that vary between people, linear risk factor models are especially unlikely to fit many youths' experience. Rather, transactional models suggest that the product of these cyclical iterations is a change in youths' developmental trajectory, or a new array of potential outcomes and experiences. Altered developmental trajectories bring forth new potential behaviors, and different environmental responses, thus further eliciting complexities in the association between environmental stimuli and individuals' responses. Aggressive behavior may lead to negative reputations among peers, and the resulting ostracism or exclusion may deprive youth of normative opportunities to develop prosocial play behavior, for example. Children with deficits in prosocial behavior may be especially likely to form deviant peer groups that promote the development of antisocial behavior. Externalizing psychopathology is caused neither by peer rejection nor by prior aggressive behavior but rather the altered developmental trajectory in social behavioral development produced by conjoint effects between aggression and peer rejection.

Moreover, transactional models assume developmental variation over time. Not only do youths' repertoire of behaviors become increasingly differentiated and nuanced over time, but also changes in the social environment are predictable. Adult supervision decreases as youth mature. Behavioral expectations also are modified over the life span, as are concomitant norms for (in)appropriate social behavior and the form of social consequences. Each of these factors further is influenced by youths' history and their prior behavior.

Second, a dynamic systems perspective also is necessary for understanding the role of peer relations on the development of psychopathology (e.g., Magnusson & Stattin, 2006). Systems of development include various developmental competencies (e.g., emotional, cognitive, social) and contexts (e.g., biological, peer, family, school, neighborhood)—literally including contexts as innate as one's cellular development and as broad as community or cultural influence. Developmental systems are mutually informative and influential as youth mature. Experiences with peers are embedded within broader systems of development and have a potential impact on numerous competencies outside the peer or even social domain more broadly. Increasingly, research has embraced multilevel investigations conceptualizing social environmental experiences as relevant for understanding cognitive and biological developmental processes that promote psychopathology. For instance, recent work suggests that chronic social rejection and concomitant negative cognitive appraisals may have long-lasting effects on the central and peripheral nervous systems. These effects likely are the consequence of epigenetic modifications at the molecular level that alter gene expression and subsequently may compromise immune functioning, alter brain activity, and perhaps promote psychopathology symptoms (Slavich & Cole, 2013). A related line of research suggests that negative social experiences may trigger neural responses similar to the effects of physically injurious experiences

on the affective experience of pain. In other words, social pain triggers brain regions in a manner similar to physical pain and may have implications for affective regulation and the development of psychopathological symptoms (Eisenberger, 2012; MacDonald, & Leary, 2005).

The study of peer processes as relevant contributors to other developmental systems, and to multilevel processes has gained attention only recently. Yet this is an especially important direction for ongoing study in the relevance of peer experiences in the development of psychopathology.

Organization of This Chapter

This chapter was written to accomplish several objectives. First, the chapter offers an overview of the constructs frequently examined within peer relations research. This overview is not exhaustive, as it would be impossible to provide sufficient coverage of the many topics that peer relations researchers have examined. Key constructs that have received the greatest attention within the study of psychopathology have been highlighted. For each, operationalization of theoretical constructs is discussed. A second goal of this chapter is to review patterns of consistent findings linking peer relations constructs with indices of psychopathology. Third, theories of psychopathology with implications for understanding the role of peers are noted and used to interpret results within the peer relations field. Due to the unfortunate segregation of research into increasingly artificial subdisciplines of psychology (e.g., developmental, clinical, cognitive, neuroscience), prior research in peer relations rarely has integrated conceptual frameworks from the broader discipline. This chapter attempts to offer some directions for further collaboration and cross-pollination within social science fields. Last, a main emphasis of this chapter is to note efforts to understand peer processes from a developmental psychopathology perspective, incorporating transactional and dynamic systems frameworks and emerging research examining broader multilevel models.

The chapter is organized developmentally, beginning with a review of research examining infancy and early childhood, followed by work on school age-children and adolescence. Naturally, the organization of this chapter into half-decade segments is an artificial categorization of both the nature of developmental processes and the approach used within some peer relations research. Nevertheless, this offers a useful framework for organizing a large body of research. The depth of coverage of work across developmental periods is broadly commensurate with the focus on each phase of youth in the peer relations literature.

INFANCY AND EARLY CHILDHOOD

Infants and youth in early childhood have meaningful peer interactions. Newborns attend not only to their parents but also to peers through mutual eye contact, touching, and vocalizing (Vandell, Wilson, & Buchanan, 1980). Over the first two years of life, toddlers begin to engage in some play behaviors with peers, developing rudimentary reciprocal turn-taking skills, sharing, and directed vocalizations. By 3 years of age, most children can express empathy and engage in some conflict regulation skills (Mueller & Brenner, 1977). Toddlers exhibit surprisingly advanced social knowledge; they can identify a peer's distress and provide comfort through emotional support (Caplan & Hay, 1989). Within the third year, children also can express fairly stable preferences for one another, reporting which children they like the most or least (Denham, McKinley, Couchoud, & Holt, 1990). Ages 3 to 4 years are accompanied by increased sophistication in social behaviors. Play interactions include increasingly complex scenarios and games, which include an increase in the communication of rules, negotiation of leadership skills, and peers' mutual use of social consequences (Fein, 1981). Although children express preferences for one another earlier in life, reciprocated friendships become apparent by the age of 3 to 4 years. These friendships involve a clear preference for mutual companionship and increased levels of positive behavior. Children express different types of affect among friends compared with nonfriend peers (Gershman & Hayes, 1983).

Social Withdrawal

Not all children adapt to the early peer environment in similar ways, however. Although most children actively seek interactions with other peers, some children do not. Social withdrawal is defined as a consistent display of solitary behavior when encountering unfamiliar or familiar peers (Rubin, Bowker, & Kennedy, 2009). Social withdrawal is differentiated from *active isolation* (i.e., rejection and exclusion by others), instead referring to children's own choice to remain alone. Building on approach and avoidance theories, at least three subgroups of internally motivated social withdrawal have been articulated (Coplan & Armer, 2007). First, anxious-withdrawn children include those who wish to interact with other peers (i.e., high social-approach motivation) but withdraw to fearfulness and anxiety that accompany these social situations (i.e., high social-avoidance motivation). A second subgroup includes unsociable (or socially disinterested) children who

lack a strong desire to interact with other peers (i.e., low social-approach motivation) but on the contrary do not experience emotional dysregulation (e.g., anxiety) in social situations (i.e., low social-avoidance motivation). Finally, socially avoidant children show a low social approach and a high social avoidance motivation. Although at least from a theoretical point of view avoidant children can be identified, this subgroup of children has received remarkably little empirical attention, likely due to the challenges of operationalizing this construct.

Despite the theoretical relevance of differentiating between social withdrawal subtypes and the growing body of research focusing on unsociable children, to date most extant work either has operationalized social withdrawal as a unidimensional construct (without distinguishing internal motivations of social isolation) or exclusively has examined anxious and fearful withdrawn children. Consequently, comparisons within the literature among studies of withdrawn children can be difficult. Moreover, related research on behavioral inhibition, shyness, and anxious solitude also overlap with studies of social withdrawal (see Rubin & Coplan, 2010, for a review). Next, social withdrawal is discussed broadly, and particular attention is dedicated toward research that has differentiated internal motivations underlying social isolation.

Research has suggested that social withdrawal may have its origin in behavioral inhibition, a temperamental trait that can be identified already within the first years of life (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001). Young toddlers who are behaviorally inhibited display negative emotional and motor reactivity in front of unfamiliar social and nonsocial stimuli, including people and objects (Kagan, Reznick, Clarke, Snidman, & Garcia-Coll, 1984). Behavioral inhibition has been proposed to have a biological basis and is associated with a number of unique physiological responses (see Fox, Henderson, Marshall, Nichols, & Ghera, 2005). When confronted with novel stimuli (e.g., visual images), inhibited children demonstrate right frontal electroencephalogram (EEG) asymmetry, increased heart rate variability, and heightened cortisol release compared with their uninhibited peers. Such findings suggest that behavioral inhibition is characterized by amygdala hyperactivity—a hypothesis that has received further direct support in recent functional magnetic resonance imaging (fMRI) studies (e.g., Schwartz et al., 2012).

Studies examining the homotypic and heterotypic continuity of behavioral inhibition throughout childhood (as well as adolescence) have revealed only moderate continuity. In selected samples of inhibited toddlers, approximately 70% show signs of behavioral inhibition later in childhood; within unselected samples only half of toddlers show behavioral continuity in inhibited behavior (for a review, see Degnan & Fox, 2007). Thus, although behavioral inhibition may be an antecedent to social withdrawal, not all inhibited toddlers will display withdrawal behaviors later in childhood when in the presence of other peers, and, accordingly, not all socially withdrawn children show behavioral inhibition earlier in life. In this regard, ample work has been dedicated to identify potential (intrinsic and extrinsic) moderating factors that alter the development of behavioral inhibition and influence the pathway from behavioral inhibition to social withdrawal and, eventually, to psychopathology (Degnan & Fox, 2007). For instance, Rubin, Burgess, and Hastings (2002) demonstrated that inhibited 2-year-old toddlers who had psychologically overcontrolling mothers (i.e., intrusive and derisive mothers) were more likely to exhibit social withdrawal (e.g., reticent behavior) in the presence of unfamiliar peers by age 4 years compared with inhibited toddlers with nonovercontrolling mothers. Notably, some researchers have emphasized that children who display withdrawal behaviors in the presence of unfamiliar (or familiar) peers may be specifically at risk for developing psychopathology compared with children who are inhibited exclusively among nonsocial situations or among unfamiliar adults. Thus, social withdrawal is a distinct and perhaps more risky phenotype compared with behavioral inhibition. Compared with behaviorally inhibited youth (generally), socially withdrawn children in particular may have altered peer experiences and ultimately greater risk for developing psychological disorders (Rubin, Bowker, & Kennedy, 2009).

To date, there is ample evidence that socially withdrawn children have unique peer experiences that likely deprive youth of opportunities to develop typical social competencies (Rubin, Coplan, & Bowker, 2009). For instance, in dyadic free play interactions, socially withdrawn children rarely initiate interactions with other peers and more frequently engage in solitary behaviors, such as reticent behavior (i.e., prolonged observation of other children without accompanying play and being unoccupied; Coplan, Rubin, Fox, Calkins, & Stewart, 1994), and solitary-passive play (i.e., exploration of objects or constructive activity while playing alone). Compared with nonwithdrawn children, socially withdrawn children also are less socially assertive and have limited social problem-solving strategies (Stewart & Rubin, 1995). Thus, not only do withdrawn children interact less frequently with their peers, but also when they do they appear to be less socially skilled. Perhaps not surprisingly, therefore, social withdrawal is

associated with short- and long-term difficulties in peer relationships (Rubin, Bowker, & Gazelle, 2010). Young children engaging in reticent behavior receive fewer interactional initiations from peers (Chen, DeSouza, Chen, & Wang, 2006) and are more likely than others to be excluded, rejected, and victimized by other children, both concurrently and later in development (Gazelle & Ladd, 2003).

Socially withdrawn children are equally as likely as nonwithdrawn children to have at least one mutual stable friend (e.g., Rubin, Wojslawowicz, Rose-Krasnor, Booth-LaForce, & Burgess, 2006); however, their friendships are likely to be less adaptive in at least two ways. First, withdrawn children tend to have friends who are similarly as withdrawn as they are (Haselager, Hartup, van Lieshout, & Riksen-Walraven, 1998). Second, the friendships of withdrawn children are characterized by limited positive interactions and lower relationship quality (Rubin et al., 2006).

Notably, differences in play behavior and social skill are evident across subtypes of withdrawn children. Compared with anxious-solitary children, unsociable youth can demonstrate competent social behaviors when in a social interaction (Harrist, Zaia, Bates, Dodge, & Pettit, 1997). Anxious-solitary children demonstrate consistent social deficits, however. Both unsociable and anxious-solitary children are at risk for being rejected by peers, at least in early childhood (Coplan & Weeks, 2010). Later in development, unsociable children do not appear to be at as great a risk for peer difficulties as are anxious-solitary youth (Coplan et al., 2012). The few studies examining socially avoidant youth suggest that, similarly to anxious-solitary youth, they are likely to experience difficulties with other peers (e.g., Bowker & Raja, 2011).

Social Withdrawal and Internalizing Distress

In light of the temperamental characteristics of withdrawn children and the interpersonal difficulties to which they likely are exposed, the link between social withdrawal and symptoms of psychopathology is not surprising. Social withdrawal is a concurrent predictor of social anxiety, depressive symptoms, and loneliness (e.g., Rubin, Chen, & Hymel, 1993; Strauss, Forehand, Smith, & Frame, 1986; Vanhalst, Luyckx, & Goossens, 2014). Gazelle, Workman, and Allan (2010) revealed that compared with their nonanxious-solitary agemates, anxious-solitary children are more likely to be diagnosed with anxiety or mood disorders.

Social withdrawal during early childhood also has long-term effects on internalizing symptoms. Early social withdrawal prospectively predicts depressive symptoms and loneliness in middle childhood (Hymel, Rubin, Rowden, & LeMare, 1990). Similarly, shy-inhibited temperament in childhood prospectively predicts anxiety in adolescence (Prior, Smart, Sanson, & Oberklaid, 2000). It has been suggested that the effects of social withdrawal on internalizing problems may increase with age (Rubin et al., 2009); that is, early social withdrawal may become a stronger risk factor for internalizing symptoms during middle and late childhood than in early childhood. Social withdrawal also has been associated with negative self-perceptions and depressogenic attributional styles (Burgess & Younger, 2006). When subtypes of social withdrawal have been examined, results suggest that anxious-solitary (or shy-withdrawn) and avoidant children are both at risk for internalizing outcomes, while unsociable children may not be at risk for developing psychopathology (Coplan et al., 2012).

Thus, substantial evidence suggests that socially withdrawn children, and anxious-solitary youth in particular, are at increased risk for internalizing psychopathology. Of course, a parsimonious interpretation of research findings might therefore suggest continuity in anxious/inhibited behavior across development, in which temperamental traits are expressed as social difficulties and ultimately internalizing disorder later in development. However, social withdrawal appears to affect the continuity of anxious behavior in meaningful ways.

Recent research has examined hypotheses utilizing such a developmental psychopathology perspective. First, studies suggest that the effect of social withdrawal on later symptoms of psychopathology occur via peer relationships (e.g., Boivin, Hymel, & Bukowski, 1995; Katz, Conway, Hammen, Brennan, & Najman 2011). For instance, Katz and colleagues (2011) revealed that indicators of social withdrawal measured at age 5 years did not have a direct effect on depression diagnosis at age 20; instead, an indirect pathway was observed, in which social withdrawal at age 5 years predicted social impairment at age 15, which in turn increased the probability of a major depressive disorder diagnosis at age 20.

Second, empirical evidence indicate that prospective bidirectional effects may occur between social withdrawal and peer relationships throughout childhood and adolescence. Although most studies have demonstrated that social withdrawal may increase children's risk for experiencing peer difficulties, other work also has documented that in childhood and adolescence peer relationships prospectively may affect social withdrawal (e.g., Booth-LaForce et al., 2012; Gazelle & Ladd, 2003; Oh et al., 2008). For example, peer factors in middle childhood distinguish among children with different developmental trajectories of social withdrawal from middle childhood (Grade 5) to

early adolescence (Grade 8) (Oh et al., 2008). Interestingly, higher peer exclusion in middle childhood enhanced children's probability of membership in an increasing rather than low stable trajectory of social withdrawal. Moreover, among children who followed an increasing trajectory, those who did not have a mutual best friend, and a stable friendship at baseline, revealed steeper increases in social withdrawal, compared with children with a best friend and a stable friendship. These findings indicate that peer relationships, both at the group and dyadic levels, may alter the development of children social withdrawal.

Finally, a number of studies have demonstrated that withdrawn children who also experience peer difficulties (e.g., peer rejection) are particularly at risk for internalizing problems. Bukowski, Laursen, and Hoza (2010) examined a specific type of cascade model (i.e., snowballing cascade) to see the combined effect of withdrawal and peer relationships (i.e., peer exclusion and friendship) on trajectories of preadolescents' depressive symptoms over a three-year period. Results indicated that friendship moderated the conjoint effect of social withdrawal and peer exclusion on the development of depressive symptoms. Rejected-withdrawn children who also did not have a mutual best friend had steeper increasing trajectories of depressive symptoms; however, rejected-withdrawn children who were involved in a mutual best friendship had declining trajectories of depression.

In sum, evidence is accumulating to support a developmental cascade multilevel model involving mutually influential transactions between young children's temperamental traits and evoked environmental experiences that conjointly influence internalizing symptom trajectories. This model suggests that behavioral inhibition in the first years of life among children may evoke overprotective caregiver responses that in turn may further exacerbate children's inhibition and withdrawal behaviors during interactions with peers (Rubin, Coplan, & Bowker, 2009). Socially withdrawn behaviors, and resulting peer difficulties, may conjointly influence the development of later internalizing symptoms.

SCHOOL-AGE CHILDREN

By the time children reach 5 to 6 years of age and enter formal schooling in most communities, most have developed *peer competence*, including the capacity to engage in mutual, cooperative peer interactions that are characterized by positive affect. Yet considerable variability in children's peer competence is evident. Difficulties emerge in children's ability to develop reciprocated interest among peers, both within the overall peer group and within dyadic interactions. For instance, some children develop negative reputations within the peer group, leading to rejection, unpopularity, or victimization from peers. Some children also experience significant difficulties forming stable friendships or relationships characterized by positive friendship qualities. Each of these specific peer experiences (i.e., peer status, peer victimization, and friendships) has been examined as distinct constructs within the peer relations literature.

Peer Status

One of the most frequently used indices to capture children's overall success within the peer group is their level of acceptance or rejection among peers. The use of peer nominations to capture children's peer acceptance or rejection (i.e., peer likeability) has been common for many years, and this construct probably has been examined more frequently than almost any other aspect of children's peer relations. Moreover, although research certainly has examined peer acceptance/rejection prior to the school-age period, and well into adolescence, most prior work has measured this construct among youth during the school-age years. Recent developments in the conceptualization of peer status, particularly its developmental heterogeneity, have led to semantic obfuscation, however. In prior literature, this construct has been referred to as peer status, sociometric status, social preference, likeability, or even popularity. We elect to refer to this construct as peer acceptance/rejection to remain most consistent with the manner in which this construct is operationalized.

Due to known biases in self-, parent-, and teacher-reported indices of youths' overall peer experiences and the high ecological validity associated with the use of an aggregated peer report measure to understand children's experiences among peers, the use of peer ratings or nominations is considered a gold standard for assessing peer acceptance/rejection. Quite simply, peer nomination measures customarily involve research participants' unlimited selection of peers from a roster of classmates/grademates that they like the most and like the least, yielding two orthogonal scores. A standardized difference between each child's standardized tally of positive and negative nominations, respectively, is computed as a continuous measure of peer acceptance/rejection (referred to as social preference), while a standardized sum between these standardized tallies can be used as an index of visibility within the peer network (i.e., social impact). A commonly used algorithm can be employed to categorize scores of peer acceptance, rejection, social preference, and social impact into five

sociometric status groups: popular, rejected, neglected, controversial, and average (see Coie & Dodge, 1983). Notably, the classification of some youth as popular based on this assessment of peer acceptance/rejection may be a misnomer, as subsequent research recently has identified a unique construct that more closely resembles what most youth consider to represent popularity.

Children's peer acceptance/rejection appears to be quite stable across time and contexts. Longitudinal work suggests that children's peer status categories remain consistent over multiple developmental transitions, with moderate stability over several consecutive assessments (see Cillessen, Bukowski, & Haselager, 2000). Innovative experimental work also demonstrates that children's level of peer acceptance/rejection among familiar peers is very quickly replicated within groups of unfamiliar peers (Coie & Kupersmidt, 1983; Dodge, 1983). Similarly, a meta-analysis including more than 18,000 participants has shown high stability for the continuous measures of peer acceptance, rejection, and social preference across childhood as well as adolescence (Jiang & Cillessen, 2005). Such intriguing results suggest that peer status may serve as a marker for other child traits or difficulties that persist across lengthy developmental periods or across multiple contexts.

Indeed, many determinants of peer status have been identified in studies of children's behavioral and physical characteristics, cognitive and emotional competencies, and family factors. Some of these predictors are relevant to consider as possible precursors of psychopathology in themselves. Perhaps not surprisingly, the most robust predictors of children's peer acceptance/rejection appear to be youths' own social behaviors. Children who are aggressive are highly likely to be rejected by their peers. Rejected children also exhibit greater internalizing difficulties than others (e.g., anxiety, depression, withdrawal) and demonstrate poorer social skills (Newcomb, Bukowski, & Pattee, 1993). In contrast, popular youth often are rated as social leaders with high ratings of prosocial skill (e.g., helping others, kind) and athleticism. Neglected youth exhibit few differences from their peers with average sociometric status other than less frequent social interaction and somewhat elevated levels of social withdrawal. Interestingly, neglected peer status is the least stable of the nonaverage status groups over time (Cillessen et al., 2000). Controversial youth possess a blend of traits that are common among both rejected youth (i.e., aggressive behavior, breaking rules) and popular youth (i.e., positive social interactions, extroversion, and good humor). At younger ages, higher levels of intelligence are associated with higher levels of peer acceptance; by preadolescence, higher levels of intelligence, particularly when combined with children's effortful presentation of academically oriented goals, are associated with lower levels of peer acceptance (Juvonen & Murdock, 1995). Correlates of high intelligence, including high problem-solving skills, high academic achievement, and teacher preferences, also are associated with popular peer status among young school-age children. Numerous studies have demonstrated that markers of facial and body attractiveness also predict high levels of peer acceptance, while child obesity has been associated with peer rejection (Bell & Morgan, 2000; Dodge, 1983).

In addition to children's physical and behavioral characteristics, family determinants of children's peer status also have been identified. Some of these family determinants are markers for the social environment in which children are raised (Parke & Ladd, 1992). For example, maternal psychopathology, particularly depressive symptoms, and mothers' own social skill deficits are associated with their children's peer rejection. Parents' engagement in authoritarian or lax parenting, low emotional expressiveness, and parent–child play behavior characterized by power assertion all are associated with children's peer rejection. Children who demonstrate insecure attachment relationships also are more likely than others to experience rejection by peers (Parke & Ladd, 1992). Parents' management of their children's social experiences also is associated longitudinally with their child's peer acceptance/rejection; however, associations are dependent upon the developmental appropriateness of these parenting behaviors. Parents who actively initiate social interaction for their young children, and closely monitor their children's peer interactions have children more likely than others to experience peer acceptance. However, these same parenting behaviors are associated with peer rejection when measured among older children. Like other aspects of development, results suggest that parents' scaffolding of social interaction experiences appear to produce maximally adaptive outcomes (Parke & Ladd, 1992).

Peer Acceptance/Rejection and Externalizing Symptoms

It should be noted that many of the child and family determinants of school-age children's peer acceptance/rejection also are known risk factors for psychological symptoms among youth. For instance, children's aggression with peers and poor problem-solving skills are known risk factors for later externalizing symptoms. Maternal depression, insecure attachment relationships, and maladaptive parenting also have been associated longitudinally with children's own internalizing and externalizing symptoms.

Thus, a critical question among researchers examining peer acceptance/rejection as a putative risk factor for psychopathology has been whether peer experiences offer incremental predictive value in the prediction of later psychopathology. Studies using prospective longitudinal designs, predicting psychological symptoms while controlling for initial levels of psychopathology, largely have supported this hypothesis.

Over 30 prospective longitudinal studies have demonstrated that peer rejection is associated with later aggressive, delinquent, oppositional, and illegal behavior (e.g., Coie, Terry, Lenox, Lochman, & Hyman, 1995). Findings suggest long-term effects (i.e., peer rejection predicts outcomes up to 10 years later; Laird, Pettit, Dodge, & Bates, 2005) and robust effects across multiple informants of peer rejection (i.e., peer and teacher reported; Coie et al., 1995). Moreover, results indicate similar effects at different developmental stages. Peer rejection predicts externalizing symptoms in early childhood (e.g., kindergarten and first grade; Dodge et al., 2003), middle childhood (e.g., Coie et al., 1995), and adolescence (e.g., eighth to tenth grade; Prinstein & Cillessen, 2003). Results are consistent among studies predicting elevations on symptom checklists (Kupersmidt & Patterson, 1991), the presence of externalizing diagnoses (Miller-Johnson et al., 2002), and criminal offenses according to public records (Nelson & Dishion, 2004). It appears that these findings are similar for predominantly Caucasian samples (Lewin, Davis, & Hops, 1999), exclusively African American samples (Rabiner, Coie, Miller-Johnson, Boykin, & Lochman, 2005), and ethnically heterogeneous samples (Prinstein & La Greca, 2004).

Yet, despite the many studies examining a main effect of peer rejection as a risk factor for psychopathology, little theory initially had been offered to suggest why peer rejection may lead to externalizing symptoms. Indeed, children's peer acceptance/rejection likely does not act in isolation as a risk factor, but it may be one part of broader person–environment transactions that promote maladaptation. Recent theory and research suggests bidirectional effects between peer rejection and psychopathology. Moreover, there is some evidence that children's experiences with peers act in concert with perturbations in other developmental systems, offering a more thorough understanding of how peer rejection may contribute to trajectories of psychopathology.

Aggressive behavior and peer rejection are mutually reinforcing; results reveal bidirectional effects between peer rejection and externalizing problems beginning in early childhood (Sturaro, van Lier, Cuijpers, & Koot, 2011). For instance, youths' aggressive behavior, particularly reactive aggression, may be a response to exclusion, victimization, or other manifestations of rejection by peers; simultaneously, in most contexts, aggressive behavior elicits aversive responses from others (Dodge et al., 2003). Interestingly, the stability of peer rejection is greater among aggressive youth than among nonaggressive youth (Cillessen, van IJzendoorn, Van Lieshout, & Hartup, 1992). The combination of peer rejection and aggression delays developmental competencies more pervasively than either of these characteristics alone (Cillessen et al., 1992) and predicts later externalizing symptoms especially potently (Bierman & Wargo, 1995). For example, Bierman and Wargo (1995) revealed that compared with rejected/nonaggressive or nonrejected/aggressive youth, rejected/aggressive boys exhibited the highest risks for later externalizing symptoms. Coie and colleagues (1995) demonstrated that compared with others rejected/aggressive boys had the steepest increasing trajectories of self-reported externalizing problems beginning in the third grade and consistent levels of elevated parent-reported behavior problems beginning in the sixth grade for over four years. Additionally, Lochman and Wayland (1994) revealed that peer rejection moderated the association between aggressive behavior and externalizing symptoms four years later.

Some of the especially pernicious effects of peer rejection and aggression on later externalizing symptoms may be due to interplay between youths' interpersonal functioning and their social-cognitive development. In particular, much past work has focused on the manner in which children's peer experiences may be associated with specific social information processing behaviors and how these behaviors may mediate or moderate longitudinal associations with later psychological symptoms.

Crick and Dodge's (1994) social information processing model most often is cited in the study of peer relations and social information processing. The model indicates that individuals' responses within interpersonal interactions (i.e., to a specific social stimulus) are mediated by several specific cognitive steps; intra- and interindividual variability at each of these steps is associated with interpersonal schema, scripts, and data from past experiences. The presence of cognitive biases at any of these steps alters the trajectory of subsequent processes, thus leading to aberrant or maladaptive behavior. Specifically, this model suggests that individuals first encode social stimuli, generate an interpretation (i.e., causal and intent attributions) of encoded information, and form social goals. Behavioral strategies are generated, selected, and enacted that follow from these social goals.

Rejected, aggressive, and rejected/aggressive children are at greater risk than others to develop a unique cognitive bias suggesting a tendency to interpret ambiguous or benign social stimuli as due to hostile intent (i.e., a hostile attribution bias) (e.g., Crick & Dodge, 1996). This hostile attribution bias is associated significantly with a tendency to generate aggressive solutions to hypothetical provocation dilemmas and to behave aggressively toward peers (Dodge, Bates, & Pettit, 1990). Moreover, a hostile attribution bias is associated with a greater risk for continued and persistent aggressive behavior across development (Dodge, Pettit, Bates, & Valente, 1995). Research suggests that individuals with a hostile attribution bias may be especially likely to generate, select, and enact aggressive behaviors (Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002). Effects between hostile attribution biases and aggression are significantly stronger among peer-rejected children (Orobio de Castro et al., 2002).

Recent work offers compelling evidence for transactions among peer rejection, aggression, and a hostile attribution bias in a manner that is consistent with dynamic systems theory. Examining a developmental cascade model, Lansford, Malone, Dodge, Pettit, and Bates (2010) demonstrated mutually reinforcing, and gradually escalating longitudinal associations between these three constructs over time within a sample of young children over four years (i.e., kindergarten to grade three). Moreover, results suggested direct and indirect effects between these constructs across 12 time points (Lansford et al., 2010). Dodge, Greenberg, Malone, (2008) further demonstrated that a hostile attribution bias and peer rejection are included within a sophisticated developmental cascade model linking adverse social contexts and harsh parenting with later externalizing behaviors, deviant peer group affiliation, and serious violence in adolescence.

Research on children's peer relations most often examines community-based samples, examining risks for elevated, if not clinically significant, levels of psychopathology. However, studies of clinically referred youth similarly support a link between peer rejection, social-emotional-cognitive deficits, and externalizing symptoms. For instance, studies of maltreated youth consistently offer evidence for poor emotion regulation strategies, greater physiological reactivity, and concomitant rejection by peers (e.g., Rogosch, Cicchetti, & Aber, 1995). Peer rejection also may partially mediate the continuity of externalizing symptoms among maltreated youth (Kim & Cicchetti, 2010).

The peer relations of children with attention-deficit/hyperactivity disorder (ADHD) have been examined somewhat frequently; results suggest that these children are particularly likely to be rejected by peers (see Landau & Moore, 1991, for a review). Given that many of the behavioral symptoms most associated with ADHD (e.g., talking and fidgeting excessively, impulse control problems, inattention) are socially aversive and that children with ADHD tend to be aggressive, links with peer rejection are not entirely surprising. Erhardt and Hinshaw (1994) found that after only three days of interacting with previously unfamiliar peers at summer camp, children with ADHD earned lower liking ratings and were overwhelmingly more rejected than campers without ADHD. Aggression and disruptiveness, two major behavioral features of ADHD, were the strongest predictors of negative peer status across both groups. In another study utilizing peer sociometric methods, Hoza and colleagues (2005) found that a disproportionate number of boys and girls with ADHD were rejected by age- and sex-matched peers. Notably, peer rejection among children with ADHD has been linked to an increased risk for externalizing problems. Specifically, high levels of peer rejection assessed approximately 20 months postclinical treatment for ADHD prospectively predicts externalizing problems over a subsequent four-year period (Mrug et al., 2012).

Children with ADHD also demonstrate certain social cognitive deficits, including both cue encoding and cue interpretation biases (see literature on positive illusory biases; Hoza, Murray-Close, Arnold, Hinshaw, & Hechtman, 2010). Indeed, despite their low sociometric status and probable experience of peer rejection, children with ADHD tend to perceive their own social acceptance as no worse than controls (Hoza, Pelham, Milich, Pillow, & McBridge, 1993) or even see their social performance and behavior as more favorable than their peers' (Hoza, Waschbusch, Pelham, Molina, & Milich, 2000). Recent work indicates that among children with ADHD, these social-cognitive deficits are associated longitudinally with diminished social skills, peer rejection, and increases in aggressive behavior. Moreover, peer rejection reciprocally predicts exacerbations in aggressive behavior, positive illusory biases, and social skill deficits, supporting a dynamic systems theory (Murray-Close et al., 2010).

It should be noted that much of the research examining links between peer acceptance/rejection and externalizing symptoms has focused on boys. Given substantial gender differences in the prevalence of many externalizing symptoms, particularly during the years in which much of this research was conducted, a focus on boys' externalizing

symptoms offered an important opportunity to examine predictors of behaviors that are of high public health priority. However, recent data regarding sharply increasing levels of externalizing behaviors among young females have prompted greater attention to gender diversity.

As among boys, results indicate that peer rejection, particularly in combination with aggressive behavior, is an especially potent predictor of later externalizing behavior among girls (Prinstein & La Greca, 2004). However, in the past 20 years, research has identified a set of aggressive behaviors that may be more common among girls than the types of overt and physically violent behaviors assessed in prior work on boys (Crick & Grotpeter, 1995; Galen & Underwood, 1997; Lagerspetz, Bjorkqvist, & Peltonen, 1988). Studies of peer reputations and later externalizing behaviors sometimes have focused specifically on the prediction of social aggression or relational aggression. Unlike physical forms of aggression, social and relational forms of aggression utilize one's social reputation or an interpersonal relationship as a target for harm (e.g., through gossip, social exclusion, withdrawal of friendship support). As with the prediction of overt/physical externalizing symptoms among boys, peer rejection is a significant predictor of social and relational aggression. Werner and Crick (2004) revealed that peer rejection among children was associated with higher levels of girls' relational aggression one year later. Comparatively little work has examined whether links between peer acceptance/rejection and social/relational forms of aggression also may be best understood through social-cognitive deficits, however, extant research suggests that processes may be similar to the results for overt aggression (Mathieson et al., 2011).

Peer Acceptance/Rejection and Internalizing Symptoms

Compared with work examining externalizing outcomes, studies examining links between peer acceptance/rejection and internalizing symptoms are remarkably rare. This may be due to mixed results in extant research. When examining internalizing symptoms as a broad domain of psychopathology (e.g., from an overall symptom checklist) peer rejection is a significant statistical predictor (e.g., Coie, Lochman, Terry, & Hyman, 1992). Some evidence suggests that peer rejection may act in combination with other behavioral traits, such as aggression (Coie et al., 1992) or withdrawal (Bell-Dolan, Foster, & Christopher, 1995) to predict internalizing symptoms longitudinally. Peer rejection also may be an especially potent predictor of internalizing difficulties when rejection is chronic over multiple years (Burks, Dodge, & Price, 1995). Theoretical accounts for why peer acceptance/rejection may lead to internalizing symptoms are perhaps best conceptualized to the study of specific symptom domains.

For example, a rather straightforward hypothesis suggests that peer rejection may be associated with (1) social isolation, (2) failures to establish close, supportive friendships; or (3) increased risk for aversive peer experiences that reinforce a sense of lack of belongingness; each of these experiences may contribute to loneliness. Although loneliness is not specifically an internalizing disorder in itself, it is a symptom of mood disorders, and an especially important predictor of suicidality. Indeed, research examining specific internalizing outcomes that follow peer rejection has revealed especially potent longitudinal effects for loneliness, including work across the school-age years (Ladd & Burgess, 1999) and at the adolescent transition (Boivin et al., 1995). Some evidence for a link between peer rejection, isolation, and loneliness also is available. Specifically, Pedersen and colleagues (2007) suggested that peer rejection is prospectively associated with loneliness over time, both directly and partially mediated by fewer mutual friends (Pedersen, Vitaro, Barker, & Borge, 2007).

Longitudinal associations between peer rejection and depressive symptoms have been more elusive, however. Some research has revealed links between peer rejection and later depressive symptoms (Kiesner, 2002; Panak & Garber, 1992). For instance, depressed youth are more likely to receive negative sociometric nominations than are nondepressed children (Kennedy, Spence, & Hensley, 1989). However, other research has failed to replicate these effects (e.g., Woodward & Fergusson, 1999). Recent work alternatively has begun to conceptualize peer rejection as a potential stressor within contemporary cognitive theories of depression. Cognitive models generally suggest that stressful experiences can activate dysfunctional cognitive schemas (Beck, 1976), affecting social-cognitive processing of subsequent social stimuli. Stressful experiences may influence one's perception of stimuli as aversive (i.e., threatening or affirming low self-worth), or affect one's interpretation of stimuli through the use of maladaptive explanatory styles (e.g., a depressogenic attributional style; Abramson, Metalsky, & Alloy, 1989). Research supports transactional, reciprocal associations between depressive symptoms and the development of negative cognitions (Garber, Keiley, & Martin, 2002).

Cognitions have been cited as important mediators or moderators of the links between peer rejection and depressive symptoms in prior work. Some of these cognitions pertain to youths' perceptions of their own peer status. For example, youths' perceptions of rejection by peers are more

proximal longitudinal predictors of depression (e.g., Kistner, Balthazor, Risi, & Burton, 1999) and may mediate the association between actual peer rejection and later depressive symptoms (Panak & Garber, 1992). Youths' underestimations of their levels of peer acceptance are predicted by their depressive symptoms (De Los Reyes & Prinstein, 2004; Rudolph & Clark, 2001), and these underestimations reciprocally are associated with later increases in depression (Cillessen & Bellmore, 1999).

Youth with specific cognitive dispositions also appear to be at heightened risk for the deleterious effects of peer rejection on depressive symptoms. For example, consistent with cognitive vulnerability models of depression, youth with a depressogenic attributional style (i.e., a tendency to interpret negative life events as due to internal, global, and stable causes, and positive events to external, unstable, and specific causes) appear to be at greater risk for increases in depressive symptoms if also rated by peers as rejected, compared with nonrejected peers (Panak & Garber, 1992). Consistent with self-discrepancy theory (Higgins, 1987) youth who place high value on their level of peer status, yet are rejected by peers (i.e., a condition that would produce cognitive dissonance) appear to be especially at risk for increases in depressive symptoms over time (Prinstein & Aikins, 2004). In sum, research has indicated that compared with externalizing symptoms, internalizing outcomes are less consistently associated with early peer rejection. However, research increasingly suggests that peer rejection may be a relevant stressor interacting with prior vulnerabilities for internalizing symptoms, consistent with a transactional hypothesis. For instance, a recent study demonstrated that the role of peer rejection on the development of youths' internalizing problems could be better conceptualized within a cascade model, in which externalizing problems contribute to the development of internalizing psychopathology via negative peer relationships. Specifically, high levels of externalizing problems in kindergarten were found to predict negative peer relationships, including peer rejection and peer victimization, in first grade. In turn, transactional effects were revealed between peer rejection and peer victimization from first to third grade; ultimately, these effects resulted in peer rejection in third grade to predict internalizing (as well as externalizing) problems in fourth grade (van Lier & Koot, 2010). Conversely, among maltreated youth, evidence suggests that adaptive levels of emotional regulation are associated with greater peer acceptance, ultimately lowering the longitudinal risk for internalizing symptoms (Kim & Cicchetti, 2010).

Peer Rejection and Immune System Activity: A Biological Pathway to Internalizing Symptoms

There are many theoretical reasons to suspect that peer rejection is especially relevant to the development of internalizing symptoms, particularly depression. However, research in the peer relations literature has not yet fully taken advantage of opportunities to integrate with related theories or disciplines. For example, research focusing on social genomics and psychophysiological processes related to interpersonal stress events suggests that the innate immune system may play an important role in understanding the long-term effects of stressful interpersonal experiences on the development of psychopathology. In short, social adversity is related to immune system responses that in turn may affect the synthesis of monoamines implicated in depressive symptoms. A brief review is offered below.

One of the key functions of the innate immune system is to eliminate pathogens (e.g., bacteria) and to enhance wound healing by activating inflammatory response in white blood cells (i.e., leukocytes). The activity of the innate immune system is genetically regulated and begins when, in response to infections and injuries extracellular signals activate the release of intracellular proteins, specifically the transcription factor nuclear factor kappa-B (NF-kB), from its inhibitory protein. The activated NF-kB moves from the cytoplasm of the cell to the nucleus where it activates genes that encode pro-inflammatory cytokines (i.e., cell-signaling proteins). Pro-inflammatory cytokines (e.g., interleukin-1; tumor necrosis factor-α (TNF-α)) are protein molecules that drive the immune system response by attracting leukocytes (e.g., macrophages) toward the injured or infected body areas in order to expel the pathogens or heal the wound.

Researchers recently have acknowledged that the social environment also may regulate the activity of the genes involved in the innate immune response (see Irwin & Cole, 2011; Slavich & Cole, 2013). Specifically, it has been suggested that adverse social experiences (i.e., interpersonal stress) may influence the expression of inflammatory genes. The effect of interpersonal stress on inflammatory activity may, at least partially, occur via the endocrine and sympathetic nervous system (SNS). This process starts when social stressors activate a series of adaptive physiological responses within the central nervous system involving both the hypothalamic-pituitary-adrenal (HPA) axis and the SNS. The HPA axis and the SNS stimulation can subsequently influence the activity of pro-inflammatory genes in the leukocytes. For instance, glucocorticoids released by

the HPA axis inhibit pro-inflammatory activity. Specifically, glucocorticoids (e.g., cortisol) bind to glucocorticoid receptors (i.e., intracellular proteins) in the cytoplasm of leukocytes and move in the nucleus where they reduce the activity of one of the major pro-inflammatory transcription factor, NF-kB. Conversely, catecholamines (e.g., norepinephrines) released by the SNS in several body tissues to stimulate a fight-or-flight reaction activates the transcription factor NF-kB, thus promoting pro-inflammatory activity.

Notably, all these biological responses are expected to be regulated by the central nervous system, meaning that only if the individual perceives the external social stimuli as threatening these processes occur (Slavich & Cole, 2013). In other words, the way individuals perceive external social stimuli, rather than the stimuli themselves, give rise to these biological responses.

An increasing number of observational and experimental studies have provided empirical support for the influence of social stress on the immune system activity. First, it has been demonstrated that chronic interpersonal stress may lead to greater pro-inflammatory reactions in response to other psychological stressors (e.g., recent episodic stress) or pathogenic agents (e.g., bacteria). For example, chronic interpersonal stress was found to lead to higher production of interleukin-6 (IL-6), a pro-inflammatory cytokine, in response to bacterial stimuli (Miller & Chen 2010). Second, high levels of biomarkers indicating (anti- and) pro-inflammatory activity have been found in individuals who experienced (chronic) interpersonal stress, even in the absence of external agents (e.g., pathogens). Specifically, these studies revealed that greater stress was associated with a) increasing levels of messenger RNA (mRNA) for the transcription factor NF-kB (e.g., Murphy, Slavich, Rohleder, & Miller, 2013), and b) increasing levels of systemic pro-inflammatory activity in the bloodstream, as reflected in high levels of circulating pro-inflammatory markers, including IL-6, or C-reactive protein (CRP) (Fuligni et al., 2009). Third, evidence supporting the hypothesis that chronic social stress may lead to sustained inflammation comes from genome-wide studies comparing transcriptional activity of individuals with and without histories of chronic stress. Among individuals with chronic stress, genes bearing pro-inflammatory activity are up-regulated whereas genes bearing anti-inflammatory activity are down-regulated (e.g., Cole et al., 2007).

Two important aspects from this work are herein potentially noteworthy for studies of peer relationships. First, research suggests that early-life stress, early interpersonal stressors, and chronic interpersonal stress experienced later in life may be related to pro-inflammatory activity. That is, acute forms of stress during developmentally sensitive periods (e.g., early childhood) as well as chronic forms of stress occurring at different developmental periods may both result in enhanced inflammation (Miller, Chen, & Parker, 2011). For instance, children raised in a stressful family context, characterized by maltreatment and harsh parenting, tend to show higher inflammatory activity later in life (for a review, see Miller et al., 2011). Accordingly, during adolescence and adulthood, recent experiences with chronic interpersonal stress are associated with higher inflammatory activity (e.g., Miller, Rohleder, & Cole, 2009). Second, among the interpersonal stressors that may influence the immune system, social stressors that directly threaten individual social connection, including social rejection, may be especially powerful. For example, Murphy and colleagues (2013) examined adolescent females' inflammatory activity during six-month intervals over two years. During some of these six-month intervals, adolescents experienced social rejection experiences, but during other time intervals they did not. Social rejection experiences were associated with adolescent females' higher inflammatory activity, as indicated by greater levels of mRNA for the transcription factor NF-kB and the inhibitory factor I-kB, as well as a lower ratio of NF-kB/I-kB. Recent findings from a large population-based study (Copeland et al., 2014) indicate that being bullied during childhood and adolescence prospectively predicted higher levels of inflammatory markers (CRP) several years later during early adulthood, even after accounting for prior levels of inflammation and a number of relevant physical and mental health covariates (e.g., body mass index, early life-adversity). Interestingly, contrary to bully victims, children who were identified as bully perpetrators showed lower levels of inflammatory markers during early adulthood than children who were not involved in bullying. These social rejection experiences may be particularly harmful as they may directly threaten the innate human need to belong (Slavich, O'Donovan, Epel, & Kemeny, 2010). In sum, it seems that throughout childhood and adolescence, interpersonal stress events, including social rejection, may regulate the expression of genes involved in the immune system and may therefore lead to chronic mild inflammation.

The effect of stress on inflammatory activity may derive from innate adaptive biological responses to prepare the body to deal with potential injuries and infections arising from adverse physical threats (see Slavich & Cole, 2013). However, under conditions of chronic stress or during

developmentally sensitive periods (e.g., early childhood), these adaptive biological reactions may lead to stable physiological changes (i.e., allostatic load), including mild levels of inflammatory activity, which, in turn, may have long-term consequences on individuals' psychological well-being and similarly increase risk for psychopathology.

To date, the specific molecular pathways through which stress gets under the skin and leads to sustained levels of inflammation have not yet been fully elucidated. One of the most empirically supported hypotheses suggests that the glucocorticoid receptor (GR), a ligand-activated transcription factor, may play a crucial role in linking social stress to stable pro-inflammatory activity (see Irwin & Cole, 2011). The GR is an intracellular protein that regulates gene expression by binding to glucocorticoids. The GR has a major role in inhibiting both HPA axis (i.e., glucocorticoids release) and pro-inflammatory activity (acting on NF-kB; see Meaney, 2010). Two main lines of research have provided evidence supporting the importance of GR to explain the link between stress and chronic inflammation. First, studies have shown that GR-mediated gene transcription was reduced in individuals with a history of chronic stress, a phenomenon referred to as GR resistance (or GR desensitization; see Miller et al., 2011). Specifically, findings from this work suggest that exposure to chronic stress may reduce immune cells sensitivity to the anti-inflammatory effect of glucocorticoids (Cohen et al., 2012). Notably, this phenomenon seems to depend not on the unavailability of GR, as indicated by similar levels of mRNA for GR in individuals with and without chronic stress (Miller, Chen et al., 2009). Instead, it may be the case that posttranslational modifications are responsible for GR resistance, explaining why high levels of glucocorticoids and pro-inflammatory cytokines may co-exist even with available quantities of GRs (see Miller et al., 2011).

Second, evidence from animal studies have demonstrated that exposure to early-life stress may result in epigenetic modifications (e.g., DNA methylation) in the glucocorticoid receptor gene in the hippocampus. Specifically, these studies revealed that in rats, high maternal care (e.g., high licking and grooming) in the first week of life was associated with higher expression of the GR gene in the hippocampus (Weaver et al., 2004). Notably, because GR has a negative-feedback loop on glucocorticoids release, higher GR expression led to lower HPA axis reactivity to stress. A similar epigenetic variation in response to chronic stress (or early life stress) also may occur in immune cells, which may contribute to maintain chronic mild levels of inflammation. Although evidence for DNA methylation of the GR gene in immune cells has not been provided yet, this hypothesis would converge with recent work suggesting that epigenetic modifications are system-wide (that is, they occur across different types of cells; Szyf & Bick, 2013). These molecular modifications may explain how immediate physiological responses resulting from stress exposure may yield long-term physiological changes, including inflammation.

Of particular relevance, sustained levels of inflammation resulting from exposure to chronic interpersonal stress may be linked to a higher risk of depressive symptoms (see Slavich & Irwin, 2014, for a review). The key role that inflammation may exert on the development of psychopathology is supported by the known effects of pro-inflammatory cytokines on central nervous system activity (Miller, Maletic, & Raison, 2009). Throughout different molecular pathways, inflammatory activity in the periphery of the body may reach the brain and activate pro-inflammatory responses by microglial cells (i.e., brain immune system cells) in the central nervous system (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008). In the brain, pro-inflammatory cytokines (e.g., TNF-α) elicit sickness behaviors which imply emotional, motor and cognitive alterations (Irwin & Cole, 2011). Notably, these changes strongly correspond to the behavioral symptoms which characterize depression, including social withdrawal, fatigue, and physical inactivity. This has led researchers to hypothesize that pro-inflammatory cytokines in the brain may induce depression. Specifically, pro-inflammatory cytokines have been suggested to influence the release of monoamines (e.g., serotonin and dopamine) in the brain, which may have direct effects on the development of psychopathology in general, and depression in particular (Miller, Maletic, et al., 2009). Prior work has provided support for this hypothesis by showing that high levels of inflammation are associated with increased risk for depression (e.g., Miller, Maletic, et al., 2009). For example, high levels of circulating CRP and IL-6 in the bloodstream were found to predict depressive symptoms over a 12-year period (Gimeno et al., 2009). More importantly in this context, other recent work has specifically provided some empirical support for the hypothesis that inflammation may give rise to one of the biological pathways linking social stress to depression. In an observational study (Miller & Cole, 2012), pro-inflammatory activity and depression were found to cluster together among female adolescents who experienced high levels of adversity during their childhood. Of specific interest, high levels of IL-6 led to increased risk for depression six months later only among adolescents who reported childhood adversity; however, this association was not found in female

adolescents who did not experience childhood adversity. In another study (Eisenberger, Inagaki, Rameson, Mashal, & Irwin, 2009), the effect of pro-inflammatory cytokines on depressive symptoms was examined in an experimental design. Specifically, participants' pro-inflammatory activity was experimentally manipulated by administrating either endotoxin (i.e., microbial stimuli) or placebo. Subsequently, participants in both conditions were exposed to a social rejection task while assessing neural activity using fMRI. As expected, administration of endotoxin increased both participants' pro-inflammatory activity, measured as levels of circulating IL-6, and depressive symptoms. Moreover, although no differences in neural responses to social exclusion were found between participants in the endotoxin and placebo condition, circulating levels of IL-6 in response to endotoxin emerged to be positively associated with neural activity in the anterior and posterior insula of the brain. Notably, neural activity in response to the social stress task mediated the association between inflammation and depressive symptoms (among females only).

In sum, research suggests that chronic social rejection is associated with unique immune system, epigenetic, and neuropsychological responses that have clear implications for the study of peer relationships, and potentially peer rejection in particular. Unfortunately, few studies have operationalized youths' chronic social rejection in a manner that is consistent with developmental theory or findings within the peer relations literature. This remains an important direction for future work.

Peer Acceptance/Rejection and Health Risk Behaviors

Health risk behaviors have been examined relatively infrequently within the literature on peer status compared with research that has focused on traditional diagnostic symptoms. However, some work has examined the association between peer acceptance/rejection and substance use, largely supporting the hypothesis that peer rejection in childhood is associated with long-term substance use (i.e., nicotine, alcohol, and marijuana) outcomes, especially among boys (Dishion, Capaldi, Spracklen, & Li, 1995; but also see Allen, Porter, McFarland, Marsh, & McElhaney, 2005). One study suggests that children rejected at ages 10–13 years are eight times more likely than sociometrically average children to abuse alcohol as young adults up to 10 years later (Zettergren, Bergman, & Wångby, 2006).

Similar to findings on externalizing outcomes, results also indicate that a combination of peer rejection and aggression is an especially potent predictor of substance use outcomes. Rejected/antisocial eighth-grade students are more likely to use tobacco and alcohol two years later compared with rejected, nonantisocial or peer accepted students (French, Conrad, & Turner, 1995). Among girls in fourth through sixth grade, peer rejection moderates the long-term association between peer aggression and adolescent substance use. Among girls with low social preference scores (i.e., peer rejection), peer aggression was significantly associated with heavy episodic drinking, marijuana, and hard drug use six years later; however, among girls with high social preference scores, peer aggression was not a significant predictor of later substance use (Prinstein & La Greca, 2004).

Although studied rarely, peer acceptance/rejection may be associated longitudinally with several additional health risk behaviors. However, findings have yielded sometimes conflicting patterns of results. For example, Miller-Johnson and colleagues (1999) revealed that childhood aggression, but not peer rejection, significantly predicted teenage motherhood (see also Feldman, Rosenthal, Brown, & Canning, 1995). Underwood, Kupersmidt, and Coie (1996) revealed that girls with childhood controversial sociometric status (i.e., both liked and disliked by peers) and aggressive girls were more likely to give birth in adolescence, had experienced more births than other adolescent mothers, and had given birth to their first child at earlier ages compared with other adolescent mothers. Brendgen, Wanner, and Vitaro (2007) revealed indirect associations between peer rejection and early sexual initiation for girls via lower levels of self-esteem.

With regard to weight-related risk behaviors, Lieberman, Gauvin, Bukowski, and White (2001) found that higher levels of girls' friendships nominations from peers (i.e., a possible proxy for peer acceptance) were associated with lower levels of body self-esteem and higher levels of dieting and bulimic behavior (Lieberman et al., 2001). Yet Graham, Eich, Kephart, and Peterson (2000) examined associations between peer ratings of likeability among peers, revealing that peer acceptance was associated with lower levels of body dissatisfaction (see also Rancourt & Prinstein, 2010). Research examining links between peer factors and self-injury are rare, but at least some short-term longitudinal evidence suggests that peer rejection is associated with later increases in suicidal ideation (Heilbron & Prinstein, 2010).

Social information processing models may be relevant for understanding links between childhood peer rejection and adolescent health risk behaviors, perhaps due to the mediating effects of social problem-solving skills deficits or broader emotion dysregulation that influences both cue interpretations and later behavioral enactment (Lemerise & Arsenio, 2000). Consistent with a broader dynamic

systems theory, it also has been suggested that childhood peer rejection inhibits adaptive social skill development, consequently narrowing later friendship choices to other similarly skilled peers. Together, these friendships between rejected and maladjusted (e.g., aggressive) youth form deviant peer groups, creating a powerful context for the socialization of a large array of risk behaviors.

Data offer support for the critical role of peer rejection and low social skills in the development of deviant peer group affiliation, particularly when peer rejection is combined with school failure and poor parental management (e.g., Dishion, Patterson, & Griesler, 1994). Patterson, Dishion, and Yoerger (2000) further suggest that early involvement with deviant peers at age 10 is associated with increases in new forms of risk behavior by age 14. Accordingly, in a recent study testing a developmental cascade model of adolescent substance use, peer rejection assessed in early childhood was associated with an increased probability in substance use engagement (i.e., cigarette and marijuana use) throughout high school, via affiliation with deviant peers in seventh grade (Lynne-Landsman, Bradshaw, & Ialongo, 2010). An indirect pathway also was found between affiliation with deviant peers in seventh grade and substance use trajectory membership during high school via eighth-grade conduct problems. These findings clearly emphasize how peer rejection may have long-term effects on health behaviors by affecting other peer domains such as friend affiliation.

Peer-Perceived Popularity

Peer status is a construct that has important developmental heterogeneity in its operationalization. Among preschool-age and young school-age children, youths' peer status can be understood as an index of how much children are well liked. However, by the middle of the school-age period, a separate construct emerges that reflects the extent to which youth have reputations of popularity. Here, *popularity* refers to an individual's levels of status, dominance, access to resources, and prestige (Vaughn & Waters, 1981), which are not isomorphic constructs to individual's likeability among peers. This distinct construct has been examined for decades by sociologists, human ethologists, and within ethnographical research (Cillessen, Schwartz, & Mayeux, 2011). However, it was more formally introduced to the study of peer relationships in the developmental psychopathology literature in the late 1990s (Parkhurst & Hopmeyer, 1998), and subsequent work revealed that it becomes further differentiated from peer acceptance/rejection as children grow older (Cillessen & Mayeux, 2004). As with peer acceptance/rejection, popularity traditionally is measured using peer nominations. Youth select peers who are most and least popular, and a standardized difference score between standardized tallies of nominations on each item is computed to provide a continuous measure of popularity, or social reputation. Popularity is only moderately correlated with peer acceptance/rejection by early adolescence (Parkhurst & Hopmeyer, 1998), and a substantial proportion of youth high in popularity meet criteria for the controversial sociometric status group.

Research examining popularity reveals somewhat surprising associations with measures of adjustment. Substantial research indicates that peer rejection is both a determinant and consequence of aggressive behavior. In contrast, reciprocal associations between high levels of popularity and aggressive behavior have been revealed (Cillessen & Rose, 2005). High levels of popularity also are associated with several health risk behaviors, including alcohol use, sexual risk behavior, and engagement in drug use (Prinstein, Choukas-Bradley, Helms, Brechwald, & Rancourt, 2011). Given the relatively new distinction between peer acceptance/rejection and peer popularity, it is unknown whether popularity may be relevant to the development of psychopathology. As discussed in turn, research suggests that popularity may be highly relevant for identifying the most influential peers within a social context, however. Peer influence proves to be a powerful process related to psychopathology risk, especially in adolescence.

In sum, compared with research conducted only 15–20 years ago, research on peer status has become fairly dormant. Rarely do researchers examine peer sociometric status categories. Moreover, studies of peer acceptance/rejection have been conducted infrequently, in part due to greater restrictions among human subjects committees and disproven fears among school administrators regarding the potential harm that peer nominations may cause other children (see Bell-Dolan, Foster, & Sikora, 1989). This may be quite unfortunate, as peer acceptance/rejection has proven to be a powerful variable that can be measured quite well and is remarkably stable over time, suggesting an important source of chronic interpersonal rejection and stress.

Peer Victimization

Although somewhat neglected for several decades within the peer relations research literature, the study of peer victimization recently has become quite popular, particularly since the onslaught of school shootings and youth suicides that have been attributed to peer victimization experiences.

Peer victimization certainly is far more common among youth rejected by peers; however, the two constructs are not isomorphic. For example, compared with peer rejection, peer victimization is correlated differently (and sometimes in different directions) with aggression. As discussed below, this difference is due, in part, to different aggressive functions and to only recently articulated differences between aggression (broadly defined) and bullying behavior (Salmivalli & Peets, 2009).

Peer victimization refers to experiences in which one has been the target of intentional, repeated, aggression from peers. A subtle but important distinction has been offered between being the recipient of peer victimization (i.e., a more inclusive term representing broadly defined peer aggressive acts) and bullying behavior, which is focused specifically on situations in which the target is less powerful than the perpetrator of peer aggression (Salmivalli & Peets, 2009).

Moreover, there is substantial heterogeneity in aggressive behavior, which has been a focus of recent research. Aggressive behavior varies not only in function, but also in form. Semantic issues are problematic in the literature, and there is a need for uniformity to help create a more consistent dialogue in this rapidly growing area of research. A brief review of forms and functions of aggression is offered.

Aggression and Bullying

Compared with the study of peer victimization, studies of aggressive behavior are as old as psychological research itself. Almost a century ago, Dollard, Doob, Miller, Mowrer, and Sears (1939) posited that aggression served a function of behaviorally expressing internal feelings of frustration (i.e., the frustration-aggression hypothesis). *Frustration* is defined as an affective response to an inability to achieve one's goal. Thus, this aggressive function is referred to as reactive aggression and it is considered to be hot-blooded and reflective of impulsivity and poor emotional regulation skills. Frustration can be a reaction to interpersonal goal-blocking (e.g., a peer taking away a toy), or it can be internally derived (e.g., failure to accomplish a solitary task). For interpersonal sources of frustration, reactive aggression is associated with short-term behavioral reinforcement, but long-term consequences. For example, aggression directed toward a peer who has caused frustration can produce immediate results (e.g., return of the stolen toy). However, in most contexts aggression is regarded as an inappropriate behavior, and thus is associated with long-term decreases in peer status and sanctions from adults. High levels of reactive aggression among youth are associated with higher levels of prior maltreatment experiences, and lower social preference (Dodge, Lochman, Harnish, Bates, & Pettit, 1997). Higher levels of youth's reactive aggression also are associated with unique physiological responses to stress. Hubbard and colleagues revealed that compared with predominantly proactively aggressive youth, children with high levels teacher-reported reactive aggression evidenced greater parasympathetic reactivity in response to an experimentally induced stressor (Hubbard et al., 2002).

Aggressive behavior is not always a behavioral response to frustration. Proactive aggression is conceptualized as cold-blooded, planful, manipulative, and strategic (Dodge & Coie, 1987). Proactive aggression involves the use of aggression to obtain a specific reward. Rewards may include instrumental goals (i.e., access to resources) or person-oriented goals, typically to assert dominance. Successful uses of proactive aggression (i.e., acts that produce the desired reward) are behaviorally reinforced, as articulated by social learning theories (Bandura, 1973).

Proactive and reactive functions of aggression can be identified in a variety of species and are considered to be inherent characteristics of social groups. Ethologists contend that aggression contributes to social organization by enforcing a social hierarchy, group structure, and transparent, if not equitable allocation of resources among group members. Characteristics of aggressive behavior observed among nonhuman species have been directly adapted to the study of youth (Vaughn & Waters, 1981).

Bullying has been defined as a specific example of proactive aggression (Hartup, 1974). Bullying is directed toward members of one's social group who occupy lower levels on the status hierarchy. Interestingly, ethological research suggests that the highest members of a status hierarchy typically are unchallenged and do not need to use aggression to maintain their social ranking. Aggression is more common among members of social hierarchy at near-adjacent positions, who realistically may vie for a reorganization within their group. An explicit goal of bullying is to elevate the perception of the perpetrator's dominance by reducing the power of the victim. Note that proactive and reactive uses of aggression have different social-psychological correlates. Proactive uses of aggression are associated longitudinally with increases in (reputationally based) popularity; reactive aggression is associated with increases in peer rejection (Cillessen & Rose, 2005; Prinstein & Cillessen, 2003). Proactive aggression is associated with later delinquency, while reactive aggression is associated with greater risk for internalizing symptoms, aggression within relationship contexts (e.g., dating violence), and social isolation (Brendgen, Vitaro,

Tremblay, & Lavoie, 2001; Vitaro, Brendgen, & Tremblay, 2000; Vitaro, Gendreau, Tremblay, & Oligny, 1998).

Unfortunately, peer bullying and victimization have not been conceptualized in a manner consistent with these theories within the peer relations literature. Peer aggression rarely is examined with regard to the functions of aggressive behavior, and assessments of aggression often conflate reactive and proactive functions of aggression. Consequently, assessments of peer victimization most often capture the victims of peers' aggressive behavior, but only recently has effort been made to specifically identify peers who have been victimized in manner that matches theoretical accounts of bullying.

Forms of Aggression and Victimization

In addition to variation in the functions of aggression, several different forms of aggressive behavior have been identified. Decades ago, research in this area was dominated by studies of mostly physically (i.e., hitting, kicking, pushing, etc.) and sometimes verbally (i.e., name calling, threatening) aggressive acts. Perhaps not surprisingly, these forms of aggression (alternately referred to as overt, direct, or physical aggression) largely were perpetrated by boys, and victims also were more likely to be male. Gender socialization likely contributes to the perception that exerting dominance among males involves acts that threaten boys' physical strength and feelings of power.

Compared with boys, girls are socialized to place greater value in their social abilities as a component of self-worth (Bem, 1981). Assertions of dominance among girls involve acts that render victims socially weak (e.g., friendless, alienated, or impaired by damaged social reputations). Aggressive acts targeting social standing have been referred to as relational, social, and indirect aggression (Crick & Grotpeter, 1995; Galen & Underwood, 1997; Lagerspetz et al., 1988). Examples include acts meant to damage social relationships, such as excluding others, silent treatments, threatening friendship withdrawal, and acts that are meant to damage social reputations, such as telling rumors. Relational forms of aggression may become more prevalent than overt aggression as age increases, reflecting both the greater sanctions that accompany overt aggression among older youth and older children's increasing cognitive abilities that is required to successfully execute some relationally aggressive acts. Active debate on gender differences in the perpetrators of these different forms of aggression remains; however, recent meta-analytic evidence suggests that gender differences may be minimal, and both forms of aggression (i.e., physical/overt and social/relational) are highly correlated (Card, Stucky, Sawalani, & Little, 2008). The victims of overt or relational aggression are equally distributed across gender.

The assessment of peer aggression, bullying, and victimization raises complex validity issues. As with many peer constructs, overt and relational aggression often is assessed using sociometric procedures. This approach builds on a long-standing traditional assumption within the peer relations literature regarding the conceptualization of peer aggression as group-level phenomena, observable by a broad sample of peers. Peer-nominations yield measures of one's reputations or preferences within an entire peer group (i.e., within a class or grade). Consensus has not been obtained regarding the conceptualization of relational aggression as a group- or dyadic-level peer experience, however. Some relationally aggressive acts (e.g., spreading rumors) involve the larger peer group more than others (e.g., threatening friendship termination). In fact, some forms of relational aggression may be most successfully executed when the victim is unaware of who the perpetrator is. Peer reports of relationally aggressive behavior therefore may oversample estimates of perpetrators who engage in relationally aggressive acts quite visibly and conspicuously.

The assessment of peer victimization also can utilize peer-reported approaches, raising similar questions regarding the ability to adequately capture experiences that are known only among members of a dyad or small friendship group. Alternatively, a large proportion of studies have been conducted utilizing self-reported measures of peer victimization. Compelling arguments for self-reported assessments of peer bullying and victimization are presented by Solberg and Olweus (2003). Yet, while this approach allows for a more thorough assessment of aggressive acts from the perspective of the person who has been targeted by them, data ultimately yield a measure of *perceptions* of peer victimization. Perceptions of peer victimization are relevant for understanding youths' own experience, and likely are relevant for understanding links with maladjustment. However, substantial affective biases can influence the retrospective recall and self-report of peer victimization (Des Los Reyes & Prinstein, 2004).

Last, in addition to the different functions of aggression and forms of aggression/victimization, recent technological developments have stimulated an interest in the medium in which aggression and victimization take place. Presumably, most prior research on peer aggression and victimization focused on the study of social interactions that appeared in person (i.e., face to face) or perhaps using the telephone (i.e., voice to voice). Today, an increasing number of peer victimization experiences occur using online media, such as

Facebook and YouTube. Cyber victimization is especially pernicious and may have unique consequences for maladjustment. Unlike other contexts in which victimization may occur, cyber victimization utilizes a much larger audience to torment youth; indeed, aggression literally can occur on an international stage. Moreover, using the Internet, it is especially easy for aggressors to act with complete anonymity, and perhaps engage in especially brutal attacks consequently. Research suggests that cyber victimization occurs with remarkable frequency, and certainly with particularly dire consequences in some cases (Smith et al., 2008). Yet, research still is needed to determine whether cyber victimization is associated with unique adjustment consequences compared with the effects of victimization occurring in traditional contexts. Studies that investigate both online and offline victimization have documented a strong overlap between these two phenomena. For instance a recent study examining joint developmental trajectories of online and offline victimization from age 12 to age 19.5 years old documented that all adolescents who followed a low trajectory of offline victimization also followed a low trajectory of online victimization. Accordingly, all adolescents who belonged to a moderate online victimization trajectory belonged either to a moderate or to a high offline victimization trajectory, indicating that online victimization always occurred in the presence of offline victimization (Sumter, Baumgartner, Valkenburg, & Peter, 2012).

Peer Victimization as a Predictor of Psychological Symptoms

One might assume that peer victimization is associated with psychological sequelae and dysfunctional behavior. The media has publicized several severe acts of violence (i.e., homicide, suicide) attributed to peer victimization experiences. The implementation of antibullying policies within many states and within several countries outside of North America also suggests that peer victimization is widely regarded as an important risk factor for severe psychological distress and symptoms of psychopathology.

Interestingly, however, empirical data have not suggested that peer victimization has deleterious effects of the magnitude that has been suggested by these well-publicized incidents and policy decisions. Certainly, there is strong evidence that peer victimization is associated with later adjustment difficulties (e.g., Hanish & Guerra, 2002; Schwartz, McFadyen-Ketchum, Dodge, Pettit, & Bates, 1998). Meta-analyses also have indicated that peer victimization indeed is associated concurrently with a wide range of adjustment indices, including depression, loneliness, self-esteem, and anxiety (Hawker & Boulton, 2000). Recent meta-analyses also summarized prospective associations, revealing significant bi-directional associations between peer victimization and internalizing symptoms (Reijntjes, Kamphuis, Prinzie, & Telch, 2010), and peer victimization and externalizing symptoms (Reijntjes et al., 2011). Most surprising, however, is that effect sizes are relatively weak for the putative effects of victimization on symptoms of psychopathology (Cohen, 1988; Reijntjes et al., 2010), particularly when examining these associations in longitudinal designs that use different informants to measure each construct (i.e., reducing method variance issues). It is estimated that the vast majority of youth are victimized by their peers, at least at some point. Consequently, research on peer victimization has begun to consider potential alternate hypotheses to help conceptualize associations between peer victimization and psychopathological symptoms within more complex and dynamic theoretical models. At least five alternate hypotheses have received recent attention. First, peer victimization consequences should be considered in the context of the determinants of peer victimization. It may be that victimization is most relevant as a predictor of continuities or discontinuities in prior maladjustment. Second, peer victimization may predict maladjustment only for a subset of victims, such as those with other vulnerability factors, or those who may have unique cognitive or behavioral responses to being victimized. The study of moderators of the association between peer victimization and adjustment has been especially active and fruitful. Third, recent work has differentiated youth who are chronic versus sporadic victims of peer aggression. Chronic peer victimization may be a unique and far more rare experience with severe psychological consequences. Fourth, peer victimization may not be directly associated with psychological symptoms but may exert important effects within more complex transactional or dynamic models of psychopathology. Fifth, and relatedly, peer victimization may be conceptualized as a stressor with consequences for the development of psychophysiological stress-response systems. Recent work suggests unique biological responses among victims of peer aggression that may be associated with a variety of behavioral and physical health outcomes. Each of these hypotheses will be discussed in more detail.

In addition to these five recent emphases in current research on peer victimization, research in affective neuroscience has suggested that at least one form of peer victimization (i.e., social exclusion) may be associated with pain responses akin to the pain experienced from physical

stimuli. This exciting direction for future research will also be briefly reviewed.

Determinants and Consequences of Peer Victimization

Peer victimization often is depicted as a stressful experience that may promote maladaptation among otherwise well-adjusted youth. To be clear, there is no doubt that many victims of severe peer aggression or bullying indeed are random targets who have evidenced no prior vulnerabilities to psychopathology. However, data suggest that some youth may be more vulnerable than others to peer victimization. Two subtypes of victims have been identified. It should be noted that most of this research has focused on the determinants of overt victimization; research examining characteristics of relational forms of victimization is relatively rare. One group of youth especially prone toward aggression from peers is characterized by indices of psychological and physical passivity. Passive victims have greater levels of internalizing distress (higher levels of depressive and anxiety symptoms, lower self-esteem) and may be physically smaller and weaker than their bullies (Perry, Hodges, & Egan, 2001). Consistent with theories regarding proactive functions of aggression, children who exhibit characteristics that suggest they may be easily dominated by others may be easy targets for peers who wish to demonstrate their own power and potentially affirm or increase their own positions within the social hierarchy. A second group vulnerable to peer victimization has been referred to as aggressive victims. Aggressive-victims are characterized by poor emotional regulation skills, hostile attribution biases, and unlike nonvictimized bullies, they tend to be less strategic, even arbitrary, in their selection of aggression targets (Schwartz, 2000). The use of aggression among aggressive victims appears to most closely resemble the description of reactive aggression. Aggressive victims are especially likely to exhibit symptoms of psychopathology (Schwartz, 2000). Nevertheless, aggression is a strong predictor of peer victimization (Brendgen, Boivin, Vitaro, Girard, et al., 2008), and evidence even suggests that the association between aggression and peer victimization is partially explained by genetic factors (Boivin et al., 2013).

Given that at least some victims have been selected due to their prior levels of psychological symptoms or distress (i.e., internalizing symptoms among passive victims, and externalizing symptoms among aggressive victims), it perhaps is not surprising that peer victimization is not prospectively associated with the *onset* of psychopathology. Indeed, recent work that examines reciprocal associations between psychopathology symptoms and peer victimization do not consistently reveal deleterious effects of victimization on symptoms after controlling for the effects of symptoms on victimization (cf., Kochel, Ladd, & Rudolph, 2012; Leadbeater & Hoglund, 2009; McLaughlin, Hatzenbuehler, & Hilt, 2009; Snyder et al., 2003). Rather, research suggests that both internalizing and externalizing symptoms likely precede peer victimization experiences in childhood and early adolescence (Rudolph et al., 2014; Vaillancourt, Brittain, McDougall, & Duku, 2013).

However, victimization experiences may predict continuities and discontinuities in the experience of symptoms, or links between different types of symptoms. For instance, van Lier and colleagues (2012) demonstrated that peer victimization contributes to the link between youths' externalizing behaviors and their subsequent internalizing symptoms. Children externalizing problems assessed at six years of age predicted internalizing behaviors at 8 years of age by enhancing children's (perceived) peer victimization at 7 years (van Lier et al., 2012).

Moderators of Peer Victimization Effects

Estimates of the proportion of children who are targets of peer aggression are strikingly high (e.g., 75%; Hoover, Oliver, & Hazler, 1992), and victimization episodes are extremely frequent within a school setting (Craig & Pepler, 1997). Of course, it is not expected that significant psychological symptoms may be observed in 75% of youth, however. Rather, it is likely that peer victimization is most strongly associated with psychological symptoms in the context of other risk factors, or of unique peer victimization responses. The study of peer victimization moderators has yielded several interesting effects supporting the notion that only a subset of peer victims are at risk.

Victimization may be most strongly associated with maladjustment in the context of cognitive biases or maladaptive coping. For instance, among children with attributional styles characterized by characterological self-blame, or a tendency to interpret ambiguous experiences as due to self-critical weaknesses, peer victimization is associated with later internalizing symptoms (Graham & Juvonen, 1998; Perren, Ettekal, & Ladd, 2013; Prinstein, Cheah, & Guyer, 2005). Among children with adaptive attributional styles and unbiased social information processing, no significant associations between peer victimization and later adjustment are evident. Youths' coping responses to peer victimization also relates to clinical outcomes. Emotion-focused coping in the context of peer victimization may be especially associated with lower

risk for internalizing symptoms (e.g., Kochenderfer-Ladd, 2004). Evidence indicates that the deleterious effects of peer victimization also are most pronounced among youth with genetic vulnerabilities compared with victimized youth without genetic markers for psychopathology (Benjet, Thompson, & Gotlib, 2010; Brendgen, Boivin, Vitaro, Girard, et al., 2008).

Chronic Versus Sporadic Peer Victims

Unfortunately, the vast majority of longitudinal studies examining peer victimization as a putative risk factor for psychopathology have employed a two-time-point design. These studies often examine peer victimization at an initial time point, and indices of maladjustment at both time points to understand peer victimization as a prospective risk factor for increases in symptoms over time. Thus, a single snapshot of peer victimization is captured, yielding many false positives. For many youth, peer victimization is a transient experience and in fact may be a rite of passage for the majority of children at some point in their development. Data regarding the test–retest reliability of peer victimization assessments yield only moderate consistency over annual time periods indicating that a substantial proportion of children identified as peer victims at one time point may no longer be experiencing significant victimization at all just a few months later (Zwierzynska, Wolke, & Lereya, 2013). For instance, Snyder and colleagues' (2003) playground observations revealed that over 90% of youth were victims of peer aggression at least once during the kindergarten and first-grade years. Overidentifying peer victims (i.e., including many false positives) from a single-time-point snapshot would attenuate apparent associations between peer victimization and later psychopathology.

Moreover, note that recent work on physiological concomitants of interpersonal stress has emphasized the recurrence of interpersonal stressors, rather than single stressful experiences, as relevant for stable physiological changes (e.g., in the stress response systems). Thus, the operationalization of peer victimization as a chronic stressor may provide more overlap with research in related fields.

However, relatively few studies have differentiated chronic versus sporadic victims of peer aggression. Extant data suggest that a small proportion of youth are chronic victims, with high levels of victimization reported over multiple time points (e.g., Hawker & Boulton, 2000). In a recent epidemiological study of young twins (Bowes et al., 2013), approximately 13% of children were identified as being chronic victims of frequent bullying during the transition from primary to secondary school. Notably, children who were chronic victims were found to be at higher risk for poorer mental health and academic outcomes compared with their peers who were never bullied or who were bullied only in primary (age 7–10) or secondary school (age 12). Research utilizing a person-centered approach to examine the developmental course of victimization across childhood and adolescence has been especially useful in this area. For instance, Barker and colleagues (2008) identified three distinct developmental trajectories of peer victimization during preschool years. Between the ages of 3 and 6 years, approximately 4% of children experienced high chronic levels of victimization, 25% were classified as belonging to a moderate/increasing victimization trajectory and 71% to a low/increasing trajectory (Barker et al., 2008). Compared with more sporadic victims, chronic victims are at greater risk for psychopathology, including depressive symptoms and broader internalizing symptoms (Biggs et al., 2010; Nylund, Bellmore, Nishina, & Graham, 2007; Zwierzynska et al., 2013).

Peer Victimization Within a Dynamic Systems Framework

Recent research has examined peer victimization as a factor that contributes to more complex processes. For instance, some research suggests that peer victimization can interact with other intra- and interpersonal domains to predict psychopathology. For example, Schwartz, Lansford, Dodge, Pettit, and Bates (2013) revealed that the association between harsh parental discipline in kindergarten and trajectories of academic achievement over six consecutive years was exacerbated under conditions of peer victimization. Another recent study demonstrated that the interplay between peer victimization and genetic makeup may increase risk for depressive symptoms among children with a history of maltreatment (Banny, Cicchetti, Rogosch, Oshri, & Crick, 2013). Specifically, child maltreatment was positively associated with depressive symptoms via peer victimization (both overt and relational) and these indirect effects were moderated by the children's genotype, with children who carried the long/long variant of the serotonin transporter gene (5-HTTLPR) being at greater risk for depressive symptoms, than children with a short allele.

Peer victimization may be especially relevant to the development of cognitions about the self or others; these cognitions may then be relevant predictors of symptoms. For instance, Troop-Gordon and Ladd (2005) and Ladd and Troop-Gordon (2003) provided some evidence supporting the notion that the effect of peer victimization on children's development of internalizing problems may be mediated by third factors, including self and peer beliefs. Similarly, the prospective effects of peer victimization on

externalizing symptoms likely occur at least in part via third factors, such as hostile attributions (Perren et al., 2013). Other work has suggested that peer victimization may exacerbate certain specific symptom dimensions. For instance, studies of antisocial behavior in youth have become especially focused on an understanding of callous/unemotional traits that appear to be relevant for prolonged, chronic antisocial behavior and psychopathy in adulthood. Callous/unemotional traits can be due to a heritable predisposition, or acquired following negative environmental experiences. A recent study using the Avon Longitudinal Study of Parents and Children dataset demonstrated that peer victimization at the age of 8 years prospectively predicted both internalizing symptoms and callous/unemotional traits at age 13 years via youths' irritability at age 10 years (Barker & Salenkin, 2012). In sum, there is very little research that has examined peer victimization in the broader context of other developmental risks or systems; however, extant work suggests that this may be an important direction for the future.

Psychophysiological Correlates of Peer Victimization

A growing area of research suggests that peer victimization may be best conceptualized as a stressor and consequently may be associated with changes in physiological stress responses. Most studies in this area have examined associations between peer victimization and the HPA axis, whereas relatively little attention has been devoted to the other main stress response system, the sympathetic-adreno medullary (SAM) system. The HPA axis involves central and peripheral system responses to stress. Specifically, the perception of threat or stress leads neurons in the medial parvocellular region of the paraventricular nucleus of hypothalamus to release corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP), which signals the pituitary gland to release adrenocorticotropic hormone (ACTH) within the body. ACTH in turn crosses the blood–brain barrier and triggers the adrenal gland to release glucocorticoids, which in humans include cortisol.

As noted already, glucocorticoids have a crucial function in regulation gene expression across different cells within the brain as well as throughout the body. Specifically, glucocorticoids can bind to glucocorticoid receptors (GRs; ligand-activated transcription factors), which are located in the cytoplasm of the cells. When glucocorticoids bind to GRs they translocate into the nucleus of the cell, where they activate gene transcription. Moreover, in a negative feedback loop, glucocorticoids inhibit the activity of the anterior pituitary, hypothalamus, and hippocampus, which ultimately down-regulate glucocorticoid release. The effects of glucocorticoids on gene transcription result in a series of physiological outcomes within the body, including down-regulation of immune responses (i.e., pro-inflammatory activity) and the sympathetic nervous system.

In the context of environmental challenges these physiological changes have important adaptive functions and prepare the organism to deal with stressful and potentially threatening stimuli. In other words, HPA axis responses, similar to other physiological responses to stress, represent accommodations to the environmental requests to maintain a homeostatic equilibrium (i.e., allostatic accommodation; Ganzel, Morris, & Wethington, 2010). Yet extreme and sustained stress may lead to *allostatic load*, or the cumulative physiological wear-and-tear that result from the organism's effort to adapt to adverse environmental conditions. Under conditions of high allostatic load, the organism loses its flexibility to respond to the environment, resulting in *fixed automatisms* that can have long-term negative outcomes (see Ganzel et al., 2010). For instance, high chronic levels of cortisol in the body can damage the hippocampus; similarly, dysregulated HPA axis may alter the immune system activity, which ultimately may increase risk for psychopathology.

Research investigating the effects of stressors on HPA axis activity has examined both diurnal cortisol levels and reactive cortisol. Cortisol production typically follows a circadian rhythm over the course of the day. High cortisol levels are evident 30 minutes postawakening and tend to decrease throughout the day reaching the lowest levels about 30 minutes after sleep onset in the evening. Because the HPA axis is a self-regulating system, atypical patterns of cortisol release, resulting from chronic adversity, can lead to longer-term changes in diurnal cortisol production.

Ample research has suggested that both chronically enhanced or blunted diurnal cortisol levels are associated with psychopathology, although this has been examined among adults substantially more than among youth. Relatively little work has examined the link between peer victimization experiences and diurnal cortisol. Extant research consistently indicates that high levels of peer victimization are associated with lower levels of diurnal cortisol (Murray-Close, 2013). For instance, compared with nonvictimized adolescents, victimized adolescents showed a blunted cortisol diurnal pattern that, in turn, was found to associate with higher health problems (e.g., fatigue, stomachache). Thus, the link between peer victimization and health problems was partially mediated by cortisol levels (Knack, Jensen-Campbell, & Baum, 2011).

Reactive cortisol refers to cortisol release in response to acute stressors, and is commonly measured in a laboratory setting after exposing participants to experimentally induced acute stressor (e.g., giving a speech in front of an audience). Given that HPA axis reactions peak approximately 20 minutes after exposure to stress, typically a pretask assessment occurs just before the stress task; subsequently, cortisol is collected one or more times poststressor. Adaptive HPA axis responses typically are observed when participants show moderate cortisol increases in response to a stressor and then return to baseline poststressor, indicating adaptive changes of the body in response to the stress stimuli, and thus the physiological capacity to summon the necessary resources for acute stressors that arise. Conversely, hyper- (exaggerated reactivity) and hypocortisolism (underreactivity to stress) represent dysregulated response patterns that are associated with psychopathology. Most studies examining the effect of peer victimization on HPA axis reactivity to acute stress have demonstrated that higher levels of peer victimization are associated with dysregulated HPA axis reactivity, even after controlling for other known predictors of reactive cortisol response (Calhoun et al., 2014). Ouellet-Morin and colleagues (2011) investigated whether chronic experiences of peer victimization affected cortisol responses to a stress task in a sample of discordant monozygotic twins. They found that twins who experienced chronic victimization showed a blunted cortisol reaction compared with their nonvictimized twins. By using a twin design, this study controlled for genetic and familiar environmental effects, thus providing strong evidence that peer victimization may alter physiological responses to stress. Studies using unselected samples also suggest that repeated peer victimization is associated with allostatic load characterized by hyporeactivity rather than hyperreactivity.

Thus, peer victimization may confer risks for changes in youths' biological stress-response system, perhaps leading to physical or mental health consequences. Recent research also suggests a biological sensitivity model in which the longitudinal association between peer victimization and youths' depressive symptoms is exacerbated among youth with high levels of anticipatory cortisol (i.e., cortisol levels measured before the stress task; Rudolph, Troop-Gordon, & Granger, 2011).

Peer Victimization and Social Pain

Recent work has suggested that social stressors such as exclusion, rejection, or perhaps victimization may lead to physically painful responses. Theory and research suggest that this may be an adaptive response meant to alter subsequent social behavior. This relatively new area of research has important implications for peer victimization research that have not yet been fully realized.

Social scientists have long recognized that human beings have a fundamental motivation to connect to other people, to form and maintain social ties (Baumeister & Leary, 1995). This basic need to belong may have an evolutionary basis. For example, living in groups allowed our ancestors to share tasks (e.g., gathering food), and remain protected from external threats (e.g., predators). Thus, from an evolutionary perspective, experiences of social disconnection, such as social exclusion and rejection, may directly threaten individuals' safety and survival. The negative emotional states arising from social disconnection, also referred to as social pain, may therefore have strong adaptive functions, similar to the ones of physical pain (MacDonald & Leary, 2005). Recent work has revealed an overlap between social and physical pain and has indicated that social pain may share the same physiological mechanisms of physical pain. Two distinct components of physical pain have been identified, including a sensory and an affective component. Whereas the sensory component provides information on the intensity, location, and quality of the pain, the affective component specifically encodes the unpleasant feelings associated with the pain. As a consequence of these negative feelings, the affective component, rather than the sensory one, elicits behaviors aimed to terminate, reduce, or escape the pain. Social pain relies on the same physiological processes of affective pain (MacDonald & Leary, 2005). This would explain why even in the absence of injuries, social experiences could still be perceived as painful. In sum, experiencing pain in response to social disconnection is evolutionary adaptive because it reduces individuals' likelihood to approach social contexts that may potentially elicit social disconnection and because it prepares individuals to properly react when episodes of social disconnections occur.

Extant work has empirically supported the notion that physical and social pain share common biological pathways. Over the last decade, a particularly promising area of research has focused on examining the neural substrates associated with social pain. Specifically, a growing number of studies have employed fMRI to investigate neural activity of individuals exposed to social rejection using a number of different experimental paradigms (for a review, see Eisenberger, 2012). For instance, in the most commonly used paradigm, participants are instructed to take part to a virtual ball-tossing game (i.e., Cyberball). Participants are told to play via the Internet with other two

individuals, which in reality are two computer-simulated players. Participants are exposed to both an inclusion and exclusion condition. In the inclusion condition, they receive the ball from the other virtual players during the entire game session. Conversely, in the exclusion condition, after initially receiving the ball participants are subsequently excluded from the rest of the game session, during which the two virtual players keep on throwing the ball to each other. By comparing neural responses across the two conditions, this work has documented the neural underpinnings of social pain and supported the notion that social pain may be processed by the same neural circuitry of affective physical pain. Specifically, compared with the inclusion condition, social exclusion is associated with higher activation of the dorsal anterior cingulate cortex (dACC) and anterior insula (AI), two brain regions that are involved in processing affective physical pain (e.g., Eisenberger, Lieberman, & Williams, 2003). Moreover, in multiple studies the activation of these regions was found to positively correlate with participants' report of social distress (see Eisenberger, 2012).

Notably, studies revealing the neural substrates of social pain provide crucial information to understand how interpersonal experiences that are perceived as potential threats for social connection may impact psychological health. The brain regions involved in processing social pain, in particular the dACC and the AI, are part of a broader neural network (including also the amygdala and the periaqueductal gray), which is implicated in responding to threating stimuli (Eisenberger & Cole, 2012). That is, the activation of these brain regions gives rise to a number of physiological processes that, evolutionary, prepared individuals to deal with potential threatening external stimuli. Specifically, both the dACC and the AI can elicit the endocrine and autonomic nervous systems. For instance, greater dACC activity has been linked to greater HPA axis and sympathetic nervous system responses (see Eisenberger & Cole, 2012). In turn, in a type of biological cascade, the HPA axis and SNS can regulate immune system activity. Accordingly, a recent study has provided compelling evidence for the association between activity in these regions and the immune system (Slavich, Way, Eisenberger, & Taylor, 2010). Higher dACC and AI responses to an experimental rejection task were found to associate with higher levels of immune system activity after exposure to a different social stress task (as indicated by higher levels of TNF-α, a pro-inflammatory cytokine).

Again, from an evolutionary perspective, the activation of the immune system is adaptive as it prepares the human body to respond to infections and bacteria arising from injuries that potentially are more likely to occur when in social isolation or when facing a threatening situation. However, experiencing chronic episodes that undermine social connection may lead to stable high levels of cortisol and pro-inflammatory cytokines (as a result of immune system activity) in the body, which may have a strong long-term impact on individual physical and mental health. As such, these neural responses may represent the first step of a number of biological processes that potentially may connect the interpersonal context to individual psychopathology.

Clearly, this area of research has direct applications for the study of peer relationships, including peer victimization, and youth development. However, despite promising evidence indicating the neural correlates of social rejection, to date little work specifically has been conducted among youth. Extant studies focusing on social pain inconsistently have replicated adult findings in youth samples. For example, experimentally induced social rejection elicited increased activity of the AI in youth (e.g., Moor et al., 2012). Yet evidence supporting the role of the dACC is somewhat less consistent (e.g., Masten et al., 2009). In addition, the subgenual anterior cingulate (subACC), a brain region that did not emerge to be salient among adults, is implicated in a number of youth studies (e.g., Masten et al., 2009; see also Eisenberger, 2012). The subACC is not directly involved in the affective circuitry of physical pain, yet it is implicated in processing affective states. Interestingly, enhanced activity in the subACC has been associated with higher levels of depressive symptoms in clinical samples. Moreover, higher subACC activation in response to a social rejection task was prospectively associated with youth depressive symptoms over a one-year period (Masten et al., 2011). Future research examining neural correlates of social pain among youth is strongly needed to corroborate existing findings, underscore potential developmental differences and better elucidate how brain neurocognitive processes linked to negative peer experiences may contribute to the development of psychological symptoms.

In sum, research on peer victimization has been prolific in recent years, and there are numerous societal forces (e.g., news media, parent advocacy groups, school district and legal systems) promoting anti-bullying efforts. Research has lagged behind a bit, however. Associations between peer victimization and psychopathology are less straightforward than previously thought. Peer victimization clearly is a relevant construct within complex, dynamic systems models of development. However, main effects of peer victimization on adjustment are somewhat less obvious within

the research literature. Greater attention to chronic peer victimization experiences, and the role of peer victimization within the development of youths' psychophysiological stress responses are needed in future work.

Friendship

As children reach the school-age years, many have achieved the capacity to form stable, true friendships with peers. Within the psychological literature (but notably differently from within sociological or anthropological studies), friendships often are described as relationships that are voluntary, mutual, and horizontal/bilateral (i.e., among peers of equal power; Bagwell & Schmdit, 2011). Compared with interactions with other (i.e., nonfriend) peers, interactions with friends are more frequent, are characterized by greater positive affect, and involve more reciprocal play (Newcomb & Bagwell, 1995). Some of these qualities are evident even within toddler-age youth; however, it is unclear whether young children are simply responding favorably to familiar peers or whether true friendships have emerged (Furman, 1982). Friendships among toddler and preschool years also are more strongly dictated by parental choices than are friendships developing during the school-age years. By school age, children are able to engage in reciprocal communication patterns (i.e., sharing and clarifying feelings, sharing goals for play, conflict resolution) that are thought to be a cornerstone of friendship formation and maintenance (Gottman, 1983). As children mature through the school-age years, friendships involve increasing levels of loyalty, affection, and companionship. In preadolescence, friendships evolve further to include emotionally intimate exchanges, self-disclosure, mutual support, and a general ability to understand and meet each other's psychological needs (Laursen & Hartup, 2002).

Importantly, children's friendship experiences appear to be fairly distinct from their overall experiences within the larger peer group. Although peer rejected children typically have fewer friends than nonrejected youth, and are more likely than others to befriend other rejected youth, they are equally likely to report at least one very best friendship that includes an array of positive and negative friendship qualities at levels sometimes comparable to other children's friendships (e.g., Parker & Asher, 1993). Thus, within the peer relations literature, great efforts have been made to differentiate children's group level peer experiences (e.g., peer status and reputations, peer victimization), from their dyadic peer experiences (e.g., friendships), as distinct aspects of peer functioning with unique correlates.

It is surprisingly difficult to measure the number of children's friends, perhaps because no formal definition exists for distinguishing friendships of different levels (i.e., best friends, close friends, or friends) or to identify friends from other amicable relationships (acquaintances or peers that children hang out with). Most commonly, children are asked to identify an unlimited number of their friends or their closest friends from a roster of peers. Demand characteristics are high for such a task, and youth are highly reluctant to list fewer friends than they believe is considered appropriate by the experimenters. An unlimited nomination procedure yields a very large range of the number of friends children will report, further obfuscating the definition of friendship. The common use of the Internet, and social network sites such as Facebook in particular, have only further obscured the meaning of the word *friend* within our society. Contemporary research combines several approaches by asking youth to nominate an unlimited number of their closest friends and also to identify their top three friends from this larger list. This approach allows for at least an ordinal clarification between youth who are identified as best friends versus other close friends. However, the use of school- or grade-wide rosters for this task often presents limitations in identifying friends from across multiple contexts.

In many studies, investigators determine whether children's friendship nominations have been reciprocated in an effort to identify true friendships that meet most investigators' a priori definitions of close friendship. Reciprocity typically is only possible to determine if children's selected friend also is a consented participant and has the opportunity to complete a similar nomination procedure. Reciprocal nominations may reveal that a target child's very best friend agrees that the target is a very best friend (i.e., ranked as their #1 friend), a close friend (i.e., ranked within their top three friends), a friend (selected as a friend, but not among their top three closest friends), or not a friend at all. Thus, some advocate a continuous rather than a dichotomous approach for studying friendships (see Berndt & McCandless, 2009). Data indicate that approximately 50% of children's very best friend nominations are reciprocated as very best friends (Parker & Asher, 1993). Approximately 75–80% of youth have at least one reciprocated friendship (Parker & Asher, 1993). Reciprocated friendships indeed may be characterized by higher levels of friendship quality and are more likely to be stable than other friendships (but see Poulin & Chan, 2010). Children who do not have a reciprocated best friend are more likely to be rejected by peers and are more likely to be victims of peer aggression (Hodges, Boivin, Vitaro, & Bukowski, 1999). Friendless children also have higher levels of depression than children with friends (Pedersen et al., 2007). Compared with

children with nondepressed friends, friendless children show increasing trajectories of depression over time (Brendgen, Lamarche, Wanner, & Vitaro, 2010).

Some children are less likely to have stable friendships, suggesting possible reciprocal associations between psychopathology, the peer environment, and subsequent psychological reactions to changes in this environment. In the context of psychological symptoms, the termination of a friendship may deprive youth of needed social support or a context in which more adaptive skill development may occur.

Yet relatively little empirical attention has been dedicated to examining which factors may contribute to friendship (in)stability over time (Poulin & Chan, 2010). Three consistent predictors have been revealed in extant research. First, aggressive and antisocial youth tend to have difficulties in maintaining their friendship over time. For instance, early adolescents who engage in high levels of overt aggression are less likely than their nonaggressive peers to have long-lasting friendships (Ellis & Zarbatany, 2007a). Second, youth with internalizing symptoms and socially withdrawn youth tend to have shorter friendships. Interpersonal models of depression (Coyne, 1976a, 1976b; Joiner & Katz, 1999), suggest that depressed individuals engage in a variety of socially alienating behaviors that increase their experience of interpersonal stress and also contribute to truncated friendships (e.g., Prinstein, Boreli, Cheah, Simon, & Aikins, 2005). There also is evidence that compared with other youth, anxious-solitary preadolescents are less likely to remain in a stable best friendship through an entire academic year (Ladd, Kochenderfer-Ladd, Eggum, Kochel, & McConnell, 2011).

Last, data indicate that similarity between youth and their friends may contribute to friendship stability. In other words, friendships between similar youth (i.e., similar levels of self-esteem, aggression, substance use) tend to last longer (Hafen, Laursen, Burk, Kerr, & Stattin, 2011). Using stochastic actor-based modeling (Snijders, van de Bunt, & Steglich, 2010) recent work has suggested that similar levels of depressive symptoms, happiness, and substance use also predict friendship maintenance over time, at least at the level of a unilateral friendship (DeLay, Laursen, Kiuru, Nurmi, & Salmela-Aro, 2013; van Workum, Scholte, Cillessen, Lodder, & Giletta, 2013; Van Zalk, Kerr, Branje, Stattin, & Meeus, 2010).

Initial research on friendships focused on the psychological correlates of friendship versus friendlessness and on factors that may help to explain why some children are able to maintain friendships. More research attention has concerned the study of friendship qualities and to some extent examinations of the characteristics of children's friends (Hartup, 1996).

Friendship Quality

Children or their friends easily can report their relationship quality with specific friends using a variety of available checklists measuring friendship quality (e.g., Furman, 1998). Children can report their own friendship quality, data from children's friends can be used to jointly determine friendship quality of a dyad, or, rarely, friendship quality has been examined using observational methods. Interestingly, rejected children report higher levels of positive friendship qualities than their average-status friends, highlighting a possible social-cognitive bias that may compromise the validity of self-reported friendship quality among some youth (Brendgen, Little, & Krappmann, 2000).

Most research has identified a group of positive friendship qualities (e.g., companionship, emotional disclosure, affection, reliable alliance, intimacy, support) and negative friendship qualities (i.e., conflict, dominance, power assertion, criticism). Positive and negative friendship qualities are orthogonal constructs, rather than two ends of a single relationship quality continuum. Research consistently has documented gender differences in some positive friendship qualities (e.g., emotional disclosure, intimacy) but not all (e.g., companionship). Moreover, there is some evidence that specific behaviors (e.g., shared social interactions) foster intimacy among males more than among females, while emotional disclosure may promote intimacy among females more than males (Hussong, 2000). Gender differences in negative friendship qualities are not reported consistently.

Interestingly, recent work using quantitative twin-study genetic designs indicates that genetic factors may explain a substantial proportion of variability in positive friendship quality. In other words, there is greater similarity among monozygotic twins than among dizygotic twins in the levels of positive friendship quality with best friends (Brendgen, 2012; Pike & Atzaba-Poria, 2003). Genetically determined factors, such as temperament may partially explain how genetic factors influence friendship quality (Pike & Atzaba-Poria, 2003). Results suggest an interesting example of combined rGE and GxE effects related to the role of friendships in children's adjustment. Consistent with a transactional framework, biological (i.e., genetic factors) covary with, influence the selection of, or evoke particular social environments (i.e., friends and friendship quality). These friendship experiences within the social environment then affect an individual's biological systems, altering trajectories toward psychopathology. Specifically, correlated genetic environmental factors (rGE effects)

may influence the ability to make friends (e.g., phenotypes related to appearance, behavioral inhibition, or social skill may predict the ability to make friends) and the level of friendship quality within these friendships. In the context of adverse events, these relationships may buffer maladaptive biological (e.g., autonomic nervous system) stress responses that promote maladaptive behavioral responses, or mitigate the risks associated with other genetic risks for psychopathology.

Harry Stack Sullivan (1953) famously posited that friendships provide a context that facilitates several critical development tasks at various different phases of life. For instance, at entry to the formal schooling years, friendships offer a context for social skill (e.g., cooperation, conflict resolution) development; beginning in preadolescence, friendships offer opportunities to share emotional intimacy, to give and receive social support, and to validate an emerging sense of identity (Sullivan, 1953). Friendships offer opportunities to learn and practice perspective-taking skills, empathy, and altruism (Buhrmester & Furman, 1986). Piaget (1932) and Vygotsky (1981) emphasized the unique context afforded by peer–peer interactions compared with adult–child interactions for promoting cognitive development. In short, many theories have suggested that friendships are highly relevant for understanding adolescent development, and by extension, may be a relevant factor in understanding adjustment difficulties.

Yet at least within the developmental psychology literature, little empirical evidence supports the claim that friendship difficulties confer risk for psychopathology. Most consistent has been support for links between friendship and loneliness. Specifically, research suggests that the absence of a close friend, fewer numbers of close friends, and lower levels of positive friendship quality all are associated with higher reports of loneliness (Bukowski, Hoza, & Boivin, 1993). Some evidence similarly suggests that low levels of positive friendship qualities also are associated at least concurrently with lower self-concept and higher levels of anxiety or depression (Bagwell & Schmidt, 2011). High levels of negative friendship qualities similarly are associated with anxiety symptoms (La Greca & Harrison, 2005). Longitudinal main effects between friendship or friendship quality and later symptoms of psychopathology have been inconsistent, however (Bagwell & Schmidt, 2011). On notable exception has been work examining the role of friendship experiences on school adjustment. For instance, Ladd and colleagues report that higher numbers of close friends and an absence of conflictual friendships are associated longitudinally with better school adjustment (i.e., more positive attitudes to kindergarten transition) among young children (Ladd, Kochenderfer, & Coleman, 1996).

Far more consistent are findings that indicate that both the presence of close friends and of positive friendship qualities serve as moderators in the association between known adverse risk factors and later adjustment difficulties. This is consistent with several theories, and even results from recent neuroscience studies. A large body of research has supported the buffering effects of social support on psychoneuroimmunological functioning (Cohen & Wills, 1985; for a review, see Hostinar, Sullivan, & Gunnar, 2014). Neuroscience research similarly suggests unique benefits of close relationships. For instance, recent research examined fMRI scans of three groups of adult women experiencing anticipatory anxiety (i.e., receiving random electrical shocks; Coan, Schaefer, & Davidson, 2006). In one group, participants held the hand of their romantic partner, one group held the hand of a stranger, and a third group did not hold anyone's hand during the experiment. Compared with the other two groups, women holding their partner's hand had significantly lower levels of brain activation in areas implicated in threat–response (e.g., ventral anterior cingulate cortex), emotional regulation (i.e., right dorsolateral prefrontal cortex, caudate), and emotion-related homeostatic functions (i.e., superior colliculus; Coan et al., 2006). Moreover, among participants with higher levels of partner relationship quality, neural responses were even more dramatic (Coan et al., 2006).

Friendships similarly may provide buffering effects in the context of stress. Friends and positive friendship qualities may provide an outlet for emotional disclosure and comfort that promotes adaptive coping with negative life events. Alternatively, friendships may provide a corrective context to redirect developmental trajectories that had been distorted due to stressors in other life domains (Bagwell & Schmidt, 2011). For instance, research suggests that the presence of a close friend, and high levels of positive friendship quality each appear to buffer the deleterious effects of negative parenting and family dysfunction on both internalizing and externalizing outcomes (Bukowski, Motzoi, & Meyer, 2009). Close support within friendship also appears to moderate the association between peer victimization and emotional maladjustment (Hodges et al., 1999). Friendships also buffer the negative effects of natural disasters, chronic illness, and peer rejection; maladaptation following each type of stressor is lower among youth with close, supportive friendships compared with youth without high quality friendships (e.g., Laursen, Bukowski, Aunola, & Nurmi, 2007; Wasserstein & La Greca, 1996).

Recent evidence suggests that friendship also may moderate biological risks and physiological stress reactions. For instance, Masten, Telzer, Fuligni, Lieberman, and Eisenberger (2012) indicate that time spent with friends during adolescence predicts lower brain activity in the dACC and AI in response to an experimentally induced stress task two years later. Notably, these brain regions are associated with processing of negative affect and pain, suggesting that friendship participation may have longitudinal effects on the ability to cope with negative affect and on reduced experience of emotional distress (Masten et al., 2012). Brendgen and colleagues' (2013) examination of a twin-sample indicates that participation in a single reciprocated close friendship mitigates the genetic risk for depressive symptoms among girls (Brendgen et al., 2013). Regarding physiological stress responses, research has examined friendship qualities as moderators of children's HPA axis response to naturalistic or in vivo lab-based stressors. For instance, Adams, Santo, and Bukowski (2011) indicated that the presence of a close friend during daily stressors was associated with lower levels of cortisol secretion. Similarly, in another study peer exclusion was associated with HPA axis dysregulation, as indicated by flatter diurnal cortisol, especially among children with fewer friends and lower quality friendships (Peters, Riksen-Walraven, Cillessen, & de Weerth, 2011). Calhoun and colleagues (2014) demonstrated that higher levels of positive interactions with a best friend following an experimentally induced social stressor were associated significantly with more dramatic HPA axis recovery.

In sum, while some children are friendless and at greater risk for internalizing distress, a majority of children successfully form and maintain reciprocal and supportive friendships. The ubiquity of this experience may explain relatively weak main effects between friendship quality and indices of psychopathology. However, friendships provide a context for social support or re-routed developmental competence trajectories that appear consistently to offer stress-buffering effects. Thus, friendships are promoted as adaptive and even necessary experiences among youth. Interventions aimed at increasing children's ability to form and maintain stable, close friendships have been established, and professionals advocate that youth be given opportunities to develop voluntary relationships with their peers.

Characteristics of Friends

Peer interactions establish a context in which development occurs. The characteristics of one's friends potentially have a substantial effect on development and on youths' (mal)adaptive trajectories, therefore. Consequently, researchers have been especially interested in the factors that predict which peers a child may befriend. Results suggest that children's risks for psychopathology actively contribute to their selection into social contexts that may reinforce their own psychopathology. Thus, friendship can serve as maintenance or exacerbating factor for youth at risk.

Research findings frequently have supported a proximity–similarity model of friendship formation (Blass & Schwarcz, 1982). Not surprisingly, spatial proximity predicts friendship formation. Although findings may change as Internet-based friendships continue to expand, extant data currently indicate that children living closely together within neighborhoods or sharing the same context (i.e., classroom, school) have an increased probability of becoming friends compared with children at greater physical distance from one another (Preciado, Snijders, Burk, Stattin, & Kerr, 2012). Thus, factors that covary with neighborhood or school selection (e.g., SES) may be likely to be experienced at similar levels among friends.

Many children also are remarkably likely to select friends who are similar to themselves. Younger youth are most likely to choose friends who have similar observable characteristics to themselves (e.g., gender, attractiveness), while older youth select friends with similar attitudes, values, popularity, and behavioral preferences (i.e., homophilic selection; Kandel, 1978). Most relevant is a tendency for individuals with psychopathology to select friends with similar types of psychopathology. For instance, adolescents who engage in delinquent behaviors are more likely to select as friends peers who similarly engage in delinquent behaviors, and youth with depressive symptoms are more likely to select other depressed youth as friends (Burk, Steglich, & Snijders, 2007; Van Zalk et al., 2010).

Research examining homophilic selection largely has built on the idea that adolescents are more likely to befriend similar peers because interpersonal attraction is higher among individuals with similar characteristics. For example, the similarity–attraction hypothesis (Byrne & Griffith, 1973) posits that individuals may evaluate positive interactions with similar others as more favorable because they represent rewarding contexts by validating their own behaviors. Yet more recently it has been argued that selection based on similarity may not always be a matter of choice. Indeed, youth experiencing psychological maladjustment may wish to befriend well-adjusted peers, but because they may experience more difficulties in forming healthy friendships, they may become friends with other isolated, troubled youth. This selection process, referred to as *default selection*, has been demonstrated in the study of

deviant peer affiliation. Importantly, youth with a variety of social deficits may become friends by default, exposing each to a range of psychopathology among their friends that could prove deleterious to their own adjustment.

Parents also play a role in the types of friends that their children select. Among young children, parents explicitly select their children's playmates and provide monitoring and supervision of their children's interactions with friends (Parke & Ladd, 1992). Not surprisingly, mothers' own level of social skill and the size of mothers' social networks are associated significantly with the number of their children's friends (Homel, Burns, & Goodnow, 1987). Later in development, parenting behavior is a relevant predictor of the characteristics of their children's friends. Most frequently examined have been the predictors of youths' entry into deviant peer groups. Findings indicate that parental communication, monitoring, and prohibition predict youths' affiliation with deviant peers. However, effects are somewhat inconsistent. Some research suggests that high levels of parental monitoring are associated with lower levels of children's deviant peer affiliation (e.g., Dishion, Poulin, & Skaggs, 2000). Yet other research suggests that prohibitive parenting may enhance children's affiliation with deviant peers (e.g., Keijsers et al., 2012). Parents' sensitivity to children's desire for autonomy is likely an important consideration. Parenting practices that support youth autonomy (i.e., autonomy-supportive styles) may have the desired effects in reducing negative peer affiliations, yet parental practices that tend to deny youth autonomy (and are accompanied by a controlling style) may increase the probability of deviant peer affiliation (Soenens, Vansteenkiste, & Niemiec, 2009). An interesting recent study employing social network analyses offers supporting evidence for this hypothesis (Tilton-Weaver, Burk, Kerr, & Stattin, 2013). Using network data, including friends' own reports of their deviant behavior, results indicated that high parental rules reduced the probability that children would select deviant peers as friends only when accompanied by low (perceived) parental overcontrol. Conversely, high parental rules had the opposite effects among adolescents who felt overcontrolled.

Research examining gene–environment interplay (i.e., passive, selective, and evocative rGE; Rutter, Moffitt, & Caspi, 2006) suggests that genetic factors also may play a significant role by influencing the social environment that children select (Brendgen, 2012). In other words, some genetic factors may help determine who youth select as friends. Data mostly support selective rGE effects in relation to deviant friendship affiliation. Quantitative genetic studies using twin-designs indicate that 20–42% of variance in deviant friendship selection (i.e., deviance reported by adolescents or parents, rather than by friends themselves) may be explained by genetic factors (Brendgen, 2012). Using Add Health data, allowing for the measurement of friendship reciprocity and friend-reported risk behavior, genetic factors accounted for over 60% of variance in youths' tendencies to select similarly substance-using friends (Harden, Hill, Turkheimer, & Emery, 2008). The Add Health data set has revealed similar genetic effects on children's selection of friends with similar levels of intelligence, depression, aggression, and academic achievement (Brendgen, 2012; Guo, 2006). However, these selective rGE effects appear to be greatest among adolescents, and less so among younger children, perhaps reflecting the increasing autonomy youth have in selecting their friends as they mature (Brendgen, 2012).

Molecular genetic studies also offer some evidence for genetic effects influencing friendship selection. Results from the Add Health study suggested an association between the number of risk alleles (i.e., 10-repeat alleles) of the dopamine transporter (DAT1) gene (i.e., associated with less inhibitory control) and the number of substance using friends among male youth who also came from high-conflict family backgrounds (Beaver, Wright, & Delisi, 2008). Social network studies (e.g., Fowler, Settle, & Christakis, 2011) have further suggested that individuals may select friends who are genetically similar (the frequency of the A1 allele of DRD2, associated with alienation and antisocial behavior) or who possess complementary traits; however, evidence has been inconsistent (Brendgen, 2012).

The Dark Side of Friendships

Ironically, it appears that some friendships or behaviors exhibited within the context of a friendship actually may do more harm than good. In addition to the many adaptive opportunities afforded by this context, friendships also can be a crucible for the development of harsh, maladaptive, and even dangerous behavior. Much of this dark side of friendship pertains to the characteristics of the friends that are selected by youth and the potential for peer socialization among these friends; this will be discussed in more detail later. In addition, recent work has identified numerous interpersonal processes that are unique to the friendship context and appear to be important risk factors for psychopathology. Some of these ideas have been articulated within theories of adult psychopathology, but rarely have been applied to youth.

Interpersonal models of depressive symptoms, for example, posit that individuals with high levels of depressive symptoms are especially likely to experience interpersonal stressors. Moreover, depressed individuals

are prone toward dependent interpersonal stressors, in which their own behavior may partially contribute to the stressful event (Rudolph et al., 2000). Indeed, depressed individuals appear more likely than nondepressed people to evoke more sad affect from conversation partners, and to engage in a variety of interpersonal behaviors that contribute to interpersonal rejection and exacerbations of depression (i.e., frequently referred to as a downward spiral; Coyne, 1976a, 1976b).

Similar phenomena have been observed among youth and help to elucidate friendship behaviors that are associated with deleterious outcomes. For example, data indicate that youth with sad affect and histories of peer rejection are more likely than others to engage in excessive reassurance-seeking behavior (Prinstein, Borelli et al., 2005). Reassurance seeking typically involves requests from close others (e.g., friends) to reinforce feelings of positive self-worth or of relationship stability. However, friends' compliance with these requests often is not sufficient; a reassurance seeker may continue to make repeated requests, followed by repeated disbelief in the reassurance received (Coyne, 1976a, 1976b). Eventually, and ironically, close friends from whom excessive reassurance is sought experience declines in their perceptions of positive friendship quality, threatening friendship stability (Prinstein, Boreli, et al., 2005). Interpersonal rejection from friends is perceived as a reification of the reassurance seeker's initial doubts, contributing to increased depressive symptoms.

A second interpersonal phenomenon relevant to depressive symptoms similarly highlights specific friendship behaviors that ironically lead to increases, rather than decreases in maladjustment. Rose (2002) initially noted that close friendship discussions involving excessive self-disclosure and problem discussion with a focus on excessive speculation and sharing of negative feelings, but without a problem-solving orientation (i.e., co-rumination) appeared to simultaneously predict both positive and negative outcomes among youth. Due to emphasis on self-disclosure and emotional validation during co-rumination, this interaction style is associated with high levels of friendship intimacy. It also appears to be more common among females than males. However, co-rumination also is associated with higher levels of depression and anxiety symptoms, particularly among girls (Rose, Carlson, & Waller, 2007). Additional studies of co-rumination have demonstrated that co-rumination varies among youth with different depression histories (Stone, Uhrlass & Gibb, 2010) and also is associated longitudinally with later major depressive episodes as well as the length of severity of these episodes (Stone, Hankin, Gibb, & Abela, 2011). Hankin, Stone, and Wright (2010) further revealed cumulative and cascading effects among co-rumination, interpersonal stressors, and trajectories of internalizing symptoms, offering compelling support for a cycle of mutually reinforcing transactions between children's psychological states and their dyadic experiences.

In sum, research suggests that the vast majority of youth have close friends characterized by positive relationship qualities. Children tend to befriend youth who are similar to themselves in behavioral characteristics and even psychological symptoms. Friends provide a context for support and assistance in times of distress. Consistent buffering effects of friendship have been observed, mitigating the psychological and physiological effects of adverse events. Friendships may even serve protective functions against the development of psychopathology among those at heightened genetic risk. However, friendships also provide a context for rehearsal and reinforcement of maladaptive interpersonal behaviors that increase the risk for psychopathology.

ADOLESCENCE

The transition to adolescence is a critical developmental vulnerability period for a range of psychological symptoms, including conduct disorder, depression, eating disorders, health risk behaviors to name only a few. Adolescence also is a developmental period characterized by marked changes in peer relationships. Adolescents spend considerably more time with their peers in the absence of adult supervision, and these peer interactions are characterized by much greater sophistication, intensity, and self-scrutiny.

Many of the constructs discussed earlier in this chapter remain relevant in adolescence. As in earlier years, adolescents vary in their overall peer reputations and levels of likeability. As noted already, peer popularity becomes especially salient as a discrete construct at the adolescent transition, however, with broad implications for adolescents' social goals and opportunities for social interactions. Although empirical data are not yet available, some evidence suggests that peer status may become somewhat less salient by late adolescence, particularly as youth reach the completion of their secondary education. Peer victimization most certainly continues during adolescence, however, social/relational forms become increasingly common. Compared with the relatively benign consequences to social/relational aggressors, the legal sanctions associated with physical forms of bullying become especially threatening, likely contributing to its decrease in frequency. Friendship behaviors become remarkably sophisticated

during adolescence; relationships are increasingly defined by high levels of emotional disclosure, loyalty, and social boundaries. Cross-gender friendship emerges for many at the adolescent transition, allowing for the development of heterosexual romantic interactions for many youth. Adolescence also is characterized by several informal peer groupings that define the peer milieu at this developmental stage. Interconnected networks of friends form peer cliques (i.e., interaction-based groups) with unique identities, rules, and expectations. Reputation-based peer crowds also form (e.g., jocks, brains, burnouts), particularly in North America, highlighting differences in adolescents' adoption of peer- or adult-prescribed values as they progress through identity development (Brown, 1990). Notably, these peer crowds vary considerably in their members' engagement in a variety of significant health risk behaviors (La Greca, Prinstein, & Fetter, 2001).

It frequently has been suggested that adolescence is a period marked by heightened susceptibility to peer influence; however, compared with the emphasis on the previously discussed peer relations constructs, less attention has been dedicated toward the study of peer influence. Peer influence effects are relevant to a wide range of psychological domains, including many different psychological symptoms. A brief review of this research is now offered.

Peer Influence

It is surprising that peer influence has been a somewhat understudied phenomenon among peer relations researchers. The apparent strong associations between adolescents' attitudes/behaviors and the attitudes/behaviors of their peers are among the most consistent and potent effects in all of developmental psychopathology research. Peer influence effects also have broad implications for many sectors of society. Among psychologists, there has been interest in peer influence as a normative phenomenon (among developmental psychologists), to illustrate persuasion and influence theories (among social psychologists), and to understand risk for psychopathology (among clinical psychologists). In fact, recent peer influence findings have indicated that the aggregation of exclusively deviant peers within treatment or recreational settings sometimes can produce iatrogenic treatment outcomes (see Dishion & Andrews, 1995; McCord, 1992). Sociologists and public health investigators have a strong investment in understanding peer influence dynamics to construct models of communication and contagion. Economists examine adolescent peer influence as a multiplier of policy interventions designed to reduce health risk behavior. Criminologists have noted that adolescents are more likely to commit crimes in the presence of their peers, while adults are more likely to commit the same crimes while alone (Gardner & Steinberg, 2005). Research also has documented peer contagion of criminal activities among prison inmates (Bayer, Hjalmarsson, & Pozen, 2009). Educators and education policymakers have begun to reflect on peer influence theories to determine students' placements into academically tracked classrooms or detention centers that exclusively include other deviant youth (Vigdor, 2008). Political scientists understand changes in public opinion using peer influence dynamics, just as advertising executives' marketing strategies are based quite explicitly on many of the basic principles that underlie peer influence effects. In short, peer influence effects are relevant for many, but remarkably little empirical attention has been dedicated to some basic, fundamental questions regarding these strikingly prevalent phenomena.

Adolescence likely is a period of heightened vulnerability to peer influence effects. This assertion is supported by developmental theory and findings from social neuroscience (Gardner & Steinberg, 2005). As noted earlier, data indicate that, compared with childhood, adolescence is accompanied by substantial increases in the frequency of adolescents' interactions with peers and concomitant decreases in parental monitoring. Changes in adolescents' social context yield increased opportunities to interact with peers autonomously, develop more sophisticated interpersonal behaviors, and experiment with new social roles. For instance, adolescents' peer relationships are characterized by higher levels of intimacy and emotional disclosure than in childhood, and begin to invest in peers as primary sources of social and emotional support (Harter, Stocker, & Robinson, 1996). In addition, adolescents develop relationships with broader social networks than in childhood and become increasingly cognizant of their status within the overall peer group hierarchy.

Developmental changes in youths' ability to form a stable sense of self-concept, contemplate the future, and engage in more sophisticated perspective-taking skills facilitate a unique period of identity development in adolescence. Identity development occurs in the context of adolescents' new social experiences. Through reflected appraisal and social comparison processes, peers offer an especially salient source of feedback and an opportunity for self-other contrast as adolescents experiment with their own values, preferences, and developing self-concept. Data suggest that, compared with younger children, adolescents become especially attuned to the peer context when making behavioral decisions. By early adolescence, youths' motivation to engage in behaviors that may earn

favorable status among peers usurps their desire to engage in behaviors primarily rewarded by adults (Juvonen & Murdock, 1995).

Adolescence also is a period of substantial changes in brain development, including rapid neuronal myelination and neural pruning, allowing for more rapid processing between brain regions (Giedd, et al., 1999). However, areas of the brain develop at different rates and maturation periods (Dahl, 2004). Research suggests that limbic and paralimbic regions of the brain, responsible for affectively motivated and reward-oriented behaviors, develop more quickly than the prefrontal cortex, responsible for rational decision making, contemplation, and inhibition (i.e., a dual systems model; e.g., Dahl, 2004). Indeed, studies using fMRI indicate that the nucleus accumbens (within the limbic system, responsible for processing rewards) is more likely to be activated during a monetary reward task among adolescents compared with younger children or adults (Galvan et al., 2006). Adolescence also involves increased circulation of sex hormones that bind to receptors in the limbic system, also contributing to heightened sensation-seeking. Decreases in dopamine production in adolescence lead to lower sensations of pleasure, and possibly adolescents' engagement in more extreme behaviors to reach similar levels of reward.

While changes in the limbic system occur early in adolescence, the development of the prefrontal cortex lags behind, with ongoing myelination, synaptic pruning, and greater integration with other brain regions continuing into early adulthood (Dahl, 2004). Consequently, adolescents' motivations toward reward-oriented behavior (i.e., risk behaviors) easily overpower logical reasons that may inhibit them to behave riskily. Data indicate that adolescents are less likely than adults to show activated neural responses in the medial prefrontal cortex when processing the loss of a reward, suggesting that adults are more likely to avoid harm or punishment (Ernst et al., 2005). Note that research clearly indicates that adolescents and adults are equally capable of recognizing the risks involved with specific behaviors, but the conscious awareness of these risks influences behavior less than the perception of immediate rewards. Thus, adolescents' decisions to engage in risk behaviors are likely influenced by social and affective factors and not by cognitive limitations in understanding risk (Cauffman et al., 2010).

Adolescence is associated with greater attention to social cues, rewards, and sanctions across many species—not only in humans. Gonadal hormone production during puberty is associated with increased oxytocin receptors in the amygdala and striatum, promoting increased attention to social stimuli (Albert, Chein, & Steinberg, 2013). Adolescents are especially attuned to social cues regarding inclusion/exclusion and social evaluation and are more invested in mentalizing, or thinking, about their peers' perspectives on their own behavior (Somerville, 2013). Clearly, these psychological and biological changes provide a perfect storm to increase susceptibility to peer influences in adolescence.

Indeed, recent data indicate that the mere presence of peers strongly influences adolescents' (but not adults') decisions to engage in risk behaviors and their biological responses to these behaviors. Gardner and Steinberg (2005) demonstrated that adolescents, but not children or adults were more likely to engage in risky behavior on a computer analog task when peers were present, compared with when alone. O'Brien, Albert, Chein, and Steinberg (2011) reported that late adolescents were more likely to pursue immediate rewards (as opposed to delayed rewards) when with peers, than when alone. Notably, these peer effects are significant even when adolescents believed they were being observed by an unknown peer (Weigard, Chein, Albert, Smith, & Steinberg, 2014), suggesting that peer influences on reward sensitivity may not necessarily be attributable to the familiarity of observing peers. Chein, Albert, O'Brien, Uckert, and Steinberg (2011) revealed that during a computerized risk-taking task the presence of peers led to increased activation in the limbic reward-processing systems among adolescents, but not adults. Steinberg and colleagues (Logue, Chein, Gould, Holliday, & Steinberg, 2014) revealed that even adolescent mice, but not adults, are more likely to consume alcohol in the presence of peers than when alone.

However, it should be acknowledged that recent evidence contradicting the dual-systems models also has been reported (see Crone & Dahl, 2012; Pfeifer & Allen, 2012). For example, studies have shown that tasks that require cognitive control are associated with both age-related increases and decreases in the activation of the prefrontal cortex. Moreover, other work has documented that activation of the limbic regions (e.g., ventral striatum) are associated with positive outcomes in adolescence (e.g., higher resistance to peer influence) rather than maladjustment. Drawing on these findings, researchers have begun to question the validity of the dual-systems models, suggesting that more complex developmental processes may characterize brain development throughout adolescence. For instance, researchers have suggested that brain regions involved in processing social motivation as well developmental and physiological changes associated with

puberty should be taken into account to better understand the behaviors associated with brain development during adolescence (Crone & Dahl, 2012; Pfeifer & Allen, 2012).

Although the specific mechanisms responsible for potentially higher peer influence susceptibility remain a topic of debate, most agree that adolescence is a period in which youth are especially likely to engage in behaviors at levels similar to that of their peers. Associations between adolescents' and their peers' behavior are due to two tenets of *homophily* (Kandel, 1978). *Selection* effects refer to the tendency for individuals to befriend individuals who possess similar attitudes and behaviors. *Socialization* effects suggest that individuals' behavior is influenced by the behavior of others. There is strong support for both selection and socialization effects among adolescents. Moreover, there is growing support to suggest that homophily effects are relevant to a broad array of adjustment indices. Perhaps most frequently studied, data indicate that adolescents befriend others who engage in levels of aggressive and substance use behavior similar to their own. Moreover, substantial data suggest that adolescents' perceptions of their friends' engagement in aggressive and substance use behavior is among the strongest longitudinal predictors of adolescents' own engagement in similar behavior (Prinstein & Dodge, 2008). Peer socialization effects have been revealed for adolescents' aggressive and delinquent/illegal behavior, alcohol, cigarette, marijuana use, and engagement in related health risk behaviors (e.g., sexual risk behavior; Brechwald & Prinstein, 2011). More recently, research has suggested that peer socialization effects also may be relevant for understanding adolescents' depressive symptoms (Giletta et al., 2011) weight-related behavior and body dissatisfaction (Rancourt et al., 2013), engagement in nonsuicidal self-injury (Prinstein et al., 2010), and happiness (Fowler & Christakis, 2008; van Workum et al., 2013). Research examining the presence of selection or socialization effects consistently suggests that peer experiences are among the most reliable predictors of adolescents' own mal/adaptation.

Peer Influence Contexts

Despite the seeming ubiquity of peer influence effects, remarkably little research has been conducted on several fundamental issues that are necessary for better understanding, and ultimately preventing deleterious peer influence. For instance, at present little is known regarding variability in peer influence across different types of peer relationships. A predominant approach for measuring peer influence involves the assessment of adolescents' engagement in a clinically relevant behavior as well as adolescents' perceptions of their friends' engagement in the same behavior. Unidirectional longitudinal associations between adolescents' perceptions of their friends' behavior and their own behavior are examined to reveal potential peer socialization effects. However, recent research has suggested that this approach may impede accurate estimation of peer influence phenomena for at least three reasons. First, studies have varied considerably in the operationalization of a friend who may serve as a source of peer influence. Current developmental psychopathology methods advocate the use of peer nomination procedures to assist adolescents in the identification of specific individuals who are their closest friends (and a single very best friend); in many cases participants' responses can be used to determine whether friendship nominations are reciprocated. Current evidence is mixed regarding the differing potential for influence within reciprocated or unreciprocated friendships. Supporting the hypothesis that close, mutual relationships may provide more opportunity for information exchange and social reinforcement, some research has suggested that stronger socialization effects are observed in reciprocated, compared with unreciprocated friendships (Stevens & Prinstein, 2005). However, other research suggests that socialization effects may be as strong, or stronger within unreciprocated friendships, suggesting that emulating another adolescents' behavior may be a strategy adolescents use to develop a closer relationship with an admired peer (Bot, Engels, Knibbe, & Meeus, 2005).

Investigators' methods for assessing friendships as a potential context for peer influence rarely account for the transient nature of many adolescents' relationships. As noted earlier, many adolescent friendships are short-lived; still other friendships may vary in closeness, such that a very best friend at the time of an initial assessment may become merely a best friend, a friend, or an acquaintance before the follow-up assessment has occurred in a traditional longitudinal design. Currently it is unknown whether there is a minimal dose of exposure to a friend's attitudes or behaviors that is necessary to produce a socialization effect. Therefore, it is unknown whether stable friendships may exert greater influence than unstable friendships; however, recent evidence suggests that stable friendships may be more potent context for peer influence (Laursen, Hafen, Kerr, & Stattin, 2012).

Second, studies that have examined adolescents' reports of their best friends' behavior as a predictor in peer influence research more precisely are measuring the socialization effects of adolescents' *perceptions* of their friends'

behavior. This may be a highly relevant construct to consider; studies suggest that adolescents' perceptions of their friends' behavior may be more proximal predictors of their own behavior and may even mediate the association between adolescents' friends' behavior and adolescents' own behavior (Fromme & Ruela, 1994). However, it should be noted that estimates of peer influence effects relying on adolescents' perceptions of their peers' behavior likely overestimate the magnitude of these effects due to shared method variance. Moreover, substantial theory and research indicate that individuals are notoriously poor at accurately estimating the attitudes and behavior of others. False consensus effects demonstrate that individuals overestimate the similarities between their own and others' behaviors (Ross, Greene, & House, 1977). The uniqueness bias indicates that people underestimate how many of their peers may engage in desirable behaviors that they themselves engage in (Goethals, Messick, & Allison, 1991). Pluralistic ignorance theories suggest that even when engaging in behaviors as frequently as others, individuals may erroneously estimate the underlying attitudes of others as different from their own. For example, a reluctant drinker may estimate higher levels of pro-alcohol attitudes among others who are drinking at levels identical to their own. Empirical work has demonstrated that adolescents' engagement in health risk behaviors is associated with their overestimations of others' engagement in similar behaviors (Prentice, 2008). Research examining the effects of peer socialization relying on an external informant (e.g., friends' own report) of peers' behavior has supported peer socialization effects; however, effect sizes may be somewhat attenuated.

Third, accumulating evidence suggests that adolescents may be influenced within many types of peer relationships. A substantial focus of prior work has been the study of peer influence within adolescents' very best friendships. Emerging evidence suggests that socialization also may occur within adolescents' romantic relationships (Simon, Aikins, & Prinstein, 2008). Data also indicate that adolescents are highly influenced by the behavior of high status peers, with whom they may not have a friendship. For example, experimental research indicates that when presented with identical injunctive social norms, ostensibly communicated either by high-status (i.e., popular and liked) or low-status (i.e., unpopular and rejected) peers (i.e., electronic confederates), adolescents' publically and privately demonstrated greater conformity to high status peers (Cohen & Prinstein, 2006). Adolescents are more likely to behave aggressively when they observe high-status peers doing so compared with when they observe low-status peers engage in identical behavior (Cohen & Prinstein, 2006). Research on media influences has frequently proposed that adolescents' behavior can be socialized by peers whom they have not even met. Empirical data sorely are needed regarding the relative power of different influential agents, as are data on the manner in which adolescents reconcile conflicting messages from different socializing forces in their peer network. Recent data suggest that the most potent peer contexts for socialization may vary by the behavior that is being influenced. For example, recent work has suggested that socialization of depressive symptoms may be most likely to occur within best friendship dyads, while socialization of alcohol use occur within larger social networks (Giletta et al., 2012). This may reflect differences in the mechanisms underlying peer influence effects for different domains of adolescent adjustment and the contexts in which these mechanisms are most likely to occur.

Although most research examining peer influence effects focuses on socialization processes within a dyadic relationship (i.e., very best friendships), researchers agree that very best friendships most often occur within the context of broader friendship groups. Only recently has research begun to understand socialization processes within this broader context. For instance, an especially popular trend has been the use of statistical software that can estimate simultaneously the magnitude of selection and socialization effects among all of an individual's multiple dyadic friendships.

An especially popular recent approach has involved stochastic actor-based modeling (Snijders et al., 2010). This approach is grounded on the notion that individual behaviors and social networks are dynamic and interrelated entities. That is, behavioral changes of individuals within a social network (i.e., actors) are strongly related to the characteristics of the social network and vice versa. Hence, stochastic actor-based models provide a methodological tool to investigate the co-evolution of social networks and individual behaviors over time. These models address several limitations of earlier peer influence analytic approaches. Of most relevance, many observational studies (i.e., nonexperimental studies) do not disentangle selection and socialization processes because they do not take into account that unobserved changes may occur between two discrete observation moments (for a more detailed description, see Steglich, Snijders, & Pearson, 2010). In contrast, stochastic actor-based models assume that unobserved changes occur between two discrete time points. These continuous changes are assumed to occur one at a time via so-called micro steps, which are directly controlled by

actors. That is, actors can change (i.e., increase or decrease) either their behavior or a network tie (i.e., they can form or dissolve a friendship). Actors' decisions to make and select a particular micro step depend exclusively on their current behavior and on the current state of the network, regardless of the previous state (i.e., Markov process). Using a continuous-time Markov chain Monte Carlo (MCMC) approach (Snijders, Steglich, & Schweinberger, 2007), overall changes in actor's behaviors and friendship ties between two discrete time points are estimated through an iterative simulation procedure. This procedure generates unstandardized parameters and their standard errors, which describe changes in actors' behaviors and friendship ties. Notably, when estimating socialization effects, these models control not only for selection effects, but also other confounding effects related to the structure of the social network (i.e., endogenous effects), such as the tendency to reciprocate friendship ties or to form cohesive groups (e.g., triadic relationships). In stochastic actor-based models, peer influence effects typically are operationalized as the tendency of adolescents to become more similar to the average level of behavior among the peers whom they nominated as friends.

Since the first study demonstrating how stochastic actor-based modeling could be applied to estimate socialization effects within adolescent friendship networks (Burk et al., 2007), an increasing number of studies have employed this approach to examine peer influence effects. Overall this growing area of research has provided compelling evidence indicating that peer influence effects contribute to behavioral similarity between adolescents and their friends, even after controlling for selection and network structural effects. Socialization effects in adolescent friendship networks have been documented in relation to a variety of behaviors, including health risk behaviors (e.g., substance use, eating behaviors) and externalizing behaviors (e.g., aggression, delinquency; for a review, see Veenstra, Dijkstra, Steglich, & Van Zalk, 2013). For instance, a number of studies have demonstrated that although adolescent similarity in aggression and substance use is partially due to the tendency of adolescents to select as friends peers with similar levels of aggression and substance use respectively, adolescents also become more similar to their friends' aggression and substance use, as result of peer influence network effects (Veenstra et al., 2013). A few studies also have provided evidence of socialization effects within social networks in relation to internalizing behaviors, including depressive symptoms, loneliness, and social anxiety (Mercer & DeRosier, 2010). Notably, peer influence effects have been demonstrated across different types of friendship networks, including class and grade networks as well as school and outside-school networks. Moreover, these peer influence effects have been reported across different developmental periods, from middle childhood throughout adolescence.

It should be noted that although research using stochastic actor-based modeling has offered a notable contribution to studies of peer influence, this approach typically measures peer socialization effects as the extent to which individuals and their friends' behaviors become more similar to one another over time. It is unclear whether the peer influence effects estimated have direct relevance to the development of psychopathology, therefore. Increasing similarity between adolescents' and their friends' behaviors, as estimated in stochastic actor-based modeling, may reflect adolescents' increases or decreases in the frequency of maladaptive behavior. For instance, network influence effects measured in stochastic actor-based modeling related to aggressive behaviors may indicate that adolescents become more similar to their friends by increasing their levels of aggressive behaviors (conforming to the behavior of their more aggressive friends) or by decreasing their levels of aggressive behaviors (converging to the behavior of their less aggressive friends). Importantly, distinguishing the direction of peer influence effects is a methodological challenge that pertains to many analytic approaches. Most peer influence research tends to neglect the hypothesis that changes in adolescents' behaviors could also reflect positive friends' influence (Berndt & Murphy, 2002). Recent advances in stochastic actor-based modeling (i.e., creation and endowment effects) may allow disentangling deleterious from beneficial effects of peer socialization.

In addition, note also that stochastic actor-based modeling relies on a conceptualization of friendship networks as a summary of (i.e., an average across) all of an individual's friendship dyads. Differences in the strength of the relationships among some of these friends typically are not accounted for. Peer influence effects consequently may be mitigated by averaging socialization among best, close, and casual friends. In addition, social networks should not be confused as similar to peer cliques. Stochastic actor-based modeling does not measure peer influence within cliques.

In fact, extant data suggest that peer influence also occurs within cliques, offering an additional interesting contribution to understanding peer socialization. Developmental theory suggests that peer cliques represent organized groups of peers defined by interconnected friendships, with discrete boundaries, hierarchies, and social norms. Cliques represent more than an amalgam of

multiple friendship dyads. Cliques include a core nucleus of individuals as well as more peripheral ties (Lansford et al., 2009). Cliques have distinct rules and sanctions that differ from how these parameters are expressed within the constituent friendship dyads. Clear hierarchies within peer cliques are associated with different levels of power, different frequencies of contact, and potentially varying levels of peer influence.

Unfortunately, peer cliques are remarkably difficult to operationalize and examine. The notorious difficulties associated with accurately categorizing youths' best friends, friends, and acquaintances (concepts that youth themselves have difficulty articulating with adequate reliability) are compounded when attempting to understanding the breadth of adolescent peer cliques.

Nevertheless, recent work indicates that peer socialization occurs in friendship cliques, and adolescents' position in their clique may significantly alter their susceptibility to clique norms. For instance, Rancourt, Conway, Burk, and Prinstein (2013) revealed that within all-male peer cliques, the average level of dieting behavior of adolescents' cliquemates was associated longitudinally with adolescents' own levels of dieting behavior. These same researchers demonstrated peer clique-level socialization of depressive symptoms, with adolescents' gender and position in their peer clique acting as significant moderators of peer socialization effects. Specifically, compared with other adolescents, the longitudinal association between adolescents' cliquemates' depressive symptoms and adolescents' own depressive symptoms (i.e., both self- and peer-reported) was significantly stronger for female adolescents and adolescents at the periphery of their peer cliques (Conway, Rancourt, Adelman, Burk, & Prinstein, 2011).

Peer Influence Mechanisms

There is little doubt that peer influence processes affect adolescents' development and can promote adolescents' maladaptation. However, it is difficult to reduce peer influence effects. Indeed, efforts to dissuade adolescents from befriending risky peers largely are unsuccessful. Thus, it is critical to identify malleable processes that underlie adolescents' tendencies toward peer conformity.

Recall that developmental theory suggests that peer influence occurs most dramatically during a period also associated with adolescents' heightened sensitivity to peer feedback and acceptance; this developmental period also is associated with rapid identity development. Two theories thus are especially relevant for understanding possible peer influence mechanisms. First, social learning theories contend that individuals adopt behaviors to gain rewards or avoid punishment. Specifically, behaviors are learned through modeling, direct operant reinforcement in the form of social reward or sanctions, and vicarious reinforcement through observational learning (Bandura, 1973). Second, identity-based theories suggest that emulation of idealized others' behavior and adherence to perceived social norms within a valued reference group help confer a favorable sense of self; the adoption of a favorable sense of self is intrinsically rewarding (Festinger, 1954). Accordingly, research on peer influence mechanisms has focused on social reinforcements and identify-enhancing reinforcements that may underlie peer influence effects.

There is substantial evidence that adolescents are likely to engage in behaviors that they believe will earn them social reinforcement. For many adolescents, high peer status is socially reinforcing. This is particularly evident when examining reputation-based forms of peer status, or popularity. Indeed, many of the behaviors especially relevant to peer influence (i.e., aggressive and health-risk behaviors) are associated with high popularity among peers, and research therefore has focused on understanding the social norms of popular peers in particular (Mayeux, Sandstrom, & Cillessen, 2008; Rancourt & Prinstein, 2010). Juvonen and Ho (2008) revealed that middle school students who associate peer-directed aggressive behavior with high popularity (coolness) in the first semester of middle school demonstrated increased antisocial behavior in the second year at that school. Adolescents are more likely to engage in these behaviors and endorse deviant-related attitudes if they believe that doing so has been endorsed by high-status peers (Cohen & Prinstein, 2006). If adolescents are led to believe that these same deviant-related attitudes are endorsed by low-status peers, adolescents demonstrate anticonformity, adopting opposite-valenced attitudes (Cohen & Prinstein, 2006). Related research suggests that failure to adhere to dominant or valued social norms may be met with social punishment in the form of exclusion and rejection by peers (Juvonen & Galvan, 2008).

However, not all adolescents are motivated toward popularity. Some adolescents may be especially influenced toward behaviors that are associated with social norms of peer subgroups that occupy a less central position within the larger peer network. For instance, work has suggested that rejected/aggressive youth may be especially likely to affiliate with deviant peer groups, who actively reject the behavioral norms of the overall peer context and instead adopt a local set of social norms that may be more salient to these adolescents' identity development (Dishion et al., 1995).

Social reinforcements occur not only within the broader peer context but also within dyadic peer relationships; this is an especially important area of inquiry given the large focus of prior work on dyadic friendships as a primary context for peer socialization. In a series of groundbreaking studies, Dishion and colleagues revealed that adolescent dyads engage in subtle but important differences in nonverbal reinforcements during discussions of deviant and nondeviant topics. Within friendship dyads of adolescent males without histories of deviant behavior, utterances regarding deviant activities are followed by neutral affect, whereas discussion of prosocial activities often are followed with nonverbal reinforcements, such as smiling, nodding, and laughing. However, the opposite pattern is evident within friendship dyads of deviant adolescents; deviant talk is followed by positively reinforcing utterances and gestures. This interaction pattern (i.e., referred to as deviancy training) elucidates a process by which peer socialization may occur (Dishion, Spracklen, Andrews, & Patterson 1996). It has been posited that deviancy training represents an attractor state for deviant adolescents (Granic & Dishion, 2003). In other words, deviancy training may be an interaction that deviant adolescents favor; thus, they are especially likely to get stuck in this maladaptive interaction pattern, subsequently predicting ongoing deviant behavior (Granic & Dishion, 2003). Adolescents' exposure to deviancy training is associated longitudinally with increases in problem behavior in middle adolescence (e.g., Dishion, Eddy, Haas, Li, & Spracklen, 1997), and young adulthood (Dishion, Nelson, & Bullock, 2004). In one study, deviancy training observed in a 10-minute dyadic interaction sample predicted criminal arrest rates at least two years later (Dishion et al., 1996), and deviant talk within group therapy contexts has been proposed as a possible explanation for iatrogenic effects of this therapeutic approach among deviant teens with conduct disorder. Interestingly, the effects of deviancy training have been observed among females as well as males (Piehler & Dishion, 2007) and even among kindergarten-age children (Snyder, Schrepferman, Bullard, McEachern, & Patterson, 2012).

In addition to social reinforcement theories, studies of peer influence mechanisms indicate that peer conformity may serve identity-enhancement functions. In other words, peer conformity may be motivated by internal needs and ultimately self-evaluation. Identity-based theories have been discussed at length within the social psychology literature. Generally, these theories suggest that individuals are likely to engage in behaviors that help them establish or maintain a positive sense of self-concept (e.g., Markus & Wurf, 1987). Peers' behaviors offer an opportunity for social comparison. Thus, adolescents may evaluate themselves in reference to their perceptions of others' behavior (i.e., social norms) and modify their behavior in a manner that will confirm a favorable sense of self. Although several derivations of this theory exist, relatively few have been applied to the study of actual risk behaviors among adolescents in a naturalistic context.

For instance, the prototype/willingness model proposes that peer conformity may be the result of two distinct processes (Gibbons, Gerrard, Reimer, & Pomery, 2006). First, individuals evaluate the behavior of those that match their own idealized selves (i.e., prototypes). Behaviors that are perceived to be associated with a desired self-image increase one's favorable attitudes toward the behavior (Ajzen & Fishbein, 1975). Second, the perception that a behavior is similar to the behavior of a desired self or prototype leads to a perception of potential social rewards (i.e., engagement in this behavior will lead to a more favorable self-evaluation). This perception of potential social rewards increases an individual's willingness to engage in a behavior spontaneously should an opportunity become available. In combination, an individual's perception of social norms that align a behavior with their idealized self and an increasing willingness to engage in the behavior conjointly predict behavior engagement (Gibbons et al., 2006).

Blanton and Christie's (2003) deviance regulation theory also emphasizes an underlying motivation to establish a positive self-concept as a basis for peer conformity. While the prototype/willingness model emphasizes a desire to enhance self-concept by achieving similarity with favorable prototypes, deviance regulation theory suggests that individuals are most motivated to achieve a balance between similarity and differentiation from their peers. Such a balance is achieved by consistently aligning one's behaviors with members of a salient and desired reference group through conformity, while still maintaining a sense of uniqueness that engenders feelings of autonomy and distinctiveness from others. Both intrinsic (e.g., sense of self-worth) and extrinsic (e.g., social approval) reinforcements are thought to provide feedback to adolescents, thus potentially serving to maintain the behavior (Blanton & Christie, 2003).

Similarly, Berger's (2008) marketing model of social memes (i.e., fads, trends) posits that social comparison processes and alignment with salient, desirable groups (or nonconformity to undesirable groups) may explain peer socialization. Berger contends that individuals initially engage in a behavior that they feel helps differentiate them

from others, particularly through identification with a special subgroup that matches their desired identity. For example, if alcohol use initially is associated with a typical high status schoolmate, then high status adolescents may be especially likely to adopt this behavior to signal their membership in this in-group. However, when alcohol use begins to become adopted among other, lower status adolescents (i.e., among out-groups), it loses its value as a marker for in-group status and will quickly fade as a preferred behavior among the high status adolescents themselves (see Berger, 2008).

Understanding the mechanisms of peer influence effects that promote youths' maladaptive behavior will require greater empirical attention. At least two neglected putative mechanisms warrant further explanation. First, deviance regulation theory and Berger's model suggest that differentiation from others may be a powerful motivation for peer conformity (or anticonformity). This elucidates an especially pernicious peer influence mechanism that has not been studied extensively, namely, anticonformity effects. By deliberately engaging in behaviors that violate adaptive social norms, adolescents may have the impression that they are not susceptible to the values of their peers, and thus not susceptible to peer socialization. Yet anticonformity is indeed a form of peer socialization, albeit one in which adolescents do not necessarily realize that they are being influenced by others. Second, surprisingly few studies have examined indirect models of peer influence, in which adolescents' behaviors (i.e., X) may be influenced by different, but perhaps related attitudes or behaviors (i.e., Y) of their peers. To date, peer influence research has almost exclusively examined a direct modeling hypothesis, suggesting that adolescents' peers' engagement in a specific behavior (X) will be associated with adolescents' engagement in this identical behavior (X). Several other possibilities deserve consideration. For instance, indirect peer influence may occur through socialization of predisposing, underlying characteristics, which are differentially expressed among members of a friendship dyad. Socialization of impulsive behavior, for instance, may be associated with either drug use or nonsuicidal self-injury, perhaps based on adolescents' own prior experiences (see Giletta, Burk, Scholte, Engels, & Prinstein, 2013). Indirect peer influence also may occur by promoting similarly themed behaviors. A longtime marijuana using friend's initial experimentation with hard drugs may be influential in another adolescent's decision to experiment with marijuana for the first time. Importantly, it is likely that the mechanism of peer influence varies based on the behavior that is subject to socialization. This issue requires greater attention.

Peer Influence Moderators

Some adolescents may be more susceptible to peer influence than others. However, remarkably few research studies have examined the construct of peer influence susceptibility. Theory also is lacking. It is unknown whether peer influence susceptibility is a stable trait or a characteristic that varies substantially within an individual across time, development, or contexts. It also is not known whether adolescents can reflect upon their own level of peer influence susceptibility or whether like many instances of peer socialization itself, this is a process that occurs outside of an individuals' awareness. Susceptibility has been measured using self-report checklists, responses to hypothetical vignettes, and performance-based measures that utilize deceptive elements (Allen, Porter, & McFarland, 2006; Prinstein, Brechwald, & Cohen, 2011; Steinberg & Monahan, 2007). The concurrent and predictive validity of such instruments has been a main focus of research to date.

Although little is known regarding the construct of peer influence susceptibility itself, research increasingly has examined correlates of susceptibility, often referred to as moderators of peer influence. Studies of peer influence moderators typically identify constructs that appear to moderate the association between adolescents' and their peers' behavior. At least four levels of moderators have been identified; notably, moderators likely interact across each of these levels. First, and most frequently examined, are characteristics of the influenced adolescent (i.e., the target adolescent) that may moderate the potency of peer influence effects. Data regarding the moderating effects of gender have yielded inconsistent findings. However, evidence is accumulating to suggest that age may be relevant, with older adolescents and young adults perhaps less susceptible to peer influence, at least for deviant acts, than are younger adolescents (Monahan, Steinberg, & Cauffman, 2009). Research suggests these age effects may be due to higher levels of self-regulation and inhibitory control (Gardner, Dishion, & Connell, 2008). Data also indicate that measures of internalized distress, such as low self-concept, or high social anxiety, may increase the strength of associations between adolescents' and their peers' behavior (Cohen & Prinstein, 2006); however, these effects are not consistently observed (Larsen, Overbeek, Vermulst, Granic, & Engles, 2010). Additionally, poor family functioning appears to augment susceptibility to peer influence (Vitaro, Brendgen, & Tremblay, 2000).

More recently, research has examined possible genetic factors that function as peer influence moderators. For

example, Harden and colleagues (2008) revealed that the impact of best friends' substance use on target adolescents' use was most pronounced for adolescents with the highest genetic vulnerability for using tobacco and alcohol. Similarly, in two samples of young twins, youth were most likely to be physically aggressive if they were both genetically at risk for this behavior and were exposed to highly aggressive peers (Brendgen, Boivin, Vitaro, Bukowski, et al., 2008). Friends' alcohol use was significantly associated with adolescents' own alcohol use more strongly among adolescents with a genetic predisposition for alcohol-based reward responses (i.e., DRD4 VNTR polymorphism; Larsen, van der Zwaluw, et al., 2010).

Second, research has examined characteristics of the influencer that may augment peer socialization effects. There is some evidence to suggest that higher status peers exert greater influence over lower status peers (Cohen & Prinstein, 2006; Laursen et al., 2012; Prinstein, 2007). Similarly, more central members of an adolescents' peer clique appear to exert greater influence over more peripheral members rather than vice versa (Conway et al., 2011). Some data suggest that certain groups (i.e., those with greater centrality in the overall peer context) may exert greater influence over its members than less central groups (Ellis & Zarbatany, 2007b).

A third group of moderators includes relationship attributes between the target and the influencing peer that may alter peer susceptibility. Recent research examining relationship qualities through observational coding has suggested that the effects of deviancy training appear to be strongest within dyads low in entropy (i.e., highly organized and predictable) and high in dyadic mutuality (i.e., reciprocal, shared understanding). Questionnaire-based studies suggest that high levels of positive friendship quality also magnify peer socialization effects for depression symptoms (Prinstein, 2007), substance use (Urberg, Luo, Pilgrim, & Degirmencioglu, 2003), and prosocial behavior (Barry & Wentzel, 2006). As noted already, studies examining friendship reciprocity as a moderator of peer influence effects have wrestled with competing hypotheses. Reciprocated friendships may provide a context for high levels of communication, emotional disclosure, and shared understanding that promotes socialization. On the other hand, an unreciprocated friendship suggests that one member of the dyad desires to develop a closer relationship with the other and may therefore be especially susceptible to socialization. Extant research findings support both hypotheses (cf. Bot et al., 2005; Hall & Valente, 2007; Mercken, Candel, Willems, & de Vries, 2007; Stevens & Prinstein, 2005).

Last, peer susceptibility may vary based on contextual factors, including the context in which socialization processes occur (i.e., in school/home, presence/absence of adults), the number of peers involved, including potential allies for adolescents (Asch, 1952), or even the specific behavior that is at hand. Berndt (1979) initially suggested that susceptibility to peer pressure depended on the social and legal value associated with the target behavior. Alternatively, adolescents' level of prior engagement in specific behaviors (i.e., abstention versus prior experimentation) may affect peer susceptibility. For instance, adolescents who have already initiated alcohol use may be more prone to peer influence toward risky alcohol use than someone who has never consumed alcohol before (Maxwell, 2002). Within studies of social network influence effects, stochastic actor-based modeling offers a unique opportunity for examining contextual factors that could alter socialization effects. For example, a recent study examining socialization of risk attitudes (e.g., substance use and deviant behaviors) revealed stronger influence effects in class networks in which risk attitudes were more strongly associated with peer status than in class networks in which risk attitudes were not or less associated to status (Rambaran, Dijkstra, & Stark, 2013).

Peer Influence Effects Within Multilevel Investigations

Studies of peer influence that adopt a dynamic systems perspective are rare. However, recent work in neuroscience has offered some evidence to suggest more complex models of peer influence effect. For instance, G×E studies indicate that peer influence likely occurs in a manner consistent with a genetic diathesis-stress hypothesis. Results from quantitative twin-design genetic studies consistently indicate that friendships with deviant or substance using peers significantly increases delinquency, alcohol use, and substance use among adolescents with genetic risks (Guo, Elder, Cai, & Hamilton, 2009; Harden et al., 2008; van Lier et al., 2007). Boardman, Saint Onge, Haberstick, Timberlake, and Hewitt (2008) revealed that youth with genetic risks for nicotine use were more likely to smoke when in a school setting with a context that appeared to offer social rewards for smoking (i.e., in schools where smoking was associated with peer popularity).

Evidence from molecular genetic studies similarly supports the genetic diathesis stress effects of deviant peer influence. Lee (2011) revealed a significant interaction between the high-risk MAOA genotype (i.e., dopamine synthesis) and deviant peer affiliation in the prediction of adolescent criminal behavior and Latendresse and colleagues (2011) revealed a similar moderating effect of

deviant peer affiliation in the association between CHRM2 gene (i.e., sensation seeking, disinhibition) and adolescents' externalizing behavior (Brendgen, 2012). Larson and colleagues (2010) revealed that adolescents with the long allele of the DRD4 gene (i.e., alcohol craving/use) demonstrated more alcohol use conformity in a heavy-drinking peer group than adolescents without genetic risk.

In sum, substantial research has suggested that peer influence is a real, powerful, and consistent phenomenon with implications for the development of externalizing, internalizing, and health risk behaviors. The empirical base offers substantial evidence to suggest that adolescents' best friendships serve as a context that can exacerbate risks for psychopathology. Both main effects and interactive effects have been revealed, indicating that the best friendship context may exert direct socialization effects on the development of symptoms, or may interact with preexisting risk factors that are more likely to be expressed in the context of deleterious peer influence. Research increasingly suggests that other peer relationships (e.g., romantic relationships, cliques, networks) and other sources of peer influence (e.g., popular peers) also may be relevant for understanding peer influence effects. Ongoing work also has helped to elucidate the specific mechanisms that explain why adolescents conform to their peers, as well as moderators that help to identify specific youth who may be especially susceptible or resilient to peer influence. Research that integrates peer influence effects into broader dynamic systems models is needed to help understand more complex socialization processes that are relevant to development.

CONCLUSION AND FUTURE DIRECTIONS

For many decades, peer relations researchers have provided empirical data demonstrating that peers contribute meaningfully to youths' development, and to the development of psychopathology. This has been a fruitful and successful endeavor. Few would argue that peers present an important context in which development occurs and that negative peer experiences confer unique risks for maladjustment. Indeed, peers matter for development, and peer experiences can provide risk or protection for psychopathology.

In fact, in many related literatures, including research in associated social and biological science disciplines, there has been substantial appreciation for the importance of social experiences within children's and adolescents' lives. Research indicates that adverse interpersonal experiences, including social rejection among peers, may produce physical pain, affect short- and long-term physiological stress-response systems, compromise the human immune system, activate previously dormant genes, and alter neurochemistry in a manner that augments risk for psychopathology. Conversely, supportive peer relationships can mitigate genetic risks for psychopathology and are associated with activation of brain regions that promote adaptive emotional processing.

Findings from related disciplines also have indicated that peers exert a unique role in the development of youths' attitudes and behaviors. In adolescence, the peer context is a crucible for developing identities; peer interactions are remarkably important for understanding the development of values, consumer choices, the effectiveness of educational policies and clinical interventions, and have clear effects on the development of maladaptive cognitions and behaviors. In sum, the need to substantiate the importance of peer relations has been met.

Perhaps most important given the current state of the literature is the integration of theories and findings from the peer relations literature with the ongoing advances in these related disciplines. For many decades, peer relations researchers have articulated a variety of discrete constructs that help to explain the complex social worlds of children and adolescents. Research has revealed a clear picture of normative developmental peer competencies as well many constructs that characterize atypical development. This chapter offered a brief review of several peer experiences that have been examined most thoroughly as concurrent and longitudinal correlates of psychopathology (e.g., social withdrawal, peer status, peer victimization, friendlessness and friendship quality, and peer influence). Importantly, the distinctions between these constructs, and the methodological advances that have been offered to examine each of these discrete peer experiences, have not been reflected within ongoing work in related disciplines. There is substantial opportunity for peer relations research to integrate with this related work to develop more holistic models for understanding the associations among peer experiences, development, and psychopathology. The field of psychological science has begun to embrace transdisciplinary approaches to inquiry, and team science collaborations; peer relations researchers should be at the forefront of this movement, as their expertise is sorely needed.

In addition to the need for better integration with related scientific disciplines, future research on child and adolescent peer relationships also would benefit by attending to several conceptual issues. First, as is evident in this review, studies in this area only recently have begun to consider the role of peer relationships within the broader context of multiple developmental systems. Reciprocal, transactional

associations between peer experiences, and other developing competences or influences also have been considered in earnest only recently. As has hopefully been demonstrated in this chapter, peer experiences are relevant not only as direct predictors of psychopathology, but also as relevant factors in the development of skills, cognitions, and biopsychosocial processes that are antecedents (or products) of psychopathology. The peer literature would benefit from a consideration of complex developmental models.

Second, greater attention to multiculturalism is needed, including a more thorough understanding of diversity (e.g., gender, ethnicity, sexuality) within a single culture and of cross-cultural differences that may be relevant for understanding associations between peer relations and psychopathology. With regard to diversity, most prior research has examined the peer group as a homogenous context, with measurement of peer status or peer influence, for example, in reference to the entire group at-large. This is not consistent with many youths' peer experiences, however. Subgroups reflecting diversity within the overall peer milieu (i.e., same-ethnic peers, same-gender peers) may be highly relevant for some youth, particularly within large school or community settings, and perhaps especially with youths' increasing participation in peer groups online. In many cases, youths' experiences with these subgroups may deviate considerably from their experiences in the overall peer group, suggesting different pathways between peer experiences and psychopathology. For instance, recent work has revealed that while popularity is a strong longitudinal predictor of adolescents' alcohol use trajectories among White/Caucasian youth, it is not a relevant predictor among African American adolescents at all (Choukas-Bradley, Giletta, Neblett, & Prinstein, 2015). Research capturing these diverse experiences is needed.

In recent years, more work has been conducted with samples of youth from regions outside of North America, offering an opportunity to replicate and extend findings from studies predominantly conducted in the United States and Canada. Developmental psychopathology models emphasize transactions between developmental systems residing not only within individuals, but also multiple environmental systems including broader community and cultural influences (e.g., the exosystem). Research is needed to examine how these cultural norms may influence the meanings and functions of peer relationships. Transactions between peer experiences and the exosystem would help not only to interpret possible cross-cultural differences in peer studies but also to inform theories on how peers affect development universally.

Last, it will be important for research examining links between peer relationships and psychopathology to be informed by theories within the clinical psychology literature. A broad approach for examining adjustment outcomes, including a wide range of possible symptoms and markers of dysfunction has been used too often in prior research. Such an approach lacks predictive specificity and precludes the articulation of specific theories to help understand results. Such a broad, even exploratory approach likely originates from the desire to demonstrate that peers are relevant to adjustment. A focus on multifinality models assumes a focus on predictors of interest rather than a concentrated effort to understand a particular disorder or outcome. Although research must continue to examine the broad implications of negative peer experiences, such efforts should be balanced by studies examining specific clinical outcomes, incorporating extant theories of psychopathology, and understanding how peer experiences are relevant within those existing models.

Related, peer relations science could be especially helpful to inform clinical assessment, prevention and intervention. This chapter highlights myriad distinct constructs that each deserve discrete attention in the assessment of youth social functioning but rarely are included in traditional clinical assessments. It is not sufficient to assess children's peer relationships by asking whether a child gets along well with peers; rather, as suggested by Hartup (1996), an assessment should minimally inquire whether a child is liked by peers, whether a child has a friend, and what that child's friend is like. A more thorough assessment would involve an understanding of youths' desire to interact with peers, their provision or receipt of bullying behaviors, youths' participation within multiple friendships and mutual antipathies (Hartup, 2003), the emergence of cross-gender and perhaps romantic attractions among peers, as well as the behaviors that youth engage in when with, and perhaps influenced by peers. The development of clinical assessment instruments that more comprehensively evaluate youths' peer competence would be of value not only to understand psychopathology risk factors but also to help adequately assess levels of social impairment that are part of the criteria for almost all *DSM* diagnoses.

Peer relations research also has substantial translational implications for prevention and intervention efforts. One notable current issue pertains to bullying prevention programs. Within the United States, there has been a substantial call for antibullying legislation and peer victimization prevention programs. Unfortunately, these policy efforts have been advanced without adequate attention to

scientific progress and findings. As reviewed already, peer aggression and victimization must be understood in the context of aggressive functions (i.e., proactive, reactive); it may be unrealistic to expect that all forms of peer aggression will be reduced using similar intervention methods. Scholars developing preventive intervention approaches that specifically target bullying behavior as a subtype of proactive peer aggression have been more successful, however (Kärnä, Voeten, Little, Poskiparta, Alanen, et al., 2011; Kärnä, Voeten, Little, Poskiparta, Kaljonen, et al., 2011). It will be critical to ensure that antibullying policies and efforts reflect current scientific findings to have maximal impact.

Research regarding friendship and peer influence similarly has implications for practice. Note that predominant models of psychotherapy typically involve amelioration of youth mental health symptoms through contact with children and adolescents themselves and with youths' parents and perhaps teachers. Adolescents' peers rarely are included in the treatment process, yet findings suggest that many maladaptive cognitions and behaviors are developed and reinforced within close friendship interactions. Interestingly, clinicians rarely consider whether their therapeutic progress may be undone by peer socialization processes. Conversely, there is underutilized potential to use these same peer processes to promote adaptive development. Just as co-rumination may foster the development of maladaptive cognitive processing, for instance, therapist-guided friendship interactions may assist adolescents with adaptive coping and problem solving. The peer context is increasingly important to youth as they mature; thus, it makes sense that this context should be considered and perhaps even recruited as particularly potent sources of support and behavior modification. In sum, the integration of basic developmental psychopathology research on youths' peer relations with more applied work on treatment development, efficacy, or mechanisms of treatment effectiveness is a relatively untapped domain with great promise for meaningful contributions.

For many children and adolescents, peers offer a context for enjoyment, exploration, autonomy, and maturation. For many, the peer context provides opportunities for learning and rehearsing new skills, ideas, and behaviors. Peers foster growth and allow youth to achieve developmental competencies needed for successful adaptation. However, some youth experience the peer context quite differently. Whether experienced as a feared setting to avoid, an environment characterized by rejection, torment, and loneliness, or an atmosphere that fosters experimentation with risky and dangerous behavior, the peer context can be destructive. Research understanding how youth relate to their peers always will be critical for understanding adaptive and maladaptive development.

INVITING FAMILY SYSTEMS THEORY TO THE TABLE

Almost two decades have passed since, in the first edition of this volume, Wagner and Reiss (1995) pondered whether the relationship between family systems theory and developmental psychopathology could best be characterized as a "courtship, marriage, or divorce." Despite some thoughtful steps toward fostering integration between these fields (e.g., Cicchetti & Howes, 1991; Cox & Paley, 2003; Cummings, Davies, & Campbell, 2000; Davies & Cicchetti, 2004; Howes & Cicchetti, 1993), on the whole, it seems fair

to say that systemic thinking has not been fully embraced within the developmental psychopathology literature. The current relationship between the two bodies of work might be better captured by the metaphor of the estranged relative who, although invited to the feast and even heartily welcomed by some, nevertheless has no place-marker at the table and stands slightly outside the family circle.

Although certainly research in developmental psychopathology in the present day shows no lack of appreciation for family-related variables, and many if not most interventions for childhood psychopathology include attention to the family, relatively little of this work can be said to derive from family *systemic* constructs. In that regard, in the second edition of this volume, Philip and Carolyn Cowan (2006) made a helpful distinction to which we would offer the friendly amendment of rephrasing as a *family variables* approach versus a *family systems* perspective. The family variables approach is a long-standing and well-integrated aspect of traditional research in abnormal child psychology as well as in developmental psychopathology. This approach focuses on identifying risk and protective factors within the family that play a role in the etiology of psychological problems, protection against them, or their amelioration in treatment. For example, poverty, domestic violence, and harsh parenting are all family-relevant variables that increase the likelihood of maladaptation, just as interventions that promote positive development typically go beyond the individual child to include the family. However, as Cowan and Cowan (2006) pointed out, inherent in the family variables approach is that each of these family influences on childhood psychopathology, whether viewed individually or in combination, is conceptualized as having a unidirectional effect on the individual. In contrast, a *family systems* approach considers not the individual but the entire system of interrelationships within the family to be the object of study or the target of treatment. Moreover, it is in the structure, the patterns, and the dynamic and reciprocal transactions in that system of relationships that maladaptation and adaptation arise. Given that the inclusion of family variables permeates virtually all research in childhood psychopathology, a comprehensive review of family variables research would entail an unwieldy compilation of studies on the topics spanning all three volumes of the present anthology. By the same token, the majority of families are composed of parents and children (although there are notable exceptions, such as sibling-headed households), and thus any and all of the voluminous research regarding parent–child relations could said to be relevant to the study of the *family*. Consequently, to maintain a sharper focus for the present chapter, this review will be specific to a discussion of the historical underpinnings of and current state of research regarding family systems perspectives as here defined.

HISTORICAL ORIGINS AND THEORETICAL UNDERPINNINGS OF FAMILY SYSTEMS THEORIES

Progenitors of Family Systems Theory

In the United States of the mid-1950s and early 1960s, a number of groups of researchers and clinicians independently began to raise objections to the prevailing psychoanalytic perspective and its emphasis on psychopathology as an individual phenomenon, promoting instead the idea that dysfunction might occur at the level of the family system. Nathan Ackerman (1962), head of the institute in New York later to bear his name, was an early proponent of working conjointly with parents and children in treatment, although his approach continued to show its psychoanalytic roots in focusing on the individual psychopathology of each of the family members in the room. Around the same time, Theodore Lidz and his colleagues (Lidz, Cornelison, Fleck, & Terry, 1957) at the Yale Psychiatric Institute took on as their target a particularly hurtful legacy of psychoanalytic dogma, that psychosis originated with the *schizophrenic mother* (Fromm-Reichmann, 1948). Novel in their approach was bringing fathers into the room and examining ways disorder was demonstrated in multiple relationships in the family—not just between mother and child but also between father and child as well as the members of the couple. This team made the important observation that in many cases the source of the problem was in the marital relationship, whether as a function of high levels of unresolved conflict (*marital schism*) or conflict that was denied and subterranean, expressing itself in covert ways such as overt agreement followed by invalidation or undermining of the partner (*marital skew*). Another suggestion that these investigators offered that has ramifications for developmental psychopathology is that these problematic family patterns could be discerned across three generations, from parents to children to grandchildren.

Schizophrenia also was the focus of work going on simultaneously in the lab of Lyman Wynne and his colleagues (Singer & Wynne, 1965; Wynne, Ryckoff, Day, & Hirsch, 1958) at the National Institutes of Mental Health in Washington, DC. Their seminal study involved a demonstration that disordered psychological processing was more evident among individuals with schizophrenia when they were involved in interaction with family

members than when they were alone. Therefore, the disorder was seen as residing not in the individual but in the family system. The innovative method the researchers used to reveal these processes (asking family members to come to a consensus regarding responses to the Rorschach inkblot test) provided a model for many subsequent studies utilizing family observational methods in which family members have been challenged to come to a mutual agreement on a task (e.g., completing a questionnaire, planning a meal, designing an ideal vacation; see Kerig & Lindahl, 2001).

Bowen Family System Theory

Also at the National Institute of Mental Health during this time period was Murray Bowen (1961), whose initial observations emphasized the importance of poor psychological boundaries among family members of patients with schizophrenia, whom he described as evidencing an undifferentiated ego mass or fusion. Consequently, the *differentiation of self* and its extrication from the family groupthink became central to Bowen's notions of psychological health. Another of Bowen's contributions that has become pivotal in family systems theory is his articulation of the idea of the *triangle* as a basic building block of family interaction (Bowen, 1978; Kerr & Bowen, 1988). Bowen (1978) offered the insight that a relational system comprised of two persons was inherently unstable and "easily disturbed by emotional forces within it and from outside" (p. 135, particularly when the participants in that relationship were poorly differentiated from one another. To reduce this anxiety, therefore, the two-person constellation naturally gravitates toward including a third person in its orbit. The resulting triangular system is a more stable one, and one that serves the function of diffusing anxiety and preventing any particular relationship from becoming overheated.

> There are several ways a twosome can incorporate a third person into its tension. The uncomfortable insider (A) can pull the outsider (C) into the situation through complaints to him about the other insider (B). If C responds sympathetically, taking sides with A, a comfortable closeness (based on undifferentiation) is established between A and C. B is the new outsider ... Or a third person may play a very active role in getting himself in the middle of a problem between two others. Through years of "training," such a person has learned to gravitate toward the disharmony he senses in others, regardless of whether an "invitation" is actually extended. A poorly differentiated child often occupies this type of position with his parents. He predictably makes himself a problem whenever tension reaches a certain level between his parents. This draws one or both parents' focus to him, thus reducing tension between them (pp. 136–137).

Intriguingly, Bowen (1978) also offered the observation that a live person need not be available for the establishment of a triangle—fantasied relationships, objects, even pets can be mustered to serve the purpose of creating a third leg to maintain the emotional equilibrium of the family stool. Further, although the term triangulation currently tends to be used to refer exclusively to pathological processes in families, Bowen abjured such value judgments, instead construing triangles as natural. The third party's participation in the relationship was seen not as inherently problematic but as having the potential to be helpful, so long as the third member of the triangle remained simultaneously emotionally connected to both parties while also emotionally detached from their conflict. His observations of the processes involved in detriangling—"probably the most important technique in family systems therapy" (p. 150)—likewise emphasized a therapeutic stance of nonjudgmental emotional neutrality along with the capacity to see relationship problems from multiple points of view. "To observe triangles, it is necessary to see 'past' the symptoms to the underlying emotional process: the interplay of individuality and togetherness and the impact of anxiety on that interplay. To observe triangles, it is also necessary to recognize the influence on one's perceptions of one's own emotional reactivity to the system" (p. 151).

Nevertheless, in Bowen's theory triangles are implicated in the development of psychopathology, particularly because symptoms may serve a function within the triangular system of relationships. For example, becoming symptomatic may serve to bring family members closer when one has been made an outsider in the family system. Bowen also suggested that parents may attempt to triangulate children in their conflicts by projecting the problem on to them. This *family projection process,* he proposed, is precipitated by marital fusion. When a lack of differentiation between parents evokes anxiety, they may seek to alleviate this tension by turning to the child.

The MRI Group

Another of the seminal teams of family systems thinkers of this period was based at the Mental Research Institute (MRI) in Palo Alto and included experts from the fields of psychiatry (Don Jackson), anthropology (Gregory Bateson), social work (Virginia Satir), and communications theory (Jay Haley, John Weakland, and Paul Watzlawick). Again focusing on schizophrenia, the MRI group proposed the idea that distorted communication processes in the family were responsible for the disorder. In particular, they originated the idea of the *double bind*, in which family

members (and here, unfortunately, the theory tended to backslide to targeting *schizophrenogenic* mothers) confronted the patient with irreconcilably contradictory messages or commands such that following either would constitute an act of disobedience or a violation of family rules. Moreover, one of the family rules that ensnared children in those binds was the rule that the bind was not to be acknowledged or spoken about openly, just as another was that the child was not allowed to exit the scene. Therefore, the child was left in an emotionally and cognitively impossible situation that was, literally, crazy-making. Although highly influential, the theory was not able to be empirically validated because the binds referred to were so subtle (e.g., a lack of correspondence between content of speech and tone of voice) that observers were not able to agree on their presence or code them reliably (Ringuette & Kennedy, 1966).

Perhaps the most significant legacy of the MRI group to modern family systems theory is the overarching conceptual framework that Bateson contributed, based on the philosopher Bertalanffy's (1973) general systems theory, which he integrated with game theory and cybernetics. From general systems theory came the idea of organic systems as organized and open to change, but also as self-regulating and striving toward balance by the use of internal mechanisms that serve to achieve a self-righting function when the organism undergoes an excess of change or stasis. From cybernetics and the study of nonorganic systems, Bateson derived the idea of homeostasis, which suggests that systems are in fact resistant to change, with internal mechanisms that act like thermostats which regulate a return to a prior state after disruption has occurred. This theoretical groundwork subsequently inspired the development of a number of approaches to family therapy that can be understood as offshoots of the MRI approach, including Haley's (1976) strategic approach and the therapeutic formulations of the Milan group in Italy (Palazzoli, Boscolo, Cecchin, & Prata, 1978).

Borzormenyi-Nagy's Contextual Approach

Another influential school of thought in the family systems pantheon was housed at the Family Institute of Philadelphia, led by Ivan Borzormenyi-Nagy (1962). Although maintaining a psychodynamically informed focus on the individual within the family system, Borzormenyi-Nagy brought to the forefront the ways family systemic processes comprised a legacy spanning multiple generations. In their seminal text, *Invisible Loyalties,* Borzormenyi-Nagy and Spark (1973) introduced a dynamic that has become a centerpiece of a significant amount of research in family systems theory, that of *parentification*, also termed role-reversal, between parent and child. "By definition, parentification implies the subjective distortion of a relationship as if one's partner or even children were his parent" (p. 151). Although such dynamics might reflect or precipitate problems in the family, Borzormenyi-Nagy and Spark emphasized that they were normative relational processes that weren't necessarily associated with maladaptation. In fact, they proposed, parentification might play a function within the family relational system that was associated with adaptivity. Although it might seem improper and unethical for a parent to abdicate responsibilities or seek caregiving from a child, the young person who successfully takes on those roles serves an important function by normalizing the family and enabling it to remain intact. Thus, although perhaps at a personal sacrifice of the nurturance and care usually provided a child, the parentified youth helps to meet the needs of the family and its members, therefore fulfilling an overarching fundamental need of his or her own for an intact and operational family system. In this view, parentification only becomes problematic when children's contributions to bolstering parental well-being are unfair, unacknowledged, unappreciated, or unreciprocated. Nonetheless, Borzormenyi-Nagy and Spark also clearly associated parentification with pathological processes in families, processes that were passed on across generations. Adults who had been leaned upon too heavily by their own parents, they suggested, were those most likely turn to their own children in order to fulfill those unmet needs for nurturance and care. In effect, this account-due or debit perspective suggests that a parent who was deprived of nurturance in childhood will feel entitled to balance the ledger by extracting those provisions from the emotional stores of their own offspring.

Minuchin's Structural Family Theory

Another major architect of family systems theory was Salvador Minuchin, who established the Philadelphia Child Guidance Clinic (PCGC) for the training of family therapists and wrote some of the most influential conceptual and clinical works on understanding and treating psychopathology from a family systems perspective. Minuchin and colleagues' (1967) first book, *Families of the Slums,* was a groundbreaking description of clinical work with a population of disadvantaged families who were rarely the subject of more traditional psychoanalytic treatment. His subsequent book, *Families and Family Therapy* (Minuchin, 1974) became one of the most widely cited

textbooks in family systems theory and intervention techniques. In this work the PCGC team literally drew maps of family dynamic processes to reveal the ways problems in family structure contributed to psychological dysfunction.

Minuchin's structural family perspective built upon the earlier groundwork laid by Bowen (1978) and Haley (1977) regarding the importance of maintaining appropriate boundaries around the subsystems in the family. As Minuchin (1974) suggests, "The family is the matrix of its members' psychosocial development" (p. 48), and an essential part of that matrix is the opportunity the family provides its members to experience simultaneously a sense of belonging as well as of separateness. This occurs naturally through the subsystems that comprise the family, connecting some members to one another while differentiating them from others. In particular, clear boundaries should separate the *parental subsystem*, which defines the executive and complementary roles played by the parents, from the *parent–child subsystems*, which are defined by hierarchical and nonreciprocal caregiving roles, and the *sibling subsystem*, in which brothers and sisters share the same status as children but also are differentiated by age. What allows these subsystems to function adaptively is the presence of clear boundaries between them. "For proper family functioning, the boundaries of subsystems must be clear. Boundaries must be defined well enough to allow subsystem members to carry out their functions without undue interference, but they must allow contact between the members of the subsystem and others" (p. 54). Thus, in Minuchin's perspective, boundaries could be problematic at either extreme; they could be overly *diffuse*, resulting in enmeshed and poorly differentiated family relationships, or they could be overly *rigid*, resulting in family disengagement and a loss of connection.

Particularly important in the structural perspective is the clarity of the boundary around the parental subsystem. When this boundary is not maintained and children become inappropriately involved in the interparental relationship, neither the family system nor its individual members are able to function adaptively. Minuchin went on to describe specific ways this boundary might be violated, which he referred to as *rigid triangles* in the family. First, one parent may form a *coalition* with the child in which an overly close relationship develop that excludes the other parent and compromises the ability of the couple to achieve intimacy or effectively carry out their executive functions in the family. In the second scenario, termed *triangulation,* each parent attempts to enlist the exclusive support or loyalty of the child, essentially placing the child in a form of double bind in which there is no way to achieve emotional closeness with one parent without alienating or angering the other. The third triangular form, *detouring*, is reminiscent of Bowen's family projection process in that parents circumvent their conflicts or marital unhappiness by focusing on the joint project of caring for their ostensibly troubled or needy child. Detouring may be further defined as *supportive* (e.g., with the parents uniting around the task of providing nurturance for a child that is perceived as fragile, special, or delicate) or as *attacking*, in which the child is scapegoated, ostracized, or blamed. Essential to the concept of detouring is that having a symptomatic child serves a function for the larger family system, which therefore leads all family members—including the emotionally disturbed child—to be resistant to changing this family pattern. Thus, to have a child who is an identified patient serves to maintain homeostasis in the family.

The Functional Family Perspective

Although ultimately evolving into a technique of family therapy rather than a research-generating school of family theory, as is true of so many of the foregoing frameworks, the Functional Family Therapy (FFT) perspective (Alexander & Parsons, 1982; Alexander, Robbins, Waldron, & Neeb, 2013) also contributed a number of seminal ideas that warrant consideration. One of these is the idea that family relationships can best be understood by attending to the *relational functions* that family members are striving to achieve with one another. The influence of interpersonal theory can be seen in the definition of these relational functions as comprising the two orthogonal dimensions of hierarchy and connection. *Relational hierarchy* refers to the relative balance of power in the relationship, such that family members strive toward roles that are one-up, one-down, or symmetrical in relation to one another. In describing the role of hierarchy in parent–child relationships, FFT is unusual among family systems models for not being prescriptive that this necessarily should comprise a dynamic in which the parent is "in charge" and the child "in tow" (Kerig & Alexander, 2012). Instead, the FFT model proposes that there is diversity in what comprises an adaptive family structure, and no form is inherently maladaptive; rather maladaptation arises when family members are not able to successfully meet their relational functional needs. The second dimension of relational functions concerns *relational connection*, the balance between family members' needs for autonomy versus connection. Here again, the presumptions are made that there are individual differences in the extent to which family members

have needs for autonomy or connection and that neither of these extremes is inherently problematic. Dysfunction instead arises when there is a mismatch between family members' relational functions (e.g., a connection-seeking adolescent with an autonomy-seeking father) that prevents one or both from getting their relational needs met.

Another way in which the FFT perspective differs from most family systems theories is that, rather than typologizing the family as a whole—as, for example, hierarchically organized or autonomous—FFT's conceptualization of relational functions is particular to an *individual* in the context of a particular *dyad*. For each dyad in the family, the assessor evaluates the extent to which each partner seeks closeness versus distance in that specific relationship and considers the ways the individual's behavior (e.g., acting out on the part of the connection-seeking adolecent) might serve a function in that relationship (e.g., to bring an autonomy-seeking father closer). Once the underlying functions of the behavior are understood in the light of family members' relational needs, the clinician can foster change by encouraging the development of more adaptive ways of getting those needs met, ways that are respectful of and matched to the relational needs of each dyad. For example, rather than risking resistance, or merely awkwardness, by proposing that an autonomy-seeking father spend his day off in intimate togetherness with his contact-seeking son, the FFT therapist might suggest the judicious use of text messaging to allow the father to communicate more comfortably that his son is in his thoughts during the day. Furthermore, because relational functions operate at the level of the dyad, each family member may exhibit different relational functions in those dyads; for example, a youth may be contact seeking toward his father yet distancing with his mother. By the same token, parents develop different relational functions with individual children in the family and may seek closeness with one while maintaining distance from another.

Because of its focus on clinical implementation, FFT has tended to organize its thinking around the implications of family relational processes for the individual child as the identified patient, and therefore less attention in the theoretical model has been paid to the intersections of these various relational functions among the dyads in the family and how they might affect one another. And, as with most of the family models discussed so far, the priority of FFT-related research has tended to focus on establishing the effectiveness of the intervention rather than testing hypotheses about the underlying assumptions of the theory.

Social Learning Perspectives on the Family

Subsequent to the 1980s, little groundbreaking new work emerged in the elaboration of these earlier seminal family systems theories, perhaps due to a larger change in the zeitgeist in psychology that increasingly favored behavioral approaches. The most influential figure in this school of thought is Gerald Patterson (1986), whose studies of the families of antisocial youth at the Oregon Social Learning Center were groundbreaking not only for astuteness of their observations but also for the sophistication of their methods. In addition to developing a highly influential model of parent management training, Patterson's work has contributed many important conceptual and methodological components to modern family systems research. One of these is their recognition of the importance of reciprocal processes in the family and their construction of observational methods to capture and quantify those processes. Another is the consistent inclusion of fathers in the research (at least among those families with two-parent households) and the recognition that each parent may have a specific parenting style and relational quality with the child that has unique effects on development.

Summary

This brief outline of the early historical origins of family systems theory suggests a couple of observations. One is that a likely reason for the limited influence of family theory on research in developmental psychopathology may be that so many of the influential figures in the field conducted their work at independent institutes rather than in mainstream academia, where they might have had more influence on shaping the thinking of the next generation of clinical scientists and scholars. In addition, many of the seminal family systems theorists were more invested in clinical work than in research; therefore, the focus of the training offered was not conducive to the development of a program of empirical inquiry. Moreover, this review of the origins of the field brings home the point that the family systems label comprises a canopy for a quite diverse set of perspectives that derived as offshoots from different theoretical branches. Some show their roots in psychodynamic thinking, whether overtly labeled as such (Slipp, 1991) or more covertly displayed through their attention to unconscious dynamics and the construal of the family system as internal conflict made manifest (e.g., Boszormenyi-Nagy & Spark, 1973). Others have firm roots in behavioral and social learning theories that hold no truck with unconscious notions (e.g., Patterson, 1982), and still others rely

on constructs that were quite novel and groundbreaking at their time, such as communications theory and semiotics (e.g., Watzlawick, Weakland, & Fisch, 1974). Nonetheless, despite these differences in theoretical origins, a number of shared features characterize systemic theories, and these we turn to next.

WHAT MAKES A FAMILY THEORY SYSTEMIC?

Holism

Central to family systems theory is the construct of holism, the idea that "the whole is more than the sum of its parts" (Bertallanffy, 1968, p. 55):

> Systems theory begins with the observation that nature can be viewed in a hierarchically arranged continuum, with the more complex, larger units superordinate to the less complex, smaller units. Each level needs to be regarded as an organized whole, with distinctive properties and characteristics that are altered by interchange with other levels, but with no level reducible to simpler levels. Thus, organs are more than simple aggregates of cells, the person is more than an aggregate of organs, and the family is more than an aggregate of persons. In this hierarchy of organizations, each level has distinctive and unique qualities (Wynne, 1984/2004, p. 2).

Rather than a collection of individuals, each with his or her own pathology, systemic thinking involves viewing the family as an entity that has unique properties not merely reducible to the individual constituents of its members. The source of pathology or well-being therefore derives from the system and the interrelations among its members rather than the individual members themselves. By the same token, the study of individual dyads within the family does not act as a proxy for understanding the family as a systemic whole (Kerig, 2001). Family members' roles and behaviors change as they move between dyadic and triadic relationships; for example, a child interacting together with both mother and father involves the simultaneous dynamics of three different relationships—mother–child, father–child, and the interparental dyad—as well as the repercussions of each of those for the others (e.g., the father's reaction to a daughter's expression of disrespect for her mother). Similarly, for the adults in the family, moving from the dyad to the triad involves balancing the role demands of parent and partner—and "thus the parent–child dyad is transformed into a family system" (Gjerde, 1986, p. 297). Observation at the whole-family level also has the potential for conferring a possible higher order of meaning to dyadic interactions such that, for example, a parent may affect a child indirectly through the ways he or she affects the relationship of the other parent with that child (Parke, 1990) (e.g., the father who encourages disrespect by finding humor in his daughter's sassiness toward her mother).

Further, being part of a system has both constraining and potentiating influences on the behavior of its members, pulling them toward participation in the family's typical dynamics in ways that bring to the fore qualities that cohere with family patterns while at the same time dampening latent tendencies that might otherwise be expressed in different contexts. Thus, something new arises in the chemistry of the family crucible that could not have been predicted from knowledge of its individual members on their own.

However, one point of contention in the family systems literature has been whether families can be accurately described in holistic ways—to be typologized as an enmeshed or disengaged family, for example—versus whether the family system is better construed as a matrix of dyads, each of which might be represented by a different point along these continua and each of which has an impact on the other dyads as well as the family process as a whole. For example, although there certainly may be families in which all relationships can be described equally as enmeshed, clinical descriptions of pathological families are more likely to involve those in which one enmeshed relationship (e.g., between a parent and an eldest child) contributes to problems in rest of the system, such as increased friction (e.g., in the interparental dyad) or imbalance (e.g., among the siblings). Therefore, as Philip and Carolyn Cowan (1990) pointed out, if one enmeshed dyad is counterbalanced by another one that is disengaged, "How then, are we to describe the *family*?" (p. 42, italics in original).

McHale, Kuersten-Hogan, & Lauretti (2001) offered a helpful distinction between *whole-family* constructs, which refer to abstract characteristics of the family gestalt, and *family-level* constructs, which comprise observable behaviors that arise when the family members are considered as a group. Notably, however, these processes may arise even when one member of the system is not present, such as when parents engage in covert coparenting conflict behaviors such as denigrating the absent spouse to the child (McHale, 1997) or, on the positive side, when there is good coordination and synchrony between parents in the absence of one another. "The ability of mothers and fathers to parent in ways that are consistently supportive of and coordinated with one another—*especially* when apart from one another—may provide the child the most convincing demonstration of the firmness and security

of the marital alliance" (Kerig, 2001, p. 9). Therefore, we can add to this definition a third category, *family dynamic* processes, "referring to those interactions that have implications for family-level functioning even when they do not take place in the presence of all family members" (Kerig, 2001, p. 10).

In sum, the study of family-level processes requires neither a group of people to be in the same room nor the typologizing of a family into a particular category. As Belsky, Putnam, & Crnic (1986) asserted, "[Family-level] dynamics include events and processes that involve all family members together or a family subsystem (parent–child or husband–wife) that affects and is affected by the other subsystems in the family" (p. 46). Whereas many of the early conceptual attempts to bring family systems constructs to bear in the study of psychopathology imposed this whole-family typological approach, research more often has assessed either family-level constructs or, even more often, dyadic relationships within the triad.

The Effects of Relationships on Relationships

A middle-way position between the extremes of holism and individualism is the broader systemic idea of interdependency—in other words, that relationships have effects on other relationships (Emde, 1988). As Rutter (1988) argued, despite the fact that the "functioning of the whole is qualitatively different from the sum of its parts . . . the properties of the family as a whole derive from the properties of the relationships between the individuals in the family" (p. 333). This is a way family systems thinking most clearly differentiates itself from individualistic or unidirectional approaches to psychopathology: rather than relationships affecting the person, systems theory proposes that relationships affect other relationships in the family system (Gjerde, 1986). Thus, the family is viewed as an interrelated web in which perturbations in one strand send reverberations along the threads interconnecting other parts of the system. "The most important clues to the significance and meaning of an interaction to the participants may be the context of other interactions in which it lies" (Hinde, 1976, p. 4).

The relationships that affect and are affected by others in the family may be dyadic, or triadic, or may involve intersections among more complex combinations of subsystems. A prototypical example of such interrelatedness of relationships is provided by the idea of triangulation, in which an imbalance in the closeness and distance between members of one family dyad has implications for each of the others. For instance, an overly close relationship between a parent and child might inappropriately involve that child in the executive functioning of the marital subsystem and thus exacerbate a riff in the interparental relationship. By the same token, diffuse boundaries between a parent and child might contribute to conflict among the siblings, such as when a parentified child blocks the other children's access to emotional closeness and instrumental assistance from that parent.

A second and related example of the effects of relationships on relationships is provided by the concepts of spillover and *compensation* (Engfer, 1988; Kerig, Cowan, & Cowan, 1993). In the former process, conflict in the interparental relationship may spill over onto parent–child relationships in negative ways by increasing parental negativity (Katz & Gottman, 1996; Margolin, Gordis, & Oliver, 2004), decreasing parental emotional availability (Cox, Paley, & Harter, 2001), or compromising the child's felt security in the family system (Cummings & Davies, 2011). In the latter process, dissatisfaction in the couple relationship might instead lead to a compensatory closeness between a parent and child that, although ostensibly positive in tone, may have negative repercussions through imbalancing the family system (Kerig, 2005).

One of the important implications of this systemic view of the interdependencies of relationships is that the overarching context might confer very different meanings upon the qualities of the dyadic relationships within the family. For example, a close relationship with one parent might be associated with positive benefits for a child in a cohesive family system but have negative implications for the child whose alliance with one parent occurs at the expense of his or her relationship with the other (Kerig, 1995). As Grych, Raynor, and Fosco (2004) stated, "Whereas a strong parent–child alliance generally would be expected [to] have a protective effect, parent–child alliances formed as a reaction to discord in the marital relationship may not be protective if they lead to cross-generational coalitions that exclude the other parent [and] cause tension in the child's relationship with the other parent or lead to loyalty conflicts for the child" (p. 652).

Another related implication of this systemic view of interdependencies is that associations among family processes may vary depending on other properties of the larger family system (Davies, Cummings, & Winter, 2004). For example, a number of family context variables might moderate the strength of the association between interparental conflict and parent–child dysfunction, such as the presence of spousal violence (e.g., Margolin, Gordis, & Oliver, 2004), family hierarchy (e.g., Lindahl, Malik, Kaczynski, & Simons, 2004), or the presence of clear boundaries

(e.g., Kerig & Swanson, 2010), thus leading to heterogeneity and multifinality among families experiencing the same risk factors. Whereas some of these moderators might operate in ways that dilute the impact of family adversities, others impart vulnerability and do so particularly by increasing the interdependencies among family subsystems and the consequent spillover of negativity from one to the other.

Circularity

The term circularity in family systems theory refers to the notion that cause-and-effect in systems is not unidirectional but rather that family members influence one another reciprocally, mutually, and bidirectionally. Although it might be possible to observe family patterns in which unidirectional patterns of influence appear to be operating (e.g., a father criticizes his daughter, who then expresses negative affect), in the systems perspective these assumptions are viewed as merely deriving from a point of punctuation in an ongoing process. An observation of the same family commencing at a different time point might reveal the cause and effect to be explainable just as well from the other direction (e.g., a daughter repeatedly expresses negative affect toward her father, to which he finally responds with exasperation). The close correspondence between the construct of circularity and that of *transactions* (Sameroff, 1995) in developmental psychopathology is evident, and the link is made explicitly by some systems theorists, such as Wynne (1968): "In transactional processes, persons undergo internal change during the course of interchange with one another. All parts of a transactional field are interdependent, each modifying the rest through recursive ('circular') feedback; the whole exhibits the functional relation between the parts" (p. 4). However, as used by many systems theories, the construct of circularity lacks the important developmental dimension involving an evolving process in which actors and environments successively shape, influence, and even transform one another over time in ways that have important implications for the developing person (Kerig, Ludlow, & Wenar, 2012; Sameroff, 2010).

Research supports the idea that there are reciprocal effects among family processes. For example, sequential analyses have shown that episodes of interparental conflict are followed by increased negativity in whole-family (Christensen & Margolin, 1988; Kitzmann, 2000) and parent–child interactions (Almeida, Wethington, & Chandler, 1999); however, tensions in the father–child relationship also are predictive of an increased likelihood of subsequent interparental conflict (Almeida et al., 1999).

Homeostasis

The construct of *homeostasis* represents a contribution of the MRI group that has continued to have a long-lasting influence on family systems theory (Jackson, 1965). Homeostasis is an often-cited construct in the clinical literature that is used to explain the conundrum of why family systems seem so readily to fall back into pathological patterns and to resist therapeutic change. Consequently, homeostasis has gained the status of a kind of invisible adversary in the room that inspires family therapists to work actively and vigorously to countervail this dark force that pulls the family inexorably backward, in the direction of entropy. But, as Wagner and Reiss (1995) remind us, homeostasis needn't necessarily have only negative connotations in that "homeostasis can also be understood to be a way in which normal families maintain constancy and predictability in the face of constantly changing environmental demands … [and] maintain a sense of regularity in the presence of everyday stresses and changes" (p. 697). Thus, homeostasis has pathogenic potential for stubbornly returning the system to its set-point in ways that don't allow for adaptive change but also has an adaptive function in self-righting or balancing a system that is in danger of becoming destabilized. As Wagner and Reiss phrased it, "Threats to family stability, in the organization, power, or affective realm, tend to be counteracted by family members in a manner that will retain or restore their balance" (p. 697). In this way, homeostatic regulation may allow the family to act as a secure base from which its members can more freely explore their environment.

Families as Organized Systems

Another corollary to family members' interconnectedness in the systemic perspective is that these interrelationships are *organized* by the larger system in ways that confer coherence and lawful continuity across contexts as well as across developmental transformations (Sroufe & Fleeson, 1988). This larger organizational framework has implications for the functioning of individual members as well as the system as a whole:

> At the family level, coherence means that there is a total organization that may not be reduced to the qualities of the relationship units within the family and that relationships within the family are constrained by the total organization. Moreover, given certain qualities in one relationship, other relationships in the family are further constrained in the service of maintaining the larger organization. This view is distinct from emphases on 'influences' of one relationship upon another.

> Rather, in this organizational perspective interdependency among relationships in the family is emphasized (Sroufe & Fleeson, 1988, p. 45).

An important implication of this dynamic organizational perspective in systemic theory is that dysfunctional family patterns not only increase the risk for maladaptation in the individual, but in the family system as a whole. By the same token, adaptive family functioning confirms positive benefits that radiate outward from the individual and enhance the capacity for all family members, and the system itself, to thrive. As Diamond, Allen, and Butterworth (2012, p. 262) suggested:

> These adaptive processes are just as important for the *family's* eventual well-being as for the *adolescent's* well-being. Accordingly, perhaps the most valuable potential contribution of a family systems approach is that it prompts us to ask broader, more complex questions about how different family members' trajectories of adjustment are fundamentally interconnected, and the ways each member's adaptation (or the lack thereof) "pulls" on the system as a whole.

Boundaries and Subsystems

Also inherent in family systems theory is the idea that the larger whole is composed of subsystems that are both interconnected and demarcated from one another. Although most centrally associated with structural family theory, a common thread across perspectives is the idea that adaptive family functioning requires the maintenance of appropriate psychological boundaries between these subsystems and among the members of each subsystem. Like the membrane of a cell, boundaries need to be permeable enough to allow communication and emotional contact to traverse the divide while at the same time being firm enough to ensure the integrity of each separate unit (Kameguchi, 1996). In particular, however, the maintenance of boundaries around the couple relationship is seen as being at the heart of adaptive family functioning, and violations of that boundary create cross generational alliances and coalitions that inappropriately involve children in the marital subsystem and are associated with maladaptation. Family theory proposes a number of ways boundaries might be violated in the family system.

Enmeshment

The term enmeshment is used in a variety of ways in the family systems literature. Consistent with Minuchin's (1974) structural perspective, as a whole-family phenomenon, enmeshment refers to those families in which all members are highly overinvolved with and emotionally overreactive to one another. However, following psychodynamic models, enmeshment often is studied as a quality of dyadic relationships, which may have implications for the other relationships in the family, such as when enmeshment with one parent is counterbalanced by disengagement in the child's relationship with the other parent (Cowan & Cowan, 1990; Jacobvitz, Riggs, & Johnson, 1999). Enmeshment also is used as a superordinate construct within which other all other forms of boundary dissolution and triangulation are subsumed (e.g., Jacobvitz, Hazen, Curran, & Hitchens, 2004). Research has linked enmeshed relationships within family systems and parent–child relationships to a number of negative child outcomes, particularly those involving internalizing disorders (e.g., Jacobvitz et al., 2004; Jewell & Stark, 2003; Kerig, 2005) and attachment insecurity (e.g., Allen & Hauser, 1996). Moreover, despite the tendency in some perspectives to conflate enmeshment with other family-level constructs, such as cohesion (Olson, Russell, & Sprenkle, 1983), research has demonstrated that enmeshment is a unique construct with discriminable effects; whereas overall family cohesion is associated with positive child adjustment, enmeshed relationships are not (Barber & Buehler, 1996).

Some research suggests that enmeshment may be a culturally bounded phenomenon, however. Whereas among adolescents in the United Kingdom similar results are found to those in U.S. samples, with enmeshment associated with depression, anxiety, and perceived threats to identity, such findings have not emerged in samples drawn from cultures that more highly prioritize family members' interdependence, such as Italy (Manzi, Vignoles, Regalia, & Scabini, 2006) and India (Jackson, Raval, Bendikas, Raval, & Trivedi, in press).

Parentification

Boszomenyi-Nagy and Sparks's (1973) construct of parentification has spurred a significant body of research in developmental psychopathology (Jacobvitz & Bush, 1996; Jurkovic, 1997; Kerig, 2005; Kerig & Swanson, 2010; MacFie, Houts, McElwain, & Cox, 2005). Also termed role reversal or compulsive caregiving (Bowlby, 1977; Crittenden, 1992), this is a form of boundary dissolution in which parents turn to children for nurturance, comradeship, or instrumental assistance. Among clinical samples, role reversals and their accompanying developmentally inappropriate expectations for children are associated with maltreating parenting (Macfie et al., 1999) and are predictive of severe forms of psychopathology in youth such as borderline personality traits (Lyons-Ruth, Bureau,

Holmes, Easterbrooks, & Brooks, 2012). Research also evidences that children placed in a parental role are at increased risk for maladaptation across toddlerhood, preschool, middle childhood, adolescence, and emerging adulthood; moreover, consistent with family systems theory, problems in the marriage appear to create an emotional ground that is fertile for the development of boundary violations involving parentification (Kerig, 2005).

Some research suggests, however, that the construct of parentification conflates processes that are not equally pathological for children's development and thus should be discriminated. One such process, termed *adultification* (Kerig, 2005) or role diffusion (Jacobvitz & Sroufe, 1987), involves egalitarian relationships in which adults treat the child not as a parent but as an agemate. This might involve a parent coming down to the child's level and behaving like a childhood peer (the child-like parent) or the child being promoted to the status of an adult peer (the adult-like child).

Moreover, cross-cultural research points to the importance of differentiating between destructive forms of parentification/adultification and normative expectations for childhood and adolescence that differ across cultures, particularly among those that do not sanction the long period of childhood dependency characteristic of middle-class European American society (Jurkovic, 1997). Cultural roles valuing familism (Gibbs & Huang, 2003), parent–child mutuality (Anderson, 1999), and interdependence (Kağıtçıbaşı, 2005) as well as the practical demands incumbent upon family economic disadvantage (Boyd-Franklin, 2003) increase the likelihood that children will be assigned instrumental responsibilities in the home, such as helping to raise younger siblings, or emotional responsibilities, such as soothing others' hurt feelings, that could appear to an outside observer as involving precocious elevation to adult status. However, these *filial responsibilities* have been shown not only to vary widely across cultures but also to be associated with child distress or dysfunction only when they are perceived as unfair, unacknowledged, or unappreciated (Jurkovic, Kuperminc, Sarac, & Weisshaar, 2005).

Spousification

The construct of spousification originates from observations by Sroufe and Ward (1980) of seductive behavior demonstrated by mothers who were effusively affectionate and flirtatious toward their young sons, relating to them more as though they were adult intimate partners than children. Most often studied in the context of mother–child interactions, spousification has been found to predict child inattention in preschool (Jacobvitz & Sroufe, 1987), hyperactivity in middle childhood (Carlson, Jacobvitz, & Sroufe, 1995), and emotional and behavioral undercontrol in adolescence (Sroufe, 1991). Using data from the Minnesota Longitudinal Study of Parents and Children, Shaffer and Sroufe (2005) found that maternal seductive parenting demonstrated continuity from toddlerhood into adolescence, particularly for boys, and was associated with youth problem behavior above and beyond other measures of family dysfunction and parent–child negativity. Moreover, maternal spousification in infancy forecast the adolescent's own behavior during observed parent–child interactions, including role equalization (e.g., treating the parent as a peer) and sexualized behavior (e.g., flirting with or excessively caressing the parent; Shaffer & Egeland, 2011). Among the rare studies to include measures of paternal spousification, Rowa, Kerig, and Geller (2001) found that young women with eating disorders reported higher levels of such boundary problems with their fathers than did community women and, in a sample of emerging adults, Kerig and Swanson (2010) found that both maternal and paternal spousification mediated the association between interparental conflict and maladaptation, but paternal spousification was linked uniquely to relational aggression against romantic partners.

Intrusiveness

Also termed psychological control, intrusiveness refers to "parental behaviors that are intrusive and manipulative of children's thoughts, feelings, and attachments to parents" (Barber, 2002, p. 15), such as guilt induction or withdrawal of love. Again, a large body of research has emerged to show that intrusive parenting is associated with maladaptation across development, particularly in regard to children's capacities for autonomy and self-directedness (Kerig, 2005; Kerig & Swanson, 2010; Kerig, Swanson, & Ward, 2012). These results have emerged in widely diverse samples in the United States (e.g., Barber, Bean, & Crane, 2006; Bean & Northrup, 2009) and cross-culturally (Barber, Stolz, & Olson, 2005).

Families as Open Systems

Finally, according to systems theory, a characteristic of the family is that it is an open system, which, although self-regulating and governed by coherence and organizational structure that confer stability, is one that is open to change in response to demands from both within and without the system (Cox & Paley, 2003). As Davies et al. (2004) phrased it: "According to family systems theory,

the family unit is an open system in which family perturbations and stressors (e.g., parent psychopathology, relationship disturbances, disruptive family events) may provoke subsequent reorganizations in family functioning and function as architects of interdependencies between family subsystems" (p. 775). Although this is a conceptually important underpinning to family systems theory that provides a point of convergence with the developmental psychopathology perspective, in fact a closer look at systemic conceptualizations of change raises a number of important questions, to which we turn next.

Change Processes in Family Systems

Less a matter of consistency among family systems theories than an issue with which they each have to contend, systemic perspectives must also offer a theory of change. As noted already, the family system is conceptualized as an open system and thus one that is open to change; therefore, families cannot be understood by homeostasis alone but rather theories also must account for the processes that allow for family growth and adaptation. Systems theories also make a distinction between *first-order* change, which refers to fluctuations and minor alterations in family functioning that leave the essential structure of the system unchanged, and *second-order* change, which involves a transformation in the family structure that is discontinuous with what has gone before (Watzlawick, Weakland, & Fisch, 1974).

Three primary models of family change can be found infused throughout the family literature. The first proposes that stress precipitates change through disequilibrating the family system and requiring it to abandon ineffectual strategies to reorganize in a more adaptive way to meet the challenge (Wagner & Reiss, 1996). This model of change has inspired the development of therapeutic techniques that evoke a crisis in the family to inspire transformation, such as strategic family therapists' use of *paradoxical interventions* that throw the system off balance, including prescribing the symptom (Papp, 1983).

A second perspective on change is the family life cycle approach, modeled after Erikson's (1950) psychosocial stages of development, in which each successive stage gives rise to specific developmental tasks that must be mastered for optimal development and thus calls for adaptations in the family role structure to accommodate. McGoldrick and Carter (2003) are the most well-known proponents of this approach, which outlines the stage-salient tasks associated with each successive stage in the formation of the family system. However, this is less a model of change than of normative development in families, and thus is discussed in greater detail in a later section of this chapter.

A more process- than content-oriented approach to family development was proposed by Steinglass, Bennett, Wolin, and Reiss (1987), which they termed the *Family Life History* model. Their view of family development was organized around three sequential tasks that they viewed to be universal across family forms, with each task emerging as most salient at particular points in the family's life span. In the earliest stage of family formation, the critical task is the establishment of an identity of the family as a distinctive entity, achievement of which involves the establishment of *boundaries*, including those within the members of the newly forming family and between each member and his or her family of origin. The second stage of family life involves *commitment* of the family system to a structure, organization, and set of values. The later phase is focused on consolidation of family identity and generativity regarding *the future*, particularly the preservation and transmission of family identity, values, practices, and rituals to generations to come. Inherent in this model also is a theory of dysfunction. Steinglass and colleagues proposed that the key sources of difficulties within each of these stages of family life are asynchronies that arise between the overarching tasks and developmental status of the system and those of any of its members or subsystems. For example, a clash might be seen between a mature family form seeking to consolidate its identity into the future (e.g., an immigrant family invested in maintaining a history of strong cultural values) and the developmental tasks of members who are striving toward forging independent identities (e.g., an adult child who is starting her own family with a partner of a different cultural background).

A third approach to understanding family change—the model most truly systemic as well as the one most consonant with the developmental psychopathology approach—is the *Epigenetic Relational Systems* model proposed by Wynne (1984/2004). In this innovative work, Wynne set out to apply the principles of epigenesis to relational systems in ways that explicitly incorporated general systems theory (Bertalanffy, 1968) and its tenets, including the construct of transactional processes underlying relationships in the family. Wynne was concerned to delineate not merely changes in the content or structure of roles such as those outlined in family life cycle theories but rather changes in relational processes that occur over the course of family development.

> What is crucial for my present formulation is the point that most of these life cycle changes in family role structure proceed more or less inexorably regardless of the quality of relating of the participants. To be sure, some relational changes facilitate and are complementary to changes in family composition, but other changes in family roles and structure take place unexpectedly or precipitously or are delayed. Meanwhile, the epigenesis of relational processes, I shall contend, proceeds at a rate and in a sequence that has its own inner "logic," sometimes unfolding smoothly and continuously and sometimes destabilizing discontinuously ... as new ingredients are randomly introduced or created within each variety of relational process. This means that "structural" family change and relational development are expectably and frequently going to be out of synchrony. Thus, the traditional approach to the family life cycle, defined primarily in terms of *structural* role change by exits and entries, is in a sense orthogonal to the unfolding of *relational* processes (Wynne, 1984/2004, p. 4).

In this light, Wynne identified five processes that unfold epigenetically in the development of relational systems: (1) *attachment* and affectional bonding; (2) *communicating* and sharing meanings; (3) *joint problem solving* and shared engagement in tasks; (4) *mutuality*, which involves reengaging, reevaluating, and renegotiating the preceding relational processes in ways that accommodate shifts in the internal states of family members and external demands of the environment; and (5) *intimacy*, a deeper and more elaborated form of relatedness that emerges as an outgrowth of the other processes but that Wynne considered more of an aspirational goal than a developmental necessity. Each relational process in Wynne's model can be conceptualized as having a positive or negative pole (Figure 13.1), with the latter comprising relational failures.

Whereas the positive poles of each relational process are viewed as nodal points around which mild fluctuations occur, representing first-order change, second-order change is seen when the family moves to a different predominant relational mode. Consistent with a crisis model of change, Wynne (1984/2004) proposed that failures in navigating these processes can "serve as challenges leading to mastery ... Although prolonged, intense instability or divergence will surely impair or disrupt relatedness, divergence that is contextually and developmentally appropriate is necessary as a decisive stimulus for moving on to the next level of relating" (p. 3). In addition, like Steinglass and colleagues (1987), Wynne also noted that problems may result from asynchronies in stages of the family life cycle, the developmental status of individual members, and the epigenetic unfolding of these relational patterns. "What is 'negative' at the relational system level may, of course be 'positive' for individual participants, for example in achieving differentiation" (p. 3).

Although Wynne's model has been used to good effect in clinical descriptions of the family systemic origins of certain disorders, such as in Guttman's (2002) discussion of adolescent borderline personality, the absence of a method for assessing these relational processes has precluded their incorporation into the empirical literature (Wagner & Reiss, 1996). Moreover, until recently, the lack of statistical methods sophisticated enough for modeling such dynamic change processes also has proven an impediment, one that future research may be able to overcome.

PSYCHOPATHOLOGY AND ITS CLASSIFICATION FROM A FAMILY SYSTEMS PERSPECTIVE

A long source of frustration for family systems thinkers, and another reason that systemic thinking has tended to not have a place at the table, is the lack of attention paid to family systemic factors in the major nosological and diagnostic systems used to study childhood psychopathology (Beach, Wamboldt, Kaslow, Heyman, & Reiss, 2006; Denton, 2007; First, 2006; First et al., 2002; Wamboldt & Wamboldt, 2000). Given that much of the literature in childhood psychopathology is organized around discrete disorders—the etiology and developmental course of anorexia, conduct disorder, and the like—where is the place for a system of thought that instead construes the subject of study as the anorexic or antisocial *family*?

Inclusion of Family Factors in Existing Diagnostic Systems

DSM

In the current version of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*; American Psychiatric Association, 2013), the only diagnostic category whose etiology is explicitly related to relationships within the family is reactive attachment disorder, a syndrome which arises as a function of an extreme absence of caregiving that is rarely seen outside of dramatically physically and emotionally depriving institutions. Instead, in the *DSM-5*, clinicians are given the opportunity to take family relational factors into account in two ways. One is to allow the clinician to note significant psychosocial and contextual features, such as extent to which the child's disorder is complicated by a milieu that is stressful or fails to offer necessary support and that might compromise the child's relative capacity to function with the disorder with which she or he is being diagnosed. The second way family factors come into play in the *DSM* is in the category of Other Conditions That May Be a Focus of Clinical Attention, or V codes, which are applied when the main focus of clinical concern is not considered to comprise a mental disorder per se. Among these V codes are *relational problems* in the dyadic relationships between parent and child (e.g., impaired communication, overprotection, inadequate discipline), partners (e.g., negative, distorted, or absent communication), or siblings, with a separate category indexing problems related to physical abuse, sexual abuse, and neglect. The family system of relationships is nowhere in sight.

In a major critique of the *DSM* framework and its sequestering of relational problems into a V code ghetto, Heyman et al. (2009) argued that compelling research exists to confirm that interpersonal problems in the family constitute bona fide clinically relevant syndromes that warrant our full attention. Relational problems meet the full *DSM* definition of disorder by virtue of being associated with subjective distress and functional impairment as well as predicting poor mental, physical, and interpersonal outcomes; thus, their neglect by *DSM* is unjustified. Their concerns echo those of the Group for the Advancement of Psychiatry Committee on the Family (1989) two decades earlier:

> Compared with the distress and disability they incur, these syndromes remain neglected—a situation reinforced by the lack of a place where such problems are meaningfully identified in our official diagnostic and statistical manual. The *DSM* approach requires individual-based diagnoses for relational disorders and thereby misdirects assessment and focused treatment away from the couple, family, or other relational systems in which dysfunction is most pivotally present (pp. 1492–1493).

Moreover, given the centrality of the family context for child development, family relational dysfunctions might loom particularly large in the life of children and thus constitute the kinds of failure in the expectable environment that are associated with the highest risk of maladaptation, a point of argument that has long informed criticism of the *DSM* framework by developmental psychopathologists (Bemporad & Schwab, 1986; Garber, 1984). "Consequently, some of the most significant concerns that bring children to the attention of mental health professionals—abuse, family conflict, bereavement, family dissolution—are placed in . . . a somewhat vaguely defined category of V codes, which may not be seen as priorities for treatment" (Kerig, Ludlow, & Wenar, 2012, p. 94).

Diagnostic and Statistical Manual for Primary Care

One attempt to revisit the *DSM* and to reconstrue the diagnostic system in ways that are more sensitive to developmental and family processes is the *Diagnostic and Statistical Manual for Primary Care—Child and Adolescent Version* (*DSM-PC*; Wolraich, Felice, & Drotar, 1996). The *DSM-PC* grew out of a collaboration among pediatricians, child psychologists, and child psychiatrists concerned with providing primary care physicians with tools for evaluating the extent to which behavioral and emotional problems presented by child patients might reflect deviations from normal development serious enough to warrant intervention. Notable is that the *DSM-PC* is a diagnostic system that is particularly closely aligned with

a developmental psychopathology perspective. Not only are symptoms placed explicitly in a developmental context and understanding of normative development, and not only is the family context given priority in understanding the etiology of childhood disorders, but the manual also is explicit in referencing the transactional nature of the child's interface with the social environment:

> A critical influence on children's general well-being—including behavioural and cognitive functioning and physical health—is the quality of the environment in which the child lives. A basic tenet of this manual is the central importance of the transaction over time between the child and the environment in which the child lives and grows (p. 31).

Despite this overarching transactional conceptualization, and despite the way in which the *DSM-PC* encourages the clinician to begin diagnosis by first considering familial and broader environmental, social, and interpersonal sources of risk and protection, the manual ultimately conforms to the *DSM* strategy of locating the clinically significant developmental variation, problem, or disorder within the child rather than within the family system. Moreover, despite its strengths, psychometric data are not available and, to date, the *DSM-PC* has not gained wide usage in clinical contexts nor in the research literature (Friedman, Sadhu, & Jellinek, 2012).

International Classification of Mental and Behavioral Disorders in Children and Adolescents

The International Classification of Mental and Behavioral Disorders in Children and Adolescents (*ICD-10*; World Health Organization, 2007) is the diagnostic system more widely used outside of the United States. The *ICD* also is undergoing revision at the time of this writing; in fact, the publication of the *ICD-11* has been delayed due to attempts to better align the system with the forthcoming *DSM-5* (First, 2009). Like the *DSM*, the *ICD* includes a separate axis for Associated Abnormal Psychosocial Situations in which family factors and other contextual variables can be taken into account. However, the *ICD* is more explicit than the *DSM* in suggesting that these situations might have implications for understanding the etiology of the problem and not only in qualifying its presentation or informing treatment. Moreover, the *ICD*'s much more extensive list of such situations includes a number that go beyond static family variables and appear to reflect interrelational difficulties that are more consonant with a family systems framework than are any in the *DSM*. These include disturbed intrafamilial relationships such as discord among adults or scapegoating of a child, inadequate or distorted intrafamilial communication, abnormal qualities of parenting such as overprotection, and acute life events that negatively alter patterns of family relationships.

Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood, Revised

The *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood, Revised* (*DC:0-3R*; Zero to Three, 2005) was developed specifically as a supplement to fill gaps in the *DSM* and *ICD* systems related to their presentation of clinical syndromes in young children. Consistent with the centrality of attachment relationships for the adaptive development of children in the first years of life, the *DC:0-3R* includes not only an axis for coding psychosocial stressors similar to the *DSM* and *ICD* systems but also requires that for each child a specification be given on a separate axis for Relationship Classification. However, this relationship is explicitly defined as comprising that between the child and the primary caregiver; the larger family system of relationships affecting this dyad does not play a part. In fact, the criteria for this axis expressly preclude the consideration of family systemic processes:

> Axis II is intended to diagnose the presence of a clinical problem in the child's relationship with the primary caregiver, usually the parent. When a disorder exists, it is specific to a relationship, meaning that the child's behavioral disturbances while interacting with *one* caregiver are not observed in the child's relationships with *other* caregivers. If the relationship disorder does not affect the child's functioning in other domains, then a diagnosis would be given only on Axis II.

RDoC

Although currently an early work in progress, the National Institute of Mental Health has spawned an initiative to develop new ways of classifying mental disorder that may have a significant impact on diagnostic theory and practice in times to come. The Research Domain Criteria (RDoC; National Institute of Mental Health, 2011) propose to develop classifications that are based upon neuroscience related to major systems underlying human behavior, including negative valence, positive valence, cognitive, social process, and arousal/regulatory systems (Cuthbert & Insel, 2013). Although feared by some to comprise an attempt to reduce all of psychopathology to a matter of biology, there is potential within the proposal to incorporate family relational dimensions. As the authors of

the RDoC proposal state, "The central nervous system is exquisitely sensitive to interaction with various elements of its environment . . . environmental influences may thus be considered as another critical dimension of the RDoC matrix" (National Institute of Mental Health, 2011). In this regard, as Denton and Bell (2013) pointed out, "For humans, an important environmental influence is interaction with the important people in our life" (p. 152)—that is, the family.

Alternative Approaches to Diagnosis from a Systemic Perspective

Global Assessment of Relational Functioning

One explicit attempt to integrate family systems perspectives into the *DSM* was the development of the Global Assessment of Relational Functioning (GARF). Spearheaded by a taskforce initiated by Lyman Wynne and the GAP (1996), the GARF was designed to provide an assessment of the quality of adaptive family functioning parallel to the existing individual-based global assessment of functioning in the *DSM*. Using the GARF, family functioning is rated along three dimensions presumed to reflect the ability of the family system to meet the instrumental or emotional needs of its members: (1) *problem-solving/interactional skills* (e.g., negotiating family rules, adapting to stress, communicating, resolving conflict); (2) *organizational structure* (e.g., maintenance of boundaries generally and developmentally specific boundaries such as those between children and the marital subsystem; hierarchical structure with parents retaining an executive role in the family; and an appropriate distribution of power and responsibility); and (3) *emotional climate* (e.g., openness to expression of feelings; involvement, caring, and commitment to one another; sharing of values; affection; and appropriate sexual functioning; Yingling, Miller, McDonald, & Galewaler, 1998). Although the GARF was included in the *DSM-IV* as an Axis Provided for Further Study, a body of empirical support for its use does not appear to have been established. Moreover, the GARF still may not satisfy the systems theory mandate to view the heart of the problem as located in the family system rather than viewing qualities of the family relationships as adjunctive to the individual's mental disorder.

Relational Diagnoses

A more thoroughgoing challenge to the individualistic perspective on diagnosis was launched by a consortium of family systems thinkers who represented some 15 different organizations (Kaslow & Patterson, 2006). Throwing down the gauntlet, this coalition argued, "In our view, a defect of the current diagnostic manual is the explicit restriction to syndromes that occur 'in a person.' We recommend recognition of syndromes that are best defined and identified as occurring between persons, as relational or interpersonal syndromes. These relational syndromes often entail serious personal dysfunction and warrant inclusion as mental disorders" (GAP, 1989, p. 1492). Although not completed in time to be considered for the *DSM-IV*, this group proposed a Classification and Diagnosis of Relational Diagnoses that reformulated diagnoses to take into account the relational network that both contributes to the etiology of disorders and is as essential contributor to their treatment (GAP, 1995).

The approach taken by the GAP was to base their scheme for the categorization of families on their structure and function and to include two major divisions. The first consists of disorders within one generation, including couples (i.e., conflict with or without physical aggression; sexual dysfunction; sexual abuse; divorce dysfunction; and induced psychotic disorder, aka folie à deux) or siblings (conflictual disorder, physical or sexual abuse, and folie à deux). The second division includes disorders spanning multiple generations, whether focusing on children and youth (e.g., intrafamilial child sexual or physical abuse, under- or overinvolvement, under- or overcontrol, communication deviance) or adult offspring and their parents (e.g., physical abuse or neglect, under- or overinvolvement, cutoff or conflictual communication). Paralleling the *DSM*, for each diagnosis the scheme outlines the diagnostic and associated features, predisposing features, prevalence, course, sequelae, and guidelines for differential diagnosis.

Proposed Classification of Relational Disorders. Subsequent work revealed a wide diversity of perspectives among relationship- and family systems-oriented scholars, which suggested that a consensus on the content—as well as the utility and even the ethics—of relational diagnosis would be difficult to achieve (Kaslow, 1996). Nonetheless, some intriguing specific proposals were laid out for how disorders might be placed into a relational paradigm. For example, Kaslow, Deering, and Ash (1996) put forward a set of criteria for a Relational Diagnosis of Child and Adolescent Depression to be applied when the child met *DSM-IV* not only for a diagnosis in the depressive spectrum but also in a context in which maladaptive family patterns of relating were associated with the development

or maintenance of the disorder. Problematic patterns of relationship in the family that might cause or exacerbate depression were specified as insecure attachment, low cohesion and support, child maltreatment, excessive parental controllingness, high levels of conflict accompanied by ineffective conflict resolution, poor affect regulation, impaired communication, transmission of depressogenic cognitions, and poor fit between the child's temperament and the family's style of relating.

Subsequently revisiting this issue, Beach, Wamboldt, Kaslow, Heyman, and Reiss (2006) again made the case for the inclusion of relational diagnoses in the forthcoming *DSM-5*, citing the burgeoning research evidencing the powerful associations between relational dysfunctions and both child and adult mental health. Helpfully, these authors propose a distinction between *relational disorders*, which are recognizable as clinically distinct constellations of symptoms that interfere with functioning or cause distress, and *relational risk factors*, which might exacerbate a disorder but are not themselves the focus of clinical attention. Beach and colleagues' scheme also differentiates between problematic relationship processes that are overarching and negatively affect functioning across domains (e.g., domestic violence) and those that are specific to the etiology of a specific disorder (e.g., intrusive feeding in the case of infant eating disorders or coercive parenting in the case of conduct disorder). Whereas the *DSM*'s V codes might accommodate the former, a relational diagnosis framework is necessary to elucidate the latter. Consequently, Beach et al. (2006, p. 366) made five concrete and pragmatic suggestions for strategies that would allow future diagnostic manuals to address relational factors:

> (a) devise clear criteria for the relational disorders currently depicted in V codes, perhaps creating a relational disorder category on Axis I; (b) develop an axis devoted to relational risk factors with clear criteria for assessing empirically supported contextual processes that might be the target of clinical intervention, including both family and multisystem contexts; (c) use relational specifier codes to indicate important disorder-specific relational processes; (d) elaborate relationship criteria for existing disorders where appropriate; and (e) describe relevant relational processes in the text associated with the disorder. In addition to these five approaches, it might also be useful to provide guidelines for relational formulations in an appendix or a companion volume to guide clinical use of the new information regarding relational processes. For each option, enhancing the current system could stimulate new research, guide the integration of applied and basic research findings, and inform services.

Relational Syndromes

Another attempt to give a relational focus to diagnosis was Heyman and colleagues' (2009) proposal for the creation of a series of new *relational syndromes*. These authors identified 11 distinct relational patterns or syndromes within families that, they argued, could be identified and for which reliable and valid diagnostic criteria could be developed. The specific relational syndromes include partner relational problems, parenting problems, parent–child relational problems, partner maltreatment (physical abuse, emotional abuse, sexual abuse, and neglect), and child maltreatment (physical abuse, emotional abuse, sexual abuse, and neglect). To demonstrate their point, the authors devised formal *DSM*-style criteria and empirically tested the validity of three of their proposed disorders: partner relational problems, child physical abuse, and parenting problems. Parallel to the process used in the validation of the *DSM*, Heyman and colleagues engaged in a series of iterative steps involving developing, field testing, and refining their criteria, assessments, and decision-making rubrics, using a sample of families in the U.S. military referred for child maltreatment allegations. Although the strong evidence presented in support of the validity, reliability, and utility of these relational diagnoses mustered by these investigators offers a valuable step forward, a limitation of this work in the current context is that the diagnoses offered do not derive from a family systemic perspective in that the relations involved are all dyadic (e.g., partner–partner, parent–child) and that they do not so much capture the interpersonal dynamics of family relational problems as identify negative sequelae of those problems.

Relational Diagnosis in DSM-5 and ICD-11

Family systems thinkers have continued their efforts to bring relational diagnoses into the forefront of the newest diagnostic systems. For example, *DSM-5* had a promising start when members of the *DSM-5* task force acknowledged the value of the construct of relational disorders (First et al., 2002) and invited workgroups devoted to relational assessment and relational diagnosis to participate in discussions leading up to the development of the new diagnostic compendium (Wamboldt, Kaslow, & Reiss, 2015). The workgroups even progressed to the point of conducting field trials demonstrating the reliability and clinical utility of relational diagnoses, such as parent-child relational problem (Wamboldt, Cordaro, & Clarke, 2015). However, as *DSM-5*'s developers acknowledged, including relational disorders would necessitate "a conceptual shift in the *DSM*'s exclusive focus on the diagnosis of individual

patients" (Kupfer, First, & Regier, 2002, p. 157), a shift they ultimately were not willing to make. In the final version of *DSM-5*, the relational diagnosis workgroups' recommendations were overlooked. Relational problems were again relegated to the V code section of the manual which, although providing expanded and clarified definitions that improve on *DSM-IV*, does not include reference to the specific impacts that help raters to diagnose them reliably (Foran, Whisman, & Beach, 2015; Smith Slep, Heyman, & Foran, 2015; Heyman, Smith Slep, & Foran, 2015; Wamboldt, Cordaro, & Clarke, 2015).

In contrast, the concurrent effort to develop the new *ICD-11* criteria has appeared much more receptive to the inclusion of relational problems, albeit with due concern regarding their cross-cultural appropriateness (Foran et al., 2013). As detailed in Wamboldt, Kaslow et al.'s (2015) overview, at the time of this writing field trials are ongoing to test the reliability and clinical utility of seven relational disorder diagnoses: intimate partner relationship distress, intimate partner physical abuse, intimate partner psychological abuse, parent–child relationship problem, child physical abuse, child neglect, and child psychological abuse. Although a promising step, as noted earlier, these relational diagnoses still largely represent dyadic (i.e., couple, parent-child) problems and are unidirectional (i.e., abuse of one family member by another) rather than representing whole-family processes nor the transactional dynamics inherent to family systems thinking.

CONVERGENCE AND DIVERGENCE BETWEEN FAMILY SYSTEMS AND DEVELOPMENTAL PSYCHOPATHOLOGY

Points of Divergence

As Davies and Cicchetti (2004) noted, a number of points of divergence are apparent between developmental psychopathology and family systems models. One is the unit of analysis; whereas developmental psychopathology generally has been concerned with patterns of adaptation or pathology within the individual, family systems theory has focused on maladaptation or positive adjustment as a function of the whole family or the interrelations among those comprising it. Second, whereas much of the early family systems work emerged in the context of attempts to understand adult psychopathology, developmental psychopathology has mostly been the purview of childhood research. Third, consistent with their clinical origins, many family systems theorists have utilized case studies and qualitative methods to validate their ideas, whereas the epistemological tradition in developmental psychopathology has leaned decisively toward quantitative methods and large-sample research. Fourth, whereas developmental psychopathology has been dedicated to understanding the continuum between normal and abnormal development (Cicchetti, 2006; Sroufe, 1990), with notable exceptions (e.g., Walsh, 2003), the focus of family systems theory generally has been on the study of dysfunction among clinical populations.

Points of Convergence

Despite these differences, some points of convergence promise to contribute to a rapprochement between the fields. One of these is a shared appreciation for systemic principles, including the individual and family context as open systems involved in ongoing dynamic transactional interchange with one another as well as the larger environment (Davies & Cicchetti, 2004). Holism also represents a shared assumption, in regard to both individual organisms and families, such that dimensions of individual development and the behaviors of family members cannot be understood in isolation but rather must be viewed within the context of the greater gestalt that gives them form and meaning. Appreciation for multideterminism and multifinality also can be found in either perspective, in that both developmental psychopathology and family systems acknowledge that a variety of child outcomes may ensue from the various risk and protective factors that impinge on development. Last, both systems of thought share a belief that systems follow lawful processes of successive hierarchical organization and integration, whether in the context of individual or family development. Therefore, the two perspectives might increasingly begin to complement one another in new theoretical work that strives for a true integration of the two, particularly given recent methodological advances in the tools available to test dynamic, systemic, multidimensional, interactional, and developmental models.

Toward an Emergent Synthesis: What Can Family Systems Theory Offer Developmental Psychopathology, and Vice Versa?

Focus on Process

One of the ways family systems theory might benefit from a better integration with the developmental psychopathology perspective would be to focus more on underlying processes and mechanisms rather than on the content of family variables. In other words, rather than judging

families as enmeshed versus disengaged or balanced versus triangulated, better questions might be: What are the *functions* that different kinds of family systems might serve at successive stages of development? What are the *developmental capacities* that can be supported in different ways by different family types for optimal adaptation at those stages? How do systemic-level *interrelations, transactions,* and *dynamic processes* provide a context in which those developmental attainments are achieved or thwarted? How can the developmental needs of various family members be *coordinated, balanced, negotiated,* or *synchronized* to provide a context conducive to optimal functioning for all subsystems—interparental, parent–child, sibling—and the interrelations among those subsystems?

Multiple Levels of Analysis. A valuable contribution of research from the developmental psychopathology perspective is an appreciation of interdisciplinarity and the importance of studying phenomena from multiple levels of analysis, including intrapersonal and interpersonal, observed and perceived, and psychological as well as biological processes in addition to the transactions among these sources of influence on the development of individuals and systems (Cicchetti, 2008; Cicchetti & Dawson, 2002). Although such efforts would not be not be incompatible with a family systems point of view—and certainly there is a growing body of research that includes family variables among the levels of analysis considered in multilevel investigations (e.g., Burnett & Cicchetti, 2012)—little research from a family *systemic* perspective to date has taken full advantage of the opportunity to explore the intersections among these sources of variance.

Family Resilience

Another important developmental psychopathology construct that is reflected—yet too often neglected—in the family systems literature is that of resilience, the capacity of individuals and families to function adaptively in the face of adversity (Cowan, Cowan, & Schulz, 1996). As Minuchin, Colapinto, and Minuchin (2007) noted, the focus on much of the research attention to families has been on the dark side and the ways family systems act as sources of risk and psychopathology. However, these authors point out, there is indeed a bright side involving the ways that families serve protective functions and foster resilience. Even among the most disadvantaged and stressed families, they argue, those who look closely will see characteristics such as loyalty, connection, affection, and shared identification that serve as sources of strength.

One early model of family resilience from a stress and coping perspective was offered by McCubbin and McCubbin (1989). They proposed that family success in overcoming adversity involved the intersection of several factors: the balance between a family's *vulnerabilities* (e.g., the presence of ongoing stressors or pressures associated with stage of life challenges) versus its *strengths* (e.g., resources for resisting stress such as the ability to adjust to change), its *structural patterns* (e.g., cohesiveness, organization, communication, and balance), the availability of *coping strategies* (e.g., the presence of good problem-solving skills), and the family's *appraisals* (e.g., subjective meanings given to the stressful event that are non-toxic and allow for hopefulness in the face of adversity).

A more recent well-articulated conceptualization of resilience from a family systems perspective has been developed by Walsh (2003), who proposes that familial adaptation in the face of stress or challenge involves three key domains of resilience. The first domain involves the family's *organizational patterns,* which include the family's clarity of structure, capacity for flexibility, and ability to mobilize necessary social and economic resources. The second domain, *communication and problem solving,* includes family members' ability to communicate clearly with one another, express emotions openly, and collaboratively work toward shared goals in ways that reflect resourcefulness, conflict resolution, fairness, and reciprocity. Finally, echoing the McCubbins, the third comprises the *belief systems* that influence how family members make meaning of adversity, preserve hope, and harness spirituality to serve as a source of strength and even to achieve posttraumatic growth and transcendence.

Although valuable and insightful, these models of family resilience have been relatively unintegrated into the literature on developmental psychopathology to date. Moreover, just as has the risk literature, the research on resilience has tended to focus on family variables rather than family systemic processes. Well-researched sources of resilience include a wide range of family factors, such as economic advantage, cohesion, and cultural engagement (Masten & Powell, 2003; see Kerig, Ludlow, & Wenar, 2012). But less well-heeded is Rutter's (1990) call for resilience research to turn from a focus on static factors to the investigation of *protective processes*—the underlying mechanisms by which such family characteristics as affluence, education, organization, and the like come to have beneficial effects for the developing person. Rutter's

four proposed protective processes are readily translated into a family systemic framework. For example, Rutter's protective process of *reduction of risk impact* may be conferred by membership in a family system that provides safety, warmth, and structure and buffers its members from external stressors; for example, a family with a strong sense of ethnic identity may serve to protect children from the harmful effects of racism. In turn, *interruption of negative chain reactions* may occur through engagement in positive transactions in which family members reciprocally influence one another's behavior in beneficial ways; an example of this is Wynne's concept of the differentiated individual who helps to diffuse tensions between two family members rather than becoming inveigled or triangulated in their quarrels. *Self-efficacy and coping* in the family context is captured well by Walsh's (2006) description of family strategies for making meaning of adversity in ways that confer a shared sense of optimism and affirmation of the family's strengths. Finally, *opening of opportunities* may take the form of family receptivity to individuality, differentiation, and even risk-taking among its members as they explore identities, lifestyles, or extrafamilial goals; an example here might be the family that not only passively accepts but also actively supports and validates the life choices of its sexual minority status child.

An intriguing process-oriented view of the family's contributions to the development of resilience is offered by Fivush, Bohanek, and Duke's (2005) studies of family narratives. The investigators first developed a measure assessing the extent to which children were knowledgeable about their family history (e.g., Do you know where your grandparents grew up; where your parents met; the story of your birth?). Their investigations showed that awareness of their family's history was one of the best predictors of children's self-esteem, perceived control, and positive view of their family. Subsequently, the investigators taped family conversations at the dinner table and distinguished among three types of family narratives: ascending (stories of unbridled family success), descending (stories involving family misfortune), and oscillating (stories in which the family was depicted as experiencing but overcoming adversities). Taking advantage of a natural experiment, the investigators were able to assess youth before and after 9/11 and found that growing up in a family characterized by oscillating narratives was associated with youths' resilience and the ability to modulate the effects of stress. Fivush and colleagues refer to the capacity that is fostered by these family narratives as an intergenerational self—the perception that one is part of something bigger with a place in history and the greater scheme of things (Fivush, Bohanek, & Zaman, 2011).

Infusing Development into Family Systems Theory

Another of the salient characteristics of the developmental psychopathology approach is the importance it places on understanding the emergence, organization, and integration of psychological, interpersonal, and biological processes over time in the ontogeny of the developing person. In contrast, with the notable exceptions described already, work in family systems theory has not consistently been attentive to developmental factors. In fact, many of the early systemic theory builders based their observations on families of adult children and did not explicitly give consideration to how those processes might relate differently to families with children at different developmental stages. Even those whose work focuses on younger families tend make reference to children without discussing ways family processes might play out differentially with infants, toddlers, preschoolers, school-age youth, and adolescents.

As Cicchetti and Toth (2005) pointed out, however, considerations of developmental differences are essential to our understanding of how family processes might contribute to psychopathology or adaptation. What comprises an adaptive family process at one stage of development may in fact be maladaptive at another (Barnett, Manly, & Cicchetti, 1993). For example, close emotional synchronization among family members plays an important role in fostering secure attachment during infancy, whereas autonomy promotion is conducive to healthy functioning in adolescence. In addition, the function and meaning of family processes might change over the course of development in several ways (Kerig, 2005). First, the relative impact of particular family processes might vary as a function not only of the stage-salient issues the child is navigating at each stage (Sroufe & Rutter, 1984) but also of how the family system is organized so as to support or conflict with those developmental tasks. For example, given the salience of differentiation of self as a stage-salient task for the toddler years, family enmeshment might be particularly injurious to adaptive functioning during that developmental period. In turn, given the salience of autonomy strivings in the teenage years, child triangulation in interparental disputes might come to the fore as the family process most disruptive to adolescent development (Davies et al., 2004).

A second way development comes into play concerns changes in how each successive stage-salient task of childhood might challenge or interact with family systemic

processes. For example, the terrible twos, or practicing phase of separation–individuation, is characterized by an *ambitendent* (Lieberman, 1992) alternation between proximity and distance seeking that may be particularly difficult to accommodate by those family systems with less adaptable structures and less tolerance for negative emotionality. By the same token, parenting school-age children requires a delicate balance between the provision of a secure base and the simultaneous promotion of extrafamilial competencies (Cummings et al., 2000); therefore, the school-age child's increasing shift toward prioritizing peer relations and achievements outside the home might present a particular challenge to those family systems that are organized around family-centeredness.

A third developmental dimension involves how, over time, children's emerging developmental capacities allow them to become increasingly active agents and architects of family processes (Becker-Blease & Kerig, 2015; Cummings & Schermerhorn, 2003). This is seen most clearly in the developmental psychopathology construct of transactions, in which family members influence one another's behavior in ways that foster the emergence of new qualities in one another and in the relationship between them. With the increasing differentiation and sophistication of their cognitive, emotional, and interpersonal capacities across development, children have a wider range of capacities with which to influence parents, siblings, and the nature of the interrelations among the various subsystems in the family.

By the same token, one way children increasingly can exercise their agency with age is to extricate themselves from problematic family processes. Age opens up expanding opportunities for children to become engaged with extrafamilial activities and peer associations that emotionally and physically separate them from and potentially create a buffer against family stress. Thus, it may be that, over the course of development, the impact of maladaptive family system processes is weakened for those resilient children who enjoy prosocial activities and relationships outside the home. However, in keeping with the concepts of developmental pathways and canalization, it also is possible that there are constraining effects of a bad beginning such that, at least for children without such extrafamilial protective factors, "spending one's early years within the context of a negative or hostile family system sets them on a [negative] trajectory" (Leary & Katz, 2004, p. 596) from which it is difficult to deviate.

A fourth way development comes to play concerns age-differentiated expressions of family systems processes. Related to the idea of *transformations* in symptom expression across development (Sroufe, 1990), the manner in which family systemic processes such as triangulation, communication, or cohesiveness manifest themselves might be expressed differently among families that are focused on the tasks of raising infant, school-age, or emerging adult children. An excellent example of this is Shaffer and Sroufe's (2005) longitudinal work investigating boundary dissolution in the family system across developmental periods spanning early childhood to adulthood, which required the creation of unique coding systems to capture these processes as they were played out between parents and children in the toddler, preschool, school-age, and adolescent years. A reflection of the power of the underlying theory is its ability to inform the investigators with strategies for coding different manifest behaviors while detecting consistencies in their latent purpose and meaning in the family system. Despite differences in the specific behavioral signs indicative of spousification, for example, the investigators were able to identify lawful continuities and coherence in the underlying patterns seen among family members.

Another intriguing developmental line concerns the child's ability to engage in and coordinate the complexities of family process. Fivaz-Depeursinge and Corboz-Warnery (1999) use the term *triangular capacity* to describe the child's ability to track the exchanges between two parents and to enter their interaction in ways that influence—and at times improve—its flow. Although this is a capacity that is observed in infants as young as 3 months of age and to date has been investigated only in relation to the child–mother–father triad (e.g., McHale, Fivaz-Depeursinge, Dickstein, Robertson, & Daley, 2008), it seems reasonable to expect that, over the course of development, children's triangular capacities become more sophisticated and they are increasingly able to comprehend, mediate, or avoid becoming entangled within problematic interactions among increasingly complex combinations involving other members of their family, including quarreling siblings.

A fifth way development might impact family processes concerns the other side of the coin, namely, changes in how family members respond to children across different age periods in ways that impact the entire system. For example, enmeshed families that perceive differentiation of their members from the collective to be a source of threat might be characterized by overtly intrusive processes when children are young but by subtler and sophisticated autonomy-limiting processes, such as psychological control and guilt induction, when children reach the adolescent years. Sixth, there may be lawful developmental progressions in family systems processes such that some emerge as developmental antecedents of others (Kerig, 2005). Again,

boundary dissolution constructs provide an example here, whereby psychologically controlling processes might foster the development of enmeshed relationships in the families of young children, which in turn might set the stage for the later emergence of a role-reversed family system in which adolescents become preoccupied with caring for their parents' emotional needs.

Seventh, as was noted already, McGoldrick and Carter (2003) pointed out that it is not only children who develop over the life span. Parents also navigate different stage-salient issues over the life course and family systems themselves must change in order to accommodate these developmental processes. In the first stage of these authors' family lifecycle framework, the salient tasks involve members of a couple redefining their relationships with their families of origin and establishing a new partnership and level of intimacy with one another. The birth of a child requires a further reorganization of the system to accommodate this new family member and often involves a significant renegotiation of roles within the marital subsystem (Cowan & Cowan, 1992). Another major shift in family structure and functions occurs as children enter late adolescence, when the system must become more flexible to allow youth to more freely move in and out of the intimate hold of the family. The next stage involves launching the emerging adult into the world and realigning the family to encompass new members, including children's own intimate partners, in-laws, and offspring. The final stage identified in McGoldrick and Carter's (2003) family life cycle is a poignant one, in that parents in midadulthood are confronted with the new freedoms (or fears) represented by their now-adult children's independent status while often simultaneously taking on new caregiving responsibilities involving their own aging parents. Although the literature reflects appreciation of this model, it has not been subject to empirical validation, nor has it been incorporated into family systems research in a systematic way. In addition, criticisms of this model have included its limited applicability to diverse family forms as well as its focus on the tasks of family members rather than on changes related to the structure or function of the family as a system more broadly (Wagner & Reiss, 1995).

CHALLENGES TO FAMILY SYSTEMS THEORY

Bringing Fathers into the Fold

If we are truly to view family dynamics from a systemic rather than a dyadic parent–child perspective, it is necessary to acknowledge the unique role that fathers play in two-parent families. Family systemic thinkers can be credited with stimulating our thinking in this regard, and particularly with calling our attention to the long neglect of fathers in the literature on parent–child relations. Just as Phares (1992) queried humorously in the title of her seminal articles, "Where's Poppa?" and "Still Looking for Poppa" (Phares, Fields, Kamboukos, & Lopez, 2005), Minuchin (1985) quipped, "Psychological researchers created the single-parent family long before it was a characteristic of American society" (p. 296). In addition, however, family systems requires not viewing fathers as just a second parent and father–child relations as just a second dyad in the family but rather understanding the influence of father–child and father–mother relationships on the dynamics of the family as a whole (Lamb, 2013).

Feminist Critiques of Family Systems Theory

A pointed challenge to the prevailing wisdom in family systems theories in the 1970s and 1980s was raised by feminist scholars who noted the highly gender-stereotyped assumptions made about men's and women's "proper" roles in the family system (Hare-Mustin, 1978; Walters, Carter, Papp, & Silverstein, 1988). These were particularly noticeable given how strikingly at odds they were the zeitgeist of the emerging women's movement and evolution of gender roles in U.S. families and society more broadly during that era. In addition, feminist scholars have continued to raise questions about some of the unarticulated assumptions underlying systems theory that inform its practice in the therapy room, particularly in regard to dynamics of power, control, and hierarchy, both among family members and between the family and the therapist (Luepnitz, 1988). Instead, feminists have suggested that construals of family relationships and the relationships between family members and therapists can be based on assumptions of cooperation, mutuality, and egalitarianism more consistent with feminist perspectives (Hare-Mustin, 1994; Walters et al., 1988). In addition, these writers have argued, family systems also must be understood within the interconnecting contexts of race and class as well as gender (Silverstein & Goodrich, 2003).

Cultural and Ethnic Diversity in Family Systems

Attempts to integrate developmental psychopathology and family systems perspectives (e.g., Cox & Paley, 2003; Lynch & Cicchetti, 1998) have pointed toward the importance of transactional processes involving the larger ecological contexts that " . . . may shape, affect, and be affected by that which happens in families and children's lives" (Lindahl, Malik, Kaczynski, & Simons, 2004, p. 610). Consequently,

another challenge to family systems theories has been to demonstrate that models of family development, adaptation, and psychopathology are relevant across a range of cultural and ethnic groups (McGoldrick, Giordano, & Garcia-Preto, 2005).

Cross-Cultural Perspectives on the Family

As Kağıtçıbaşı (2005, 2007) argued, the family as a system must be viewed within the contexts of the larger cultural and social structures in which it is embedded. These contexts inform the sense of purpose that guides the family in all respects, including family structure, parents' socialization goals, family practices and rituals, and the emotional tone of family relations. Similarly, Chao (2000) suggested that the socialization goals imparted to the family vary across cultures, and those socialization goals guide parenting practices and family interactions in systematic ways. Culturally shared understandings of the purpose and meaning of family relatedness are further seen as embedded deeply in historical culture and as representing "accumulated knowledge of prior generations within that environment" (Keller & Otto, 2009, p. 997). Moreover, Bornstein and Cheah (2006) implied the family itself represents a microcosm of the overarching culture. The larger society imparts information about what is expected of families and their members (e.g., norms, customs, and shared values), but parents then "select, edit, and refashion" (p. 15)—in other words, assimilate—which information to communicate to their children. In essence, then, each family can be construed as its own culture in which parents and caregivers pass on their attitudes, behaviors, and values to their children. Although children take in and process the information received from their parents, this also should be seen as an active, bidirectional process in which both parents and children contribute to the making of meaning. In sum, culturally constructed family beliefs and behaviors directly influence the development of children and contribute to the transmission of cultural information across generations.

Although much of the theory on cross-cultural differences among families has focused on a distinction between collectivism and individualism (e.g., Markus & Kitayama, 1991), Kağıtçıbaşı (2005, 2007) offered a critique that suggests this duality does not reflect the complexity of family forms associated with culture. In Kağıtçıbaşı's model, underlying the cultural expectations that influence family functioning are two dimensions: *agency*, defined by the poles of autonomy and heteronomy; and *interpersonal distance*, defined by the poles of separateness and relatedness. Using the matrix of these two dimensions, Kağıtçıbaşı proposed that cultures may promote each of four family interaction patterns that influence parenting styles, and in turn, the development of the child's sense of self. The first of these is a family pattern of *interdependence*, defined as high in relatedness and low in autonomy. Interdependence arises as an adaptive family form among rural, farming communities in which family members must rely heavily on one another for meeting both emotional and material needs, often seen in developing societies. Such families are typically hierarchically arranged with parents adopting an authoritarian parenting style related to the instrumental functions of the family, as it strives to ensure the material well-being of its members. In particular, because children are needed to provide economic and practical support to the family, especially as parents age, their independence from the family is not functional and may even represent a threat to family well-being. Consequently, the emotional functioning of the family is one that promotes permeable boundaries in interpersonal relationships, thereby fostering in children the development of self-constructs that are profoundly relational.

A second family pattern, *independence*, is characterized as high in autonomy and low in relatedness and is more typically seen among families in Western urbanized, industrialized societies such as the United States, at least among those in the majority White subculture. Such families are organized in ways that help their members to function well in the context of cultural expectations for autonomy and self-reliance. Parents in independent families tend toward an egalitarian or even permissive mode of interaction with their children whereas the family structure is defined by clear interpersonal boundaries that foster the development among children of a separate sense of self. The third family pattern proposed by Kağıtçıbaşı (2007) is labeled as *hierarchically neglecting*, composed of families that are high in separation and low in relatedness.

The fourth family model Kağıtçıbaşı (2007) proposes, which has been overlooked in other cross-cultural family models, is that of *psychological interdependence*, described as a dialectical synthesis of the interdependent and individualistic forms combining high levels of relatedness with high promotion of autonomy. This family mode is most likely to be seen among the rising class of suburban families in modernizing societies that have traditionally embraced interdependence. Such families function in a cultural context in which members no longer remain dependent on the family system for providing material needs throughout the lifespan and yet continue to look toward one another as important sources of emotional

connection. Parents in these families tend to engage in authoritative parenting, combining structure and direction with warmth and emotional responsiveness, which fosters in children the development of a sense of self that is termed autonomous-related; that is, simultaneously both relational and independent.

> The weakening of intergenerational material interdependencies allows autonomy to enter child rearing. This is because the child's autonomy is not any longer perceived as a threat when his or her material contribution is not required for family livelihood. Nevertheless, because psychological interdependence continues to be valued, the connectedness of the growing child is desired, rather than separateness. Therefore, together with autonomy, there continues to be control rather than permissiveness in child rearing, and control may function as a centripetal rather than a centrifugal force (Kağıtçıbaşı, 2007, p. 411).

Intriguing support for this model is suggested by research emerging from a project spanning 10 countries in which changes in family attitudes have been assessed over the course of three decades and three generations (Bond et al., 2004; Kağıtçıbaşı & Ataca, 2005). With increasing modernization, all cultures studied have evidenced a decrease in the view of the child as a utilitarian entity and economic asset and a concomitant rise in the appreciation of the child's status as a psychological contributor to the family. "These results provide evidence for a shift from the family model of interdependence to one of psychological interdependence over three decades of socioeconomic development and urbanization. In line with these changes are changes in desired qualities of children" (Kağıtçıbaşı, 2005, p. 414).

Implications of Cultural Differences in Family Dynamics for Psychopathology

One of the implications of a cross-cultural perspective is that particular family processes may affect children differently depending on the larger context which lends them social meaning. For example, culturally derived values of *familism* may confer quite different meanings on family processes such as rigid boundaries or role reversal. Among cultures valuing familism, role complementarity between parents and children and tightly structured family systems with unbalanced power differentials may be conducive to positive child functioning in ways they are not in other cultural contexts (e.g., Lindahl & Malik, 1999). Similarly, the expectations for children's ongoing familial obligations their parents and siblings in such cultures may contribute to benign associations between processes such as parentification and youth functioning (Jurkovic, Kuperminc, Sarac, & Weisshar, 2005).

Historical Changes Affecting the Family System

Yet another challenge to family systems theory is its capacity to reflect how families operate and are construed across historical epochs. For example, in contrast to the supposition inherent in much of the early family systems literature that the prototypical family takes a nuclear form, one of the most evident changes in family systems over the past few decades in the United States has been the rising rates of divorce and resulting single-parent families. According to the most recent U.S. census, only 67% of children in the United States currently are living with both biological parents. Single-parent families provide a context for development that is rife with potential vulnerabilities and sources of resilience (Murry et al., 2001). Moreover, the alternatives involving one biological parent are numerous and include households encompassing three generations, extended family members, nonmarried cohabitating partners, and shared living arrangements among multiple families. In addition, although perhaps more slowly and more slightly than some would wish, there also is evidence for changing norms in U.S. majority culture regarding the role of the father in child development, with parents increasingly indicating an expectation that fathers will be actively involved in the lives of their children (Lamb, 2013).

Another phenomenon affecting what is perceived as normative in U.S. families is the increasing length of the adolescent period into age ranges (e.g., the mid-20s), which in other eras would have been considered to be part of the adult phase. Current U.S. culture's lack of clarity about when the adolescent period ends and adulthood begins seems to be reflected in the wide range of ways different developmental theorists discuss the stage-salient tasks involved in this transition. For example, as Kerig and Schulz (2012) observed, developmental tasks such achieving individuation and psychological independence from parents are listed variously by stage theorists as emerging during the early, mid, or late adolescent period, just as leaving the family home and assuming responsibility for independent decision making are variously associated with late adolescence and emerging adulthood (e.g., Arnett & Tanner, 2006; Micucci, 2009). Studies of emerging adulthood among middle-class majority families in the United States in fact suggest that such leave taking is for many youth only metaphoric in that declining economic

prospects force them to continue living in the family home late into their 20s or beyond (Kaplan, 2012).

These observations suggest a number of research questions that deserve further exploration. What are the effects on the family system of changing norms regarding the roles of fathers and the developmental status of adult children, particularly when those children continue to cohabit with their parents and thus the organization of the system retains the form of a traditional nuclear family? Even more to the point may be the need to ask questions about the effects on the family system of a lack of overall clarity among all family members, or a lack of consensus among its members, about these changing role expectations of parents and their adult children. How do these changes in family structure and function interact with larger societal definitions and expectations for the role of parents in the lives of their adult children, and vice versa?

What Is a Family? Diversity in Family Structures and Composition

As noted already, a frequent criticism of classic family systems theories is that they are based on a highly stereotypical model of what constituted a *family*. However, in U.S. culture as well as around the world, it is clear that not all families are composed of the nuclear pattern of a mother, father, and child. To be relevant across cultures and subcultures, family systems theory must rise to the challenge of recognizing and understanding the wide range of diverse family forms. These include single-parent (e.g., Murry et al., 2001) and same-sex parent (e.g., Farr & Patterson, 2013) families, multigenerational households (Jones & Lindahl, 2011), never-married, fragile families (Carlson & Högnäs, 2011), blended/step-families with complex combinations of coparenting arrangements (Burton & Hardaway, 2012), sibling-headed households (Richter & Desmond, 2008), and families that are emotionally connected yet physically separated by such challenges as parental military deployment (e.g., Bowen, Martin, & Mancini, 2013) or incarceration (e.g., Loper, Phillips, Nichols, & Dallaire, 2014). Each of these represents a legitimate family form, and in virtually all of these kinds of families the same sorts of processes arise as do amongst two-parent families, requiring the coordination of relationships across multiple boundaries (e.g., parent–child, child–sibling, sibling–parent) as well as synchronization among those involved in coparenting the child. Even when a coparent is completely absent from the picture, such as might be the case when a biological father maintains no relationship with the child, there are important but virtually unexplored family dynamics involved in how the resident parent permits or disallows his emotional presence in the life of the child and in the defining parameters of who is family. "Thus, it may be important to take into account family members who are absent as well as those who are present" (Cicchetti & Howes, 1991, p. 274).

Extended Family and Fictive Kin

Most typically mentioned in regard to diverse family structures are extended family members who, although perhaps relegated to the periphery in the stereotypic middle-class European American family, are viewed as core members of the unit in other cultural and ethnic groups (Jones & Lindahl, 2011). For example, among African American single mothers, 97% identify another adult as centrally involved in the parenting of their child: these include not only biological fathers, grandmothers, aunts, and other relatives but also friends (Jones, Shaffer, Forehand, Brody, & Armistead, 2003). The meaning of the term family in and of itself also is a subjective and diversely defined one, in that among some subcultures and individuals, the term refers not to blood relations only—or even at all—but rather to those who are perceived to be one's core source of support, emotional intimacy, protection, and identity. Thus families may be created on the basis of choice, with members defined by the instrumental and emotional roles they play rather than by bloodline. McHale and Irace (2011) expressed this nicely from a child's-eye point of view:

> Children see their families as a collection of individuals who loves and cares for them. And children are right: in the end, their welfare in the world will ultimately be protected and assured … by the collection of individuals who step up to take responsibility for their care and upbringing (p. 15).

In this regard, fictive kin, who are rarely included in family research, may play an unexamined role in the family processes that influence child development. This may be true particularly among certain cultures, such as Mexican American families in the United States, in which the system of *compadrazgo* ensures that a significant place in family life is reserved for non–blood-related members such as godparents (Luna et al., 1996). The significance of fictive kin in a child's life also may increase with age, as adolescents become increasingly active agents in niche picking and selecting their own interpersonal environments (Becker-Blease & Kerig, 2015; Reiss, Neiderhiser, Hetherington, & Plomin, 2000; Scarr, 1992). The relative risk or protective influence of these fictive familial relations likely is complex. Although having "someone to turn to" may

provide youth with a sense of felt security that promotes adaptation, evidence also suggests that troubled youth tend to gravitate toward others who share their attitudes, behaviors, and lifestyles and thus reinforce maladaptation (van der Zwaluw et al., 2009). A particularly compelling example is provided by disaffected gang-involved youth, for whom the gang is explicitly identified as a substitute family and fellow gang members are perceived quite literally as brothers and sisters (Miller, Winn, Taylor, & Wiki, 2012).

Three-Generational Families

At the same time that many young people in the United States continue (or return to) living in their parents' home after reaching their majority, an increasing number do so accompanied by children of their own. The phenomenon of three-generational families is not new in U.S. society, having long been a family form common among low-income and minority communities, for whom cohabitation is both a means of survival and a culturally sanctioned choice (Goodman & Silverstein, 2006). Even when cohabitation is not involved, grandparents play a large role in childrearing in ethnically diverse families; for example, among single mothers in Jones et al.'s (2003) African American sample, a full 31% reported that the maternal grandmother was their key source of coparenting support. Further, research shows that the quality of the coparenting relationship between mothers and their mothers makes an important contribution to children's adjustment (see Jones & Lindahl, 2011).

In an in-depth look at this family form, Pittman, Wakschlag, Chase-Lansdale, and Brooks-Gunn (2012) discuss the intersecting developmental, family, and sociodemographic factors impacting three-generational families. Whereas individuation-promoting family interactional styles generally are found to provide a good fit for the stage-salient issues of the late adolescent period and to be associated with positive outcomes for youth, this assumption is complicated by issues of race, socioeconomic status, and the unique developmental challenges of becoming a young mother, or of becoming a young grandmother, among coresiding three-generational families. The ideal balance between the provision of adequate support and autonomy may be difficult for mother and grandmother alike to discern and to create. Further, although it can be expected that "grandmothers who support the young mothers' independence while remaining emotionally available facilitate their daughters' assumption of adult roles, . . . the specific dimensions of a supportive relationship between mothers and grandmothers that are linked to positive parenting have not been well-delineated" (p. 183). Pittman and colleagues resolved this dilemma by proposing that the interpersonal skills that allow young mothers to successfully navigate the stage-salient issues of individuation in adolescence, and the qualities of their own parents' behavior that support that individuation, are precisely the qualities that undergird young mothers' success in parenting their own children. These qualities include self-assertion, which evolves into firm limit-setting with children; perspective taking, which supports the capacity to accommodate to a child's point of view; separateness, which contributes to the ability to support children's autonomy; and mutuality, which takes the form of emotional connection and availability in parenting. As they suggest, "mothers who can maintain a sense of closeness with their own mothers, despite their differences, may also be more likely to feel emotionally connected to their children as their children become increasingly independent" (p. 184). In sum, the authors propose a lawful intergenerational continuity in relational functioning between the adolescent mother, her adult mother, and the toddler-age grandchild.

These ideas were confirmed in Brooks-Gunn's (1990) study of 96 African American mothers, grandmothers, and 3-year-old children, almost half of whom were graduates of an earlier study that followed teen mothers and their families over the course of 17 years. Thus, these were multigenerational families including teenage mothers. Results showed that, as expected, individuation in the mother–grandmother relationship was linked to the mother's own parenting practices and ability to demonstrate a balance between emotional responsiveness and appropriate parental control with their children. Moreover, these effects extended into the next generation, with children of mothers whose grandmothers supported individuation showing a greater ability to work independently on a challenging problem-solving task while still being responsive to maternal direction.

Teen Fathers

Compared with teenage mothers, adolescent fathers have been largely absent from studies of multigenerational families. This is likely because young fathers are more rarely coresident with the families of their child's mother but also because these couple relationships are highly vulnerable to dissolution and the father's subsequent disengagement from parenting (Carlson, McLanahan, & Brooks-Gunn, 2008). Nonetheless, as Florsheim and Moore (2012) pointed out, "Not all young fathers fail as relationship partners nor as parents; some are in fact able to manage the frustration, anxiety, and demands that accompany the monumental responsibility of parenthood and maintain

(or establish for the first time) positive relations with both their partners and children" (p. 201). Valuable research has been conducted examining the factors that promote successful coparenting between adolescent fathers and their partners (Carlson & McLanahan, 2006; Florsheim & Moore, 2012) and positive engagement between teen fathers and their children (Fagan, Palkovitz, Roy, & Farrie, 2009), as well as the intersection of these interpersonal processes (Florsheim et al., 2003; Moore & Florsheim, 2008). Nonetheless, an interesting set of questions remains to be answered from a family systemic perspective. For example, what are the adaptations that must be made in the young man's family of origin to accommodate his attainment of this new status of father? How do systemic processes in the paternal and maternal families of origin serve to support, foster, or interfere with the integration of this new relationship, and these new family members, into the fold? What are the three-generational family dynamics that potentiate teen father's motivation, and competence, to engage with the caregiving tasks of new parenthood? Some research has emerged to suggest that grandparents are important mediators of the relationships between teen fathers and their offspring. For example, positive relationships with the child's mother are one of the best predictors of teen fathers' involvement with their offspring (Gavin et al., 2002), and Krishnakumar and Black (2003) found that adolescent mothers enjoyed higher quality relationships with their baby's father if the maternal grandmother reported more positive affiliations with both teenagers.

Grandparent-Headed Households

In addition to three-generational families in which parents, children, and grandparents coreside, family systems theory also needs to accommodate family forms in which the middle generation is absent. Grandparents who are raising children on their own might easily be considered as caregivers interchangeable with biological parents in terms of the roles they play in the family system, but there is some reason to suspect that this is an assumption that should be questioned. Grandparents may not feel fully enfranchised to take an executive role and make decisions, either within the family or in the context of their interactions with extrafamilial contexts such as schools and social welfare agencies. This ambiguity may provide a source of tension that reverberates throughout the family system, one that is further complicated when the permanence of the custody arrangement also is not secure (Boyd-Frankin, 2003). Further, the demands of parenting a second generation may not coalesce well with the life stage of aging grandparents, particularly those in failing health, who may be oriented toward relinquishing caregiving responsibilities and moving into the phase of fulfilling their own personal late-life existential tasks. The strain that this added parenting role confers may spill over in negative ways onto the family dynamics and compromise the ability of the system to most favorably support the development of its members. On the other hand, grandparent-headed households are not a new family form, particularly among nonmajority culture communities, and a long history suggests that they also can be adaptive, overcome challenges, and provide positive contexts for children's development (Jones & Lindahl, 2011).

FAMILY SYSTEMIC RESEARCH METHODS

Before turning to a review of the current state of knowledge regarding developmental psychopathology from a family systems perspective, it is necessary to give consideration to the methods that inform that body of research. As with family systems theory itself, those research methods have been various. The diversity of methods used in family systemic research necessarily reflects the diversity of underlying theoretical models and purposes of the research.

Self-Reports of Family Processes

A number of self-report measures have been developed to assess individual family members' perspectives on the family system, with such subjective self-reports providing valuable information about how each member of the family perceives, understands, or is affected by family system processes. Among those developed to reflect a specific theoretical conceptualization of families, a premiere example is the Family Adaptability and Cohesion Evaluation Scale (FACES IV; Olson, 2011), which is designed to capture family members' perceptions of the dimensions of cohesion, flexibility, and communication encompassed by Olson's circumplex model.

In turn, widely used empirically derived omnibus measures of family characteristics include the McMaster Family Assessment Device (Epstein, Baldwin, & Bishop, 1983), which assesses family members' perceptions of a wide variety of traits, including problem solving, communication, clarity of roles, affective responsiveness, affective involvement, behavioral control, and general family functioning. Similarly, the Family Assessment Measure (Skinner, Steinhauer, & Santa-Barbara, 1983) casts a wide net, assessing characteristics such as task accomplishment,

role performance, communication, affective expression, involvement, control, and values and norms in the context of the family as a whole, dyadic relationships in the family, and one's perception of oneself as a family member.

One of the interesting but challenging outcomes of gathering multiple family members' perspectives is that they often fail to agree to one another; for example, in a study comparing ratings from multiple members of more than 26,000 families, Georgiades, Boyle, Jenkins, Sanford, and Lipman (2008) found that 54% of the variance in ratings was not shared among members of the same family. If family members' ratings are discrepant, what then is the data point to be used as the indicator of family warmth, cohesion, problem solving, or communication? Some research also suggests that disagreement about the quality of family relationships is higher in families that are functioning more poorly (Georgiades et al., 2008; Kerig, 1995); thus, the level of discrepancy among family members is a valuable data point in and of itself.

Observational Coding

Perhaps the richest source of information about systemic family processes derives from observations of family members as they interact with one another in the home or in the laboratory. Observational methods provide a unique source of data in that they are able to capture aspects of family interactions of which the participants themselves are not directly aware. "People behave in ways that are discrepant from their self-perceptions, and only direct observation can capture their behavior independently of their appraisals of it" (Kerig, 2001, p. 2). However, whereas the perspective of an outsider is useful, it is not necessarily more objective or more accurate (Weiss & Heyman, 2004). Following in the footsteps of the clinicians who founded the field, researchers devise systems for categorizing observed behaviors in ways that are lent meaning through the lenses of the investigator's underlying theoretical framework. As Margolin (1990) stated, "The coding systems themselves are derived out of researchers' a priori assumptions as to what constitutes important communication differences . . . Even when such differences are empirically validated, we have no way of knowing whether the differences discovered [are] the only ones, or are the most significant ones" (p. 210). Thus, observational methods present a number of challenges.

The Role of Theory

One of the implications of the diverse theoretical assumptions underlying family observational coding systems is that the meanings of coded behaviors are construed differently and thus even coding systems that appear to be tapping the same constructs in fact may not be. Thus, for example, a specific interactional behavior, such as a positive statement, may be interpreted as a sign of enmeshment in one coding system versus positive affect in another. In addition, similar behaviors may have different functions in the family system when they are exhibited in the context of individual, dyadic, or triadic episodes. Therefore, it is difficult to extrapolate with confidence across studies and compare findings related to specific constructs when those were obtained using different observational coding systems (Kerig, 2001).

Level of Analysis

Another limit to comparability concerns differences in the level of analysis at which coding of family processes take place. Constructs that involve a high order of inference are most likely to require molar or *macrolevel* codes that attempt to extract overall patterns of meaning or coherence. An example is Fiese et al.'s (2001) system for coding family narratives, in which observers are trained to make judgments about overarching constructs such as narrative coherence, narrative style, and relationship beliefs. Such coding systems confer a number of advantages, including the capacity to take into account the context in which behavior occurs, to synthesize complex individual data points into an organized whole, and to capture complex relational patterns. Disadvantages of macrolevel coding, on the other hand, include the cognitive complexity involved that may require extensive training of coders in order to attain reliability, the necessity to make the right a priori choices of what observations to bring to the foreground and which to leave in the background, and the possibility of lumping together categories of behavior that are conceptually distinct from one another.

At the other end of the continuum, constructs that involve more discrete or concrete behaviors may lend themselves best to molecular or *microanalytic* coding systems. Microanalysis is particularly valuable for the study of contingent responding and the investigation of the direction of influence in family processes. For example, Kerig, Cowan, and Cowan (1993) used a microanalytic coding system to investigate ways marital discord was associated with gender-differentiated patterns of interaction between parents and children. Whereas overall levels of negativity were not observably higher in the interactions of maritally dissatisfied fathers and their daughters, analyses of contingent responding showed that fathers in unhappy marriages were more likely than other parents to respond negatively

to their daughters' assertiveness. Although such contingent patterns are discernible only through microanalytic coding, a distinct disadvantage of microanalytic systems is that coding such fine-tuned behaviors may be highly time-consuming; in some cases, as many as 20 hours are needed to code a single hour of family interaction.

A third level of analysis involves analyzing constructs at the midrange or *mesoanalytic* level, which involves an integration of both of the aforementioned approaches. Rather than coding discrete behaviors during each speaking turn or brief (e.g., 10-second) time interval as in microanalytic systems or providing a single rating for the entire period of family interaction as do macroanalytic codes, mesoanalytic systems involve applying a summative evaluation of each participant's behavior during a set period of interaction. Thus, such systems allow for the analysis of transactional patterns in exchanges between parents and children while organizing those observations into higher order constructs. An example of a mesoanalytic system is Mahoney, Coffield, Lewis, and Lashley's (2001) Meso-Analytic Behavioral Rating System for Family Interactions, which was designed to assess both parent and child contributions to triadic interactions. Parent rating scales include hostility, involvement, and coercive control, whereas child rating scales include overt noncompliance and prosocial behavior.

Dimensions of Family Interaction

Coding systems also differ in the strategic choices they make regarding the underlying dimensions of family relationships to be assessed. Copeland and White (1991) offered a musical metaphor for these dimensions. The tune is represented by the structure of the interaction (e.g., timing, sequencing, order of influence), the lyrics involve the content of what is said (e.g., commands versus questions), and the sentiment refers to the affective tone of the interaction (e.g., warmth, playfulness, tension). Assaying each of these dimensions requires a different kind of coding scheme and each provides information that would be difficult to infer from the others. Another dimension on which coding systems differ might be referred to as bandwidth, that is, how narrowly or broadly defined are the set of constructs they attempt to capture. Some are quite wide-ranging and attempt to assess a wide array of family behaviors, such as the Iowa Family Interaction Rating Scales (Melby & Conger, 2001), which include 60 behavioral rating scales divided into three categories (general interaction, parenting, and problem solving) each of which includes one or more measurements across four levels of the family (individual, dyadic interaction, dyadic relationship, and group interaction). In contrast, other coding systems are very specific to measuring a single construct, such as the Repair Attempts Observational Coding System (Tabares, Driver, & Gottman, 2004) designed to capture intimate partners' efforts to heal riffs in their relationship during an interaction.

Although numerous coding systems have been developed for assessing family interactions, one particularly well-validated and widely used measure that is specifically designed to measure dimensions associated with family systems theory is the System for Coding Interactions and Family Functioning (SCIFF; Lindahl & Malik, 2001). Global whole-family codes are provided for Cohesiveness (e.g., mutual appreciation of one another while working toward a common goal versus interpersonal distance and awkwardness). In addition, each parent is rated on a scale of Triangulation, consistent with Minuchin's (1974) description of the parent who attempts to engage the child in providing support, sympathy, or to side with him or her against the other parent. Boundary formation comprises a separate rating of the extent to which families appear to have dysfunctional cross-generational alliances, assessing as to whether relationships are balanced (e.g., all family members are equally close or affectionate with one another) or demonstrate dyadic alliances (e.g., detouring, in which parents band together to control or blame the child; parent–child coalitions, in which one parent and child evidence an overly close relationship that excludes the other parent; or else children actively side with one parent against the other). Last, a lack of any strong boundaries or alliances in the family is coded as evidence of disengagement.

Setting, Task, and Participant Reactivity

One potential limit to the generalizability and even validity of observations is that family members may react in various ways to being observed. Although this may be less of a concern in the present day, when many young adults grew up with video cameras ubiquitous in their daily lives, family observations nonetheless typically are conducted in contexts in which family members know they are being watched and evaluated by the investigators. Family members may react generally, such as by becoming self-conscious or stilted, or may react in specific ways, such as by attempting to disguise their typical interactional styles to make a favorable impression. To the somewhat morbid advantage of researchers, however, it has been suggested that families are better at faking bad than at faking good; for example, those who do not know how to resolve conflicts successfully find it difficult to simulate doing so (Copeland & White, 1991). A number of strategies

can be implemented to reduce family members' reactivity, including conducting observations under more naturalistic conditions, such as in the home, assigning them tasks that are engaging as well as realistic (e.g., to talk about an actual episode of conflict they recently experienced rather than attempting to generate a mock conflict in the lab), and to sample behavior over the course of multiple interactions.

The setting and task chosen by the investigator also bound generalizability. For example, perhaps as a function of participant reactivity, some family investigators suggest that there may be systematic differences between family interactions elicited in the home versus the laboratory. In particular, family members may be more likely to display conflict and negativity in the home setting than in the lab; however, little empirical attention has been given to this issue, and, as Brody and Stoneman (1990) cautioned, we are in danger of "confus[ing] the occurrence of behavior with its representativeness" (p. 208). Similarly, the choice of task assigned to the family during the interaction is a crucial one given the capacity of various kinds of tasks to elicit specific family behaviors and interactional patterns. Structured tasks offer the advantage of directing the family to engage in the kinds of interactions most likely to relate to the investigator's constructs of interest; for example, asking parents to discuss a parenting disagreement in the presence of the child might be an effective strategy to elicit triangulation, whereas assigning the family the task of planning a vacation may better draw out themes of overall warmth and cohesion, and challenging the family to solve a puzzle together might be a preferred way to assess decision making and cooperativeness. Consequently, the range of tasks assigned in family observational studies is vast, including free play, storytelling, problem solving, sharing a meal, resolving a conflict, jointly completing a questionnaire, and others. Guided by the purposes of their research, investigators may choose markedly different kinds of interactions to code, and thus the results of these research projects may be difficult to compare or summarize across.

The Contribution of the Child to Family Interaction

An important feature of the transactional perspective underlying the family systems model is the idea that children not only receive or react to parental behaviors but also are active agents in driving the family process (Cummings & Schermerhorn, 2003; Kerig, 2001b). However, first we must consider the question of who is considered to be a child in family observational research. As noted earlier, the study of some constructs in the family research literature has been accompanied by careful attention to how they are evidenced differently across different ages; for example, the developmentally attuned measures developed by Shaffer and Sroufe (2005) to assess patterns of boundary dissolution across the lifecycle. In addition, some observational coding systems are thoughtful about providing coders with guidance about how to rate behaviors in the context of their different expressions across different ages (e.g., Florsheim & Benjamin, 2001; Robbins, Hervis, Mitrani, & Szapocznik, 2001). Others include separate coding categories for adults and children, designed to be sensitive to the different ways they contribute to family process (e.g., Lindahl & Malik, 2001). But, in the wider pantheon of family coding schemes, it is surprising the extent to which this kind of attention to development is the exception rather than the rule. Often, the child is not contextualized by age but rather is construed as an actor whose behavior has the same range and thus can be coded with the same categories, across ages and even into adulthood. As suggested previously, with increasing cognitive, emotional, and interpersonal skills and capacities across age, we would expect that children are able to become increasingly agentic and impactful contributors to the tone, lyrics, and rhythms of the family music.

Moreover, a valuable distinction may be that between family processes that are *child-driven* versus *parent-driven* (Kerig, 2001a, 2001b). For example, triangulation of the child in interparental conflict that derives from parents' efforts to place their child in the middle might have distinctly different ramifications for the family system and child outcomes compared with the family in which the child volunteers for that role. Similarly, there may be different contexts that promote, and different meanings for family members regarding, boundary violations such as parentification that arise from adults turning to their children for care as opposed to children attempting to care for their parents (Kerig, 2005). The boundaries between these processes may be difficult to discern, however, given that one may well grow out of the other (i.e., children who have been trained to respond to parents' bids for nurturing may begin anticipating those needs and offering such care unbidden), and role complementarity may be such that, in some families, the child-like parent and the parent-like child transact with apparent seamlessness.

There are a number of other ways children can play a role in the choreography of the family system. One is through characteristics they bring to the interaction that are sources of either resilience or vulnerability for the child, the marriage, the sibling subsystem, or the family as a whole. For example, there is some research to suggest that parents of temperamentally difficult infants are more

susceptible to the negative effects of a strained coparenting relationship (McHale et al., 2004). In contrast, children with a higher capacity for physiological self-regulation might be relatively buffered from problematic family processes. In this regard, Leary and Katz's (2004) observations showed that hostile-withdrawn coparenting was not predictive of poor peer relations for those children with high vagal tone who were able to regulate their own emotional state. Considered transactionally, physiologically well-regulated children may be less likely than their peers to engage in negative interactions with others outside the home that, in turn, might exacerbate family conflict (e.g., if parents are called on to respond—or conflict with one another over how best to respond—to a complaint from school about a child's fighting with peers). In contrast, children with characteristics that represent valued family attributes (e.g., academic prowess, social skill, athleticism) might bring sources of esteem back to the family from extrafamilial contexts (e.g., positive reports from teachers, sporting or academic accolades, social contacts with prosocial peers and their parents), which buffer not only the child but also the family itself from discord, thereby conferring upon all family members a more harmonious home life (Kerig et al., 2012; Werner & Smith, 2001).

Analytic Strategies in Family Observational Research

As outlined by Sayers and McGrath (2004), the questions researchers seek to answer with their data, as well as the kinds of data they gather, lend themselves to different analytic strategies. For example, some questions may rest on the frequencies with which behaviors are demonstrated, either in terms of base rates, proportions, or durations. An example might be a study examining whether families living in violent communities evidence higher levels of interactional strategies designed to constrain autonomy among their members than do those in more affluent areas. A second kind of question concerns simple sequences in behavior; an example here might be a study investigating, in distressed couples characterized by a demand–withdraw pattern of behavior, whether children are most likely to reciprocate the affect of the demanding parent. Analyses of these kinds of lag-sequential interactions require the use of strategies designed to test conditional probabilities: given that X has just occurred, what is the likelihood of Y rather than Z? Yule's Q is a commonly used statistic to estimate such probabilities based on an odds ratio. For example, in a study of parent–child discourse mentioned earlier, Kerig, Cowan, and Cowan (1993) used Yule's Q to estimate the likelihood that, given a daughter had made an assertion, her maritally distressed father would respond with a positive or negative statement.

A third question requires examining more complex series of events and analyzing data gathered in series over a longer time frame, such as a study examining whether repeated detriangulating maneuvers by a third-party shift in the family structure over time to one with more balanced alliances. This kind of question requires the use of log-linear data analytic methods that enlarge upon the logic of the simpler transitional probability represented by Yule's Q. One such log-linear analysis is a logit model which allows for the prediction of a particular event of interest from other events during a family interaction; for example, whether children's attempts to intervene in their parents' conflicts are met with encouragement or discouragement depending on whether the member of the dyad raising the conflictual issue is the mother or the father. In turn, time series analyses are used to analyze observations involving many points of data collected virtually continuously over time. Time series also can be used to test models regarding who is driving the interaction by looking for asymmetries in the probabilities of one partner's behavior predicting the other—for example, whether family interactions become increasingly negative as fathers, as opposed to mothers, attempt to triangulate children in interparental conflicts. In addition, an interrupted time-series analysis can be used to investigate the impact on the interaction of a low-frequency but notable event, such as a threat of violence by a family member, or a therapeutic intervention by a therapist.

Kashy and Kenny's (2000) actor–partner interdependence model (APIM) also can be extended to the study of family groups beyond the dyad. APIM allows the investigator to assess the extent to which each actor in the interaction is affected by, and in turn affects, the partner. In addition, the model accounts for a group effect beyond the individual or dyadic, which in family research would be represented by the effects on all members of being member of the family. For example, a dyadic actor effect would indicate that an individual's score changes depending on whether a given family member participates in the interaction (e.g., does a son's contact-seeking behavior toward his mother decrease when his father is present in the room). In turn, a dyadic partner effect would refer to whether the presence of a given dyad in the family influences the behavior of others in the group (e.g., when both parents in a maritally distressed couple are present, do all family members demonstrate a decrease in proximity seeking).

Although the study of sequences and transactional patterns in family process data has generally relied on the

use of lagged sequential models, underlying such models is an assumption of linearity which might not accurately describe the functioning of more complex systems.

> A challenging alternative might be to assume that the behaviors of interest are part of complex systems and are not linear (i.e., although topographically similar, the same behaviors function differently as the interaction progresses). What if coded elements are not additive (i.e., unfold linearly as assumed in sequential analysis) but rather follow properties of complex adaptive systems ... Chief among the defining properties of dynamic systems is that change can occur not only not linearly but catastrophically; a small input can disrupt an ongoing process in a major (disproportionate), nonlinear way (Weiss & Heyman, 2004, pp. 22–23).

Dynamic Systems Approaches

One of the most exciting developments in the integration of family systems research with developmental psychopathology is the contribution of dynamic systems (DS) theory. As defined by Granic and Hollenstein (2003), dynamic systems models in developmental psychopathology provide a metatheoretical framework for understanding how systems emerge, stabilize, form, and change as a function of their own internal feedback processes. Not only has DS theory been conceptually elaborated in ways that have increased its dissemination across fields of psychological research, but new statistical methods also have been developed that enable researchers to create and test dynamic models in family research. Thus, analyses of systems change require mathematical modeling of nonlinear parameters that reflect patterns of change. As outlined in Fischer, van Geert, and Mascolo's chapter in this volume, dynamic systems models allow for the analysis of complex patterns of behavior as these emerge and are shaped by each partner, and the relationship between them, over time. An essential construct in DS is that of *attractors*, patterns of behavior that have a pulling effect on the system, restraining it and limiting the degrees of freedom available for variation. Family members "influence each other in transactional fashion: the daily interactive experiences of mother and child lead, over time, to the emergence of relatively few but enduring behavioral patterns, or order parameters, that are characteristic of their relationship. In turn, these patterns modulate their ongoing interactions, channeling them to approximate what they have been in the past, thereby maintaining the relationship across time" (Dumas, Lemay, & Dauwalder, 2001, p. 318). One of the ways these patterns coalesce is through the *coupling* of interactional partners' emotions, appraisals, and the behavior by which affect and cognition are linked; thus, established patterns become intricately interwoven into the thoughts, feelings, and actions of each participant in the relationship. The result is *rigidity* that results in family members falling into a repetitive and narrowly defined set of behavioral repertoires with one another, as well as others outside the system (Granic & Patterson, 2006). Moreover, these patterns tend toward increasing *escalation* over time. For example, past experience with negative transactions leads family members to become sensitized to even subtle signs that the cycle is beginning (e.g., a huff of exasperation, a roll of the eyes) and to respond to these mild provocations with a level of intensity that matches the increasingly hostile exchange they anticipate coming.

Empirical evidence in support of this dynamic analytic framework is offered by Dumas et al. (2001) in their study comparing mother–child dyadic interactions in clinically distressed and normative families. Coders rated each minute of mother–child interaction to assess for maternal controlling, positive, and aversive behaviors as well as child compliance, noncompliance, positive, and aversive behaviors. Using both quantitative and graphical analyses, the investigators examined phase transitions in the interactions between dyads in the two groups. The patterns that emerged evidenced that, amongst clinical families only, mothers and children repeatedly ended up in aversive cycles in which mothers commanded and children refused to comply, even when mothers initiated the interaction in positive ways. Thus, the coercive family processes that had come to organize the system of relationships wove a sticky web from which it was difficult for mothers and children to extricate themselves. Figure 13.2 displays these findings in a four-variable Karnaugh map, which represents the frequency with which interactional partners engage in each of the various possible transitions in behavior. This map indicates that, among clinically referred families only, mothers and children tended to engage in repeated cycles involving maternal control attempts that were followed by child noncompliance (indicated by the cell labeled configuration number 8). "In other words, in average dyads, the major attractor, besides Configuration 0, was one in which children tended to respond positively to their mothers' requests and instructions, but in referred dyads, it was one in which mothers tended to 'spin their wheels' in fruitless attempts to get their children to comply" (p. 328).

To date, the majority of the work utilizing DS in family systems research has focused on dyadic exchanges between parents and children. However, an important contribution to our conceptualization of dynamic systems from a whole-family perspective is offered by Schermerhorn

and Cummings (2008) in their proposal for a model of *transactional family dynamics* (Figure 13.3).

> Transactional family dynamics refers to the myriad ways in which family members influence one another, that is, mutual influence processes within families. For example, these processes may include complex patterns of influence in interparental, father–child, mother–child, and sibling relationships. Notably, our interest is in transactional processes—not unidirectional processes—that is, influence processes continuously moving in both directions over time (Schermerhorn & Cummings, 2008, p. 188).

Using this model, Schermerhorn, Cummings, and Davies (2008) demonstrated dynamic links among children's representations of interparental, mother–child, and father–child relationships over time in a three-year longitudinal investigation of kindergarten-age children in a community sample. Structural equation modeling with autoregressive paths showed that children's representations of the destructiveness of interparental conflict predicted increased sensitization and reactivity to those conflicts, which in turn were predictive of children's representations of the security of their relationships with mothers and fathers. Moreover, evidence of transactional processes involving children's impact on the family system emerged from this laboratory's investigation of the interrelations among interparental conflict, child behavior, and child adjustment. Over a three-year period, Schermerhorn, Cummings, DeCarlo, and Davies (2007) found that interparental discord was predictive of child negative emotional reactivity, which in turn predicted behavioral reactivity. Moreover, when children's behavioral reactions took the form of agentic behavior (e.g., trying to distract, comfort,

or help parents resolve their dispute), interparental conflict tended to decrease whereas, when children's behavioral reactions took the form of dysregulated behavior, both interparental conflict and child maladjustment tended to increase.

EMPIRICAL INVESTIGATIONS OF FAMILY SYSTEMS CONSTRUCTS

Global Family Qualities

Cohesion

One of the most well-studied whole-family constructs is that of family cohesion, the idea that family members experience a positive sense of emotional bond and unity. Along with flexibility and communication, cohesion is one of the key dimensions of the Circumplex model of marital and family systems (Olson, Sprenkle, & Russell, 1979). Implicit in the construct is that cohesion is uniform across the dyads and triads in the family and, therefore, that there is an absence of the kinds of unbalanced coalitions or triangles that are associated with pathological family structure in structural family theory (Minuchin, 1974). A large body of research has confirmed the positive benefits of living in a cohesive family system for both adults and children (Olson, 2011). For example, Favez et al. (2012) found that observed family cohesion, defined by consistently balanced alliances and an absence of triangulation, was associated with more positive adaptation of children over the course of five years, from infancy to early school age. Leary and Katz (2004) similarly found that observational ratings of family cohesion (defined as adaptability, cohesiveness, and playfulness) when children were in preschool were predictive of more positive relationships with peers in middle childhood.

Moreover, family cohesion appears to provide a buffer for children against the negative impact of other family stressors, such as interparental conflict (Davies, Harold, Goeke-Morey, & Cummings, 2002). Further refining our understanding of these interrelations among family processes in a multiethnic framework, Lindahl and Malik (1999) found that family cohesion was a more powerful buffer against the negative effects of exposure to interparental conflict for children in Hispanic American versus European American families. Subsequently, Lindahl, Malik, Kaczynski, and Simons (2004) again showed that observed family cohesion and intergenerational coalition formation mediated the association between interparental conflict and child adjustment in ways that were moderated by ethnicity. Low family cohesion and cross-generational coalitions were more strongly associated with internalizing problems for children in European families than those in Hispanic families, perhaps as a function of the extended family networks that might have helped to buffer Hispanic children from the stresses of their parents' marriage. In one of the few studies to investigate the interrelationship among these family processes in a sequential manner, Kitzmann (2000) demonstrated that, following a marital conflict discussion, families displayed observable reductions in cohesion and concomitant increases in unbalanced alliances during triadic interactions.

Hierarchical Organization

Also consistent with both structural and strategic family theory is the idea that adaptive family structure requires a hierarchical organization in which the generational boundaries are respected in ways that place parents clearly in an executive position in the family (Haley, 1976; Minuchin & Fishman, 1975). In turn, lack of role clarity and organization is characteristic of clinically distressed families, such as those in which children are maltreated (Howes, Cicchetti, Toth, & Rogosch, 2000). Although a number of prior cross-sectional studies had found that violations of hierarchy are associated with childhood externalizing problems, Shaw, Criss, Schonberg, and Beck (2004) made an important contribution to this literature by examining the developmental unfolding of hierarchical structure and child behavior problems from infancy to middle childhood. The investigators used a combination of maternal report (e.g., "If you ask your child to do something and he does not do it, how often do you give up trying to get him to do it?"), observational coding (e.g., a 9-point rating of level of intergenerational boundaries), and interviewer judgment (e.g., "Parent has good control of the child") to create an index of family hierarchy. Structural equation modeling showed that lower levels of family hierarchical organization were associated with higher levels of child conduct problems over the course of development. Again, however, these associations may be tempered by culture. Lindahl and Malik (1999) found that a strongly hierarchical family structure was associated with externalizing among European American youth, whereas its opposite (a lax, permissive style) was predictive of externalizing among Hispanic youth.

Family Structural Types

Although many studies have examined triangulating processes in the family, fewer have attempted to validate the structural family (Minuchin, 1974) typology specifying the distinct and discriminable forms that rigid triangles might

take in the family system. One such investigation (Kerig, 1995) elicited self-reports of perceived family structure from mothers, fathers, and children using a revised version of Cooper, Holman, and Braithwaite's (1983) Family Cohesion Index (Figure 13.4). Although family members agreed only modestly with one another, each individual's depiction of the family structure was meaningfully related to his or her ratings of other aspects of family functioning. Specifically, parents and children in triangulated relationships gave the highest ratings of interparental conflict and negative affect in family interactions. In contrast, children in families typologized as detouring were highest in self-blame and internalizing problems, whereas children in disengaged families were rated by their parents as highest in externalizing.

Subsequently, Davies, Cummings, and Winter (2004) tested whether this typology could be confirmed in a study of school-age children and their parents followed over a one-year period. The investigators used cluster analyses to create four family profiles, based on observed and self-report measures of interparental, coparenting, and parenting behaviors. *Cohesive* families were defined as those high in interparental affection and acceptance of children and low in interparental hostility, coparenting disagreements, inconsistent discipline, and psychological control of children. *Enmeshed* families, in contrast, combined moderate levels of interparental affection and parental acceptance with very high levels of interparental hostility, coparenting disagreements, inconsistent discipline, and psychological control. *Disengaged* families, in turn, evidenced very low levels of interparental affection and parental acceptance along with moderately high levels of the other variables. Finally, a group labeled *adequate* was identified that was like the cohesive families in all respects except for showing high levels of psychologically controlling behaviors. Structural equation modeling demonstrated that family disengagement was linked to children's emotional insecurity in the family system, which in turn predicted elevations in child internalizing symptoms over the course of one year. In contrast, family enmeshment was predictive of increased child internalizing and externalizing, an association that also was mediated by children's emotional insecurity. This study provides a nice illustration of the idea that dysfunction in one dyad in the family system—such as interparental conflict—may have different implications depending on the larger context of the organization of the family system. In particular, the diffuse boundaries of enmeshed families appear to create a context in which the spillover of family tensions is exacerbated and potentiates their negative impact on child development.

In turn, using observational and qualitative methods, Fivaz-Depeursinge, Lopes, Python, and Favez (2009) also found evidence for three of Minuchin's rigid triangular types with families of toddlers: *detouring*, characterized by parents shifting their tension onto the child, to which children tended to respond by adopting an overly engaged role-reversed style; *triangulation*, in which parents each vied for the child's affection and the child attempted to cope with the strain by either withdrawing or playing the role of go-between; or the binding of the child into a *coalition* with one parent. Finally, focusing specifically

on the latter family process, Lindahl and Malik (1999) also used observational coding to show that coalitions between one parent and the child that excluded the other parent were associated with externalizing problems in an ethnically diverse sample of families.

Spillover of Marriage onto Parenting and Family Process

Although a rich literature points to ways marital conflict spills over onto dyadic parent–child relationships, a smaller body of work has been devoted to the interactive contributions of interparental conflict, parenting, and whole-family processes (Buehler & Gerard, 2002). The majority of these studies have examined parent–child dyadic interaction within the triad, however, rather than whole-family processes. Among the studies that have led the field in this regard, Katz and Gottman (1996) demonstrated that observed marital hostility contributed to boys' peer aggression through the mediating factor of parental rejection during triadic family interactions. In turn, Gordis, Margolin, and John (1997) and Margolin, Gordis, and John (2001) found that marital hostility and aggression were associated with increased parenting hostility during observed family interactions, which in turn was associated with boys' withdrawal, anxiety, and behavior problems.

Siblings

A rich literature has emerged suggesting that sibling relationships play a significant role in child development (Buist, Deković, & Prinzie, 2012), one that can be disrupted by other family processes such as interparental conflict (Dunn & Davies, 2001; Rinaldi & Howe, 2003). However, little of the research to date on family systems theory has included siblings, an unfortunate yet understandable omission given the difficulty of coordinating so many different data points and sources of influence in family interactional research. In one suggestive study, Grych, Raynor, and Fosco (2004) found that sibling empathy and similarity did not help to buffer children from perceived threat regarding interparental conflict; a possible explanation for this finding is that sibling closeness reflects an overall climate of diffuse boundaries in the family, which fosters carryover of emotional reactivity from one relationship to the other.

Triangulation

One of the challenges to integrating the research that has been carried out on family systemic constructs is that they have been defined and operationalized in diverse ways. For example, as we just reviewed, the term triangulation in Minuchin's (1974) original usage referred to only one of several rigid triadic forms in the family, whereas in current parlance it tends to be used as the superordinate construct under which various pathological structural processes are subsumed. As originally defined by Minuchin (1974), triangulation referred to a family form in which parents competed with one another to establish an alliance with the child, consistent with the construct of competitive coparenting (McHale, 1997) or, in its extreme form, parental alienation when the other parent is actively excluded, estranged, or vilified (Johnston, Walters, & Olesen, 2005).

In turn, a related but distinguishable use of the term triangulation focuses on the child's perspective of feeling caught in the middle or being entangled in a loyalty conflict (e.g., Buchanan & Heiges, 2001; Fosco & Grych, 2008; Grych, Seid, & Fincham, 1992). Another related but not identical construct is that of child involvement in parents' quarrels, whether observed (e.g., Davies & Cummings, 1998), reported by parents (e.g., Kerig, 1996) or reported by children (e.g., O'Brien, Bahadur, Gee, Balto, & Erber, 1997). Again, although not identical constructs, these are related in that children who feel caught in a loyalty conflict might well feel compelled to intervene in their parents' conflicts, as evidenced empirically (Grych & Fincham, 1993). Nonetheless, from a systemic perspective, the behavior of intervening also may arise from a different family process, such as the formation of a parent–child coalition that leads a child to feel obligated to step into the fray on behalf of the parent with whom she or he has aligned. As noted previously, child involvement also might be initiated either by parents (e.g., parents who enlist the child as a "co-combatant") or by children (e.g., children who attempt to intercede in their parents' quarrels, even if unbidden) (Kerig, 2001a, 2001b). Triangulation also has been defined as inappropriate child elevation to the role of fellow-adult and decision-maker in the family which might, but might not, take the form of intervening in their conflicts, and thus which might blend into other boundary dissolution-related constructs such as parentification or adultification (Kerig, 2005).

The interrelatednesss of these constructs is illustrated by the literature that has emerged investigating children's involvement in interparental conflict, as variously defined. In studies deriving from the cognitive contextual model (Grych & Fincham, 1990), children's perceptions that they are implicated in their parents' quarrels are associated with distress and maladaptation (e.g., Grych, Harold, & Miles, 2003; Grych, Raynor, & Fosco, 2004; Kerig, 1998). By the same token, emotional security theory (Davies & Cummings, 1994) accurately predicts that children's

anxiety about threats to the security of the family system will motivate them to intervene when their parents argue (Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006). Studies also have shown that interparental conflict increases the likelihood that parents will form cross-generational coalitions with children and involve them in discussion of marital issues (Christensen & Margolin, 1988; Lindahl, Clements, & Markman, 1997). In turn, children who become involved in coalitions characterized by siding with the father against the mother during observed family interaction are at increased risk for the development of externalizing problems (Davis, Hops, Alpert, & Sheeber, 1998).

In an important contribution to this literature, Lindahl and colleagues (2004) demonstrated the interrelations among interparental discord, whole-family processes, and child adjustment. In particular, these authors found in a multi-ethnic sample that a latent construct of family functioning (composed of observed cohesion, triangulation, and cross-generational boundary violations), fully mediated the association between couple conflict and child behavior problems. This study points to the value of understanding the family as an organized system in which the parts are inextricably interrelated with one another. As the authors note, "In the language of structural family systems theory, conflicts that erode the solidity of the marital subsystem can create fault lines in the family structure, affecting dyadic, triadic, and whole-family subsystem relationships as well as child functioning" (p. 625).

Dimensions Underlying Triangulation

As noted already, however, the various ways triangulation has been defined and operationalized complicate our ability to integrate and learn from this literature. As a way of untangling these skeins, we might consider five underlying dimensions along which these various definitions of triangulation can be distinguished. One helpful way of thinking about the different ways these constructs have been construed across studies is a distinction between *process* (e.g., a parent attempts to enlist the child as an ally against the other parent) and *outcome* (e.g., a parent and child have formed an entrenched alliance that excludes the other parent). For example, some studies focus on capturing the ongoing dynamics in the family (e.g., parents vying with one another to establish a special relationship with the child, as in competitive coparenting), whereas others assess the family structures, or outcomes, which may arise from those processes (e.g., the establishment of a parent–child coalition as a fait accompli). A good reason for differentiating between process and outcome is that the same process might lead to different outcomes, either across families or within the same family. Consider, for example, the possibility that in a family characterized by marital conflict, a mother succeeds in forming a cross-generational alliance with her adolescent son, perhaps fueled by concomitant negativity or disengagement in the father-son relationship, whereas the preschool-age daughter's intensified security needs lead her to experience a loyalty conflict upon feeling herself to be forced to choose between her parents. We can complicate the picture even further by proposing a school-age son who acts out in ways that serve to detour around the parents' conflicts and, at least briefly and transiently, unite them in the task of responding to his misbehavior. By the same token, parent- and child-driven processes may lead to the same or to different outcomes. Knowing that the adolescent son in the family above intervenes in interparental quarrels in order to defend his mother's point of view does not inherently tell us whether his mother has encouraged him to take such a role, versus whether he has mistakenly construed protecting her as his duty. Similarly, the daughter's feeling of being caught in the middle might arise from a misplaced belief that it is her responsibility to mediate between her parents even though her parents actively discourage this.

A second dimension discriminating the ways these constructs have been construed is whether they are measures of *behavior* (e.g., a child attempts to intervene in her parents' quarrels) versus *perceptions* (e.g., a child feels caught in the middle between her parents). For example, some operationalizations of triangulation involve observed or reported actions (e.g., "When my parents argue, my mother tries to get me to side with my father") whereas others focus on the child's felt experience (e.g., "I feel caught in the middle when my parents argue; I feel it is my job to try to help my parents get along with each other when they fight"). These have been shown to be correlated in that children whose parents entangle them in their conflicts are those most likely to feel responsible for solving them (Grych et al., 2004), yet one cannot be presumed to be caused by the other. Children's egocentric perspective may inflate their sense of responsibility for, and beliefs that they have control over interparental conflicts even when parents do not encourage them to believe so (Kerig, 1998).

In this regard, as noted previously, a third dimension underlying triangulation is whether it is *child-driven* (e.g., a child steps in to defends her mother against her father) or *parent-driven* (e.g., a mother invites the child to join her in criticizing the father) (Kerig, 2001a, 2002b). As Grych et al. (2004) noted, however, there likely are transactional associations between these two processes. Although their study

established that children involved in cross-generational coalitions were vulnerable to feeling caught in the middle of their parents' conflicts, it also may well be the case that children's triangulation affects parent–child relationships, such as by drawing the child closer to one parent than the other. Thus, parents who engage children in unbalanced alliances may increase the likelihood that children become involved in interparental conflicts, which in turn may further disrupt family cohesion.

A fourth distinction worth considering is whether child involvement is *overt* (e.g., a child walks into the room and asks her quarreling parents to stop; parents ask a child to pick sides during their argument) or *covert* (e.g., a child knocks over the CD tower in the next room as a way of distracting her parents from their quarrel; parents express disparaging views about the other parent when engaging in one-to-one interactions with the child). A higher level of inference is needed to determine that the child's purpose in engaging in misbehavior is to intervene in the conflict, and this has seldom been queried directly (Kerig, 2001b).

Last, a little-studied dimension underlying these various forms of boundary violations is their *valence* (Kerig, Swanson, & Ward, 2012)—that is, whether they are conveyed in the context of a positive or negative emotional tone in the family. Sometimes the message is mixed; for example, Jacobvitz and colleagues (2004) point out that sweetness and coyness of seductive parenting often is accompanied by harsh and punitive behavior. But in other cases, a clearer discrimination can be made: for example, between hostile versus seductive spousification; between detouring processes that scapegoat a child versus parent–child coalitions that make that child special; or between psychological control that is demanding and critical versus warm and appreciative. For example, Rohner (1986) proposed that perceived parental warmth might potentiate the effects of intrusiveness by pulling the child even closer to the parent emotionally. Some evidence in support of this idea has emerged in studies showing that psychological control is most strongly associated with youth depression when perceived parental acceptance is high (Barber, Stolz, & Olson, 2005). Further, Kerig, Swanson, and Ward (2012) found specificity in the ways that emotional valence modified the association between psychological control and youths' mutuality of autonomy in intimate peer relationships. Youth whose intrusive parents were perceived as accepting were those most likely to develop imbalanced relationships in which they put others' needs before their own, whereas youth whose intrusive parents were perceived as rejecting were most likely to develop nonmutual relationships in which they put their own needs before those of others.

Again, a major shortcoming of the investigations of these constructs to date is how little research has investigated the larger family systems of interrelationships in order to examine how process or outcome, behavior or perceptions, child driven or parent driven, overt or covert, and positively or negatively valenced boundary violations between members of one subsystem of the family are influenced by and influence those among the other dyads and triads. Sibling relations have been neglected here too, in that siblings might provide support that helps to buffer a brother or sister who is triangulated between parents and yet also might play the role of active contributors who collude in the exclusion, scapegoating, or differential treatment of one another.

Coparenting Conflict and Family Process

The coparenting literature provides a number of examples of studies encompassing the interrelations among whole-family, interparental, and parent–child processes. The construct of coparenting follows clearly from the structural family model in which healthy family functioning requires that parents be united with one another, with clearly demarcated boundaries between their executive unit and those of the child subsystems. However, coparenting brings additional clarity to this picture by distinguishing the alliance that partners maintain related to the tasks of *parenting*, as distinct from their adult intimacy or marital relations (McHale, 1997). Thus, coparenting is inherently a triadic process in that it concerns how parents coordinate with one another in relation to the child. Further, through observing their parents interacting together as coparents, children glean important information about the quality of each parent's relationship with the child and with one another, about how relational partners coordinate with one another within the family system, and, fundamentally, about the intactness of the family and their security within it.

The evidence that the coparenting relationship has significant implications for child development is clear. Research has shown that coparenting warmth and cooperation are associated with positive marital and parent–child relationships as well as child well-being (McHale, Kuersten, & Lauretti, 1996). In contrast, hostile-competitive coparenting, as we have seen, represents a form of triangulation that has demonstrated negative effects for children, including internalizing and externalizing symptoms as assessed both contemporaneously (McConnell & Kerig, 2002) and longitudinally over the transition from preschool to schoolage (Leary & Katz, 2004; McHale & Rasmussen, 1998). Hostile-detached coparenting, in which parents

exhibit a combination of anger toward and withdrawal from one another, also has been associated with child maladaptation (Katz & Low, 2004; Katz & Woodin, 2002).

Moreover, McHale and Rasmussen (1998) explicitly investigated the links among interparental, coparenting, parent–child, and family-level processes in a study of mother-father-infant triads followed over the course of three years. In addition to obtaining self-reports of coparenting, family processes during triadic interactions were observed, including measures of coparenting, parent-to-child behavior, and total family warmth. These measures were summarized to create three factors: hostility-competitiveness (i.e., parent- vs. child-centeredness combined with a competitive coparenting relationships), family harmony (i.e., high warmth and coparenting support), and parenting discrepancy (i.e., high levels of discrepancy between ratings of each parents' warmth and investment with the infant). The results showed not only that these family process variables forecast child behavior problems over and above measures associated with marital quality, but that the coparental relationship was associated with specific aspects of family process for both husbands and wives. For example, men's reports of engaging in positive coparenting behaviors (e.g., showing affection to the spouse and child when the three are together) were related both to observed family warmth in infancy and fewer child behavior problems in preschool. In turn, mothers in families with observed negative processes in infancy were those most likely to disparage their husbands to their preschool-age children.

In turn, Katz and Low (2004) utilized a multimethod approach to investigate the combined and unique contributions of marital violence, coparenting, and whole-family processes as predictors of child adjustment. Their results showed that hostile-withdrawn coparenting behavior during triadic interactions accounted for the relationship between marital violence and children's internalizing problems while marital violence, coparenting and family-level processes also made independent contributions to predicting child maladjustment. Specifically, children in families whose interactions were characterized as fragmented (i.e., high in disengagement, parent-centered vs. child-centered balance of power, and expression of negative affect) were those most likely to demonstrate externalizing problems in peer and parental relationships.

A valuable next step in this research will be to more clearly explicate the interrelations among these dyadic, triadic, and family-level processes as they unfold over time. It will be of interest to discern to what extent, for example, whole-family dynamics such as warmth and child-centeredness might buffer children from negative effects of coparenting discrepancies. Similarly, it would be important to better understand how coparenting conflict might differentially impact the quality of mother-child and father-child relations in ways that, in turn, are reflected in changes in the overarching emotional quality of family life.

Boundary Dissolution

The literature on boundary dissolution as a concept in family systems theory dates back to its progenitors, and originates with the construct of *enmeshment*. The term enmeshment is used in two contexts regarding family systems: as a description of a form of dysfunction in the relationship between two family members, or as a description of the family system as a whole. The first derives from Bowen's ideas of the undifferentiated ego mass in which poor psychological boundaries between two family members creates a sense of psychological fusion that interferes with either one achieving individuation. The second usage refers back to Minuchin's (1974) structural perspective, in which families are characterized as having diffuse boundaries among all the members and thus as being, as a whole, enmeshed. Despite this distinction, either form of boundary dissolution—between members of a dyad or within in the entire family system—is perceived as increasing the likelihood of the involvement of third parties. In Bowen's model, such triangulation might serve a beneficial function for the dyad and the whole family system, whereas in Minuchin's perspective, third-party involvement is likely to be dysfunctional, particularly when the triangulation of a third family member requires her or him to cross generational boundaries. Thus, the boundaries between the concepts of triangulation and boundary dissolution are necessarily fuzzy, given their interrelatedness, while at the same time they have tended to spur separate programs of research and to be defined and operationalized differently by various researchers. For our present purposes here, of particular interest is the small but valuable body of research that has investigated boundary dissolution not only as a dyadic variable in the parent–child relationship, but as a dynamic in the context of the larger family system of relationships. In this regard, the literature on the interrelations of boundary dissolution and triangulation is particularly rich.

Boundary Dissolution from a Family Systems Perspective

Jacobvitz and colleagues (e.g., Hazen, Jacobvitz, & McFarland, 2005; Jacobvitz & Bush, 1996; Jacobvitz, Riggs, & Johnson, 1999; Jacobvitz & Sroufe, 1987) have

carried out a significant series of studies examining boundary dissolution in the context of both dyadic and triadic family interactions, in which they interweave the constructs of triangulation and boundaries by construing triangular processes as subsumed under the broader construct of boundary dissolution. For parents to engage in triangulating strategies, such as enlisting their child in a coalition, suggests a breakdown of intergenerational boundaries that also might emerge in other ways. For example, Jacobvitz, Hazen, Curran, and Hitchins (2004) observed mother–father–child triads when children were 2 years of age and coded the interactions for indications of patterns they subsumed under the rubric *enmeshment* in each parent–child dyad, operationalized as one parent turning to the child for caregiving (e.g., parentification of child) or intimacy (e.g., spousification) or to exclude the other parent (e.g., parent–child coalition), as well as one spouse's attempts to parentify the other. In addition, family interactions were coded for hostile (e.g., criticism, sarcasm), controlling (e.g., one family member dominating the others), disengaged (e.g., a lack of emotional connection between any two family members), and balanced patterns (e.g., families in which there is promotion of autonomy and emotional openness among all three members). Results of the study showed distinct patterns of child maladaptation associated longitudinally with each of these dimensions from ages 2 to 7. Blurred boundaries were associated with child depression, whereas controllingness and disengagement were predictive of child anxiety and depression; in turn, hostility predicted child attentional problems and somatic complaints. Gender differences also emerged, with enmeshed patterns differentially related to inattentiveness among boys and depression among girls.

The Effects of Relationships on Relationships: Parent–Child Boundary Dissolution in the Context of Interparental Conflict

As Margolin, Gordis, and Oliver (2004) pointed out, the maintenance of clear boundaries helps to protect the family from other negative processes, such as the spillover of marital tensions onto children. "When clear boundaries exist between the marital and the parent–child subsystem, spouses have their own separate adult relationship, and also are available to meet the needs of their children. Without clear boundaries, conflict from the marital relationship may intrude on the parent–child relationship and alter the nature of that relationship" (p. 754). Through the maintenance of boundaries, the diffusion of negative emotions in the family is constrained to one subsystem rather than upwelling into the "cloud of unpleasantness" (Patterson & Forgatch, 1987, p. 8) that often overshadows distressed families. In their observational research, as Margolin and colleagues (2004) hypothesized, families in which husbands were violent toward their wives were especially susceptible to the leakage of hostilities from the marital to the parent–child relationships, which was expressed in the form of reduced empathy by fathers and increased negative affect by mothers.

In the spirit of further investigating the interdependencies and interconnectedness of these constructs, Kerig and Swanson (2010) attempted to explicitly integrate triangulation and boundary dissolution in parent–child, interparental, and triadic family processes among a sample of emerging adults. A broader perspective on family boundaries suggests that interparental conflict may increase the likelihood that parents will turn toward, against, or away from children in a variety of ways, each of which involves the violation of emotional, psychological, or generational boundaries. In other words, although one way marital stress may spill over onto children is to involve children in the conflict, as triangulation is often defined, other family processes might arise which we would discern better by looking through the lenses of the boundary dissolution construct. Drawing upon a multidimensional model of boundary dissolution (Kerig, 2005), we focused on three facets of the construct for which evidence suggests the risk is greatest among families characterized by marital unhappiness or conflict: intrusiveness, hostile spousification, and parentification. Structural equation modeling showed that, among emerging adults, maternal intrusiveness, hostile spousification, and parentification all acted as mediators of the association between exposure to interparental conflict and poor adjustment. In turn, only paternal hostile spousification played such a mediational role, and its effects were specific to the development of externalizing problems, including relational aggression toward intimate partners.

GENDER DYNAMICS IN FAMILY PROCESS

Fathering and Spillover

As noted before, although long neglected in psychological research, fathering provides a unique source of influence on children's development that deserves recognition (Lamb, 2010). Some research on the spillover of marital conflict has suggested that fathering behavior is particularly vulnerable to the disruptive effects of an unhappy marriage. For example, similar to Katz and Gottman (1996), Lindahl

and Malik (1999) also found that marital conflict was more strongly associated with fathers' than with mothers' behavior during triadic family interactions, including observed withdrawal, rejection, and lack of support. One explanation proposed for these gender differences in parental behavior is that mothering is a more well-defined role in U.S. culture than is fathering, and therefore fathers are more likely than mothers to look toward their relationships with their spouses for models about how to engage emotionally with their children (Cowan & Cowan, 1992; McHale et al., 2004).

Variations in Family Processes Related to Child Gender

As noted by Cowan, Cowan, and Kerig (1993), in majority-culture heterosexual families, parents and children each come in two genders, as mothers, fathers, sons, and daughters. Attention therefore is warranted to how family dynamics might play out differently in the intersections between parent and children. However, the literature on gender differences in the effects of family process on parent–daughter and parent–son relationships is highly inconsistent (Davies & Lindsay, 2004). For example, among studies of gender differences associated with the effects of interparental conflict, some studies show differential impacts on mother and sons (e.g., Osborne & Fincham, 1996), fathers and daughters (e.g., Kerig, Cowan, & Cowan, 1993), or none of the above (Erel & Burman, 1995). Other studies have indicated that gender effects in discordant families are not specific to one gender but rather tend to affect other-sex dyads in general (Cox, Paley, & Harter, 2001). For example, Kerig and Swanson (2010) showed via path analysis that interparental discord predicted denigration of the spouse's sex role characteristics, which was associated with denigration of those characteristics in the child of the same sex as the spouse and, in turn, with child internalizing problems. However, it is likely that these dynamics do not emerge as gross main effects associated with gender across all families but rather are qualified by a number of other variables, including child age and cultural variability in family attitudes and practices related to gender roles. Therefore, the more apt question may be not whether, for example, mother–son relationships are more sensitive to the negative effects of interparental conflict in all families but rather when mother–son relationships are disrupted what are the larger family dynamics that account for disruption to that subsystem, and what then are the specific consequences for child development?

One suggestion that has received some support is that daughters may be more likely than sons to feel, and to succumb to, the pull to become involved in intergenerational boundary violations, whether overtly (e.g., as mediators) or covertly (e.g., as worriers who feel responsible for caring for their emotionally distressed parents; Kerig, Fedorowicz, Brown, Patenaude, & Warren, 1998). Gender socialization theory would predict that girls' interpersonal orientation and propensity to tend and befriend would increase their sense of responsibility for maintaining the emotional harmony in the home generally, but as Davies and Lindsay (2004) pointed out, these concerns are intensified during adolescence when gender role consolidation emerges as an important stage-salient task. Adolescence also may be a sensitive period for boundary violations specifically in the mother–daughter relationship. The literature on depression in particular points toward a special sensitivity to their mothers' affect that is exhibited by girls, and this may well intensify in the teenage years (Sheeber, Davis, & Hops, 2002). Not only may adolescent daughters' increasing cognitive and interpersonal capacities lead them to feel obligated or even equipped to take on the burden of caring for mothers who are depressed or maritally distressed, but unhappy mothers also may tend to perceive their nearly adult daughters as potential sources of companionship, solace, and emotional support (e.g., Jacobvitz & Bush, 1996). As has been pointed out, although daughters and mothers may both report finding such special bonds to be gratifying, and they even may be associated with high levels of apparent competence, there may be hidden costs related to the burden of providing friendship or parenting to a parent (Hetherington, 2003) and being a pleasing child at the expense of one's own childhood (Koslowska, 2001).

In turn, although again not entirely consistent across the literature, is the suggestion that family processes might differ when the child under study is a boy. For example, McHale (1995) found that, in maritally conflictual families, parents of sons were more likely to engage in hostile-competitive coparenting, each vying for an alliance with the child, whereas fathers of daughters were more likely to withdraw from the interaction. In contrast, Jouriles and Norwood (1995) found evidence that sons of maritally distressed parents were more likely than daughters to be involved in scapegoating or detouring patterns in which they were subject to hostility from both parents, which may have been accounted for by boys' tendency to demonstrate externalizing behavior problems in reaction to interparental conflict.

TOWARD THE FUTURE: GROWTH POINTS FOR DEVELOPMENTAL PSYCHOPATHOLOGY FROM A FAMILY SYSTEMS PERSPECTIVE

Incorporation of Biological Processes into Research on Family Systems

Although not reflected in classical family systems theory, modern systemic perspectives increasingly derive from the overarching biopsychosocial perspective shared by developmental psychopathology. In the biopsychosocial perspective, childhood adaptation and maladaptation are viewed as being a function of complex interactions among the individual's psychological and biological functioning, her or his stage of cognitive, interpersonal, and emotional development, the psychological and biological contributions of the family system in which that development takes place, and the larger societal context that shapes and constrains family members' responses to one another. "The biopsychosocial model assumes that illness in one family member affects the psychological health and relationships of other members, and, in turn, that the reactions of these members affect the functioning of the person with the illness" (Miklowitz, 2004, p. 669). The same might also be said for individual characteristics that bring to the family table sources of protection, resilience, and psychological health.

A number of different biological approaches are beginning to be integrated into research on family systems, including work from behavioral genetic, molecular genetic, and epigenetic perspectives (Beach & Whisman, 2013). Gene–environment correlations (passive rGEs) have been found to be helpful in understanding the development of externalizing disorders (Harold et al., 2013) whereas evocative gene–environment associations (evocative rGEs) have been found to account for the associations between interparental conflict and parenting dysfunctions (Ulbright et al., 2013) as well as the effects of marital strain on children's behavior problems. Moreover, additional research in molecular genetics suggests that individual differences in specific genes, such as the oxytocin receptor and serotonin transporter genes, may increase the vulnerability of family members to the spillover of interparental conflict (Sturge-Apple, Cicchetti, Davies, & Suor, 2012). Gene by environment interactions also have emerged, such as among youth carrying sensitivity alleles who are exposed to nonsupportive family environments (Brody et al., 2013). Epigenetic approaches, in turn, have shown how exposure to psychosocial toxins, such as child sexual abuse, affects gene methylation in ways that "are attributable to environmental reprogramming of genetic machinery" (Beach & Whisman, 2013, p. 2) and thus has subsequent profound and distinct impacts on developmental psychopathology (Beach et al., 2013).

Particularly exciting for the further development and testing of family systemic ideas is work that incorporates biological processes into the study of transactional processes in the family. For example, Mills-Koonce and colleagues (2007) found evidence suggestive that child polymorphism in the dopamine receptor gene had an evocative effect on parents' behavior, eliciting lower levels of sensitivity, and also moderated the association between maternal sensitivity and the emergence of child depressive symptoms.

Methodological Advances with Relevance for Family Research

In addition to new advances in available methods to test dynamic systems models, a number of methodological and statistical advances hold promise for advancing family systems research (Davies & Cicchetti, 2004). These include pattern-based approaches such as latent class analysis (e.g., Belsky & Fearon, 2004); multilevel modeling allowing for the comparison and integration of multiple sources of information within and about the family (e.g., Meunier, Boyle, O'Connor, & Jenkins, 2013); multivariate models encompassing complex interactions of moderation, mediation, moderated mediation, and mediated moderation effects (e.g., Auerbach & Ho, 2012; Lou, Lalonde, & Giguère, 2012); and growth curve modeling to investigate complex patterns and variables influencing change over time (e.g., Herrenkohl, Kosterman, Hawkins, & Mason, 2009).

Translational Research

As noted previously, from its inception the family systems perspective has demonstrated an investment in designing treatments to intervene in troubled family processes. Therefore, there is no shortage of research that is translational in that it brings family systems out of the laboratory and into the clinical arena (Spoth, 2008). Most of this family therapy research, however, has been focused on answering the question of whether these interventions work and on examining mediators and moderators of how and why they work, rather striving to use these findings to advance our theoretical understanding of family processes. A highly desirable goal of translational research is that it be transactional

and bidirectional—that is, that findings gleaned from the implementation of real-world applications of systemic constructs be used to reflect back on, refine, and enhance the development of family theory (Cicchetti & Gunnar, 2009; O'Connor, 2013).

Although there is no shortage of translational family therapy outcome research that could be cited here, far more than could be done justice in the page limits of the present chapter, a premier example comes from the multiple generations of work testing and refining the Parent Management Training Oregon (PMTO) model originally sired by Gerald Patterson's (1982) research on coercive family processes. This work has spawned a set of highly effective family systems interventions and has provided a key ingredient that has been folded with good effect into other innovative and integrative evidence-based interventions across a wide variety of presenting problems, including aggressive children (e.g., Bank, Rains, & Forgatch, 2004; Patterson, Chamberlain, & Reid, 1982); adolescents at risk for substance use (Dishion, Patterson, & Kavanagh, 1992); foster families (Eddy, Whaley, & Chamberlain, 2004); stepparents (Forgatch, Patterson, DeGarmo, & Beldavs, 2009); and families in diverse cultures (e.g., Domenech Rodríguez, Baumann, & Schwartz, 2011; Ogden & Hagen, 2008; Tremblay et al., 1991). One of the ways the PTMO model exemplifies the ideals of translational research is the attention paid to testing the underlying theory regarding the purported mechanisms of the treatment's effects (e.g., Chamberlain, Fisher, & Moore, 2002; DeGarmo, Patterson, & Forgatch, 2004; Patterson, Forgatch, & DeGarmo, 2010) and, in an iterative process, to using the findings of this research to further refine the underlying theory and, in turn, to modify and improve the interventions themselves (Patterson, 2005). Such growth edges include findings suggesting the possible benefits of incorporating components into the treatment that address parental attributions for child behavior (Snyder, Cramer, Afrank, & Patterson, 2005), that increase emotion regulation capacities (Stoolmiller & Snyder, 2004), that address sibling influences (Bank, Rains, & Forgatch, 2004), and that reduce associations with deviant peers (DeGarmo & Forgatch, 2002). In addition, moreover, this research team continues to use the insights gathered from their observations of family process to advance both research and theory, particularly in regard to developing models and methods for understanding family processes as dynamical systems (Granic & Dishion, 2003; Granic & Patterson, 2006).

CONCLUDING THOUGHTS

As this review of the historical and contemporary literature suggests, the richness of the feast that developmental psychopathology offers us can only be enhanced by inviting family systems theory to the table. The fact that so many family systems models evolved into therapy training institutes divorced from the academic, science-driven enterprise likely contributed to some estrangement, but a growing interest in translational research may help to provide a basis for rapprochement. At its heart, the family systems perspective embraces many of the fundamental principles of developmental psychopathology, including holism, bidirectionality, and the organizational perspective, and expands them further by situating each child and caregiver in a broader context of interconnected, dynamic, and developing relationships. The ongoing integration of these models promises to provide a mutually nourishing and sustaining repast.

INTRODUCTION

The initiation of romantic involvement in adolescence is an emotionally charged event that can bring with it both pleasure and pain. Navigating the world of romance can be challenging for youth, and success at this critical developmental task has important implications for psychological well-being both in the moment and in the future. In addition, adolescents' psychological well-being has implications for how well they navigate their romantic lives. This chapter reviews the literature on the associations between psychopathology and youth romantic relationships and experiences.

To set the stage for understanding these associations, we first focus on developmental aspects of dating and romantic relationships during the period from early to late adolescence (young adulthood), giving attention to some of the positive and negative features of dating and romantic relationships. The remainder of the chapter focuses on associations with psychopathology, particularly internalizing and externalizing disorders on which the bulk of the research has been conducted, as well as key peer and family contexts in which psychopathology and skills for romantic relationships are developing. The chapter closes with discussions of methodological issues and implications for prevention and intervention.

ADOLESCENT/YOUNG ADULT ROMANTIC RELATIONSHIPS

Romantic relationships in adolescence/young adulthood are a normative aspect of development. The prevalence of romantic involvement in the United States rises across adolescence, with 36% of 13-year-olds, 53% of 15-year-olds, and 70% of 17-year-olds having had a romantic relationship (Carver, Joyner, & Udry, 2003). These relationships are generally short-lived but vary in length and get longer over time, with median durations being 5 months for ages 14 years and under, 8 months for ages 15 to 16 years,

and 21 months for ages 16 years and over (Carver et al., 2003). Both prevalence and length of involvement continue to grow into early adulthood, and over 70% of men and women in the United States marry for the first time between ages 25 to 40 years (Goodwin, McGill, & Chandra, 2009).

The rates of engagement in sexual intercourse among never-married U.S. adolescents show a similar developmental progression, although at a lower prevalence. Approximately 13% of girls and 15% of boys have engaged in sexual intercourse before age 15 years; by ages 15 to 17 years, approximately 30% of girls and 31% of boys have done so; and by ages 18 to 19 years the rates of sexual intercourse reach 69% of females and 64% of males (Abma, Martinez, Mosher, & Dawson, 2004). Not surprisingly for most adolescents, dating activities and romantic relationships provide the context for engaging in sexual activities (Kuttler & La Greca, 2004), although the rates of engaging in sexual activities outside a committed relationship, including hooking up, are high. Among sexually active adolescents, 60 to 70% have engaged in a hookup (Grello, Welsh, Harper, & Dickson, 2003; Manning, Giordano, & Longmore, 2006). Clearly, engaging in romantic relationships and sexual intercourse is normative, and typically these activities occur first in adolescence.

Initial research on heterosexual adolescent romantic development indicated that it progressed in a series of relatively predictable stages (e.g., Collins, Welsh, & Furman, 2009; Connolly & Goldberg, 1999; Furman & Wehner, 1994). In early adolescence, teens primarily engage in mixed-gender group interactions or group dating, which is characterized by affiliation and companionship rather than intimacy (Shulman & Scharf, 2000). As adolescence progresses, teens are more likely to engage in dyadic dating that involves higher levels of intimacy and closeness, deeper mutual feelings, and more extensive sexual activity (Connolly & Goldberg, 1999; Shulman & Scharf, 2000). By late adolescence, teens' romantic relationships also include caretaking and caregiving functions and begin to resemble what we typically think of as adult dyadic relationships (Furman & Wehner, 1994). Over time, youth spend more time with romantic partners and, by late adolescence, report greater closeness with their romantic partners than with their best friends or their parents (Kuttler & La Greca, 2004; Laursen, 1996). Of course, the specific timing of all of these behaviors is related to hormonal, social, and cultural conditions (Collins et al., 2009; Connolly, Craig, Goldberg, & Pepler, 2004; Laursen & Williams, 1997; Richards, Crowe, Larson, & Swarr, 1998), and given recent sociocultural shifts in adolescent romantic and sexual activity (e.g., Blais, Craig, Pepler, & Connolly, 2008), further examination of normative development will be warranted.

Adolescent romantic relationships are adaptive in numerous ways that may benefit development and emotional functioning. It is generally believed that romantic and sexual experiences in adolescence serve important functions with regard to identity development and the capacity for intimacy (see Collins, 2003; Furman & Shaffer, 2003). Indeed, the data support these ideas. Being in a romantic relationship of high quality is associated with positive affect, positive self-worth, and a sense of social competence (Connolly & Konarski, 1994; Harter, 1999; Larson & Richards, 1998; Masten, Coatsworth, Neemann, & Gest, 1995; Zimmer-Gembeck, Siebenbruner, & Collin, 2001, 2004). In addition, lighter sexual behaviors (e.g., kissing, hugging, holding hands) are associated with positive family relationships, romantic relationship satisfaction, and commitment (e.g., Welsh, Haugen, Widman, Darling, & Grello, 2005; Williams, Connolly, & Cribbie, 2008).

Adolescent romantic relationships also provide learning experiences that can set the stage for romantic functioning in adulthood. For example, less romantic competence among early adolescent girls is associated with girls making stronger predictions that they will be unlikely to marry and also with greater engagement in potentially risky sexual activity (Davila, Steinberg, et al., 2009). Higher quality romantic relationships in middle adolescence are associated with positive relationships and commitment in early adult relationships (Seiffge-Krenke & Lang 2002) as well as with more adaptive relationship processes (e.g., better conflict resolution and caregiving) in young adulthood (Madsen & Collins, 2011). Overall, adolescent romantic relationships can provide support, enhance self-esteem, and serve important socialization functions that prepare adolescents for adult relationships, and also may have positive long-term effects (Collins, 2003; Collins et al., 2009; Connolly & Goldberg, 1999).

Adolescent romantic relationships can, however, be a significant challenge or stressor that contributes to psychosocial distress. Romantic relationships explain 25 to 34% of the strong emotions that high school students' experience, and about 42% of these strong emotions are negative feelings such as anxiety, anger, jealousy, and depression (Larson, Clore, & Wood, 1999). In addition, most adolescents will face specific relationship stressors, including breakups. Interactions with a romantic partner also may involve criticism, conflict, and pressure; negative interactions may be greater in adolescents' romantic relationships than in their close friendships, especially for girls (Kuttler & La Greca, 2004; La Greca & Harrison, 2005;

Laursen, 1995). Some adolescents will engage in risky sexual activity (e.g., failure to use condoms, multiple sexual partners) that results in negative outcomes (e.g., unplanned pregnancy, sexually transmitted infections), and they will face or engage in relationship aggression. Romantic experiences also can teach young people dysfunctional beliefs about relationships and maladaptive interpersonal behaviors, which they may repeat over time (Waldinger et al., 2002). Not surprisingly, then, adolescent romantic relationships and what happens in them are associated with numerous types of psychopathology.

INTERNALIZING PROBLEMS AND DISORDERS

Depression and Depressive Symptoms

Adolescent depression is common. Lifetime prevalence rates in adolescence range from 9 to 24%, with rates of subclinical depression even higher (for a review see Merikangas & Knight, 2009). Peak age of onset is at ages 13 to15 years, and as many as 40% of adolescents experience a recurrence within 2 to 5 years (for a review see Rudolph, 2009). Therefore, many adolescents will experience depression or depressive symptoms during the very time that they become engaged in romantic activities. This is particularly true for girls. Adolescent girls are twice as likely to be depressed than are boys, and this gender difference emerges in adolescence around the time of puberty and persists through adulthood (Lewinsohn, Rohde, Seeley, Klein, & Gotlib, 2003; Nolen-Hoeksema & Girgus, 1994). Not surprisingly, then, the literature on adolescent romantic relationships and depression has largely focused on girls. Although research in this area is still limited, a number of key findings have begun to emerge with regard to depression and relationship involvement as well as behavior and experiences in relationships.

Romantic Involvement

One of the most consistent findings has been that involvement in dating activities and romantic relationships during adolescence is associated with depressive symptoms, particularly for girls. To our knowledge, the first study to demonstrate this was Joyner and Udry (2000) in their analyses of ADD Health data—a large, nationally representative, longitudinal sample of adolescents. They found that adolescents, particularly girls, who became involved in a romantic relationship reported increased depressive symptoms over time. Davila, Steinberg, Kachadourian, Cobb, and Fincham (2004) replicated these findings in two samples. In a cross-sectional study of early adolescent girls, those who reported current or past involvement in a romantic relationship reported greater depressive symptoms than girls with no romantic involvement. In a longitudinal study of late adolescents (girls and boys), those in romantic relationships reported greater increases in depressive symptoms 6 months later than those not in relationships, even controlling for whether they experienced a relationship break up during that time. Vujeva and Furman (2011) also found a concurrent association between depressive symptoms and relationship involvement among tenth-grade girls and boys. The association extends to romantic activities as well. For example, Compian, Gowen, and Hayward (2004) and Quatman, Sampson, Robinson, and Watson (2001) found that adolescents who were steady or frequent daters reported greater depressive symptoms. Similarly, Davila, Stroud et al. (2009) found, in a sample of early adolescent girls, that engaging in more romantic activities predicted increases in depressive symptoms over one year.

The opposite direction of effect also has been demonstrated. Depressive symptoms among girls in early adolescence are associated with entry into romantic relationships 1 year later (Davila, Stroud et al., 2009), and a number of studies suggest that early onset depression is associated with early marriage (e.g., Gotlib, Lewinsohn, & Seeley, 1998; Kessler, Walters, & Forthofer, 1998). Therefore, there appears to be a bidirectional association between depressive symptoms and romantic involvement in adolescence, particularly among girls.

However, a recent study by Mendle, Ferrero, Moore, and Harden (2013) failed to replicate the association between romantic involvement and depression. Using a behavioral genetics approach, Mendle et al. analyzed sibling pairs in the ADD Health data to examine whether associations between dating and depression held when controlling for familial factors. They examined the concurrent association between relationship involvement and depressive symptoms and failed to find a significant association. Instead, they found a significant association—independent of familial factors—between sexual activity with a nonromantic partner and depressive symptoms and suggested that prior research may have found associations between romantic involvement and depressive symptoms because it did not control for sexual activity. Although that was not true of the Davila, Stroud, et al. (2009) study, the findings of the Mendle et al. study are important for a number of reasons.

First, Mendle et al. (2013) provide more evidence for the association between sexual activity and depression,

another finding that has begun to emerge. For example, both Compian et al. (2004) and Quatman et al. (2001) found that adolescents who engaged in more sexual activity reported greater depressive symptoms. Furthermore, in line with Mendle et al., Grello et al. (2003) found that engaging in sex outside of a committed relationship, in particular, was associated with depressive symptoms. One might take these findings to mean that adolescent sexual activity leads to depression—and it might in the case of casual sexual activity (Grello et al., 2003). Although no research has been done on adolescent hookups, among college students, penetrative hookups are associated with increases in depressive symptoms and psychological distress, particularly for girls (Fielder & Carey, 2010; Owen, Fincham, & Moore, 2011). Given that younger adolescents likely have fewer resources to manage potentially challenging sexual experiences, hookups in adolescence may also predict depressive symptoms. In addition, research shows that involvement with an older partner is associated with increases in depressive symptoms among adolescent girls (Haydon & Halpern, 2010; Loftus, Kelly, & Mustillo, 2011). Given that such involvement also is associated with early sexual initiation (e.g., Marín, Kirby, Hudes, Coyle, & Gómez, 2006), one might speculate that the association between involvement with an older partner and depressive symptoms may be a function of early sexual involvement.

Research also clearly supports the opposite direction of effect, such that depression or dysphoria leads to sexual activity. For example, Davila, Stroud, et al. (2009) found that, among early adolescent girls, depressive symptoms were associated with increased engagement in sexual activity (intercourse and nonintercourse) 1 year later. Similarly, Lehrer, Shrier, Gortmaker, and Buka (2006) found that greater depressive symptoms predicted engagement in sexual risk taking over time. In addition, adolescents who have intercourse with nonromantic partners have elevated levels of depressive symptoms even prior to their first sexual experience (Grello et al., 2003; Monahan & Lee, 2008; Welsh, Grello, & Harper, 2003), suggesting that dysphoria may be involved in the onset of sexual activity—an issue which we will return to later.

Mendle et al. (2013) also draw our attention to the need to consider sexual activity in models of adolescent romantic involvement and depression. As noted earlier, both romantic involvement and sexual activity are normative in adolescence and are intertwined; future research in this area must consider both when examining associations with depression. Furthermore, research needs to focus on mechanisms of their association, including questions of why depression might lead to romantic and sexual activity and what it is about such activities that can lead to depression.

Davila (2008) described a number of conceptual models that might explain why romantic activity predicts increases in depression. Although research is sparse at present, findings are in line with the notion that because adolescent romantic experiences are inherently challenging, they may put youth at risk for depression—particularly youth with poor coping, support, or personal resources that impair their ability to manage such challenges. Consistent with this, the association between romantic activities and depressive symptoms among early adolescent girls has been found to be most strong among those with emotionally unavailable parents (Steinberg & Davila, 2008), those who engage in co-rumination (a maladaptive emotion regulation strategy; Starr & Davila, 2009), and those with a preoccupied style of relating (i.e., who are needy and fearful of rejection; Davila et al., 2004).

Studies are even sparser regarding effects of depression on romantic and sexual activity. Researchers have posited that depressed or dysphoric youth may seek out romantic experiences to meet dependence/support needs, to compensate for poor family or peer relations, or as a search for mood-regulating experiences (Davila, Stroud, et al., 2009; see also Gotlib et al., 1998). In line with these ideas, Davila, Stroud, et al. (2009)—in their sample of early adolescent girls described earlier—found that depressive symptoms predicted increased engagement in sexual intercourse most strongly in two instances. The first instance was among girls experiencing high levels of stress in the parent–adolescent relationship (as reported by the parent and objectively coded by the interviewer). Hence, dysphoric adolescent girls who have a more stressful relationship with their parents may turn to other relationships to meet their needs. Alternatively, dysphoric adolescents with stressful relationships with parents may be rebelling through sexual activity, or such adolescents may not have learned from their parent how to make healthy decisions about sexual activity. The second instance was among girls reporting higher levels of avoidance of intimacy (Hershenberg & Davila, 2010), suggesting that dysphoric girls who are uncomfortable with being emotionally intimate may be attempting to meet their needs for support or regulate their mood through physical rather than emotional intimacy. Alternatively, it may be that dysphoric girls are reticent to communicate and, hence, agree or acquiesce to sexual intercourse. The specific function of these behaviors is an important topic for future research.

Behavior and Experiences in Relationships

Similar to the literature on adult romantic relationships and depression, the research on adolescents, although still

quite limited, points to a number of maladaptive relational processes. In general, depressive symptoms are associated with poorer romantic competence among adolescent girls as assessed via an objectively coded interview conducted with the girls (Stroud & Davila, 2008). In line with this, depressive symptoms also are associated with romantic partners' ratings of adolescent girls as less interpersonally competent (Daley & Hammen, 2002).

A number of specific relational experiences also are associated with depressive symptoms. For example, self-silencing (suppressing self-expression) is associated with depressive symptoms among adolescents in romantic relationships (Harper & Welsh, 2007); this is particularly true for adolescents engaging in more frequent sex (Little, Welsh, Darling, & Holmes, 2011). Less intimacy is associated with greater depressive mood reactivity among adolescent girls (Williams, Connolly, & Segal, 2001). Lower emotional support and higher relationship stress are associated with depressive symptoms among adolescent girls (Daley & Hammen, 2002). Moreover, romantic relationship stress predicted increases in depressive symptoms over 6 months for a sample of tenth-grade Latina and African American girls; this was most true for girls high on interpersonal sensitivity (Rizzo, Daley, & Gunderson, 2006). Depressive symptoms in adolescence also have been shown to predict increases in stressful romantic events (Hankin, Mermelstein, & Roesch, 2007), suggesting bidirectional associations between stress and depression consistent with a romantic stress generation model of depression (Davila, Bradbury, Cohan, & Tochluk, 1997).

Depressive symptoms also are associated with maladaptive interaction patterns in adolescent romantic relationships. Galliher, Rostosky, Welsh, and Kawaguchi (1999) found that reports of inequality in the contribution of emotional resources and in decision making are associated with depressive symptoms, especially for adolescent girls. La Greca and Harrison (2005) found an association between depressive symptoms and reports of more negative interactions with romantic partners among girls and boys ages 14 to 19 years. Two recent longitudinal studies provide further evidence for these associations. In a sample of 80 Dutch couples between ages 13 and 19 years, both girls' and boys' depressive symptoms were associated with their own reports of greater negative conflict resolution styles and less positive problem-solving styles (Ha, Overbeek, Cillessen, & Engels, 2012). Additionally in a 5-year longitudinal study of late adolescent boys and girls, Vujeva and Furman (2011) found that greater depressive symptoms at the initial assessment predicted increases in reported conflict and less positive problem solving in romantic relationships over time. Such findings suggest that the effects of early depressive symptoms on romantic functioning are long-lasting.

Ha et al. (2012) also found that girls' depressive symptoms were associated with time to breakup, in that greater symptoms were associated with shorter relationships. Importantly, the breakup of a relationship is associated with first onset of depression in adolescence (Monroe, Rohde, Seeley, & Lewinsohn, 1999). Again, these findings point to the bidirectional nature of depression and romantic relationship problems in adolescence.

Anxiety Symptoms and Disorders

Anxiety disorders are the most prevalent type of mental disorders among adults and are also common among children and adolescents (Merikangas, Nakamura, & Kessler, 2009). In community studies, prevalence rates for anxiety disorders in youth have ranged from 2.2 to 9.5% (see Canino et al., 2004; Costello, Egger, & Angold, 2005; Merikangas, Avenevoli, Costello, Koretz, & Kessler, 2009), with general anxiety disorder (GAD) and social anxiety disorder (SAD) being the most common. As reviewed by Merikangas et al. (2009), across all ages, girls have greater rates of anxiety disorders (of all types) than do boys, and for both sexes the typical peak period of onset is middle adolescence for SAD and young adulthood for GAD. Moreover, comorbidity between anxiety disorders and other disorders is common; in fact, the comorbidity between anxiety and mood disorders in youth is so sufficiently high that anxiety is considered a potential developmental pathway in the etiology of mood disorders (e.g., Merikangas & Avenevoli, 2002; Merikangas et al., 2009). This is not surprising in that interpersonal processes are considered to be important to the development and maintenance of both anxiety (especially social anxiety) and depression (see Davila, La Greca, Starr, & Landoll, 2010; La Greca, Davila, & Siegel, 2008).

Social anxiety, in particular, has been associated with problems in adolescents' and young adults' romantic relationships. Social anxiety is characterized by fear of negative evaluation by others as well as social avoidance and distress in social situations (La Greca, 1999; La Greca & Lopez, 1998). Although some degree of social anxiety is normative (La Greca, 1999), when socially anxious feelings and behaviors are sufficiently extreme, persist over time, and interfere with functioning they may be consistent with the diagnosis of SAD (American Psychiatric Association, 2000, 2013).

On a related note, some research with adolescents and young adults also has focused on dating anxiety. Dating anxiety refers to worry, distress, and inhibition in heterosocial situations involving dating partners or potential

dating partners (e. g., Chorney & Morris, 2008; Glickman & La Greca, 2004). Social anxiety and dating anxiety are strongly related but appear to be distinct constructs (Glickman & La Greca, 2004). Similar to social anxiety, dating anxiety is conceptualized as being composed of fear of negative evaluation (in dating situations or with other-sex individuals) and social inhibition and distress (either with a dating partner, a potential dating partner, or during heterosocial group situations; Glickman & La Greca, 2004).

We now focus on social and dating anxiety; specifically, how they may affect and be affected by romantic relationships. Although romantic relationships have many positive aspects (e.g., provide social support, enhance self-esteem, contribute to intimacy), romantic relationships also can be stressful, especially for adolescents who are just learning how to navigate them (Downey, Bonica, & Rincon, 1999). Thus, the presence of romantic relationships (and even their *absence*) might contribute to feelings of social or dating anxiety; in turn, social and dating anxiety may influence the presence and quality of romantic relationships.

Romantic Involvement

Social anxiety can interfere with youths' close relationships (La Greca & Lai, 2014; La Greca & Landoll, 2011). Socially anxious adolescents have fewer close friendships, have lower quality friendships, and are the recipients of more peer rejection and negative peer experiences than other adolescents (Greco & Morris, 2005; La Greca & Harrison, 2005; La Greca & Lopez, 1998; Siegel, La Greca, & Harrison, 2009). In particular, inhibition among socially anxious youth may limit their frequency of social interactions, and thus their ability to form close, supportive social ties (Beidel, Turner, & Morris, 1999; La Greca & Lopez, 1998). Socially anxious youth and young adults also make more negative appraisals of social situations (Flanagan, Erath, & Bierman, 2008) and display interpersonal avoidance (Darcy, Davila, & Beck, 2005; Grant, Beck, Farrow, & Davila, 2007). The inhibition, avoidance, and negative appraisals of socially anxious adolescents and young adults present challenges for forming romantic relationships. In fact, among youth followed longitudinally, shy and socially inhibited boys are more likely to marry later in life than comparison youth (Caspi, Elder, & Bem, 1988). Large-scale epidemiological studies (Lampe, Slade, Issakidis, & Andrews, 2003; Wittchen, Fuetsch, Sonntag, Muller, & Liebowitz, 2000) also reveal that socially anxious adults are more likely to have been never married or to be separated or divorced than nonanxious adults.

Evidence supports the view that socially anxious adolescents are less likely to be involved in a dating or romantic relationship than their less-anxious peers (La Greca & Harrison, 2005), perhaps because they are uncomfortable in or avoid social situations that might lead to opportunities for dating or romantic relationships (Glickman & La Greca, 2004). For example, La Greca and Harrison (2005) found that, among high school students (mean age of 16.5 years), the *absence* of a current romantic relationship was associated with greater social anxiety; in contrast, romantic relationship involvement was unrelated to adolescents' depressive symptoms. These findings are intriguing as they suggest that nondating adolescents are more socially anxious (or potentially that romantic involvement reduces feelings of social anxiety). The findings also contrast with those reported above for depression, which indicated that romantic involvement is associated with greater depressive affect, especially for early to midadolescents. Perhaps because romantic involvement is normative among older adolescents (Carver et al., 2003), such involvement is not as likely to be an indicator of depressive mood but instead might be a source of anxiety for adolescents who are not romantically involved by their late teens. Also as noted already, associations between romantic involvement and depressive symptoms may be because of youths' involvement in sexual activity, rather than youths' involvement in a relationship per se.

Findings regarding the romantic involvement of adolescents with dating anxiety parallel those obtained for socially anxious individuals. For example, compared with their less anxious peers, adolescents who report greater dating anxiety are less likely to be dating (Glickman & La Greca, 2004) and more likely to report that they never have had a romantic relationship (La Greca & Mackey, 2007). Adolescents high on dating anxiety also report having fewer close friends of the other sex (La Greca & Mackey, 2007). In the normal course of adolescent development, such friendships provide opportunities to develop social skills specific to other-sex relationships and to meet potential romantic partners (Herbert, Fales, Nangle, Papadakis, & Grover, 2013). Thus, adolescents with social or dating anxiety may miss out on key socialization experiences that then delay or preclude the development of romantic relationships (Connolly & Goldberg, 1999; Dunphy, 1963; Herbert et al., 2013). By their avoidance or lack of participation in romantic relationships, socially or dating anxious individuals also miss out on the potential psychological benefits of romantic relationships.

Behavior and Experiences in Relationships

Once dating or romantic relationships have been established, the qualities of such relationships appear to be less

adequate or skillful among socially anxious individuals. Findings reveal that social anxiety is associated with lower levels of intimacy and companionship in adolescents' close friendships (Vernberg, Abwender, Ewell, & Beery, 1992), especially for adolescent girls (La Greca & Lopez, 1998). Similarly, young adults who are socially anxious display less emotional expression and interpersonal assertiveness in their social interactions (Davila & Beck, 2002; Melfsen, Osterlow, & Florin, 2000). Such findings suggest that inhibition in close relationships might limit positive interactions within the romantic relationships of socially anxious adolescents and young adults. Although research is scant, it does appear that socially anxious adults show less emotion, fewer positive behaviors, less self-disclosure, and decreased intimacy in their romantic relationships (Sparrevohn & Rapee, 2009; Wenzel, Graff-Dolezal, Macho, & Brendle, 2005).

Along with fewer positive behaviors, socially anxious individuals also appear to engage in more negative behaviors in their romantic relationships. Kashdan, Volkmann, Breen, and Han (2007) found that for individuals low in social anxiety, the ability to express negative emotions in an open and uninhibited way fostered a good-quality romantic relationship; however, for individuals high in social anxiety, the expression of negative emotions in the context of a romantic relationship was associated with deteriorating relationship quality. Socially anxious young adults also have been found to demonstrate more negative and fewer positive interactions with their romantic partner during an observed communication task (Wenzel et al., 2005). Interestingly, research by Beck, Davila, Farrow, and Grant (2006) found that socially anxious women demonstrated more negative behavior in the context of relationships that were viewed as more satisfying. It is possible that socially anxious women might view high-quality relationships as a secure base for expressing negative feelings (Beck et al., 2006). Overall, it appears that negative emotional expression is common in the romantic relationships of socially anxious individuals.

For the most part, this area of research does not clarify the direction of causal pathways between social anxiety and relationship qualities. So, for example, it is possible that social anxiety leads to inhibited social behavior that limits the intimacy and quality of a romantic relationship. However, it is also plausible that negative interactions in romantic relationships, which are fairly common, contribute to or exacerbate adolescents' and young adults' feelings of distress and, specifically, of social anxiety (La Greca & Mackey, 2007). Moreover, once engaged in a romantic relationship, socially anxious individuals may have difficulties with social appraisal and evaluation; these difficulties may, in turn, increase symptoms of social anxiety.

In addition to research linking social anxiety with difficulties in romantic relationships, associations between romantic relationship issues and dating anxiety have been noted. Dating anxiety is associated with romantic relationship difficulties, even when controlling for other indicators of social competence (e.g., number of close friends, qualities of close friendships). For example, among adolescents who were currently dating (and thus less likely to be socially or dating anxious to begin with), fewer positive and more negative qualities in the romantic relationship were associated with higher levels of dating anxiety (La Greca & Mackey, 2007).

The previously discussed findings suggest that youth who are anxious about dating might avoid heterosocial situations, thus making it difficult to develop a romantic relationship. It is possible—once adolescents become romantically involved—that fears and worries about dating may become less salient, thereby reducing feelings of social or dating anxiety. Consistent with this latter perspective, Nieder and Seiffge-Krenke (2001) tracked the romantic relationships of adolescents from ages 14 to 17 years. As participants progressed through adolescence, their reported stress in romantic situations decreased and their romantic relationship quality increased. Thus, increased exposure to dating relationships during adolescence may decrease anxiety in dating situations over time (Nieder & Seiffge-Krenke, 2001).

Although it has not been studied directly, greater experience with romantic relationships might lead to reductions in dating or social anxiety over time, especially if the qualities of the romantic relationships are generally positive. In contrast, the presence of a high level of negative interactions with a romantic partner (e.g., criticism, pressure, conflict) might well exacerbate feelings of social anxiety and contribute to significant distress and potentially to GAD or SAD.

EXTERNALIZING PROBLEMS AND DISORDERS

The cluster of externalizing behaviors at adolescence—particularly involving delinquency, substance use, and sexual-risk behaviors—have long been sources of anguish to parents and major foci of adolescent researchers seeking to understand the emergence and consequences of these behaviors. Conduct problems—including impulsive, defiant, and aggressive behaviors—are among the most common reason for referrals to child mental health

clinics in the western hemisphere (Frick, 1998) and have a poor prognosis for adult adjustment (Kohlberg, Ricks, & Snarey, 1984). The study of romantic relationships at adolescence generally was a separate area of research; thus, the influence of externalizing behavior on adolescent romantic relationship formation and functioning and the ways in which such relationships may influence externalizing behaviors are more recent areas of research.

In consideration of these issues, we draw heavily on two sources. First, on research conducted by Capaldi and colleagues (e.g., Capaldi, Shortt, & Kim, 2005) using the Oregon Youth Study (OYS)-Couples Study sample that examined problems in romantic relationships in late adolescence and young adulthood—notably intimate partner violence (IPV, including here both physical and psychological aggression)—and second, on a recent systematic review of risk factors for IPV (Capaldi, Knoble, Shortt, & Kim, 2012). As discussed by Capaldi, Knoble, et al. (2012), IPV includes physical, psychological, and sexual abuse by men and by women toward romantic partners of the same or opposite sex. Physical violence involves forceful physical contact ranging from low force pushes and slaps to severe beatings and lethal violence. Sexual abuse includes coercive and physical behaviors varying from trying to persuade someone to perform a sexual act against their will, ignoring "no" responses, to physically forced sex acts (Teten, Hall, & Capaldi, 2009; Tjaden & Thoennes, 2000). Psychological aggression (or emotional abuse) involves acting in an offensive or degrading manner toward a partner—including threats, ridicule, withholding affection, and restrictions (e.g., social isolation, financial control; O'Leary & Maiuro, 2001).

Minor or occasional psychological aggression is very common (Shortt et al., 2012). Psychological and physical aggression are significantly associated. Capaldi and Crosby (1997) found that at age 18 years the two types of abuse perpetration were significantly associated for young men and young women ($r = .60$ for men, $r = .55$ for women, both $p < .001$), and psychological abuse has been found to be predictive of physical abuse and to have severe impacts (O'Leary & Maiuro, 2001).

The Development of Externalizing Behaviors

Antisocial behaviors or conduct problems refer to a cluster of impulsive or under-controlled and societal rule-breaking behaviors, including delinquent and aggressive behaviors. Aggression is normative in the first few years of life and then decreases (Tremblay et al., 2004). Tremblay, Masse, Pagani-Kurtz, and Vitaro (1996) examined developmental trends in frequent versus occasional physical aggression (hitting, biting, and kicking) from ages 24 months to 12 years for boys and girls. The highest levels occurred at age 2 years and declined over time. Similarly, in a study examining externalizing behaviors from ages 3 to 9 years, both boys and girls decreased or improved across this period (Capaldi, Pears, Kerr, Owen, & Kim, 2012). Thus, there is evidence that the normative pattern is for children to improve in inhibitory control with age. Despite this improvement overall, some children remain high in externalizing behaviors—thus not showing the normative developmental improvement—and some increase in externalizing behaviors in childhood.

In contrast, delinquent behaviors peak between ages 14 and 17 years (Blumstein, Cohen, Roth, & Visher, 1986) for the key symptoms of adolescent conduct disorder—namely behaviors that would be illegal in adulthood (e. g., theft, assault) and status offenses or behaviors that are illegal due to the youth being younger than age 18 years (e.g., minor in possession of alcohol). Peak ages at police arrest for the life span are typically at ages 18 and 19 years for both boys/men and girls/women in the United States (e.g., Uniform Crime Reports, 2009). In addition, substance use beyond very light experimentation (e.g., trying a sip of alcohol) mostly emerges in adolescence, with accelerated onset and use particularly in the early high school years (Capaldi, Stoolmiller, Kim, & Yoerger, 2009; Washburn & Capaldi, 2013). Thus, the adolescent years of dating onset are also the years of high levels of externalizing behaviors (including aggression) and essentially an explosion of substance use. Although symptoms of externalizing and internalizing disorders differ considerably, there is a significant association between externalizing and internalizing (e.g., sadness, anxiety) problems at adolescence (Angold, Costello, & Erkanli, 1999). Thus, important associations between conduct problems and particular aspects of romantic relationships may also apply to youth with internalizing symptoms (and vice versa).

The Oregon Youth Study and the OYS-Couples Study

Before going further, and because much of the following review draws heavily on the OYS, we describe the design of the OYS-Couples Study. The OYS is a community-based longitudinal study of males who were considered at increased risk for delinquency due to the neighborhoods where they lived in childhood (within a medium-sized town). The sample is predominantly White and lower or working class. The boys were followed from childhood (Grade 4, ages 9 to 10 years), and the study had very strong recruitment and retention rates (Capaldi, Chamberlain, Fetrow, & Wilson, 1997). The sample proved to be at

risk for delinquency, despite the fact that most were not showing high levels of conduct problems in childhood. In fact, in the period prior to age 18 years, about one half of the boys were arrested one or more times, with 20% having five or more arrests. Only 49% graduated from high school with their class.

In late adolescence (ages 17–18 years), the young men were invited to participate in an ancillary study with a romantic partner; a further assessment was conducted at about age 21 years. The assessments with the partner included interviews for the young men and women (few participated with male partners) and an observed discussion of issues in their relationships. The OYS-Couples Study continued with data collection waves about every other year through the 20s, and arrest records for IPV were later collected. In late adolescence, at an average age of around 18 years, 31% of the young men with partners and 36% of their female partners had engaged in physical aggression toward a partner in the prior year (Capaldi & Crosby, 1997), a typical prevalence of physical aggression for couples of this age (Langhinrichsen-Rohling, Misra, Selwyn, & Rohling, 2012). Observed aggression was found to be significantly associated with reported aggression, and the correlation between physical and psychological aggression toward a partner in late adolescence was .60 for the young men and .55 for the young women ($p < .001$).

Mixed-Sex Friendship Groups

As noted earlier, other-sex friendships increase in frequency in early adolescence (Feiring, 1999; Poulin & Pedersen, 2007), setting the stage for mixed-sex friendship groups from which dating and romantic relationships often emerge. Whereas it might be expected that adolescents who enter mixed-gender friendship groups (and date) relatively early might be more mature; in fact, there is evidence of higher levels of conduct-problem behaviors among adolescents who transition from same-gender to mixed-gender groups earlier than their peers. For example, Poulin and Pedersen (2007) found that girls (but not boys) who were rated as more antisocial than their peers by their sixth-grade teachers had more male friends in Grade 7. Further, higher growth in mixed-sex friendships from Grades 6 to 10 was related to earlier onset of puberty for the girls. Stattin and Magnusson (1990) found associations between other-sex friendships and delinquency that were associated with early maturing girls developing friendships with or dating older more deviant boys. However, a large longitudinal study of sixth to ninth graders, Molly, Gest, Feinberg, & Osgood, (2014) found consistent evidence that mixed-sex groups were composed of the most at-risk youth in the sample, with such groups showing relatively high levels of substance use and delinquency. Thus, both boys and girls in mixed-sex groups may be more at risk, particularly during early adolescence. Among older adolescents, other-sex friendships tend to develop among high status and more socially skilled youth (see Herbert et al., 2013; La Greca & Harrison, 2005).

One study found interesting evidence that adolescent romantic partners may be network bridges, connecting daters to new peer contexts (Kreager & Haynie, 2011). Using couples (average ages 14 to 15 years) from the AddHealth project, Kreager and Haynie found unique contributions of partners' drinking, friends' drinking, and friends-of-partners' drinking to daters' own later drinking frequency and heavy episodic drinking. Thus, other-sex network influences may be intimately involved in the accelerated growth in alcohol use, which occurs in the high school years.

Romantic Involvement

Consistent with findings regarding mixed-sex networks, there is evidence that youth with higher levels of conduct problems begin dating earlier than their peers. Capaldi and Crosby (1997) found for the OYS-Couples Study at ages 17 to 18 years that the boys who participated with a partner showed higher levels of problems than those who did not participate (usually because they did not have a partner). The boys who participated were more likely to have been arrested and had more than twice as many arrests on average than those who did not. They also had twice the prevalence of marijuana use and were much more likely to have already fathered a child. Similarly, Connolly, Pepler, Craig, and Taradash (2000) found that young adolescents (Grades 5 to 8) who bullied their peers started dating earlier and engaged in more advanced dyadic dating than did their peers. Bullies were found to be strongly relationship oriented, yet their views of their boy/girlfriends were less positive than those of other adolescents. The bullies were more developed pubertally, but this did not fully account for the dating precocity. Finally, they were more likely to report dating violence.

The association of conduct problems with early dating may be part of a pattern whereby conduct-problem youth follow a more accelerated pathway to adult behaviors (Capaldi & Shortt, 2003; Newcomb, 1987). High school dropout is a large factor in such acceleration, as it is strongly associated with conduct problems and other early risk factors (Eliott & Voss, 1974) and because adolescents are then likely to leave the family-of-origin home prior to age 18 years (Capaldi & Stoolmiller, 1999). Also, conduct

problems are associated with an early age at initiation of sexual intercourse (Capaldi, Crosby, & Stoolmiller, 1996).

Intimate Partner Violence

In a recent review of risk factors for IPV, Capaldi, Knoble, et al. (2012) examined risk from deviant peer association, antisocial behavior, and alcohol and other drug use.

Conduct Problems/Antisocial Behavior, Anger, and Hostility

Surprisingly, given that aggression and violence are part of the definition of conduct problems, they have been a focus of study as developmental risk factors for IPV only in the past 10 to 15 years. In fact, a review by Schumacher, Feldbau-Kohn, Slep, and Heyman (2001) of risk factors for male perpetration of IPV did not mention antisocial behavior as a risk factor. This is partly because of the history of romantic relationships and externalizing problems being separate fields of research. Fortunately, there have now been a relatively large number of prospective longitudinal studies examining these issues.

As discussed by Capaldi, Knoble, et al. (2012), one study (Magdol, Moffitt, Caspi, & Silva; 1998) found that early problem behaviors were the most consistent predictor of IPV of a number of early risk factors, and others have found similar strong associations with different samples (Ehrensaft et al., 2003; Lussier, Farrington, & Moffitt, 2009). There is evidence that earlier onset of conduct problems (i.e., in childhood versus adolescence) is predictive of a more severe course of antisocial behavior (Patterson, Capaldi, & Bank, 1991). Consistent with this, Woodward, Fergusson, and Horwood (2002) found that individuals with younger onset antisocial behavior were more likely than those with later or no onset of antisocial behavior to be perpetrators or victims of IPV, and there was no gender difference in IPV perpetration. Also for the Dunedin Study, Moffitt, Krueger, Caspi, and Fagan (2000) found that IPV and general crime shared risk from negative emotionality (e.g., anxiety, anger, hostility). In a third Dunedin Study related to IPV, Ehrensaft, Moffitt, and Caspi (2004) found that women in relationships resulting in injury or police contact had childhood family adversity, adolescent conduct problems, and aggressive personality, and that men had disinhibitory psychopathology since childhood and pervasive personality deviance. Capaldi and Clark (1998) found for the OYS-Couples Study that boys' antisocial behavior in midadolescence was significantly associated with their IPV perpetration in late adolescence (at age 18 years); for the same sample, Capaldi, Dishion, Stoolmiller, and Yoerger (2001) found that antisocial behavior at ages 17 to 18 years was predictive of IPV perpetration at ages 20 to 23 years. In a study including young men and women, Andrews, Foster, Capaldi, and Hops (2000) found, after controlling for a number of risk factors and their interactions, that family-aversive communication and participant antisocial behavior predicted IPV in couples. Herrenkohl, Kosterman, Mason, and Hawkins (2007) found for young men and women that the odds of moderately severe IPV perpetration were double for chronic youth offenders compared with nonoffenders.

Findings from these and other predominantly fully prospective longitudinal studies indicate that conduct problems and associated hostility are a robust and substantial risk factor for later IPV perpetration and victimization, and that it is a developmental risk factor for both perpetration and victimization for both girls/young women and boys/young men. This is consistent with the finding that much IPV both in adolescence and young adulthood is bidirectional (i.e., that both partners are engaging in physical aggression), estimated to be about 50 to 60% of couples where there is any IPV present (Langhinrichsen-Rohling et al., 2012). Also, Capaldi, Knoble, et al. (2012) concluded from their review that antisocial behavior is frequently found to be a mediator for earlier risk factors such as harsh parental treatment.

An important issue is the extent to which antisocial behavior and IPV relate to risk for injuries in young couples. Capaldi and Owen (2001) examined levels of antisocial behavior for young men and women, aged 21 years, who showed frequent physical aggression toward a partner—at about the frequency reported by shelter samples. They found that both men and women showed elevated antisocial behavior levels if they perpetrated such frequent physical aggression toward partners, and the highest levels for both men and women were found for couples where the physical aggression was both bidirectional and frequent. Higher levels of injuries were reported when the men and women were frequently physically aggressive.

Alcohol and Drug Use

Alcohol and drug use are closely associated with antisocial behavior (Donovan, Jessor, & Costa, 1988) and are a key aspect of externalizing behaviors in adolescence and adulthood. Whereas alcohol use is thought to be a proximal predictor of IPV because of its hypothesized disinhibitory effect on aggression (Flanzer, 2005), drug use has been less frequently examined as a predictor until more recently. In fact, there are relatively few prospective longitudinal studies that have examined prediction to IPV from either alcohol or drug use for adolescents and young adults. A problem with studies in this area is that when this association is

examined, antisocial behavior—which would be expected to account for an association of substance use and IPV—is often not controlled in the analyses.

As discussed by Capaldi, Knoble, et al. (2012), Reyes, Foshee, Bauer, and Ennett (2011) found for a rural school-based sample that heavy alcohol use was significantly associated with the overall cohort trajectory of physical dating aggression perpetration with no evidence of sex differences. Whereas adolescents with heavy alcohol use initially reported higher levels of dating aggression perpetration during early and middle adolescence, by late adolescence there were no differences in perpetration levels between heavy alcohol users and nonusers. In within-person analyses, a negative interaction between heavy alcohol use and grade was found—indicating that the effect of heavy alcohol use on dating violence perpetration diminished as grade level increased, possibly suggesting that as early heavy use is associated with antisocial behavior that the effect might be explained by antisocial behavior (i.e., later onset heavy alcohol users showed less antisocial behavior). In a study of victimization, Buzy et al. (2004) found that higher levels of alcohol use predicted physical and sexual victimization months later. Counter to common wisdom, for a predominantly African American and Hispanic sample, Schnurr and Lohman (2008) found that drug and alcohol use were predictive of perpetration of dating violence for girls but not for boys. In a study of dating violence victimization, Maas, Fleming, Herrenkohl, and Catalano (2010) found that externalizing behavioral problems predicted IPV victimization for boys, whereas internalizing, externalizing, and alcohol consumption predicted IPV victimization for girls.

The association of drug use with IPV has more frequently been examined in cross-sectional than in longitudinal work. In a study of IPV victimization for a high school sample, Temple and Freeman (2011) found that, after controlling for demographic variables and alcohol use, lifetime use of any controlled substance significantly increased the likelihood of dating violence victimization. A second study of victimization using a national sample of ninth to 12th graders (Eaton, Davis, Barrios, Brener, & Noonan, 2007) found that dating violence victimization was associated with alcohol use and marijuana use for girls but not for boys. For a school-based sample of students in Grades 11 and 12, O'Keefe (1997) found that alcohol and drug use were associated with dating violence perpetration for both boys and girls.

Although there is evidence for an association of indicators of alcohol use with IPV perpetration and victimization, it is not as strong or as consistent as has generally been supposed, likely partly because of alcohol and IPV sharing a common risk factor of antisocial behavior. Furthermore, the association may be stronger for girls and young women than for boys and young men. There are fewer studies on the use of drugs and IPV, but some suggest that there could be a stronger association between such use and IPV. Findings in the area of substance use and IPV therefore suggest that some prevailing assumptions regarding both causal and gender associations may need modification and further study to understand how to tackle prevention in this important area of health risk.

One important question regarding dating violence or IPV in very young couples is whether it is predictive of IPV in the future or whether IPV shows stability over time. This question has rarely been examined; however, Shortt et al. (2012) found that IPV in young adulthood (at average age 21 years) predicted IPV into the late 20s, and this was true for both physical and psychological aggression. Thus, IPV in young adulthood is predictive of longer-term problems with aggression toward a partner. Capaldi, Kim, and Shortt (2007) examined observed (during a problem-solving discussion) initiation and reciprocity of physical aggression. They found that the likelihood of injury over about an 8-year period was about twice as high for those couples where both young man and woman were observed to use some physical aggression, compared with couples for whom either no physical aggression or aggression by only one partner was observed.

On a positive note, and contrary to early reports that IPV increases over time (e.g., Walker, 1984), there is evidence that IPV peaks in young adulthood and then declines with age (Fritz & O'Leary, 2004; Kim, Laurent, Capaldi, & Feingold, 2008). In this respect, it shows a similar pattern to crime more generally, which peaks at young ages—with peak ages at arrest for males and females in the United States being ages 18 to 19 years (Uniform Crime Reports, 2009)—and then shows a sharp decline.

Behavior and Experiences in Relationships

Whereas there is now a substantial body of work on the association of conduct problems and IPV, much less work has been conducted regarding the association of conduct problems with other aspects of romantic relationship functioning at adolescence, such as relationship satisfaction and relationship stability or longevity. It is well established in the adult couples' literature that couples' conflict is related to aggression or antisocial behavior and that crime and antisocial behavior predicts divorce or relationship breakdown (Farrington, 2003). Whereas couples' conflict may not necessarily involve psychological aggression, it is rare to have substantial conflicts that avoid such behaviors.

In fact, some degree of psychological aggression is ubiquitous in young couples, with 80% of the young men and 86% of the young women in the OYS-Couples Study either reporting or being observed to engage in such behaviors (Capaldi & Crosby, 1997).

Shortt, Capaldi, Kim, and Owen (2006) examined prediction to relationship separation over the course of 6 years from dyadic physical aggression assessed at age 21 years for the OYS-Couples Study. Over this period, 62% of couples separated. Physical aggression significantly increased the likelihood of relationship dissolution—controlling for psychological aggression, prior relationship satisfaction, and relationship contextual factors including length of relationship, relationship type, and children in the household. In the models, including all these factors, psychological aggression was not a significant predictor of relationship breakdown. Both physical and psychological aggression were associated with low relationship satisfaction. Thus, aggression toward a partner, associated with externalizing behaviors, is predictive of additional problems in the relationship including greater likelihood of relationship breakdown.

In another study with the OYS-Couples Study and using the Specific Affect Coding System (SPAFF; Gottman, McCoy, Coan, & Collier, 1996), Shortt, Capaldi, Kim, and Laurent (2010) examined the association between three categories of observed affect—including positive affect, externalizing negative affect (criticism, domineering, contempt, belligerence, threats, defensiveness, anger), and internalizing negative affect (sadness, fear/tension, stonewalling, or refusing to respond)—and both IPV and relationship satisfaction from ages 21 to 25–26 years. Externalizing negative affect showed a robust negative association with relationship satisfaction for both the young men and young women, being associated at each of the three study time points. Internalizing negative affect showed some significant associations with relationship satisfaction but not as consistently as for externalizing negative affect.

Problems in the family of origin that are related to externalizing problems are related to conflictual and poor quality of relationships in young adults. Andrews et al. (2000) examined the association of antisocial behavior and family functioning at ages 16 to 17 years, and romantic relationship functioning 6 years later at around age 23 years. They found that low relationship satisfaction, higher observed aversive communication, and higher physical aggression were predicted by observed family aversive communication in adolescence, and adolescent antisocial behavior was associated with lower relationship satisfaction and higher physical aggression. Parent–adolescent conflict predicted lower levels of observed couple facilitative communication. Thus, there is evidence that conduct problems are associated with pervasive relationship problems over time, and prevention of such problems could have a strong beneficial impact on romantic relationship functioning.

EATING DISORDERS

Eating disorders are prominent in adolescence, particularly among girls (Hudson, Hiripi, Pope, & Kessler, 2007; Lewinsohn et al., 1993). However, there are relatively few studies of eating pathology and romantic functioning among this age group. These relatively rare studies point to a few key findings. First, romantic and sexual involvement may attune youth more to their physical appearance and lead to insecurities about their bodies. Cauffman and Steinberg (1996) found, among adolescents, an association between high levels of involvement in heterosexual social and sexual activities and reports of greater disordered eating and dieting (also see Compian et al., 2004). Moreover, the belief that thinness is important for dating success is associated with dietary restraint, body dissatisfaction, and bulimic symptoms among adolescents (Paxton et al., 1991). Longitudinal research demonstrates that adolescent girls and female college students become less satisfied with their appearance after engaging in sexual intercourse for the first time, although the opposite is true for males (Valle, Røysamb, Sundby, & Klepp, 2009; Vasilenko, Ram, & Lefkowitz, 2011). Therefore, interest and experience in romantic and sexual activities may increase body dissatisfaction—leading to subsequent eating pathology, at least for women.

Second, there also is evidence that eating pathology affects romantic and sexual involvement; in some cases, it might inhibit involvement. Compared with non–eating disorder youth, youth (ages 14 to 21 years) with anorexia had fewer dating experiences and more negative attitudes about sexuality (Ruuska, Kaltiala-Heino, Koivisto, & Rantanen, 2003). However, in other studies, eating pathology and body image issues are associated with greater or more risky sexual involvement. Among girls, a number of studies show that poorer body image (e.g., negative body evaluation, lower body satisfaction, greater body objectification) predicts earlier onset of sexual intercourse (Kvalem, von Soest, Træen, & Singsaas, 2011; Pearson, Kholodkov, Henson, & Impett, 2012) and less condom use (Schooler, 2013). In addition, compared with girls (ages 13 to 25 years) without eating disorders, those with eating disorders are less knowledgeable about sexual-health risks and the prevention of HIV and pregnancy (Hicks et al., 2013).

It appears that male youth with eating pathology may be similarly at risk. Ackard, Fedio, Neumark-Sztainer, and Britt (2008) found that, compared with males without disordered eating, those with such disorders reported a greater number of sex partners. Conversely, among adolescent boys, body satisfaction is associated with sexual agency and clarity in sexual values (Schooler, Impett, Hirschman, & Bonem, 2008).

Among adolescents, it is unclear how eating and body image issues play out within relationships. One study found that perceived pressure from dating partners to be thin was not associated with increases in body dissatisfaction among adolescent girls and boys (Presnell, Bearman, & Stice, 2004). However, there is a somewhat larger literature on young adults, typically college students, indicating that eating pathology/body image issues and relationship functioning affect one another. Bidirectional associations exist between relationship functioning and young women's eating, weight, and shape concerns (Morrison, Doss, & Perez, 2009). Goins, Markey, and Gillen (2012) found that young men were more likely to be satisfied with their body when their partners were and when they experienced high levels of sexual intimacy in the relationship. Greater body dissatisfaction is associated with lower perceived trust among young women and lower perceived support among young men in romantic relationships (Juarez & Pritchard, 2012). Sanchez and Kwang (2007) found that the more young women's self-worth is dependent on a romantic relationship, the more they report body shame and bulimic symptoms. In addition, factors such as anxious romantic attachment and low perceived romantic support are associated with body image disturbance (Cash, Theriault, & Annis, 2004; Weller & Dziegielewski, 2004). Therefore, although one study failed to find associations between females' body satisfaction and reports of relationship quality (Markey & Markey, 2006), it does appear that varied aspects of young adult relationships, for both young men and women, are related to their body image and eating behavior.

One aspect of relationship functioning that has been consistently related to eating and body image pathology in adolescents and young adults is aggression in relationships. Youth who experience dating violence, date rape, unwanted sexual contact in dating situations, physical aggression, or psychological aggression report greater eating pathology (e.g., Ackard & Neumark-Sztainer, 2002; Skomorovsky, Matheson, & Anisman, 2006; Thompson, Wonderlich, Crosby, & Mitchell, 2001).

It should be noted that, as the previous review shows, although some of the literature has focused on actual eating disorders or symptoms, much of the research has focused on body image issues. Whether these studies capture associations and processes that also pertain to diagnosable eating disorders is unknown.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER AND OTHER DISORDERS

There is very little research on associations between romantic relationships and other disorders in adolescence. The few available studies have focused on different aspects of romantic relationships.

With respect to youth or adults with attention-deficit/hyperactivity disorder (ADHD), one study found that girls diagnosed with ADHD in childhood were involved in fewer romantic relationships in late adolescence compared with their non-ADHD peers (Babinski et al., 2011). In contrast, however, another study (Siegel & La Greca, 2009) found that, among adolescents in a community sample, those with higher levels of ADHD symptoms were more likely to be romantically involved than those with lower levels of such symptoms. Barkley, Fischer, Smallish, and Fletcher (2006) similarly found that young adults with ADHD had begun dating earlier than those without ADHD and were younger during their first sexual experience. It is possible that the impulsivity that accompanies ADHD, or associated conduct problems, leads to earlier romantic experiences for such adolescents. Furthermore in the Siegel and La Greca (2009) study, although adolescents with symptoms of ADHD had more romantic partners, these relationships were characterized by higher rates of negative interactions. This is troubling, as negative experiences in romantic relationships during adolescence predict poor intimate relationship quality in adulthood (Connolly, Furman, & Konarski, 2000). Indeed, a recent study of young adult men (ages 18 to 25 years) found that those with childhood ADHD, especially those with conduct problems, were more likely to be verbally aggressive and violent with their romantic partners than were young men without histories of ADHD or conduct problems (Wymbs et al., 2012). Others have found that the marital functioning of adults with ADHD is significantly poorer than that for matched non-ADHD controls (Eakin et al., 2004). Thus, emerging evidence suggests that adolescents and young adults with ADHD, and especially those with concurrent conduct problems, represent an at-risk population for romantic relationship difficulties.

Other studies have focused on personality pathology, finding that such pathology was associated with romantic dysfunction over 4 years among late-adolescent women (Daley, Burge, & Hammen, 2000). In addition,

Kim, Miklowitz, Biuckians, and Mullen (2007) found that, among adolescents diagnosed with bipolar disorder, greater chronic stress in intimate relationships was associated with less improvement in mood symptoms over the following year. However, the measure of stress in intimate relationships was a composite of romantic and family relationships, so whether this association is specific to romantic relationships is unclear. Given the scarcity of research on other disorders, it is hard to draw meaningful conclusions.

COMORBIDITY

Rates of comorbidity of psychopathology (or of co-occurrence at the symptom level) are high in adolescence and young adulthood (Kessler, Chiu, Demler, Merikangas, Walters, 2005; Lewinsohn et al., 1993; Merikangas et al., 2010). Yet, up to this point, we reviewed associations between psychopathology and youths' romantic relationships by key disorders, with limited attention to the issue of comorbidity. The neglect of comorbidity primarily reflects the way that research on developmental psychopathology has evolved, but this neglect also underscores the need for more complex models that incorporate issues of comorbidity.

To emphasize the importance of the issue, consider recent findings from the National Comorbidity-Adolescent Supplement (NCS-A). Among adolescents (ages 13 to 18 years), data from the NCS-A (Merikangas et al., 2010) revealed that the most common disorders were anxiety disorders (31.9%), behavior disorders (19. 1%, including 8.7% for ADHD and 6.8% for CD), mood disorders (14.3%), and substance-use disorders (11.4%). Strikingly, almost 40% of those with one class of disorder also met criteria for another class of disorder (lifetime prevalence). Specifically, 25% met criteria for two classes of disorder, 11% for three classes, and 3% for four classes; anxiety disorders were the most likely to occur alone. Similar findings emerged from the National Comorbidity Survey Replication (Kessler et al., 2005), conducted with adults age 18 years and older, in that 45% of adults evidenced comorbid disorders (22% with two diagnoses, 23% with three or more diagnoses).

Not only is comorbidity high across classes of disorders, but it also appears that youth with comorbid psychopathology are likely to be from high-risk family backgrounds. Copeland, Shanahan, Costello, and Angold (2009) examined psychosocial risk factors in two community samples using latent class analysis. Their findings identified a latent class of 8.6% of youth who had experienced high levels of parental mental illness, parental crime, interparental problems (e.g., conflict, poor communication, dissatisfaction), and parent–child conflict. These high-risk youth were uniquely at risk for comorbidity, being both the most likely youth in the samples to be diagnosed with a disruptive behavior disorder and also one of the two classes at high risk for emotional disorders.

Furthermore, youth with comorbid disorders appear to be at high risk for social dysfunction. For example, in a review of the comorbidity of depression and conduct disorder, Capaldi and Kim (2014) found that youth experiencing comorbidity (or co-occurrence of high levels of symptoms) were at risk for a broad range of problem outcomes and experienced difficulties in their social relationships. Given the family risk factors experienced by these comorbid/co-occurring youth and the problematic outcomes associated with comorbidity or co-occurrence, such youth would likely be at high risk for problematic romantic relationships.

Others have recently reviewed issues of comorbidity among adolescents and young adults with social anxiety and depressive disorders (Starr, Davila, La Greca, & Landoll, 2011), suggesting that such comorbidity is related to impairments in youths' social functioning. Moreover, impaired social functioning with peers is common among youth with anxiety, depression, and disruptive behavior problems (La Greca & Lai, 2014) and thus is likely to be impaired among youth with comorbid conditions.

There is, however, very little research that specifically speaks to the issue of comorbidity or co-occurrence of psychopathology in relation to adolescent romantic relationships. Most research, as reviewed in the earlier sections, has examined specific disorders or symptoms without considering or controlling for comorbid conditions. However, one study of early adolescent girls (ages 13 to 15 years) did examine the unique associations between different types of psychopathology (depressive, anxiety, externalizing, and eating symptoms) and romantic and sexual experiences (Starr et al., 2012). In models including all four types of symptoms, both depressive and externalizing symptoms uniquely predicted increases in sexual activity over 1 year, and eating pathology was marginally associated with decreases in dating activities. In models predicting symptoms from dating and romantic activities, greater dating activities predicted increases in depressive, externalizing, and anxiety symptoms, and greater sexual activity predicted increases in externalizing and eating pathology over 1 year. These findings suggest bidirectional associations between dating/sexual involvement and psychopathology among early adolescent girls. In addition, the study found that girls with more comorbid disorders reported more dating and sexual activities, suggesting that comorbidity may

put adolescent girls at greatest risk for potential negative outcomes. Overall, these findings provide evidence of equifinality in that different types of symptoms may lead to problematic romantic and sexual outcomes, as well as multifinality, in that romantic and sexual experiences each lead to multiple types of symptomatic outcomes.

Another study examined the association of antisocial behavior and depressive symptoms of both partners with risk for IPV in young adults (ages approximately 20 to 24 years) in a lower socioeconomic sample (Kim & Capaldi, 2004). In multivariate models predicting to IPV from both partners' antisocial behavior and depressive symptoms, it was found that young women's antisocial behavior and depressive symptoms were significantly related to concurrent levels of men's physical and psychological IPV, and women's depressive symptoms remained significant in predicting men's psychological IPV over time. Overall, the men's risk factors had little effect on their partner's IPV. These findings indicate increased risk for IPV if individuals have high levels of co-occurring symptoms of psychopathology in the externalizing and internalizing domains, and that risk also is increased because of assortative partnering by such symptoms.

ADOLESCENT PARENTHOOD AND ITS ASSOCIATION WITH PSYCHOPATHOLOGY

There is clear evidence that adolescent parenthood is associated with various types of psychopathology. High rates of depressive symptoms are found among adolescent mothers (e.g., Brown, Harris, Woods, Buman, & Cox, 2012), even higher than those among adult mothers (e.g., Deal & Holt, 1998). Furthermore, reduced support may play a role in depression among adolescent mothers. A study of low-income, single Latina and African American adolescent mothers indicated particularly high rates of prenatal depressive symptoms among those reporting low-maternal availability (Milan et al., 2007). Another study with a similar population found that increases in depressive symptoms 3 years postpartum were predicted by stressors and low levels of support (Leadbetter & Linares, 1992). Similar findings exist for young men. Not only do expectant fathers report more internalizing disorders than nonexpectant fathers (Moore & Florshein, 2001), but Lee, Fagan, and Chen (2012) also found that late adolescent fatherhood was associated with depressive symptoms, particularly among those reporting low levels of support.

Early onset depression is associated with increased risk for adolescent parenthood, particularly for females (Kessler et al., 1997). This also is true for anxiety, substance use, and conduct disorders (the latter particularly for males; Kessler et al., 1997). In line with this, a number of additional longitudinal studies have found that both male and female adolescents who in childhood demonstrate aggressive behavior, substance use, or association with deviant peers are at greater risk of adolescent parenthood (Fagot, Pears, Capaldi, Crosby, & Leve, 1998; Miller-Johnson, Winn, Coie, Malone, & Lochman, 2004; Miller-Johnson et al., 1999, Underwood, Kupersmidt, & Coie, 1996). Similarly, compared with nonexpectant males, expectant males report higher rates of behavioral disorders and substance-use disorders (Moore & Florsheim, 2001).

Psychopathology puts youth at risk for adolescent parenthood, but parenthood can increase risk for psychopathology. As noted earlier, depressive symptoms increase over time among adolescent mothers with high stress and low support (Leadbeater & Linares, 1992). In addition, adolescent males show a rise in alcohol consumption after becoming parents, whereas young-adult men do not (Little, Handley, Leuthe, & Chassin, 2009). Taken together, the data suggest that there may be bidirectional associations between adolescent parenthood and psychopathology. This is consistent with a study by Oxford et al. (2005), who categorized unmarried, pregnant 17-year-old females into three groups and followed them over time: problem prone (those who demonstrated mental health and conduct problems), psychologically vulnerable (those who demonstrated mental health problems but not conduct problems), and normative. Compared with the normative group, the psychologically vulnerable group continued to show mental health problems over time, and the problem-prone group had the worst long-term outcomes across a variety of dimensions. This may suggest that being pregnant in adolescence is primarily associated with negative outcomes among those already demonstrating conduct and mental health problems.

Psychopathology among adolescent parents is associated with relationship problems. Moore, Florsheim, and Butner (2007) found, for a sample of adolescent co-parenting couples, that mothers with a history of substance abuse and fathers with a history of conduct disorders were more likely to engage in IPV. The same research team also found that adolescent co-parenting couples in which both partners had a substance-use disorder displayed (during interaction) more hostile and less warm behaviors with one another compared to couples in which neither partner had a substance-use disorder (Florsheim & Moore, 2008).

Not surprisingly, relationship problems among adolescent parents also are associated with psychopathology. Two domains of functioning have been implicated across

a number of studies. First, IPV experienced by adolescent mothers is associated with depressive symptoms (Gavin, Lindhorst, & Lohr, 2011; Lindhorst & Oxford, 2008). Second, adolescent parents, both females and males, who are less satisfied with their partners' provision of support or involvement in caregiving report greater depressive symptoms.

Adolescent parenthood is part of a pattern of premature adulthood among conduct problem and comorbid youth (Capaldi & Stoolmiller, 1999). Because of the peak of delinquency in mid to late adolescence and high rates of substance use, becoming a parent during these years is problematic for the adolescent parent and also for the child. These young parents have not yet reached the age for the improvements associated with development and maturation.

SAME-SEX RELATIONSHIPS

There is ample evidence that sexual-minority youth experience greater psychological distress (especially depression, suicidality, and substance-use problems) than heterosexual youth (Mays & Cochran 2001; Meyer, Dietrich, & Schwartz, 2008; Ueno, 2010). These disparities are in place by early adolescence (Jager & Davis-Kean, 2011). There is some evidence that they are particularly large for youth who are attracted to both sexes (Russell, Driscoll, & Truong, 2002), youth who have greater changes in sexual orientation over time (Ott et al., 2013), and youth who identify as heterosexual but report same-sex attractions (Jager & Davis-Kean, 2011). There is evidence that these disparities remain largely stable over the transition from adolescence to adulthood (Needham, 2012) or narrow over time (Jager & Davis-Kean, 2011). Thus, although there is ongoing risk for sexual minority youth, the lack of evidence that the disparities increase over time is a positive aspect.

Compared to the research on mental health disparities among sexual-minority youth, there is very little research that examines romantic and sexual functioning and its association with psychopathology for these youth. As Russell and Consolacion (2003) describe, initiation of romantic relationships in adolescence for sexual-minority youth does not tend to follow the progression identified for heterosexual youth (see D'Augelli, 1988; Koch, 1993; Savin-Williams, 1994). The typical progression of romantic development in adolescence in which youth move from friendships to intimate dyadic relationships may not apply to sexual-minority youth who may not feel comfortable initiating, or may not be able to safely initiate, romantic or sexual involvements. As such, sexual-minority youth likely face challenges that may impact their well-being and mental health. Indeed, Glover, Galliher, and Lamere (2009) found that gay, lesbian, bisexual, and transgender (GLBT) youth (ages 14 to 21 years), who described themselves as isolated from intimate relationships, reported lower levels of relational self-esteem and higher levels of relational depression, which included beliefs about not being able to be a good partner and being disappointed in relationships.

The few additional existing studies provide a mix of good news and bad news. On the positive side, there is some evidence that sexual-minority youth are as likely to be in a romantic relationship as heterosexual youth (Russell & Consolacion, 2003), suggesting that sexual-minority youth are pursuing relationships, hence providing them the opportunity to reap the benefits of relationships. In line with this, gay male youth (ages 15 to 19 years), who reported being in a same-sex relationship, reported greater self-esteem than gay male youth not in a relationship (Bauermeister et al., 2010). Bauermeister et al. (2010) also found no differences in anxiety and depression among GLBT youth (males and females) who were in versus not in a same-sex romantic relationship. Unfortunately, comparisons with heterosexual youth could not be made in this study because it included only GLBT youth. In addition, the sample was from drop-in centers in New York City, which may not be representative of youth from other areas of the country and which may represent a sample of youth who already have better coping skills.

On the less positive side, Russell and Consolacion (2003) found that same-sex daters reported more suicidal thoughts than heterosexual daters. Interestingly, same-sex daters did not report greater depression (although they did so in comparison to heterosexual singles). The researchers suggest that this may be because being in an open same-sex relationship may increase stigma and bullying, resulting in suicidal ideation. Russell and Consolacion (2003) also found that, compared to all heterosexual youth (single and dating), sexual-minority youth who are single or who are in an opposite-sex relationship report greater anxiety. This finding has a number of implications. First, it may be that, for sexual-minority youth, although being in a same-sex relationship has some potentially negative consequences (e.g., stigma and suicidal ideation), not being in a same-sex relationship may deprive them of the benefits of intimate relationships. In addition, being single or in an opposite-sex relationship may increase feelings of isolation, loneliness, or a sense of false identity or identity confusion that may result in anxiety. Similarly, being in an opposite-sex relationship may reflect internalized homophobia, which also is associated with heightened levels of anxiety (and depression) (Bos, Sandfort, Bruyn, & Hakvoort, 2008;

Igartua, Gill, & Montoro, 2003; Szymanski, Chung, & Balsam, 2001).

Cleary, the existing literature shows that the associations between romantic and sexual functioning and psychopathology among sexual-minority youth are not simple. Although mental health disparities exist between sexual-minority and heterosexual youth, when and how they do so in the context of actual relationship and sexual functioning is not entirely clear. Furthermore, there are likely to be complex issues, revolving around issues like identity, stress, and environmental support that bear on and complicate developmental trajectories. Further research designed to examine these potentially complex associations is needed.

One area that is problematic for sexual-minority youth is that of increased risk of sexually transmitted infections associated with anal intercourse. According to CDC surveillance statistics, in 2010 the majority of new HIV infections was attributed to male-to-male sexual contact (63% overall and 78% among males). The results of a meta-analysis conducted by Herrick, Marshal, Smith, Sucato, and Stall (2011) indicated that sexual-minority youth are almost twice as likely as heterosexual youth to report engaging in sex while intoxicated. These high-risk behaviors have implications for mental as well as for physical health.

Further research regarding romantic relationship development for sexual-minority youth, using new samples, is greatly needed. The majority of research comes from the Add Health data set. Although this is a large and nationally representative data set, repeated analyses of the same sample will, eventually, fail to yield new knowledge. Furthermore, there are limitations to the data available from any one data set. Moreover, changes in sociocultural and sociopolitical contexts in the United States may result in important changes in how sexual minorities are viewed and the types of stressors they experience, which may eventually bear upon associations between romantic functioning and psychopathology.

THE PEER CONTEXT

In earlier sections, we reviewed the ways in which problematic romantic relationships (or lack of romantic relationships) have been linked with psychopathology, and particularly with depression, anxiety, and antisocial behavior. Here we take a step back to examine key antecedents of adolescents' romantic relationships—specifically, the presence and quality of their friendships—and to also consider other peer contextual issues.

There is no doubt that peer relations play an instrumental role in the development of youths' romantic relationships. As noted earlier, during early to midadolescence, other-sex close friendships become common (Collins et al., 2009; Kuttler, La Greca, & Prinstein, 1999), and youth engage in mixed-sex group interactions or group dating that is characterized by affiliation and companionship (Collins et al., 2009; Schulman & Scharf, 2000). These mixed-sex peer groups set the stage for the more intimate dyadic romantic relationships that occur in later adolescence (Collins et al., 2009; Connolly & Goldberg, 1999) and that involve higher levels of intimacy and closeness and more extensive sexual activity (Connolly & Goldberg, 1999; Shulman & Scharf, 2000).

Here we briefly describe ways that the peer context contributes to problems within romantic relationships. As Furman, Low, and Ho (2009) emphasized, adolescent romantic relationships have both positive and negative correlates; they are associated not only with social competence but also with aggressive and risky behaviors that emerge in peer contexts.

Number and Quality of Friendships

The number and quality of adolescents' same- and other-sex friendships facilitate (or hinder) romantic relationships (Connolly & Goldberg, 1999; Feiring, 1999: Furman, Simon, Shaffer, & Bouchey, 2002; Kuttler & La Greca, 2004; La Greca & Mackey, 2007; Shulman & Scharf, 2000). For example, Feiring (1999) followed youth from ages 9 to 18 years, finding that the frequency of other-sex friendships increased markedly during early adolescence and that adolescents with fewer other-sex friendships began dating later than those with more other-sex friends. Adolescents (especially girls) with more peer friendships are more likely to be involved in romantic relationships (Kuttler & La Greca, 2004).

Furthermore, across community samples, findings indicate that less socially competent youth have poorer quality romantic relationships than those who are more socially competent (e.g., Connolly et al., 2000; Herbert et al., 2013; Kuttler & La Greca, 2004; Kuttler et al., 1999; La Greca & Harrison, 2005). For example, Connolly et al. (2000) found that adolescents' reports of low friend support and negative friendship interactions predicted similar problems in their romantic relationships. Additionally, adolescents with few or no close friends or with limited interpersonal skills appear to have delayed or problematic romantic relationships (La Greca & Harrison, 2005; La Greca & Lopez, 1998).

The above developmental findings suggest that adolescents with limited close friendships, or with poor quality friendships, are at risk for problems with or delays in developing romantic relationships. In turn, absent, delayed, or problematic romantic relationships can contribute to adjustment problems and psychopathology. A recent study by Herbert and colleagues (2013) examined some of these processes in detail. Specifically, adolescents (aged 14 to 19 years) with a prior or current history of romantic relationship involvement were evaluated with respect to the number and quality of their same- and other-sex friendships and their functioning in romantic relationships. Using structural equation modeling to evaluate a developmental psychopathology model, the authors found that adolescents with greater social anxiety had poorer functioning in their same- and other-sex friendships (i.e., fewer friends, less satisfaction with friends, and less social support) that, in turn, was associated with poorer romantic relationship functioning. Impairments in same-sex friendships appeared to mark the initial deviation from normative social development for socially anxious adolescents.

Peer Selection and Socialization Processes in Romantic Relationships

Peer selection and socialization processes, also known as homophily (Kandel, 1978a, 1978b), play a key role in peer friendships and also are important for adolescents' romantic relationships (e.g., Furman & Simon, 2008; Furman et al., 2009; Simon, Aikens, & Prinstein, 2008; Wargo Aikins, Simon, & Prinstein, 2010). *Selection* refers to the process of individuals forming relationships with others (friends, romantic partners) who are similar to themselves; whereas *socialization* refers to the process of being influenced or socialized by one's friends and partners.

In the context of romantic relationships, selection processes (also referred to as "assortative partnering") may lead adolescents to select partners who share similar behaviors, attitudes, or personal characteristics. For example, Simon and colleagues (2008) examined selection processes among middle school youth, finding that even *before* developing a romantic relationship, adolescents and their romantic partners were similar on variables such as popularity, attractiveness, and depressive symptoms.

Selection and socialization processes have been most widely studied in the context of adolescent conduct problems and substance use (e.g., Dishion & Patterson, 2006; Kupersmidt, DeRosier, & Patterson, 1995). Specifically, adolescents who are high in conduct problems and substance-use behaviors often choose to associate with peers like themselves. Similarly, as discussed by Rhule-Louie and McMahon (2007), there is a significant degree of similarity between romantic partners for conduct-problem behaviors and substance use (e. g., Capaldi & Crosby, 1997; Haynie, Giordano, Manning, & Longmore, 2005; Kim & Capaldi, 2004) as well as for association with deviant peers (Krueger, Moffitt, Caspi, Bleske, & Silva, 1998); both selection and socialization processes may come into play in explaining these findings.

As discussed by Capaldi et al. (2005), selective or assortative partnering tends to occur because of at least two individual-environment interaction effects. The first effect is by active selection of environments (e.g., a young woman who likes to "party" and use substances is likely to meet young men with the same preferences). Second, engagement in conduct problems and related adjustment failures (Capaldi & Shortt, 2003) leads to unintended restriction of environmental options (e.g., an adolescent who drops out of high school may not attend a 4-year college and is less likely to date a young woman attending such a college).

In addition to selection processes, peers may influence future deviant behaviors through socialization (Dishion & Owen, 2002); and there is evidence of such socialization processes within young couples. For example, Moffitt, Caspi, Rutter, and Silva (2001) showed that controlling for the individual's prior levels of antisocial behavior, partners' antisocial behavior contributed to and encouraged antisocial behavior during the transition to adulthood.

Moreover, given higher levels of conduct-problem behaviors and delinquency in boys than in girls, such socialization influence within couples appear to be more detrimental to girls. Moffitt and colleagues' (2001) findings suggest a social amplification effect (i.e., an effect of an interaction between the individual's and partner's antisocial behavior) in predicting the persistence and growth in antisocial behavior for the girls who already showed higher levels of antisocial behavior than their female peers in adolescence.

On the other hand, young women are often considered to have a steadying or reforming effect on young men who show problem behaviors, and an association between marriage and desistence or decreases in problem behaviors in men has been found in numerous studies (Sampson & Laub, 2005). However, there is considerable heterogeneity in antisocial behavior in both girls/women and boys/men, and partner influences are likely to vary depending on their levels of antisocial behavior. Capaldi, Kim, and Owen (2008) examined influences of romantic partner's and peers' antisocial behavior on crime persistence from late adolescence through the late 20s (as indexed by official arrest records). Controlling for men's prior arrests, substance use, and depressive symptoms, findings indicated

that the young women's antisocial behavior predicted both arrest persistence and arrest onset for young men who had no previous history of arrest, whereas romantic relationship stability was protective against desistance.

Other studies, such as those by Wargo Aikins and colleagues (2010), illustrate romantic partners' socialization effects for youths' cigarette use and behavior problems. Also, in a study of high school aged adolescents, La Greca and colleagues (La Greca & Landoll, 2010) demonstrated that a romantic partner's use of cigarettes and alcohol predicted adolescents' substance use, even when controlling for friends' substance use.

Involvement with Antisocial Peers/Peer Victimization

As noted above, youth with peer/friendship problems are at risk for problems in their romantic relationships. It also appears that associations between the negative aspects of friendships and romantic relationships are *even more striking among aggressive or antisocial youth*. For example, in a rare observational study of late adolescent at-risk boys (aged about 18 years), Shortt, Capaldi, Dishion, Bank, and Owen (2003) examined the role of adolescent friends, romantic partners, and siblings in the emergence of the adult antisocial lifestyle. Across relationships, observations were coded for two behavioral domains: interpersonal negative engagement (e.g., criticism, name calling) and antisocial talk involving societal rule-breaking (e.g., suggesting the two go out and get drunk, swearing). Significant associations across relationships were seen for both negative engagement and antisocial talk, providing evidence that processes related to continuance of psychopathology in adolescence—in this case externalizing or problem behaviors—show some similarities across key close and influential relationships, including friends and romantic partners.

Moreover, there is relatively robust evidence that *involvement with antisocial and aggressive peers* is predictive of involvement in adolescent dating aggression. For example, Vézina et al. (2011) examined deviant-peer affiliation and dating violence victimization among adolescent girls. Girls with a higher level of association with antisocial peers were more likely to be involved in a risky lifestyle and report higher levels of dating violence victimization. The authors concluded that dating violence prevention efforts should target antisocial peer groups and girls displaying problem behaviors. For both boys and girls, Schnurr and Lohman (2008) found that early involvement and an increase in involvement with antisocial peers were linked to perpetrating dating violence. In addition, Foshee and colleagues (2011) found that having friends who were perpetrators or victims of dating violence was strongly associated with an adolescent's own experiences as both a perpetrator and a victim of dating violence (Arriaga & Foshee, 2004).

Being victimized by peers has also been directly linked to trajectories of dating violence victimization in adolescence. In a recent study, Brooks-Russell, Foshee, and Ennett (2013) examined heterogeneity in physical dating violence in adolescents (Grades 8 through 12) using growth mixture modeling. In multivariate models predicting to class membership, being victimized by peers distinguished the high-dating violence victimization from the noninvolved class for girls and was the only factor distinguishing the victimized from the noninvolved class for boys.

Associations have also been found for peer relational aggression and dating aggression. In a longitudinal study involving midadolescents and peer nominations, peer-group relational aggression at Time 1 positively predicted dating abuse, victimization and perpetration, and negatively predicted romantic relationship quality 6 months later—over and above individual predictions (Ellis, Chung-Hall, & Dumas, 2013). However, membership in physically aggressive peer groups at Time 1 was positively related to romantic relationship quality 6 months later.

In an unusual comparison of peer and family variables, Arriaga and Foshee (2004) compared the contributions of a much-researched predictor of dating violence, namely interparental violence, to that of having friends in violent romantic relationships. Among midadolescents, both friend-dating violence and interparental violence showed unique concurrent prediction to dating violence perpetration and victimization, but only friend violence consistently predicted dating violence 6 months later.

Peer violence has also been related to sexual aggression across partners. In a longitudinal study, Ozer, Tschann, Pasch, and Flores (2004) found that adolescent boys who engaged in peer violence were also at risk for perpetrating sexual aggression and dating violence. Results for girls were less consistent.

Overall, adolescents' involvement with antisocial and aggressive peers predicts their involvement in dating aggression, although higher friendship quality appears to be a protective factor. Peer behavior is a relatively strong and proximal predictor of adolescents' behavior in romantic relationships.

Online Communication with Peers and Partners

Technological advances that allow for immediate, rapid, and readily available communication represent another important peer context that affects adolescents' romantic relations. According to Lenhart, Ling, Campbell and

Purdell (2010), 72% of teens report using text messaging, and those who do send about 3000 messages per month. The use of social networking sites has also increased exponentially in recent years, especially among adolescents and young adults (Lenhart, Purcell, Smith, & Zickuhr, 2010).

Online communication tools, such as instant messaging, social networking sites, email, smartphone applications, and text messaging have the potential to enhance existing relationships with friends and romantic partners (e.g., Ellison, Steinfield, & Lampe, 2007; Subrahmanyam & Greenfield, 2008), enabling them to stay in touch. Indeed, Blais et al. (2008) found that greater instant messaging use was associated with greater romantic relationship quality in adolescence.

Although often a benefit to close relationships, cell phones, social networking sites, and the Internet also have the potential to complicate and even undermine romantic relationships. Adolescents and young adults report that cell phones and the Internet have been used by their romantic partners to stalk, harass, and "spy on" them (Magid, 2009). In recent work on cyber-related peer experiences, Landoll, La Greca, and Lai (2013) found that 26% of the adolescents and 8% of the young adults in the sample reported that their boyfriend/girlfriend broke up with them via a social networking site or other communication tool, and over 30% of both the adolescents and young adults reported that a peer made them feel jealous by "messing with" their boyfriend/girlfriend on a social networking site (such as by posting pictures together or writing on their Facebook wall).

Also concerning is a recent national survey indicating that about 20% of teens (aged 13 to 19 years) participate in "sexting" (i.e., sending sexually explicit picture messages) and that such activities increase among young adults ages 20 to 26 years (National Campaign to Prevent Teen and Unplanned Pregnancy, 2008); rates of sending suggestive messages via text, email, or instant messaging are even more prevalent, with 39% of teens and 59% of young adults reporting such activities. Sexting often occurs in the context of a romantic relationship (either current or desired) (Drouin & Landgraff, 2012), but when such images are distributed after a break up with a romantic partner or released with malicious intent, sexting can be associated with high levels of psychological distress (Willard, 2010).

In fact, studies of the psychological ramifications of such cyber experiences are relatively few but recently emerging. For example, negative social networking experiences have been associated with adolescents' and young adults' reports of social anxiety and depressive symptoms (Landoll et al., 2013), even when controlling for other forms of peer victimization. In another recent study, Temple and colleagues (2014) surveyed over 900 ethnically diverse high school students, finding that sexting was associated with symptoms of depression, impulsivity, and substance use. Drouin and Landgraff (2012) also found that sexting was more common among older adolescents/young adults with insecure attachments in their romantic relationships. Although further study is needed, it is reasonable to expect that these examples of cyber victimization and sexting, in particular, could undermine romantic relationships and contribute to substantial psychological distress.

THE FAMILY CONTEXT: INTERGENERATIONAL TRANSMISSION AND IMPLICATIONS FOR LONG-TERM OUTCOMES

The association between adolescent romantic functioning and psychopathology can develop in the context of the family of origin and, once developed, has implications for the adolescent's future mental health and relational well-being. A number of studies have examined the evidence for intergenerational transmission of relationship conflict and problems and the pathways or processes that may underlie such associations. Indeed, as reviewed by Capaldi, Knoble, et al. (2012), many researchers hypothesize that the primary cause of IPV perpetration is having witnessed IPV in the family of origin.

Although numerous studies have supported this association, most have involved retrospective data and did not address mechanisms. In addition, a number of studies point to a variety of additional factors beyond simply witnessing IPV. For the OYS described earlier, intergenerational transmission of IPV was examined; evidence was found for indirect rather than direct effects. Parental antisocial behavior was found to predict both IPV in the parents and poor parenting of the son, and the poor parenting was predictive of antisocial behavior in the sons, which in turn was predictive of their IPV (Capaldi & Clark, 1998). In addition, there is substantial evidence from other studies that child maltreatment and IPV are associated (for reviews see Capaldi, Kim, & Pears, 2009; Slep & O'Leary, 2001). Furthermore, in a recent study, Feiring, Simons, Cleland, and Barrett (2013) studied 160 youth with confirmed childhood sexual abuse (CSA). They found that greater shame and self-blame following the abuse were associated with dating aggression 6 years later; this was mediated through reports of greater anger. In addition, two longitudinal studies (Ehrensaft et al., 2003; White & Widom, 2003) found that conduct problems mediated between childhood physical/sexual abuse and adult IPV

perpetration. Intergenerational transmission, therefore, is a more complex issue than modeling (in adulthood) IPV that was witnessed in childhood, although this may be a part of the transmission pattern.

In addition to evidence of transmission of relationship problems via antisocial behavior, there also is evidence that depression and emotional dysregulation play a role in the intergenerational transmission of relationship dysfunction. There is growing evidence that maternal depression sets the stage for poor relational functioning and depression among offspring. The most direct evidence of this comes from a study by Katz, Hammen, and Brennan (2013). They followed 182 youth from birth to age 20 years; at age 20 years all were in committed romantic relationships. Katz et al. found support for a series of mediational models showing that maternal depression predicted greater mother-child discord at age 15 years, which then predicted poorer romantic relationship quality at age 20 years (as reported by both partners) that then predicted increases in depressive symptoms from ages 15 to 20 years. Therefore, youth growing up with depressed mothers, with whom they have poor relationships, are at increased risk for poor quality romantic relationships and greater depression. There is ample evidence for a bidirectional association between poor romantic functioning and depression in adulthood (see Davila, Stroud, & Starr, 2014). The Katz et al. study suggests that this association begins early and can have roots in the family of origin.

Kim, Pears, Capaldi, and Owen (2009) examined the role of emotional dysregulation in the intergenerational transmission of conflict with partner for the OYS sample. Emotional dysregulation was defined as intense negative affect and emotional lability. Conflict included arguments and behaviors such as shouting, but short of psychological or physical aggression. Associations were modeled prospectively across a 20-year period into early adulthood for the male offspring. No direct association of relationship conflict across generations was found. Emotion dysregulation was associated across generations, however, and there was evidence for an indirect association of conflict across generations via both emotion dysregulation and poor parental discipline.

A number of other studies, although not as direct as the Katz et al. (2013) study, are relevant for understanding and theorizing about how maternal depression and interpersonal dysfunction can lead to similar outcomes for youth. For example, maternal mood disorders increase risk of earlier puberty among girls; this is particularly true in the absence of a biological father in the house, in the presence of a stepfather, or in the presence of a stressful home environment (Ellis & Garber, 2000). This is important because girls with early pubertal timing are at greater risk for depression and risky sex (Galvao et al., 2014; Marceau, Ram, Houts, Grimm, & Susman, 2011) than their on-time or late-developing counterparts. Keenan-Miller, Hammen, and Brennan (2007) found that maternal depression predicted IPV victimization at age 20 years for young women, and this association was mediated by poorer social functioning at age 15 years. This suggests that growing up with a depressed mother may put girls at risk for more problematic, and ultimately violent, relationships in the future.

CONCLUSIONS AND FUTURE DIRECTIONS

The literature on adolescent/young adult romantic relationships has grown dramatically in the last 20 years with the increased recognition that these relationships matter, both in the moment and over time as they set the stage for subsequent relationship development and individual well-being. In line with this recognition, researchers have begun to demonstrate the ways in which adolescent romantic functioning both contributes to and is affected by psychopathology, including depression, anxiety, and externalizing problems. There have been numerous gains in knowledge in these areas, although much more research is needed. In this concluding section, we review theoretical and methodological issues in need of continued attention, and we discuss the implications for prevention and intervention.

Issues in Theory Development

The main point we want to make here is that theory development will be critical for the research on adolescent romantic relationships and psychopathology to progress. Researchers need to develop conceptually grounded hypotheses not only about whether romantic functioning will be associated with psychopathology, but about how, why, for whom, and for which specific types of romantic experiences. Theory needs to be developmentally informed to answer, for example, questions about how early experiences relate to or shape later ones and the likelihood of associations, as well as their nature, between different types of romantic functioning and psychopathology at different ages. Theory also needs to be sensitive to potential gender differences in associations over time and their differing implications for functioning. We see advances in specific models of associations as characterizing the next generation of research in this area. The section below contains further suggestions for specific variables on which to focus.

Methodological Issues

In this section we briefly highlight some methodological issues that will be important considerations for the continuing growth and development of this critical area of research.

Study Designs

There is an ongoing need for prospective studies, particularly long-term ones, that evaluate temporal associations and bidirectional influences between romantic relationships and psychopathology. Although a number of important, methodologically strong studies exist, such as the OYS, most of the existing research was not designed to well evaluate temporal associations. For example, much of the research linking social anxiety with problems in romantic relationships has focused on concurrent or short-term prospective research designs. Multi-wave prospective studies that extend over longer time periods would be useful, as well as studies that use theoretically based and conceptually driven structural models (e.g., Herbert et al., 2013) to test temporal associations among the key variables of interest.

Sample Issues/Study Populations

Much of the available research has been conducted with community samples of adolescents and college samples of young adults. Although such studies have been invaluable for examining the role of romantic relationships as both risk and protective factors for psychological disorder, they do not reveal the full story. For example, studies of adolescents' or young adults' romantic relationships that are conducted with community samples are likely to have an underrepresentation of socially anxious individuals, as such individuals are less likely to date or be romantically involved than their peers (as noted earlier in this chapter).

Future studies are needed that evaluate the romantic relationships of adolescents and young adults with clinical levels of problems as well as those with a known risk factor for clinical disorder (e.g., offspring of depressed parents). Moreover, studies of clinical populations should address a broad array of psychological problems. As is apparent from this chapter, much of the available evidence on romantic relationships and psychopathology comes from studies of youth with conduct problems, substance-use problems, depression, or social anxiety. Considerably less is known about those with eating disorders, ADHD, bipolar disorder, or other clinical and adjustment difficulties.

The diversity of study samples is also an issue for consideration. Future studies might recruit samples that are ethnically and culturally diverse, or diverse with respect to other important variables such as sexual orientation, religion, or socioeconomic status.

In particular, the current literature has focused predominantly on heterosexual relationships; thus, the literature on sexual-minority youths' romantic relationships is sparse. Most of the available research on sexual-minority youth comes from the large and nationally representative Add Health data set. However, further research examining romantic relationship development and its psychological benefits and consequences for sexual-minority youth is greatly needed.

Measurement Issues

Many studies rely on self-reports from adolescents or young adults and focus on questionnaires and survey measures. Studies that incorporate observational data (e.g., Shortt et al., 2010), reports from romantic partners (e.g., Daley & Hamman, 2002), daily diaries (e.g., Starr & Davila, 2012), or objectively coded structured interviews (e.g., Davila, Steinberg et al., 2009; Shulman, Davila, & Shachar-Shapira, 2011) would help advance the field. Furthermore, studies that incorporate data from the dyadic romantic relationship would be especially informative.

A big question concerns which types of relationship behaviors should be the focus of study and how best to define or measure them. At present, many of the relationship variables studied are disorder specific. Thus, for example, romantic relationship variables—such as self-disclosure, emotional expression, and levels of intimacy (Sparrevohn & Rapee, 2009), as well as negative emotional expression (Kashdan et al,, 2007)—have been examined among socially anxious individuals; negative interactions, aggression, and antisocial talk have been examined among youth at risk for conduct problems (e.g., Shortt et al., 2003); and excessive reassurance seeking (Starr & Davila, 2008) and self-silencing (Harper & Welsh, 2007) have been examined among depressed adolescents and young adults. Given the high co-morbidity across psychological disorders, efforts to measure romantic relationship variables comprehensively, and to capture both positive and negative aspects of such interactions, would be important and desirable.

In addition to the relationship qualities that may be linked to psychological difficulties, other descriptive aspects of romantic relationships are important to evaluate. Especially with adolescents, such variables might include the length of the romantic relationship, its intensity (e.g., casual vs. committed), whether it includes sexual intimacy, and the frequency and duration of break ups with partners.

Finally, future studies need to consider technological and cultural trends. For example, studies are needed that

examine the impact of technology on the course and outcomes of romantic relationships, as well as studies that keep abreast of emerging cultural trends in dating and romantic relationships (e.g., hooking up, oral sex, friends with benefits).

Psychological Outcomes and Issues of Comorbidity

For the most part, investigators have approached psychological outcomes as if they were discrete. However, studies are needed that measure multiple psychological outcomes and examine co-morbid psychological variables in a more consistent and sophisticated manner. In general, externalizing problems (e.g., conduct disorders, substance use) have been associated with greater problems in romantic relationships (e.g., more negative qualities, more IPV); whereas internalizing problems, and especially anxiety, have been more closely associated with the absence or delay of romantic relationships or poor communication skills within such relationships.

As noted earlier in the chapter, psychological comorbidity is high. In particular, studies are needed that examine co-morbid depression and externalizing disorders such as conduct disorder. For example, several problematic romantic relationship issues (e.g., early dating, early sexual activity, early transition from same-sex to mixed-sex groups) have been associated both with depression and conduct problems.

The neglect of comorbidity primarily reflects the way that research on developmental psychopathology has evolved. However, this neglect also underscores the need for more complex models that incorporate issues of comorbidity.

Important Mediating and Moderating Variables

As reflected in our comments on theory development, in building conceptually driven models of the impact of romantic relationships, investigators would also do well to focus on mechanisms of association. The literature on depression provides a model for doing so. For example, researchers have begun to question why depression might lead to romantic and sexual activity and what it is about such activities that can lead to depression; specific theory-driven predictions are now being tested. In general, it has been suggested that romantic experiences are inherently challenging and consequently may put youth at risk for depression, anxiety, aggressive behavior, or substance use—particularly youth with poor coping, social support, or personal resources that impair their ability to manage such challenges. Alternatively, certain youth (depressed or aggressive youth) may seek out romantic experiences to meet their support needs, compensate for poor family or peer relations, or as a means of mood regulation. These hypotheses would now be important to examine using study designs that allow for their testing.

In developing more sophisticated, conceptually driven models to understand the linkages between romantic relationships and psychopathology, concerted efforts are needed to examine variables that moderate these associations. Consistent with our earlier suggestions, several variables warrant serious consideration in this regard. In particular, *age/developmental level* may be incredibly important for understanding what is healthy or dysfunctional (e.g., sexual activity may be related to psychopathology at certain ages but not at other ages). Similarly, the *timing* of transitions to dating or to mixed-sex friendship groups may be an important consideration for mental health, as appears to be the case for youth with conduct problems. *Gender* is another key variable for understanding the connection between romantic relationships and psychological functioning. Among the findings reviewed in this chapter, it appears that girls date earlier than boys but are also more likely to report depression in romantic relations; girls also appear to be more adversely affected by sexting and IPV. Systematic attention to gender as a moderating variable is needed.

Other variables of interest include those that may be important links or mediators between romantic relationship difficulties and psychological dysfunction. Potentially important candidates for mediating variables include *interpersonal and cognitive processes* that could affect the relationship/adjustment linkages, such as co-rumination, problems with emotion regulation, communication deficits, or poor problem-solving and conflict-resolution skills.

Public Health Implications and Translational Efforts

Finally, future studies are needed that address outcomes that are clinically and practically relevant. Investigators need to translate their findings into practical implications for assessment, intervention, and prevention. In the next section, we discuss some of the clinical implications that can be drawn from the findings presented in this chapter.

Translational Implications

As this chapter demonstrates, not only are youth romantic relationships significant for normative development, they play a particularly significant role in the development and course of psychopathology. That their joint courses start early, continue into adulthood, and are transmitted across generations suggests that intervention and prevention

efforts that target their association are needed. At present, few exist.

As our review shows, the association between depression/depressive symptoms and romantic relationships is one of the most well-studied and consistently demonstrated. Yet, for the most part, there are no depression prevention or treatment programs that are explicitly aimed at or include components designed to address navigating romantic relationships. Perhaps the one exception is Interpersonal Psychotherapy for Adolescents (IPT-A; Mufson et al., 2004), a clinical treatment for depressed adolescents, and a related depression-prevention program, Interpersonal Psychotherapy - Adolescent Skills Training (IPT-AST; Young, Mufson, & Davies, 2006; Young, Mufson, & Gallop, 2010). IPT-A and IPT-AST both focus on enhancing adolescents' interpersonal relationships and teaching effective communication strategies, particularly for relationships that contribute to depressed mood. Thus, although IPT-A and IPT-AST were not designed to focus explicitly on issues of romantic relationships, in practice, they may do so for depressed adolescents who are concerned about their romantic relationships and want help with navigating them successfully. Notably, IPT-AST has shown positive effects in improving adolescents' functioning in social and dating relationships (e.g., Young, Kranzler, Gallop, & Mufson, 2012).

As discussed earlier, adolescent social anxiety can also contribute to problematic or delayed romantic relationships. At present, no evidence-based programs exist for the prevention of adolescent social anxiety. However, current work is underway to extend the IPT-AST prevention model to adolescents with elevated levels of social anxiety with or without depressive symptoms (La Greca, Ehrenreich-May, & Mufson, 2013), so data on the utility of the IPT-AST model for socially anxious adolescents will be forthcoming.

There also are no intervention or prevention programs for externalizing youth that specifically include components designed to address navigating romantic relationships. This is even true for programs that target prevention of IPV, which our review has shown is strongly associated with externalizing pathology. Whitaker, Murphy, Eckhardt, Hodges, and Cowart (2013) recently reviewed IPV prevention programs conducted with adolescents. Most studies that met design-quality criteria for inclusion in the review were universal interventions (16 of 19 or 84%) and thus did not involve selection for level of IPV risk (e.g., by higher levels of conduct problems). Nine rigorous studies were identified, although none had been replicated. Four were based in middle and high school and only one of these, a universal intervention, had an unqualified positive impact on IPV behavior, including long-term effects (Foshee et al., 1996, 2005). This program has been adapted to an intervention mailing informative booklets to parents to review with their adolescent, which has promising initial results and could potentially reach many more adolescents and families. There have been only a few successful indicated IPV prevention programs with adolescents. Wolfe et al. (2003) conducted a preventive intervention with youth involved in child protective services, with positive effects on IPV perpetration and victimization. Florsheim, McArthur, Hudak, Heavin, and Burrow-Sánchez (2011) conducted a program with pregnant teens and the babies' fathers, with beneficial effects on IPV. A note of caution regarding prevention is introduced by the fact that one universal prevention program tested with early middle school students actually had iatrogenic effects, such that the intervention conditions showed greater perpetration of physical and sexual aggression.

As discussed by Capaldi and Kim (2014), despite the fact that effective behavior-based prevention and treatment programs are available for children who exhibit externalizing problems (e.g., Reid, Eddy, Fetrow, & Stoolmiller, 1999) and internalizing problems (e.g., Stice, Shaw, Bohon, Marti, & Rohde, 2009), prevention and intervention programs targeting co-occurring symptoms are limited. This is unfortunate given the high rates of comorbidity that exist. A new treatment approach involving flexible modules suitable to addressing depression, conduct disorders, and anxiety—the MATCH approach—shows promising evidence of effectiveness in a randomized control trial (Weisz et al., 2012). Such a modular approach could be a strong direction for addressing relationship issues with multiproblem youth, and could contain a module addressing positive romantic relationship skills and violence-free relationships. Adding such a component to youth prevention and intervention programs currently in place—which are designed to address factors such as deviant peer association, conduct problems, and substance use—would also be valuable because youth at risk for such problems are also at risk for romantic relationship problems and IPV. Adding a component to ongoing programs could be a relatively simple and cost-effective way to increase prevention related to romantic relationship issues (Capaldi, Knoble et al., 2012).

Related to this, developing romantic relationship education (RE) programs that are targeted to at-risk or symptomatic youth would also be an important direction for prevention efforts. At present, there are two youth RE programs that have been shown to be efficacious (see Davila and Rhoades, in preparation) and both were

designed as universal programs to be delivered in a school context. Adapting these programs and/or developing new RE programs that are uniquely suited to the needs of different at-risk/symptomatic youth, and that are based on existing empirical data such as that reviewed in this chapter, may also be an effective way to increase romantic competence and, ultimately, decrease psychopathology among high risk adolescents.

An important conclusion to be drawn from findings on the association between romantic relationships and psychopathology in youth is that associations exist for both boys and girls. Therefore, psychopathology prevention efforts should alleviate relationship problems and enhance relationship functioning for both boys and girls and RE efforts should reduce risk for psychopathology for both boys and girls. This is particularly true for the association of externalizing problems and relationship functioning. For internalizing problems, including depressive symptoms and anxiety, associations between psychopathology and relationship functioning may in some cases be worse for adolescent girls than boys. However, associations are also found for boys, especially boys who are socially anxious, and research has not yet sufficiently studied associations among boys. Furthermore, for externalizing problems, evidence of higher risk for relationship problems because of assortative partnering by problem behaviors (i.e., that adolescents with conduct problems are likely to date adolescents with conduct problems) indicates that prevention or alleviation of psychopathology may be especially beneficial.

Considering the magnitude of public health issues caused by dysfunctional or violent romantic relationships, the state of the field regarding rigorously assessed prevention programs is fledgling. Part of the reason for this has been a relative lack of federal investment in the research necessary to develop and test such programs at an adequately rigorous level. It is also the case that, in the past, programs related to romantic relationship problems have not addressed proven risk factors such as psychopathology. Greater understanding of the role that both boys' and girls' psychopathology and related risk factors play in the development of romantic relationship problems should lead to stronger intervention programs.

In conclusion, given that dating relationships form a foundation for future romantic relationships that themselves are the foundation for the family of procreation, and that adolescent dating relationships themselves may involve the birth of children, the costs of very dysfunctional and even violent relationships for the adolescents, their offspring, and society can be very high. Thus investment in programs around relationships may reap multiple benefits.

WHAT CAN DYNAMIC SYSTEMS THEORIES OF DEVELOPMENT OFFER TO THE STUDY OF DEVELOPMENTAL PSYCHOPATHOLOGY?

The field of developmental psychopathology evolved from dissatisfaction with static models of pathology developed for the study and treatment of adults. Developmentally oriented theorists, researchers, and practitioners observed that profiles of psychological dysfunction in children tended to differ dramatically from those found in adults. Models of psychopathology that were grounded in the study of adult psychopathology contained few provisions for understanding the origins and development of psychopathology over the course of ontogenesis. Since its inception, the term *developmental psychopathology* has served a dual function. It both names a field of study within psychology as well as a particular theoretical approach within that field (Cicchetti, 2006; Cicchetti &

Toth, 2009). In inaugurating the field, Sroufe and Rutter (1984) defined developmental psychopathology as "*the study of the origins and course of individual patterns of behavioral maladaptation*, whatever the age of onset, whatever the cause, whatever the transformations in behavioral manifestation, and however complex the course of the developmental pattern may be" (p. 18, italics in original). This definition differs in important ways from the presuppositions of the medical model that informs the study of adult psychopathology. First, it identifies the subject matter of developmental psychopathology as individual patterns of behavioral maladaptation rather than as psychological disorders. As such, the definition implies that psychopathology must be understood as a phenomenon that occurs at the *psychological* level of functioning. Second, the definition proceeds from the premise that patterns of behavioral maladaptation have their origins in diverse causal processes. The phrase "whatever the cause" implies that maladaptive psychological dysfunction is to be understood not as a linear outcome of a single underlying pathology but as an emergent product of relations among multiple processes that occur over time. Third, the definition is based on the proposition that maladaptive behavior patterns, like all psychological structures, undergo developmental change and thus are processes—sequences of events that occur over time—rather than conditions. This conception stands in opposition to the idea that psychological disorders consist of fixed categories of more-or-less static and homogeneous forms. If maladaptive behavior patterns undergo developmental change, then the form of psychopathology cannot be fixed or static.

The concept of *developmental psychopathology* has its origins in organismic-developmental and (Cairns, 1983; Cicchetti, 1984; Sameroff, 1983) general systems theory (Sameroff, 1995; von Bertalanffy, 1968). From an organismic perspective, human behavior is composed of open-ended systems of representational, emotional, and behavioral processes whose functioning is sensitive to social context. Development occurs when psychological structures undergo reorganization in the direction of increasing differentiation, integration and hierarchic integration (Cicchetti, 2010). Both adaptive and maladaptive patterns of psychological activity develop through complex interactions among biological (Gogtay & Thompson, 2010; Petersen et al., 2012), psychological (Broeren, Muris, Bouwmeester, Heijden, & Abee, 2011), and sociocultural (Tronick & Beeghly, 2011) processes over time. At any given point in time, interplay multiple among risk (Muris, Brakel, Arntz, & Schouten, 2012), compensatory (Yates, 2004), vulnerability (Goodman & Brand, 2009), and protective (Ivanova & Israel, 2006; Lansford et al., 2006; Pearce, Jones, Schwab-Stone, & Ruchkin, 2003) factors canalizes development toward or away from a broad range of adaptive or maladaptive outcomes (Muris, 2006; Steinhausen, 2006). Because human development is both dynamic and context sensitive, individuals can fluctuate between adaptive and maladaptive forms of behavior as a function of time and context (Myin-Germeys, Marcelis, Krabbendam, Delespaul, & van Os, 2005). Further, forms of action that may be maladaptive in one context may be adaptive in another (Andersen, 2003; Coifman & Bonanno, 2010).

In the past 20 years, there has been an explosion of theory and research directed toward elaborating dynamic systems models of both normative and nonnormative development (Dishion, Nelson, Winter, & Bullock, 2004; Fischer, 2008; Granic & Patterson, 2006; Gottlieb & Lickliter, 2007; Kunnen, 2012; Spencer, Austin, & Schutte, 2012; Steenbeek & van Geert, 2007; Thelen & Smith, 2006). Given their joint lineage in systems principles, developmental psychopathology and dynamic systems theory have much in common (Witherington & Margett, 2009). At their most basic level, dynamic systems models maintain that order and variability *emerge* in development through the process of *self-organization* (Kelso, 1995). To say that psychological structures self-organize is to reject the idea that any single process, module, or system is primary in the developmental formation of psychological activity. Dynamic systems invoke the importance of mutual regulation among component processes (Gottlieb & Halpern, 2002); multiple emergent pathways of psychological development (Fischer & Bidell, 2006); nonlinear change (van Geert, 2009); and shifting dynamics between stability and change (Howe & Lewis, 2005).

In what follows, we examine what dynamic systems approaches can offer to the study of developmental psychopathology. We begin with an examination of theoretical and methodological problems that arise in the study of psychopathology and its development. We examine the problems that arise from the traditional approach of viewing patterns of psychological dysfunction as fixed forms rather than as emergent processes. Thereafter, after outlining their basic principles, we explore the implications of dynamic systems models for the field of developmental psychopathology (Cramer, Waldorp, van der Maas, & Borsboom, 2010a, 2010b). We illustrate these ideas through analyses of (1) the dynamic development of affective splitting and dissociation among maltreated children; (2) learning trajectories in children who exhibit difficulties

in attention; and (3) the development of adaptive and maladaptive patterns of socioemotional adjustment over time. Throughout the discussion, we explore how individual developmental pathways self-organize over time. Finally, we discuss how dynamic systems thinking can provide alternatives to the prevailing medical model approach to understanding psychological dysfunction and its development.

RETHINKING PSYCHOPATHOLOGY: FROM FIXED FORMS TO DYNAMIC TRAJECTORIES

As is well understood, the study of psychological dysfunction in adults and children is heavily influenced by the medical model of psychopathology (Kawa & Giordano, 2012; Zachar & Kendler, 2007). A series of issues arise from the application of the medical model to the study of psychological dysfunction. First, in conceptualizing patterns of maladaptive psychological activity as symptoms of underlying pathology, such patterns are treated as fixed structures or static forms. Such an approach fails to account for the massive heterogeneity that occurs within and between classes of maladaptive behavior. Second, while research is intended to understand maladaptive activity that operates within individuals, most research is organized around the study of groups. The focus on group averages tends to obscure an understanding of how maladaptive behavior develops within individuals. This leads to the related problem of *ergodicity*, which concerns the question of whether relationships established between variables at the group level are the same as those that operate at the level of processes occurring within individuals. We examine the implications of each of these problems for the study of developmental psychopathology.

The Psychopathology of Fixed Forms

The view that maladaptive behaviors are symptoms of underlying pathologies or disorders immediately frames such behaviors as fixed forms or static entities. In so doing, the pathology model rests on three basic assumptions. First, for any given category of disorder, there should be a degree of homogeneity among behaviors taken to be expressions of any given pathology. Second, it should be possible to identify the pathology or pathologies that give rise to the said symptoms. Third, there should be some degree of coherence between the so-called symptoms and the underlying pathology. However, research on psychopathology has consistently revealed the problems of heterogeneity and comorbidity (Beauchaine, 2003; Lilienfeld, 2007; Spencer, Biederman, & Mick, 2007). Within particular categories of disorder, there is heterogeneity in the forms of behavior named by the category (Waschbusch et al., 2004), the causal underpinnings of those patterns (Barry, Golmaryami, & Rivera-Hudson, 2013; Nandi, Beard, & Galia, 2009); and the effects of intervention (Carter et al., 2012; Peer, Strachan, & Spaulding, 2008). A common approach to addressing such heterogeneity is to search for subtypes within particular diagnostic categories (Herman et al., 2012). Even here, however, the various subcategories are often defined in terms of overlapping behavioral criteria (Blackburn, Logan, Donnelly, & Renwick, 2008; Hastings, Fortier, Utendale, Simard, & Robaey 2009; Martel, Goth-Owens, Martinez-Torteya, & Nigg, 2010). A related problem concerns comorbidity, or the tendency of different categories of psychological disorder to co-occur within single individuals (Boylan, Vaillancourt, Boyle, & Szatmari, 2007; Hechtman, 2009; Weismer, 2006; Wichstrøm et al., 2012). Viewed from the standpoint of the medical model, the co-occurrence of clinical diagnoses within individuals makes it difficult to discriminate the properties of one disorder from another.

However, heterogeneity, comorbidity, and other sources of variation are problems only under the presupposition that patterns of maladaptive behavior exist as coherent expressions of fixed underlying pathologies. However, there is no reason to accept these suppositions. If we relax these assumptions, questions about the forms that maladaptive behavior assume in particular individuals, groups, contexts or periods of time become open ones (Boorsboom, Cramer, Schmittman, Epskamp, & Waldorp, 2011; Cramer, Waldorp, van der Maas, & Borsboom, 2010a; Dirks, De Los, Briggs-Gowan, Cella, & Wakschlag, 2012). Instead of presuming the existence of fixed forms of psychopathology, it is better to explore how patterns of maladaptive activity arise dynamically over time within particular individuals and contexts (Kagan, 1997, 2007). Actualization of this goal requires attention to a series of additional issues.

The Problem of Averages and Aggregates

Although the focus of developmental science is on the nature of individuals, most psychological research focuses primarily on establishing relations at the level of the group or population. However, it is often unclear how relations established at the level of the group relate to the development of individuals. Over the past decades, evidence

has accumulated that demonstrates the difficulty of drawing inferences about individual behavior from research conducted on groups. Molenaar (2004) argued that such inferences are possible only under certain conditions (called ergodic assumptions) that are virtually never met in psychology. Evidence suggests that more often than not, population insights represent only a small subset of individuals at best; at worst, they are statistical artifacts that represent no one (Estes, 1956; von Eye, 2009). In the study of developmental psychopathology, these problems arise in research that focuses on the analysis of group means that are tabulated by collapsing across observations of individuals. In addition, researchers tend to base assessments of individuals on aggregate estimates of individual behavior across multiple contexts (e.g., the number of times a child exhibits a certain behavior in a given time period). Thus, research in developmental psychopathology often represents children's behavior in terms of group means of a series of decontextualized variables.

The data depicted in Figure 15.1 help illustrate this problem. Figure 15.1 identifies a series of age-related trajectories for various conduct problems (Bongers, Koot, van der Ende, & Verhulst, 2003). As indicated in Figure 15.1, not only does each assessed behavior propensity undergo different age-related trajectories, but also within each class of behavior different subgroups of children are identified that exhibit different age-related profiles of change. Thus, not only do conduct problems assume different forms, but also each class of behavior develops through diverse pathways. If one were to focus merely on group means within each category of behavior, the resulting curve would obscure the massive variability that exists among individuals and subgroups.

The Problem of Ergodicity and the Study of Change

It is commonly assumed that if a theory holds for a representative set of all possible observations of a particular phenomenon, then it must also hold for a specific subset of those observations. Although this reasoning is true in an abstract sense, its application in psychological science relies upon an unproven and likely false corollary. This is the assumption of *ergodicity*—the idea that the statistical structure of relations among variables that holds *between subjects* is statistically similar to the structure of relations among those variables that holds *within* individual subjects. To illustrate the problem of ergodicity, consider the results of studies assessing the contributions of genes and environment to the formation of psychological activity. *Heritability* coefficients refer to the percentage of variation in a given psychological disposition that can be

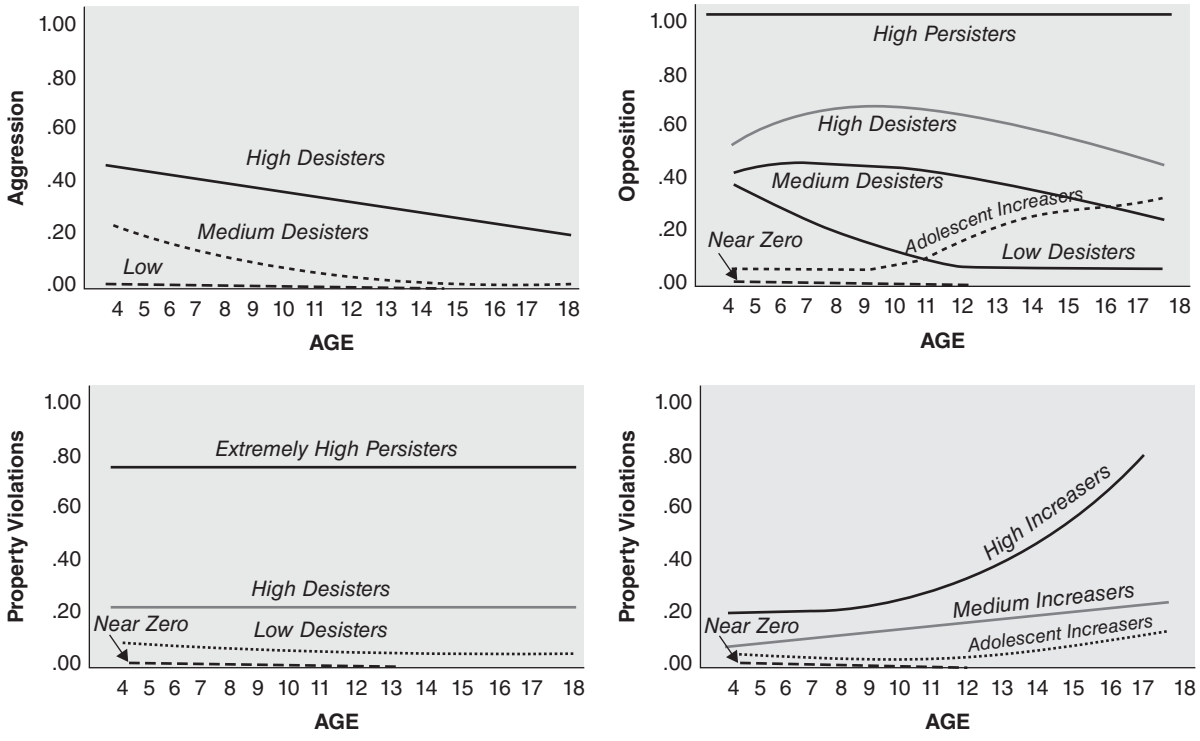

Figure 15.1 Trajectories in the development of diverse conduct problems from 4 to 18 years of age.

accounted for by differences between people in their genetics; conversely, *environmentality* refers to the percentage of variation that can be explained by differences between people in their environments. Heritability and environmentality are statistics that are derived by partitioning variation that occurs *between individuals* within a population. As such, they are concepts related to the origins of *differences between people* within populations. A heritability coefficient of .50 for IQ means that 50% of the *variation* between individuals within a population on IQ scores can be accounted for by *differences* between them in their genetics, and the remaining 50% by *differences* between them in their environments.

Problems arise, however, when concepts like heritability and environmentality—statistics that apply *only* to populations—are applied to individuals. A finding that 50% of the *variation* in IQ scores within a population can be accounted for by *differences* between those individuals in their genetics tells us nothing about the roles of genes and environment in the development of *individuals*. Individual behavior cannot be parsed into separate genetic and environmental components. To say that a disposition is *heritable* is not the same as saying that it is *inherited*. For example, adoption studies show that correlations between the IQs of adopted children and their biological parents are higher than those between adopted children and their adoptive parents. It would be a mistake to infer, however, that experience plays a less important role in the formation of intelligence than genetics. Such correlations simply indicate that the *relative rankings* of the IQs of children and their biological parents are more stable than those for children and adoptive parents. In fact, research shows that the IQ scores of adopted twins tend to be *higher* than those of nonadopted twins. Adoption tends to increase a child's IQ proportional to the socioeconomic status (SES) of the adoptive family (Duyme, Dumaret, & Tomkiewicz, 1999). When statistical relationships that hold at the level of the group fail to hold at the level of the individual, the assumption of ergodicty is violated. The assumption of ergodicity is rarely met in psychological research.

DYNAMIC SYSTEMS THEORY AND DEVELOPMENTAL PSYCHOPATHOLOGY

Dynamic systems approaches provide a framework for addressing many conceptual and empirical problems that arise in the study of developmental psychopathology. In its most basic form, *dynamic systems theory provides tools for describing how one state (of a system) develops or changes into another state over the course of time* (Weisstein, 1999). Any theory of development, learning, or intervention should be formulated as a way of describing how a particular state of a system (an early developmental state) changes into another state (a more fully developed state; improved performance) over time. In the context of developmental psychopathology, fundamental questions concern how forms of maladapative psychological functioning emerge and undergo transformation. In this paper, we describe three major principles as they relate to the dynamic development of adaptive and maladaptive behavior: (1) *dynamic systems* and *mutual regulation*; (2) *emergence* and *self-organization*; and (3) the epigenesis of developmental processes.

The Dynamics of the Person–Environment System

The word *system*, from the Greek *systema*, refers to an organized whole, or a series of things standing together. A system is not simply a set of elements or variables, or even a set of relationships among variables. Instead, a system is a collection of interrelated elements that operate as a whole. As complex dynamic systems, persons are composed of multiply nested components (e.g., organ systems, tissues, cells) whose functioning is embedded in the ecology of broader sociocultural systems. The elements of a dynamic system do not operate independently of one another. Instead, they *coact* (Gottlieb, 2002; Mascolo, 2013) and *mutually affect* (Witherington, 2011) each other over time. Novel forms of behavior emerge over time and within particular contexts as a product of local coactions among system components.

Figure 15.2 contains a model of the dynamic person–environment system (Mascolo, 2013; Mascolo & Fischer, 2010). The person–environment system is composed of five basic categories of processes: (1) individual *action* (i.e., what a person does); (2) the *objects* of action (i.e., what one's actions are performed *on*); (3) the *actions* of others; (4) *mediational means* (i.e., the tools that persons act with, e.g., language, computers); and (5) the *physical and sociocultural context*. It is essential to understand that contexts function as an integral part of the person–environment system itself, and cannot be regarded as independent variables to which persons merely react. To illustrate the functioning of the person–environment system, consider a child who experiences difficulty regulating attention. For example, when being tutored on a math problem, the child (1) performs an *act* of addition (2) *on* the math problem (e.g., 5+7). The child adjusts his actions to the ongoing and anticipated (3) guidance of his tutor. In so

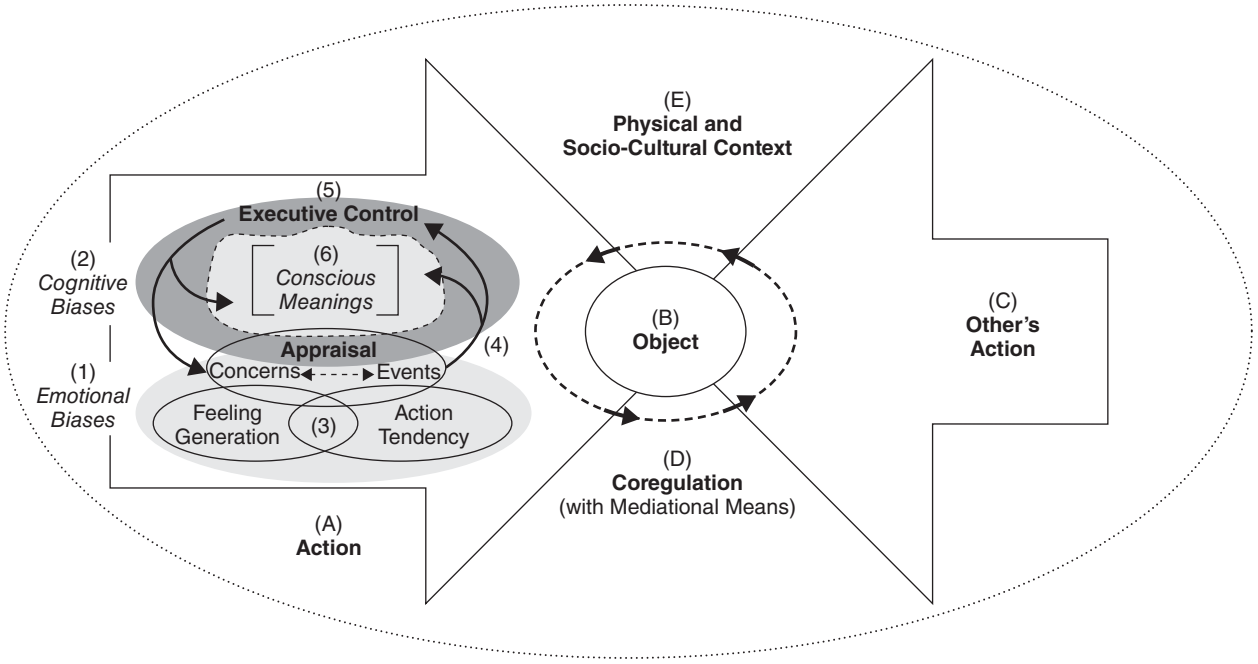

Figure 15.2 The coactive person–environment system.

doing, both the child and the tutor alike use (4) cultural tools (e.g., computer, blackboard, self-regulation techniques) to *mediate* their actions, the most important of which is *language*. Finally, the dyad's activity necessarily occurs within a (5) physical and sociocultural context (e.g., a classroom filled with desks and chairs). As a multinested system, the person–environment system contains all of the processes and dispositions that compose and mediate action, including the biological substrata that mediates a child's impulsiveness; the specific properties of the materials at hand; the representational and physical components of the problem at hand, and so forth. Within the person–environment system, there are no fundamental differences between the constraints on action that originate within individuals (e.g., executive functions), between individuals (e.g., the nature of the relationship), or from the objects on which persons act (e.g., a computer).

A system consists of sets of components (variables) and relationships among these components. The notion of relationship has various meanings. In traditional research, it means that some property of one component (e.g., its level) is associated with some property of another component. For example, if we find a component with a high level (e.g., a high level of anxiety) we can also expect to find a high (or low) level in the associated component (e.g., a high level of regulatory control). However, in a dynamic system, a relationship means that some property of one component (e.g., its level) *affects* some property of another component (e.g., its level) over the course of time. Instead of referring to relations between abstract variables, in dynamic systems, relationships among component processes are played out in the actual behavior of individuals in real time.

Figure 15.2 provides a representation of the coacting systems that operate *within* individual persons (as a part of the broader person–environment system). As indicated by the two shaded ellipses, individual action is composed of two broad classes of systems: *emotional* and *representational*. Emotion generation—which is largely nonconscious—is itself composed of three classes of mutually influencing processes: Nonconscious *appraisals* continuously monitor the relevance of event-related input for one's goals, motives, and concerns (e.g., This is a difficult math problem). Motive-relevant changes in a person's circumstances continuously modify *emotional experience* (e.g., anxiety), which thereupon provides feedback that (3) *selects* and *organizes* ongoing appraisal (4) in working memory for conscious awareness (e.g., I don't think I can do this problem!). Affective processes simultaneously activate *action tendencies* (e.g., fidgeting, withdrawal from the situation) that function in the service of an individual's broader goals, motives and concerns (Shen & Bigsby, 2010). Once conscious, (5) higher order goals (e.g., avoid being seen as incompetent) exert (6) downward control over the process of regulating thinking, feeling,

and acting (Carver & Scheier, 2013; Frijda 2009; Lewis, 1996; Mascolo, Li, Finke, & Fischer, 2003; Steenbeek & van Geert, 2007, 2008).

The Self-Organization of Adaptive and Maladaptive Forms of Action

The functioning of a dynamic system is emergent rather than predetermined. To say that psychological structures *emerge* implies that they do not exist as structures prior to their construction in development. Within dynamic systems, novel structures emerge through the process of *self-organization* (Kelso, 1995). In self-organizing systems, emergence occurs in the absence of pre-determined plans or fixed blueprints. Instead, self-organization refers to the idea that order and variability in the production patterns of adaptive and maladaptive behavior arise through the ways elements of the person–environment system mutually constrain and regulate each other over time. Dynamic systems models provide tools for tracking the ways the current state of a system self-organizes into another state.

The elements or components of dynamic systems are characterized by the fact that they can vary. Elements are properties that vary not only between systems of the same kind but also as within a system from moment to moment. Figure 15.3 depicts changes in the psychological functioning of an attention-deficit/hyperactivity disorder (ADHD)–classified child over the course of an intervention program. The figure identifies the relationship between task performance and motivation in a single child. The technical term for such a descriptive space is *state space*, and the combination of a particular system's current values on the dimensions of the space forms the system's current state. Thus, dynamic systems models assess change in a system by tracing a particular trajectory (i.e., a sequence of states) over time in a state space. As indicated in Figure 15.3, over a period of 54 days, the boy engaged in 24 sessions of computer play aimed at improving executive functioning and working memory. Before every computer game, the child was asked how motivated he was to play the game (i.e., How do you feel like playing the next game?). Total playing time was recorded, which was used as a simple measure of performance. As indicated in Figure 15.3, the changes that occur before Day 40, operating in the lower half of the state space, correspond to low levels of performance and oscillating levels of motivation. The negative covariation and oscillation observed prior to Day 40 suggests that a competitive relationship exists between these two variables. Around Day 40, this

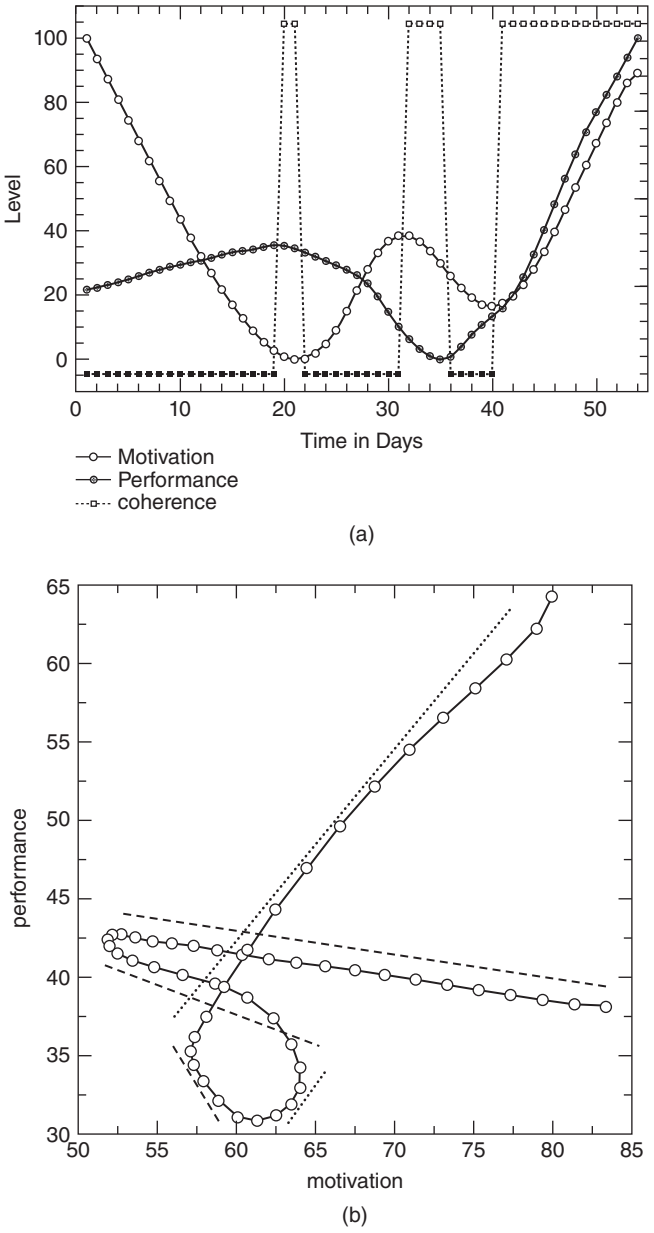

Figure 15.3 State space model of shifting relations between motivation and performance over time in a child with attention difficulties.

relationship shifted. It was replaced by a supportive relationship characterized by an increase in both motivation and in performance. Day 40 thus marked a change in an attractor—a shift from a self-sustaining conflict between motivation and performance to a pattern of self-sustaining cooperation. While these data do not indicate reasons for the shifting relation, they nonetheless indicate a change from less adaptive to a more adaptive relation between motivation and performance over time. In so doing, they

show how movement from maladaptive to adaptive action self-organizes over time.

The Epigenesis of Structure of Adaptive and Maladaptive Behavior

Over the past decades, an *epigenetic* (i.e., beyond genetic) conception of development has become increasingly prominent in the developmental sciences. At its most general level, epigenesis refers to the idea that anatomical and psychological structures emerge over time in development and are neither preformed nor predetermined (Gottlieb, 2002; Tavory, Jablonka, & Ginsburg, 2012; Wolf & Linden, 2012). In its strongest form, it refers to the idea that processes beyond the level of the genes (e.g., RNA, cytoplasm, DNA methylation) play a role activating gene expression at points of development (Danchin et al., 2011; Ferguson-Smith, 2011; Nugent & McCarty, 2011). The strong form of epigenesis challenges the central dogma of the modern synthesis (Huxley, 1942) in evolutionary theory. This central dogma states that the direction of causality between genetic and nongenetic processes in the creation of proteins is unidirectional (DNA → RNA → mRNA . . . → protein). Genes orchestrate the building of proteins but are themselves unaffected by the processes involved in protein synthesis. However, recent research has shown that nongenetic biological processes, particularly DNA methylation and histone modification, function to activate and inhibit gene expression during protein synthesis. As such, the epigenetic model embraces the idea of bidirectional rather than unidirectional causality between genetic and extragenetic processes (DNA ↔ RNA ↔ mRNA . . . ↔ protein).

Processes that regulate gene expression are sensitive to changes that occur at multiple levels of an organism's functioning in the world. Figure 15.4 contains a schematic representation (adapted from Gottlieb et al., 2006) of the hierarchical and temporal organization of the epigenetic system. As indicated in Figure 15.2, no single element of the developmental system (e.g., genes, extragenetic biological processes, individual action, or social experience) is autonomous or primary in human psychological development. Psychological structures are emergent products of coactions among both horizontal (gene–gene; cell–cell; organism–organism) and vertical (gene–cytoplasm; cell–organ; organism–ecosystem) aspects of the developmental system. For example, the offspring of rat mothers who show high levels of maternal care during a pup's first week of life (i.e., grooming, pup licking, nursing) show lower levels of stress as adults than offspring of less nurturing mothers. These maternal behaviors produce a suite of biological changes in rat pups, some of which are involved in the silencing and expressing of genes (Weaver et al., 2005). Research has identified epigenetic processes involved in the construction of psychological structures in a variety of domains in humans as well. These include the development of attachment behavior (Lickliter, 2008; Schore & Schore, 2008); emotionality and stress regulation (Champange, 2010); suicidality among adult survivors of maltreatment (Weaver et al., 2005); and other domains (Jablonka & Jones, 2005).

In the remainder of this chapter, we examine how dynamic systems models can be used to illuminate the study of the development of adaptive and maladaptive behavior in a variety of different domains. We begin with an analysis of the developmental course of affective dissociation as a strategy for managing emotional distress in maltreated children. We then examine the social dynamics of teaching and learning with children who exhibit attentional, emotional, and behavioral problems. We then turn

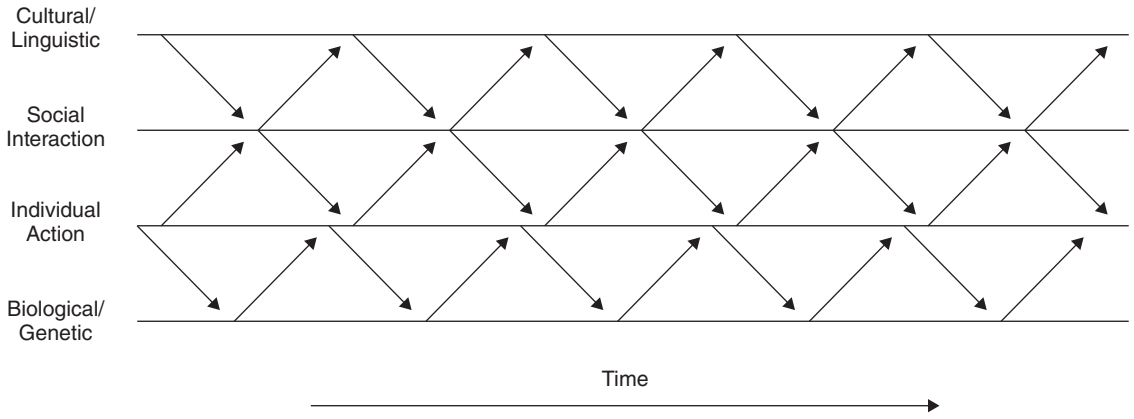

Figure 15.4 The epigenetic nature of development. Source: Adapted from Gottlieb (2002).

to an analysis of the epigenesis of adaptive and maladaptive patterns of socioemotional adjustment from infancy through adulthood.

THE DEVELOPMENT OF AFFECTIVE DISSOCIATION IN MALTREATED CHILDREN

We organize our worlds and ourselves into positive and negative splits involving right and wrong, good and bad, friends and enemies, heaven and hell, good guys and bad guys, virtue and sin (Freud, 1961/1963, 1966 Osgood et al., 1957; Sullivan, 1953; Wundt, 1905/1907). These fundamental splits identify the organizing dimension along which we structure our experiences and conceptions. We argue that positive and negative valence are the fundamental, background organizers of both normal development and psychopathology. Biases and constraints growing from positive and negative experiences organize action and shape development from birth (Fischer, Shaver, & Carnochan, 1990; Li, Wang, & Fischer, 2004). One example is affective splitting, where a person splits events, people, or aspects of a situation into positive and negative, even though to another observer the things are not simply positive and negative (Fischer & Pipp, 1984; Harter & Buddin, 1987). Examples of splitting occur naturally in young children. A 2-year-old boy had been left with his grandparents for a few days, and he split his mother into separate representations of "Good Mom" and "Bad Mom." When she called him on the telephone, he responded with affection. At the same time, he told her about the "bad Mommy" who had left him at his grandparents. A similar process occurred in a 4-year-old girl: Asked if she can be happy and sad simultaneously, she said, "No way! I've only got one head."

While these examples show normal emotional splitting, splitting can permeate a person and play a central role in psychopathology, especially in cases of abuse. Research in the area of trauma and psychopathology shows a connection between the repeated trauma of abuse and pervasive changes in relations between thinking and emotion (Figure 15.2**,** Point 3) (Cole & Putnam, 1992; Feiring et al., 2010; Hulette et al., 2011; Kenardy et al., 2007; Kim & Cicchetti, 2006; Li et al., 2004; Terr, 1991; Valentino, Cicchetti, Rogosch, & Toth, 2008). Consequences include fragmentations in the sense of self and feelings of inner badness at the core. An illustration is the case of Marilyn van Derbur.

Living in a seemingly proper middle-class family, van Derbur's father sexually abused her at night for many years through grade school and adolescence (Van Derbur Atler, 1991). She organized her experience and action into a day child and a night child. She experienced feeling quite different in her two selves:

> In order to survive, I split into a day child, who giggled and smiled, and a night child, who lay awake in a fetal position, only to be pried apart by my father. Until I was 24, the day child had no conscious knowledge of the night child. During the day, no embarrassing or angry glances ever passed between my father and me . . . because I had no conscious knowledge of what he was doing to me . . . The more degraded the night child became, the more the day child needed to excel . . . from skiing on the University of Colorado's ski team, to being a debutante, to graduating with Phi Beta Kappa Honors, to being named Miss America. I believed I was the happiest person who ever lived. I truly believed that.

The day child was bright, earned strong grades, and had many friends. The night child was afraid, ashamed, and full of night terrors. After she left home to go to a private school, her father stopped abusing her, and it took her several years to remember the nights. After she turned 18, she began to wake up with upsetting dreams and anxiety attacks that seemed to come from nowhere, particularly at night or on dates. It took several more years to remember the night child and to begin to make sense of her experience. Gradually she joined together the ways she had split her experiences.

Developmental Changes in the Structure of Skilled Action

We employ a set of tools called dynamic skills theory to analyze how splitting develops based on the intense emotions that shape learning and development (Fischer, 1980; Fischer & Bidell, 2006; Fischer, Bullock, Rotenberg, & Raya, 1993; Fischer & Rose, 1994). People develop along specific pathways, building ever more complex control systems called skills. A skill is defined not as a property of a person but instead as a property of a person in a situation. A skill comprises the joining of the person's activities with the context in which the activities happen. This principle forms one of the basics of skill theory. As indicated in Figure 15.2, the coupling between person and context (e.g., continuous perception-context-action loops) is a fundamental feature of dynamic systems models of human behavior and development. Emotion and cognition coact in the development of control systems. Over time, people build successively more complex skills—control structures that integrate increasingly complex systems of emotion, cognition, and action, both adaptive and maladaptive.

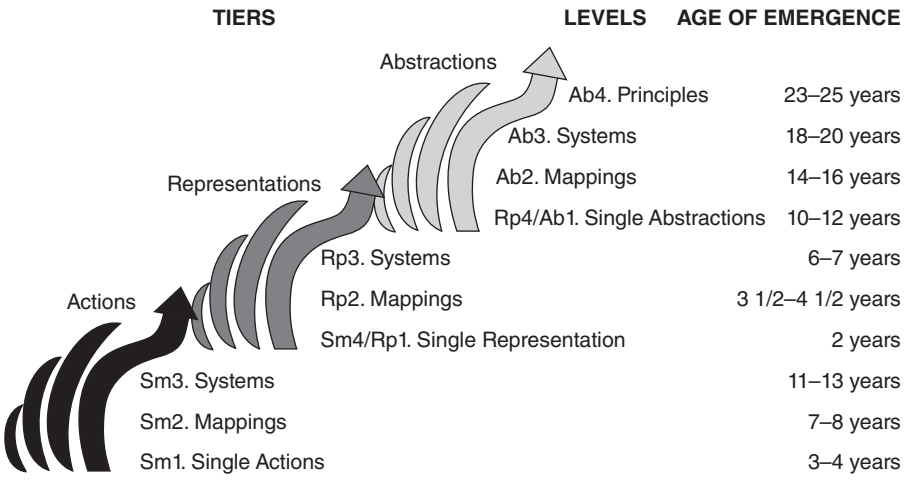

Figure 15.5 Hierarchical levels of skill development. *Source:* Fischer, 1980.

Dynamic skill theory identifies a series of 13 different levels of complexity in the development of skills from infancy through adulthood. As indicated in Figure 15.5, skills develop from the differentiation and integration of lower order skill components into increasingly higher order structures. Skills develop through four broad tiers (*reflexes*, *sensorimotor acts*, *representations*, and *abstractions*). Within each tier, skills develop through a series of four iterative steps. For example, in the *representational* tier, beginning around 18–24 months, children become able to construct concrete symbolic representations—concrete images and meanings that go beyond the information given in sensorimotor experience. Development in the representational tier begins with the ability to construct single representations (e.g., simple concrete ideas, images) at around 18–24 months of age. As shown in (1) in Figure 15.6, using single representations, a child can create simple concrete meanings like "Mommy is nice," "Daddy is mean," or "I'm a good/bad boy/girl." Around 3.5 months to 4 years of age, children gain the capacity to map one representation onto another. Such representations are called representational mappings. At this level, a child can represent the relation between two concrete ideas or representations. For example, as indicated in (2) in Figure 15.6, children can understand mappings such as "Mommy was nice because I was good" or "Daddy was mean because I was bad."

Around 6–7 years of age, children can begin to map one representational mapping onto another; this results in the formation of a single representational system. At this level, a child can relate two concrete relationships into a single integrated understanding. For example, as indicated in (3) in Figure 15.6, bringing together two mappings, a child can

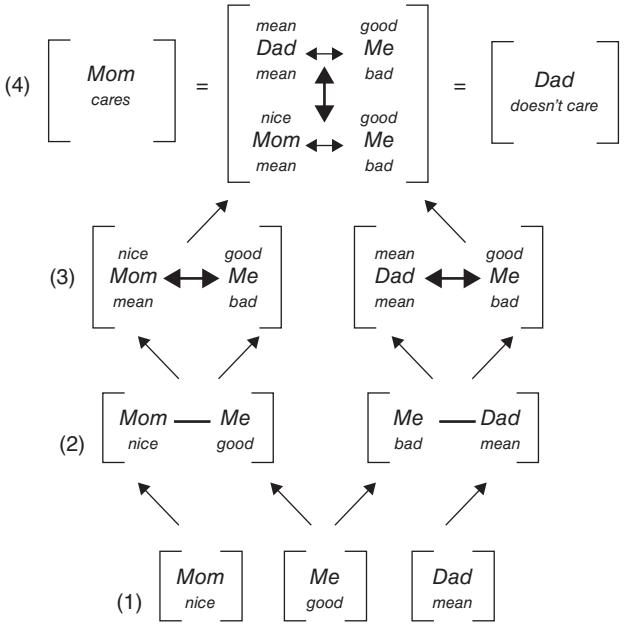

Figure 15.6 Levels within the representational tier of development.

connect "Mommy is nice when I'm good, but mean when I'm bad" or "Daddy is mean no matter if I'm good or bad." The final iterative level within a tier consists of a system of systems, which results from the intercoordination of two or more systems; a system of systems is both the fourth level of a lower order developmental tier as well as the first level of the next broad tier of development. As indicated in (4) in Figure 15.6, a system of representational systems results from the coordination of two representational systems to form a single abstraction—the first level of the abstract tier of development. At this level, abstracting across multiple

concrete interactions with her mother (e.g., Mom is angry when I'm bad but nice when I'm good), a preteen can construct a single abstract conception like "Mom has my best interests at heart." Alternatively, by abstracting across multiple interactions with her father (e.g., Dad is mean no matter if I'm good or bad), a youth can construct an abstraction like "Dad cares only about himself."

Webs of Development

We build skills for specific contexts in which we live, with no simple progression through any ladder of stages. As a result, we build diverse pathways shaped powerfully by emotions and by contexts. Thus, rather than thinking of developing skills as moving in a single direction up a ladder or staircase, it is more helpful to think of development as organized like a web of pathways, such as that shown in Figure 15.7. Automatized areas of pathways refer to behavior patterns that have been routinized and are automatically activated without effortful coordination. Functional areas refer to developmental levels operative in everyday contexts without contextual support. Optimal levels of performance refer to effortfully executed activities under the effortful control of individuals, but operating under conditions of high contextual support. Scaffolded levels of activity are those that are coconstructed between individual and in which more accomplished others support, guide task performance, or perform part of a given task.

Standard analyses of psychopathology emphasize fixation at or regression to an early stage, but we see psychopathology as development in unusual or strange contexts, such as children growing up in an abusive environment. The result of these unusual contexts is that people develop webs of skill that are adaptive in their specific world, based in their experience. Sometimes they grow up strangely. The mismatch comes with shifts outside that world, where the context-appropriate skills no longer match the particular context. People develop simultaneously along many diverse strands, building different stands and webs for acting in different contexts. Although this developmental diversity is common in both adaptive and maladaptive development, prior cognitive developmental research has used methods that made it impossible to detect such diversity in developmental pathways (Block & Block, 1980; Case & Edelstein, 1993; Rose, Rouhani, & Fischer, 2013; Stein, Dawson, & Fischer, 2010).

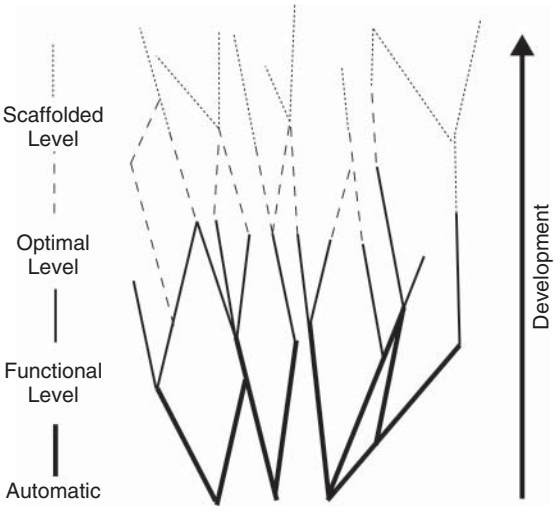

Figure 15.7 The developmental web.

At any given time in development, children (and adults) do not function at any single *point* along a pathway or strand. Instead, depending upon a wide range of variables (e.g., social context, level of support, emotional state, domain of activity), they function along a segment or range of points along a pathway (Brown & Reeve, 1987; Fischer et al., 1993). An individual's *optimal level* of performance consists of the highest level of skill that she is capable of sustaining in situations that provide high levels of contextual support. A person's *functional level* of performance refers to the level of skill at which she typically performs spontaneously in the absence of high levels of contextual support. We define the *developmental range* as the difference between optimal and functional levels of an individual's skilled activity at any given point in development. For example, suppose that a child wants to tell a story about people being mean. Often a teacher or other adult will offer support by explaining a story at the upper limits of the individual's capacity to understand. This support helps children to act at their optimal level, the upper limit on their performance. Trying to tell a story without support, children act at their functional level, which defines the limit on spontaneous performance. A person's functional level is generally lower than his or her optimal level. Further, optimal and functional levels of performance show different growth functions. While changes in one's functional level typically show continuous and slow growth, optimal level development shows abrupt changes and periods of discontinuity.

Natural Fractionation of Psychological Activity

The diverse strands in the web of development show that people's minds are naturally fractionated according to context. The control systems are distinct and independent, not coordinated or integrated (Fischer & Pipp, 1984; Stein et al., 2010). Although Piaget (1957, 1975) posited

logic as the shape of intelligence, real people do not have fully integrated or logical minds. We are driven instead by control systems that are naturally separate, but we can potentially coordinate and integrate diverse strands. Although the various control systems that drive human action are naturally fractionated rather than integrated, any particular control system (or skill) is itself an integral structure in the sense that it is composed of some sort of configuration of representation, affect and motor action that operate in relation to each other within the larger person–environment system. Real human behavior is the result of the ways separate control systems act—that is, how they cooperate, work independently, or even work against each other. For example, when learning to ride a bicycle, control systems for steering, pedaling and balancing tend to operate separate from one another. Directing attention toward balancing draws resources away from steering and pedaling, and vice-versa. Over time, as these control systems become intercoordinated, they operate together as a single seamless skill, freeing resources for the development of new skills (e.g., manipulating the gears). Although these skills start off separate, each skill nonetheless consists of a structured integration of representation, affect and motor action dynamically operating within particular physical and social environments.

One well-documented source of difference is tasks, with hundreds of studies showing that the same capacity across tasks produces behaviors at different developmental levels. The conclusion, to use Piaget's terminology, is that décalage (unevenness) is the rule in development in most domains (Bavelier et al., 2012; Block & Block, 1980; Flavell, 1982). For instance, most 7-year-olds who go to school understand that when orange juice is transferred into a container with a different shape, the total amount stays the same. But when these same 7-year-olds are asked about conservation of area (for example, the amount of area covered by an array of farm buildings in diverse locations), they do not generalize to this new task. Children need to construct each type of conservation anew. It is not a general concept but is tied to the task where it was learned. In the developmental web, this fact is represented by separate strands for the two types of conservation.

So many tasks create separate strands, creating an inevitable, pervasive fractionation. In a classroom, children learn how to do addition, but playing with marbles on the playground they learn a different addition skill. Emotions organize experience into distinct strands, as with emotional splitting. Indeed domain specificity is everywhere, and generalization takes special effort. Application and generalization of skills across contexts is not at all automatic. Instead, application of skills from one context or developmental domain to another typically takes time, effort, and even training. Skills can coordinate across contexts and domains in many ways depending upon task demands, social context, and the nature of the skills themselves. For example, distinct skills can (1) operate *independent* of one another (e.g., watching basketball while eating popcorn) or (2) *work together* (e.g., running while dribbling a basketball). Further, they can (3) *mutually support* each other (e.g., naming the ink color of words that name the same ink color in which the word is printed) or (4) *compete* with each another (e.g., naming the ink color of words that name colors that are inconsistent with the ink color in which the word is printed; the Stroop effect). While development involves the effortful coordination of skills across contexts or skills, the coactive coordination of skills also leads to new forms of learning and poses novel learning challenges for the developing person.

With fractionation so pervasive, people commonly fail to recognize what goes together in the world. We routinely simplify tasks by splitting components as if they are separate tasks. A 2-year-old who was distressed at being left by his mother emotionally split his experience of her into separate representations—one good and one bad. Alternatively, a 5-year-old split a story that his father had told him so that it left out the ways that his Dad had been nice to him and only included a mean interaction. Dealing with conservation of liquid, for instance, children commonly split amount into two separate quantities—height and width—and they ignore the other one, focusing on just height or just width (Piaget & Szeminska, 1941/1952). Thus, people routinely oversimplify challenging tasks and situations based on their level of understanding or their feelings about the events around them.

On a more positive note, with development people move *toward integration*, constructing specific coordinations of previously separate skills. Coordination is a fundamental part of development, laying a groundwork for more complex control systems (Fischer & Bidell, 2006; Fischer & Rose, 1994; Fischer & Watson, 1981; Mascolo & Fischer, 1998). Indeed vacillation between skills can be a sign of progress, marking a step toward integration. When a child vacillates between two skills, a process called shift of focus, the vacillation marks transition to a new coordination. The dual activation marks transition to a new understanding based on a novel coordination (Goldin-Meadow, Alibali, & Church, 1993). In this way, retelling an integrated story involving nice and mean themes as a sequence of two separate stories (one about nice interactions and then one about mean ones) demonstrates the shift-of-focus capacity,

which marks progress toward eventual integration of fractionated skill components.

Passive and Active Splitting and Dissociation

In splitting, elements of an action, task, or situation are separated despite the obvious need for them to be coordinated. Affective splitting happens when such elements are separated into positive and negative classes. The more general concept of dissociation happens when mental/affective elements are separated despite the fact that they should be coordinated in the everyday world. In psychopathology, the words *dissociation* and *splitting* are used to designate *motivated* separation, such as dissociating a feeling from the thought where it originated, dissociating the self into multiple personalities, or splitting family and friends into good and bad people (Breuer & Freud, 1895/1955; Putnam, 1989, 1997; Putnam, Helmers, & Trickett, 1993). Typically, clinical analyses, especially when based in Freudian thought (Freud, 1917/1961/1963, 1923/1961), presume active control of dissociation and splitting in some unconscious way. Yet if psychological activity is naturally separated into domains (naturally fractionated), then splitting and dissociation happen routinely every day, simply because a person has not coordinated skills or experiences (Feffer, 1982). There is no specific motive required to motivate splitting or dissociation.

At the same time, splitting and dissociation can be motivated, usually through unconscious processes—special cases involving a split or dissociation that is functional albeit unconscious. Analyzing the development of splitting and dissociation requires distinguishing passive separation from the types of controlled separation that permeate motivated dissociation and splitting. A vivid example comes from a case of repeated sexual abuse of 8-year-old Shirley, whose father repeatedly raped her in her bed in the basement of her home (Canadian Broadcasting Corporation, 1990). This case shows how the trauma of abuse can be partially controlled unconsciously, and how a child can survive such horrendous abuse. Whenever she resisted his efforts, he beat her up. As a coping mechanism, she focused on a little hole on the wall near her bed. She concentrated so intensely that she could experience herself as hiding in the hole. From inside the hole, she could dissociate herself from the ongoing rape, and in that way, she could survive the trauma without disruptive distress.

Coping was always difficult, but it was especially hard when her father changed what he did. When her mother went out to shop, her father committed the rape upstairs, not in the usual basement room. The context had allowed her to control her reaction, but without that context, especially the hole where she put her mind, she was unable to dissociate. She screamed and fought with her father, and he became viciously angry, knocking her unconscious and continuing with the rape. With this sort of situation involving abuse and trauma, children need skills of dissociation to survive (Cole & Putnam, 1992; Famularo et al., 1994; Feiring et al., 2010; Terr, 1991).

In this way, people can develop controlled dissociation and splitting, which vary along a dimension from actively controlled to passive. In *active dissociation*, people purposely (consciously or unconsciously) keep two experiences separated. Some psychological disorders such as multiple personality are grounded in active dissociation. Many Freudian defense mechanisms involve active dissociation, as with repression, in which one part of the mind works to prevent a thought or feeling from entering awareness. Experimental research has established that repression and active dissociation take place not only in pathology but also in normal functioning, especially in hypnosis, dreaming, and in experiences of religious spirit possession (Cepeda et al., 2013; Erdelyi, 1985; Foulkes, 1982; Hencke, 1996; Hilgard, 1977; Meares, 2012; Mischel & Mischel, 1958).

When viewed from a dynamic skills perspective, active dissociation is a developmental accomplishment: people need to create a coordination for active dissociation so that they can purposely keep components separated. The groundwork for this capacity begins to develop at about 4 to 6 years of age, when children can for the first time actively dissociate components. Shirley used this capacity when she mentally put her mind in a hole in the wall to separate her personal experience from what her father was doing to her body during the rape. As people develop ever more complex mental skills, they can construct more complex types of dissociative coordination (Freud, 1936/1966; Haan, 1977; Vaillant, 1977). We hypothesize that the strong forms of active dissociation that are often described in psychopathology begin at 4 to 6 years with the first dissociative capacity but reach full fruition during adolescence. Youth develop complex abstract skills that bring together many components of action, thought, and feeling, and this capacity gives them great potential for complex thinking, even when the complexities are not healthy.

In this chapter, we will describe a developmental pathway that produces divided consciousness. We call it *hidden family violence*, in which people live two rigidly separate worlds at home and in public. At home, they act in physically and emotionally abusive ways with their children, but they keep that pattern hidden from public view. In public, they show a world of good behavior, acting as the

perfect family. We call this pattern *isolating dissociation*, with development moving along two dissociated pathways: One is the public, "good" self, which is displayed in conventional interactions in the public world of school, community, and church. The other is the private, "bad" self, which is displayed in intimate interactions in the family. This dissociation develops originally from environmentally supported dissociations tied to children's experiences in public and private contexts. Over time, development moves toward active dissociation of private and public worlds, with the private world hidden from public view.

It is important to note the idiosyncratic nature of such developmental processes, even as they point to more universal developmental processes. The patterns of active dissociation exhibited in hidden family violence (and other forms of maltreatment) involve the construction of specific developmental pathways. Such idiosyncrasies are the result of the fact that development processes operate as a complex, dynamic system. Although the developmental pathways through which individuals develop are idiosyncratic, they nonetheless point to more universal developmental processes. However, what we conceive to be a universal process is not the average or typical trajectory abstracted across many individuals, but instead the set of underlying processes and principles that describe how such pathways are constructed. In this section, these include the emergent principles of dissociation and integration.

Growing Up Abused

Recurrent abuse radically shifts the shape of development. Our thesis is that recurring, extreme emotional experiences caused by maltreatment fundamentally alter social-emotional development, changing how people organize themselves along the positive–negative dimension and inducing dissociation based on the type of abuse. One result is predominant negativity in self-representation, spreading to many social relationships and accompanied by splitting and dissociation of both self and other. Continuing maltreatment produces repeated traumas and fundamental changes in personality, which include an affect of inner badness and self-fragmentation (Breuer & Freud, 1895/1955; Famularo et al., 1994; Hencke, 1996; Putnam, 1993; Terr, 1991; Westen & Cohen, 1992; Westen et al., 2012). Of all the patterns of maltreatment, the most destructive appear to be repeated sexual abuse and the combination of physical abuse with emotional abuse. When children try to deal with the dangers of repeated abuse, they organize themselves in ways that aid survival. These patterns often become integrated into a child's personality, and they can turn out to be maladaptive, even in benign, day-to-day interactions. Pervasive outcomes include a negativity bias and frequent dissociation/splitting, although outcomes vary widely with the type and severity of abuse. That is, abusive experiences create diverse developmental pathways, including multiple personality, hidden family violence as well as borderline, narcissistic personality disorder, and psychopathy (Meares, 2012).

Two Characteristics: Negativity Bias and Dissociation

Findings suggest a sketch of the pathways produced by abuse in children's constructions of positive and negative interactions as well as self-representations (Ayoub, Willett, & Robinson, 1993; Cicchetti & Toth, 2005; Feiring et al., 2010; Fischer & Ayoub, 1994; Fischer & Bidell, 2006; Fischer & Pipp, 1984; Fischer & Rose, 1994). Research shows that in severely maltreated children and adolescents, the positivity bias in their approach to events evaporates early on and is replaced by a negativity bias. The emotions of maltreated children tend to be dominated by negativity. Among maltreated individuals, representations about negative interactions are rich, dynamic, involving, and often frightening for people witnessing such interactions, and even for the children themselves. As the children grow older, they typically try to inhibit negative expression in certain contexts, particularly when they sense danger from a powerful adult or older child (Ayoub et al., 2006) or when other people are listening.

In addition to this transformation to a negativity bias, abuse seems to produce increased splitting and dissociation in representations of self and others. Patients with dissociative patterns such as hidden family violence and multiple personality show a remarkably high incidence of severe maltreatment (Ayoub et al., 2003, 2006; Putnam, 1989; Westen & Cohen, 1992). Maltreatment leads to prominent dissociation and splitting early in development (Calverley et al., 1994). Children show unrealistic distortions such as false positive affect (Crittenden, 1988) and overevaluations of their own competence (Vondra et al., 1989). Other findings include using fewer words about internal states, attributing those states to fewer people, and limiting their attributions to narrower contexts (Cicchetti & Beeghly, 1987). Affective splitting increases unrealistic views of others and self, which eventually leads to maladaptive patterns among adults such as narcissism and borderline personality (Meares, 2012).

In reacting to maltreatment, children struggle to see themselves as competent and in control. Abuse delays development of self and the ability to get along with others

(Aber et al., 1989; Ayoub et al., 2006). But even worse is the lack of trust and love that goes with maltreatment, often producing not simply delay but a shift to a different developmental pathway dominated by negativity and the use of splitting and dissociation to organize self in relationships. These results do not mean that only abused children show emotional splitting. Remember that splitting and dissociation occur normally in all children and adults. However, with maltreatment come new kinds of splitting and dissociation, starting with a strong negativity bias toward both self and others. Trust is a deep, broad issue for maltreated children, who typically show a marked dissociation including lack of trust in close relationships.

Abusive Relationships

The organization of action and thought adapts to fit the close relationships that children experience in the family. Child and adult come to relate to other people in ways shaped by the relationships in their family (Sullivan, 1953). Close relationships form the foundation for a child's personal development (Ainsworth et al., 1978; Bretherton & Waters, 1985; Crittenden, 1988; Fischer & Bidell, 2006; Fischer et al., 1990; Mascolo & Fischer, 2010; Vondra et al., 1990) and are candidates for the primary source of environmental influences on that development (Waller & Shaver, 1993; Westen et al., 2012). As we sketched above, a child's initial organization of these interactions naturally starts out as split into positive and negative, including good and bad self, good and bad parent, nice and mean peers, and good and evil forces in the world.

Continued maltreatment in close relationships alters how children organize their experience as positive and negative, and these consequences transform their developmental pathways. They start at a young age with normal affective splitting into good and bad. Children who are not maltreated typically develop skills for integrating opposing experiences while simultaneously focusing on the positive (although young children can enjoy playing aggressively). In contrast, maltreated children split or dissociate their experiences of relationships while focusing on negative emotions. When they grow up, many of these children have created what Westen (Westen & Cohen, 1992; Westen et al., 2012) has called malevolent rather than benevolent self-concepts. Simultaneously, they develop sophisticated strategies for dissociating their experiences of people, events, and emotions. Happily, some fortunate children discover the healing power of healthy relationships, and move away from abusive pathways, while often still showing effects of abuse (Cicchetti, 1989, 2005, 2013). Such children illustrate the idiosyncratic nature of individual pathways and suggest that the conditions that give rise to active and passive dissociation are probabilistic rather than deterministic.

Hidden Family Violence and Isolating Dissociation

One common type of maltreatment we call *hidden family violence*. It produces a specific kind of dissociation, which is grounded in sharply isolating different domains of social life. Families hiding violence sharply split their private and public worlds so as to encapsulate violence in their private relationships and maintain a positive public image. Children in such families build a dissociation between a benevolent public self and a malevolent (abusive or abused) self in private, with little integration between the two.

The pattern starts with passive dissociation of public and private, which becomes more active as children internalize the separation and strive to sustain it. The basic mechanism is isolating dissociation, shifting from public to private or vice versa, maintaining a rigid distinction. Adults developing along this pathway have great skill at sustaining the separation, keeping their experienced worlds distinct. In public settings, such as shopping or church, they are well behaved, seemingly outstanding citizens. They hide all signs of violence at home. They often champion moral causes and criticize others who do not conform, showing devout religious belief or intense commitment to an ethnic group. Asked about maltreatment, they vehemently reject it. They seem to believe that they are perfect parents. They sustain such a powerful split between the public and the private that their malevolent private world seems to disappear.

Of course, the distinction between public and private is pervasive in human cultures. Families everywhere clearly separate what is appropriate behavior in public and in private (Heider, 1991; Wallbott & Scherer, 1993). What distinguishes hidden family violence is the way the distinction is defined emotionally, centering on isolating dissociation. The private world is marked by tyranny, maltreatment, and emphasis on power. The public world in contrast shows a prosocial stance, with stereotyped, positive images and inability to talk about the private world.

Skills for Isolating Dissociation

Hidden family violence starts with dissociation arising from emotional experiences related to trauma, usually in important relationships. Hidden family violence is built around a rigid situational structure with strong dissociation between private and public domains. As a result, children

growing up in this situation develop *isolating dissociation*, separating public and private worlds with only unconscious coordination. Children learn to shift from one domain to the other, not coordinating the domains except unconsciously. They employ shift of focus, a simple shifting between skills, requiring no evident coordination but requiring decisions about which world is focal—public or private (Fischer & Bidell, 2006; Fischer, 1980; Mascolo & Fischer, 2010). In our research with young children, many have demonstrated affective splitting by the first half of the second year. Recall the 2-year-old boy who split his mother into Good Mom and Bad Mom when he talked with her on the phone.

The splitting is especially pronounced in children who have been both physically threatened and emotionally berated. These toddlers display conventional but faked positive emotion, or they take on a caretaking, parentified stance showing both a negativity bias, an attempt to control the interaction (Ayoub et al., 2006; Cicchetti & Toth, 2005; Cicchetti & Beeghly, 1987; Crittenden, 1988) as well as sequelae in adults (Main & Hesse, 1990). These children also tend to inhibit negative emotion with adults but act aggressively with peers and others they perceive as less powerful. Parents in hidden-violence families reinforce this separation by being secretive about their home life and forbidding their children from talking about it, especially with outsiders. Outside the home, the parents are polite and overtly kind to their children, while inside the home they act as abusive tyrants. The type of hidden family violence we have most frequently encountered involves physical and emotional abuse in private.

Our focus will be on this pattern, illustrated by the case of Mr. M, a 37-year-old church elder, a successful businessman, and respected leader in a New England town. He owned a fleet of ice cream trucks, which drove through neighborhoods ringing their bells to gather children and adults to buy ice cream. Mr. M indicated that he had no close friends. What mattered to him was his family, which he said was widely respected in the community, close-knit, and "good." He focused on his successful business, his family's church attendance, his children's regular school attendance, and his position in the church. He reported that his marriage was wonderful and that his wife was the perfect woman for him. In public, he acted as a model husband and father. At home, he was dominant and in constant need of being correct. He would routinely degrade and abuse his wife. He read selected passages from the Bible, and according to his interpretation, admonished her as a whore who should repent. He would then physically assault her, telling her that she must obey him as scripture demands. He was often sadistic in his punishment of the children. Under great stress, his wife eventually reported his abuse of the children and thus brought him to the attention of the Department of Social Services.

Mr. M described his own childhood in idyllic terms, but with no recollection of details. He said that his father was a good provider and a respected citizen. Evidence from family friends indicated that his father was a stern disciplinarian who was harsh with his children. Mr. M consistently denied being violent at home. His children denied that he abused them and claimed that their injuries came from accidents at home, on the playground, or in sports. When Mr. M's wife and children were able to escape to the safety of a shelter, they related information about their abuse in private. Even after allegations were confirmed with physical evidence, Mr. M denied them. Mr. M showed isolating dissociation of his public and private worlds.

Drawing on the tools provided by dynamic skill theory (Figure 15.5), we analyze the development of dissociation through a series of levels, from representations of concrete agents in social interactions to abstractions of intangible personality characteristics. In so doing, we describe developmental changes in the structure of children's dissociations in terms of a series of skill diagrams of the sort provided in Figure 15.6. Skill diagrams identify the structure and developmental level of integrative structures of thinking, feeling and acting in terms of the levels of skill identified by skill theory. Levels of dissociative skill develop over time in terms of patterns of differentiation and coordination that are typical of developmental change in general. The primary difference is that instead of acts of coordination that result in relating one skill element to another, dissociative skills involve coordinative acts of separating elements of meaning along positive and negative emotions and evaluations.

First Tier of Dissociation: Isolating Agents

Hidden family violence develops through a series of levels of isolating dissociation. First, children develop *isolating agents*, which are coordinated within each domain, public or private, but not across domains. Gradually the isolating agents of children become the *isolating personalities* of adolescents and adults, and the dissociation becomes highly skilled.

Fluent control of representations of individual agents first develops at 2 to 2.5 years, and at that time isolating dissociation starts with the shift-of-focus process. Children become nervous when their father acts angry, reminding them of previous abuse. They typically see themselves as negative $\mathbf{ME_{MEAN}}$, and so they try to shift to what

they believe their father wants, $\mathbf{ME_{NICE}}$. This kind of shift takes place normally in most children if their family becomes upset. For example, operating at the level of single representations (Level Rp1 in Figure 15.5), 2.5-year-old Jonathan heard his mother sounding angry, and he began to jump around, trying to get her to laugh and play. He tried to shift her emotion from negative to positive:

$$\left[\mathbf{ME_{MEAN}}\right] > \left[\mathbf{ME_{NICE}}\right] \tag{15.1}$$

In abusive families, parental upset often leads to abuse, and children watch vigilantly for a hint of negativity and then try to shift to the positive, such as $\mathbf{ME_{NICE}}$, and so avoid the negative, $\mathbf{ME_{BAD}}$ or $\mathbf{ME_{MEAN}}$. Through emotional splitting they try to avoid the bad.

$$\underline{\mathbf{not}}\ \left[\mathbf{ME_{BAD}}\right] \not> \left[\mathbf{ME_{GOOD}}\right] \tag{15.2}$$

In this first crude dissociation skill a child tries to suppress $\mathbf{ME_{BAD}}$ and works unconsciously to shift to $\mathbf{ME_{GOOD}}$, provided that the context supports it. If the context supports the opposite representation, $\mathbf{ME_{BAD}}$, children will have great difficulty sustaining the shift at this level, but they will gain more control as they develop.

Children of this age also start to distinguish between how to act in private (e.g., dealing with their family at home) and in public (e.g., climbing on the town's play structure). In this way, they shift between representations of private and public and thus begin to internalize differences in their public and private worlds. Children in public work to keep a focus on $\mathbf{ME_{GOOD}}$, reserving $\mathbf{ME_{BAD}}$ mostly for private settings (as parents can attest). That is, they avoid $\mathbf{ME_{BAD}}$ in public.

$$\left[\mathbf{ME\text{-}PRIVATE_{BAD}}\right] > \left[\mathbf{ME\text{-}PUBLIC_{GOOD}}\right] \tag{15.3}$$

When maltreated children differentiate public and private, they try to dissociate the two.

On the playground, they strive to keep in mind their private world, acting good and proper. They avoid acting out the private **ME**s that connect to their abuse at home. We represent this affective splitting with a bar through the symbol for shift of focus.

$$\underline{\mathbf{not}}\ \left[\mathbf{ME\text{-}PRIVATE_{BAD}}\right] \not> \left[\mathbf{ME\text{-}PUBLIC_{GOOD}}\right] \tag{15.4}$$

Isolating dissociation allows **ME-PUBLIC** to suppress and control **ME-PRIVATE** in contexts that support focus on the public sphere. The same limit was present for the isolating shift from $\mathbf{ME_{BAD}}$ to $\mathbf{ME_{GOOD}}$. Single representations have little power for overcoming context effects and so are not generally effective. The ability to relate representations using representational mappings (Level Rp2) gives children a stronger capacity to direct their own activities. That means that more stable dissociation requires the stronger structures that derive from coordination of representations into mappings, because they provide a mechanism for children to control that mapping, shifting **MOM** from mean to nice.

$$\left[\mathbf{MOM_{MEAN}} \text{ —— } \mathbf{ME_{NICE}}\right] \tag{15.5}$$

Normally the capacity to sustain mappings develops at about 4 years and creates many new skills involving relations with other people, such as mother to father or mother to child (Fischer & Pipp, 1984). Children living in a situation of hidden family violence manipulate these skills frequently in their life in private. When 4-year-old Jason's mom scolded his father sitting at dinner, Jason drew attention intensely to the drawing he did earlier that day (taped on the wall near the table). This abrupt switch led his parents to recognize immediately that he was trying to change their interaction. Jason was attempting to direct his mother's attention to something happy.

At this age children show a surge in understanding role relationships, which gives children in abusive families a capacity to separate public and private roles, thus facilitating strong isolating dissociation of public and private. For example, a child can maintain a public pattern of interaction, such as acting out **ME-PUBLIC** playing with their father, even though the primary private relationship with him is abusive boss interacting with bad child:

$$\underline{\mathbf{not}}\ \left[\mathbf{ME_{BAD}} \overset{\text{private}}{\text{——}} \mathbf{DAD_{BOSS}}\right] \not> \left[\mathbf{ME_{GOOD}} \overset{\text{public}}{\text{——}} \mathbf{DAD_{GOOD}}\right] \tag{15.6}$$

By age 6 or 7 children can build representational systems (Level Rp3), giving them more reliable control over their public and private worlds. At school or on the playground they can shift from public to private modes depending on who is more powerful. Roger shows this movement to a higher developmental step, sharply distinguishing public versus private, as for example when he tried to impose his private mode on other children whom he thought he could dominate. At age 9 Roger made a conscious effort to please his teacher and earn her approval. Being watched by adults Roger was a model student, even helping teachers to

monitor class when they had to leave the room. However, out of sight of the teacher he was a ruthless bully, threatening other children to take their possessions or make them help him with homework, based on his assessment of their power. Approached by an older, stronger boy, he would yield. Threatened by another boy, he would cry and beg for mercy. Roger bragged that he had a good family, including his father's business, money, and community respect. He did not say that his father, Mr. S, was strict and unpredictable and his mother was visibly sad and passive. Mr. S expected the children to respond quickly when he made a demand, and he often grew angry. In private, he told his children that they were worthless misfits, and he routinely degraded his wife, even physically abusing her. She often cried in silence. At home, Roger was subjected to the hidden family violence pattern and dissociated public and private, as evident in his relationships at school. In public (with teachers watching) he was a good boy, seeking the teacher's approval. At home, he was submissive (a follower or victim) and obeyed his father's commands and was frequently punished. In school with no teachers watching, the private domain dominated: Roger would take on the role of either follower or bully, based on his judgment of the other child's power. Now social relationships were becoming increasingly complex involving (1) both public and private representational systems (Level Rp3) with multiple roles and (2) an isolating shift of focus between public and private systems:

$$\left[\begin{array}{c}\text{OBEY}\\ \text{ME-FOLL'R}\\ \text{BAD}\end{array}\ \overset{\text{private}}{\longleftrightarrow}\ \begin{array}{c}\text{DEMAND}\\ \text{YOU-BOSS}\\ \text{PUNISH}\end{array}\right] \gtrdot \left[\begin{array}{c}\text{GOOD}\\ \text{ME-STUD'T}\\ \text{OBEY}\end{array}\ \overset{\text{public}}{\longleftrightarrow}\ \begin{array}{c}\text{LIKE}\\ \text{YOU-TEAC'R}\\ \text{COMMAND}\end{array}\right] \tag{15.7}$$

Here Roger acted out the roles of follower and student, **ME-FOLLOWER** and **ME-STUDENT**. In appropriate contexts he could switch his role, acting as boss or teacher (**ME-BOSS** or **ME-TEACHER**) to someone else as follower or student (**YOU-FOLLOWER** or **YOU-STUDENT**). He could shift between follower or boss, student or teacher based on his judgment of context. By Roger's age, children work hard to skillfully deceive and lie (Lamborn et al., 1994; Saarni & Lewis, 1993). Deception is at the center of hidden family violence, with individuals lying to both others and themselves. Detecting lies requires relating representations to each other, what is true and what is a lie. Understanding a lie requires coordinating two representations in at least a mapping:

$$\left[\textbf{TRUTH} \text{ —— } \textbf{LIE}\right] \tag{15.8}$$

Children develop and detect lies with representational mappings and they master them with the next level of skills, representational systems. (Consolidation of skills often requires at least two skill levels.) For instance, Roger stole a key from James and then "helped" James by blaming the robbery on the least popular child in the class, Colin. To skillfully lie required coordinating several states of James' knowledge (Roger "helping" and Colin "stealing") with claims or actions by Roger (stealing the toy and blaming Colin) in a representational system:

$$\left[\begin{array}{c}\text{STOLE}\\ \text{ROGER}\\ \text{BLAME COLIN}\end{array}\ \overset{\text{lie}}{\longleftrightarrow}\ \begin{array}{c}\text{ROGER HELP}\\ \text{JAMES}\\ \text{COLIN STOLE}\end{array}\right] \tag{15.9}$$

Second Tier of Dissociation: Isolating Personalities

As Roger grew cognitively he transitioned to the next developmental tier, moving from representational systems to abstractions for people as personalities. As a result, his isolating dissociation became more skilled, as he improved his capacity for deceiving people and for skillfully separating public and private. By coordinating representational systems into abstractions (Level A1), he could use abstractions to coordinate concrete interactions across his public versus private domains. In his private world he coordinated two representational systems for abusive bossiness, one as boss to some other victim and a second one as victim to some other boss. We name the general personality characteristic "tyranny" to reflect his goal of being a tyrant in his family:

$$\left[\begin{array}{ccc}\text{OBEY} & & \text{DEMAND}\\ \text{ME-FOLL'R} & \longleftrightarrow & \text{YOU1-BOSS}\\ \text{BAD} & & \text{PUNISH}\\ \Updownarrow & & \\ \text{DEMAND} & & \text{OBEY}\\ \text{ME-BOSS} & \longleftrightarrow & \text{YOU2-FOLL'R}\\ \text{PUNISH} & & \text{BAD}\end{array}\right] \equiv \left[\begin{array}{c}\text{ROGER}\\ \text{TYRANT}\end{array}\right] \tag{15.10}$$

Roger elaborated these personalities using isolating dissociation to keep them separate as in this formula:

$$\left[\textbf{ROGER-PRIV}_{\textbf{TYRANT}}\right] \gtrdot \left[\textbf{ROGER-PUBL}_{\textbf{COMPETENT}}\right] \tag{15.11}$$

By age 16 he had firmly established his capacity for single abstractions and started to construct abstract mappings (Level A2), establishing his public personality clearly at school, and using it skillfully:

> At 16 years Roger was a successful sophomore in high school—on the student council and the track team. But he did not have any close friends and spent lots of time seeking attention from older student council members. He helped

the vice principal, whom he believed had the power to set the rules. Roger was influential in school politics, presenting himself as knowing the answers and handling issues better than others. He was directly cruel to younger students, and especially condescending to girls. Roger was quiet and withdrawn at home with his father, who remained rigid and cold. His father often confronted Roger, who whined and hung his head. With his mother he insulted her when his father was not at home, and one time he pushed her into a door. He bullied his younger brother to do many of his chores.

Roger is building abstract mappings that connect the characteristics of victim and tyrant in the private domain, and in the public he is building the image of competent student leader and satisfied authority, as in the following isolating dissociation skill:

$$\left[\mathbf{ROGER}_{\mathbf{VICTIM}} \overset{\text{private}}{\text{———}} \mathbf{FATHER}_{\mathbf{TYRANT}}\right] \succ \left[\mathbf{ROGER}_{\mathbf{COMPETENT}} \overset{\text{public}}{\text{———}} \mathbf{AUTH'TY}_{\mathbf{IMPRESSED}}\right] \quad (15.12)$$

With this skill Roger focuses on roles of both victim and competent leader. At the same time he can reverse his stance to take the role of tyrant to someone else's victim, as shown by his treatment of girls, his mother, and younger students:

$$\left[\mathbf{ROGER}_{\mathbf{TYRANT}} \overset{\text{private}}{\text{———}} \mathbf{MOTHER}_{\mathbf{VICTIM}}\right] \quad (15.13)$$

As Roger became an adult, he used his developing skills to create the isolating dissociative roles that he has sought all along. As he searched for a wife, he soon showed affective splitting in his treatment of the young woman he fancied.

At age 24 Roger demonstrated his competence and apparent leadership in his public self. He joined the local church and became a member of the Young Republican Club. He offered to volunteer to promote his town's business for the Chamber of Commerce, and he founded his own real-estate business. He started to date a 17-year-old named June, who had recently finished high school, having met her when she worked for him as a temporary secretary. Roger was highly attentive to her, buying expensive gifts and sending flowers almost daily. He said repeatedly how special she was and that she did not have a single fault. Roger grew increasingly controlling and possessive. He accompanied her to the hair stylist to tell the stylist how to do her hair. Telling June to throw out all the clothes in her closet, he insisted on picking her new clothes. He began to complain that June was a poor cook, had no sense of style, and was too naive to go out alone.

Roger was constructing more complex skills to control June in both private and public domains, continuing to dissociate his positive public competence and negative private tyranny. He was attempting to construct his own family with an unfortunate joining of love with tyranny. He strived to bring June into the vice of his isolating dissociation, letting her be part of his public one only as a perfect stereotype. In public, in contrast, he connected his general competence with doing good for his community, limited by his rigid control of his private tyranny. Thus, he built abstract systems (Level A3) to continue his isolating dissociation of the two worlds called Public and Private:

$$\left[\begin{matrix}\text{LOVER} & \text{private} & \text{LOVED}\\ \mathbf{ROGER} & \longleftrightarrow & \mathbf{JUNE}\\ \text{TYRANT} & & \text{VICTIM}\end{matrix}\right] \succ \left[\begin{matrix}\text{PROSOCIAL} & \text{public} & \text{GRATIFIED}\\ \mathbf{ROGER} & \longleftrightarrow & \mathbf{AUTH'Y}\\ \text{COMPETENT} & & \text{IMPRESSED}\end{matrix}\right] \quad (15.14)$$

Over time, Roger will build ever more complex skills of isolating dissociation that separate his public and private worlds. These are complex, sophisticated skills, and at the same time they are clearly dangerous and pathological. Unfortunately, Roger is creating hidden violence in his family as evidenced by his actions with June. For *hidden family violence*, the pattern starts with a maltreating family that dissociates their proper public world from their private, tyrannical one. Children growing up in this family are abused physically and emotionally, and sometimes sexually. From this contextual and affective dissociation, the children isolate public from private, and eventually their maltreatment promotes active dissociation, separating the public and private worlds.

Psychopathology Is Not Developmental Immaturity

This dynamic analysis of development of isolating dissociation questions the traditional view that psychopathology comes from developmental immaturity or regression. Whereas traditional approaches tend to presume that psychopathology reflects a relative lack of skills or some form of deficiency, a developmental perspective brings forth the possibility that maladaptive behavioral development involves advances in skill development, not simply immature development. In the case of maltreated children, such advances take the form of increasingly powerful and more complex types of dissociation. Most scholars and practitioners who study maladaptive development have not detected this complexity because they have not taken the viewpoint of their patients. Moreover, patients are

commonly observed under minimizing conditions because of absence of contextual support and presence of stress. People subjected to stress and abuse follow strange pathways that organize their worlds in radically different ways, and which are characterized by increasing sophistication and complexity—and not regression or simplicity.

Modeling the Growth of Dissociation and Coordination

Dynamic mathematical modeling, based on general principles of dynamic interactions between variables, can provide deductive explanations of empirical observations. They are deductive explanations in the sense that they are derived from basic principles of developmental change and are expressed as mathematical rules generating descriptions of developmental trajectories. The strength of dynamic modeling lies in their power to deductively explain—on the basis of a small set of general dynamic principles of change—a broad range of qualitative properties that are typical of the phenomena that we can empirically observe in a particular domain such as developmental psychopathology.

According to Weisstein (1991), a dynamic system is a formal way of describing how one state (of a system) develops or changes into another state over the course of time. A highly simplified mathematical representation of a dynamic system is as follows

$$x_{t+1} = f(x_t)$$

which can be read as: the next state—at time $t+1$—of a particular variable x is a mathematical function, f, of the current state, namely the state at time t.[1] If the function f is a multiplication by a fraction such as 0.02, the dynamic model would represent stepwise exponential growth, such as money in a savings account. We have seen that most dynamic systems take the form of interactions among many components or variables. Such interactions can be modeled through the coupling of change equations.

In order to dynamically model the developmental process occurring under traumatic conditions, we shall assume that skills may vary between 0, meaning that the skill is totally absent, and some value around 1, meaning that the skill is optimally or maximally developed. Hence, for a psychologically healthy person, the value of the coordination skill may be about 1, and that of the dissociation skill about 0, meaning that there are hardly any contexts that cause dissociation in this healthy person. For young children, coordination and dissociation may still be a developmental issue, and they may still be sensitive to transient (nontraumatic) contexts in which they tend to solve the situation by dissociation (e.g., by lying about things, while suppressing the fact that they know they are lying[2]). In the discussion on dissociation, we have seen that people who suffered from serious traumas may develop sophisticated and adaptive dissociation skills. In principle, these people may still have reasonable coordination skills, which means that there are still contexts in which the person's personality is not dissociated. However, it is likely that such skills would not reach the higher levels of abstractions or principles that are typical of coordination in psychologically healthy people. We can mathematically represent this situation by values of skill levels between 0 and 1, for example, around 0.5 (for the modeling, the exact details of these numerical values do not really matter as long as they express observable differences in skill levels).

In previous work, the authors have shown that there exists a powerful and yet relatively simple mathematical expression for defining the growth of dynamic skills (Fischer & Bidell, 2006; Van Geert, 1991, 1994; Van Geert & Steenbeek, 2005). This equation is the coupled logistic growth equation, which takes the following form. Let the value C represent the level of the coordination skill of a particular person at a particular moment in the development, and D the level of the dissociation skill. For simplicity, let us focus on the growth of coordination, which can be expressed as follows:

$$C_{t+1} = C_t + \underline{C_t * r_C * (1 - C_t/K_C)} - \underline{\underline{a * D_t * C_t}}$$

The equation says that the next level of coordination (e.g., after a day or after a week, dependent on the chosen step size) is equal to the current level of coordination plus a certain amount of change. This amount of change is the result of the growth of coordination on the one hand (the underlined part of the equation), and the competition with other skills, in this particular case the competition with the dissociation skill (the double underlined part of the equation). The growth part of the equation specifies

[1] The step size +1 can be given any temporal value, such as a second, a day, or a month, but it can also be given a value that approaches an infinitely small time step, in which case we shall call the above equation a differential equation, instead of a difference equation.

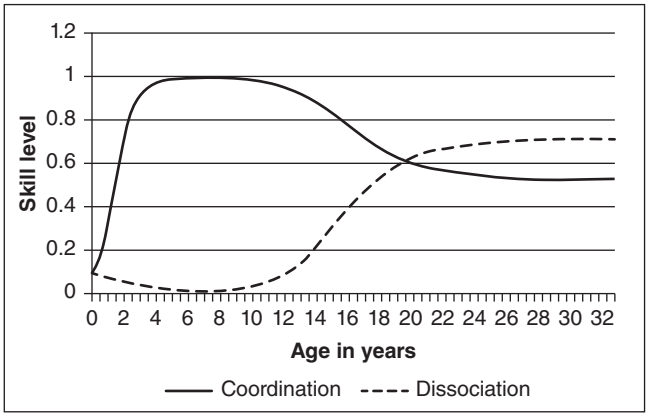
[2] See figure 15.8, illustrating the changing levels of coordination and dissociation as a consequence of childhood trauma.

change in coordination as a function of the current level of the coordination, a growth rate r and a carrying capacity K (Van Geert, 1991, 1994). Both the growth rate and the carrying capacity are an expression of the total underlying dynamic system, consisting of internal properties such as memory capacity, intelligence, information processing skills and external properties such as the family environment and experienced events. The carrying capacity is an important parameter since it is the summary of the entire underlying system, in terms of the total support it can give to this particular skill, namely coordination. In a well-functioning and caring family, this total support and hence the carrying capacity for personality coordination is likely to be much higher than in a badly functioning family characterized by many coercive interactions. The competition part of the equation describes the change of coordination as the multiplication of a competition parameter, a, the level of the competing skill, which in this particular case is the dissociation skill, and the level of the coordination skill itself. The equation says that the higher the level of the dissociation skill, the more the coordination skill will suffer from it, implying that level of the coordination skill will diminish over time, unless the competition can be counteracted by the growth of coordination, as it is influenced by all the personal and family factors that support it.

We can now present a similar equation for the growth of the dissociation skill, but with parameter values that relate to dissociation this time (for instance, in a well-functioning family the total of factors supporting the growth of dissociation will be very low compared with the total of factors supporting the growth of coordination).

$$D_{t+1} = D_t + D_t * r_D * (1 - D_t/K_D) - b * C_t * D_t$$

We shall now assume that if a serious trauma occurs in the life of a particular young person—for instance sexual abuse by the father as described in the earlier example—the total set of factors supporting dissociation as an adaptive skill is considerably increased. Hence, the carrying capacity for the dissociation skill, K_D, strongly increases as a consequence of traumatic events. In addition, the growth rate r_D of dissociation skill is increasing, because the child now feels the need for developing dissociation as a way of coping with the traumatic situation. A very simple way of mathematically expressing the effect of trauma is the following:



$$K_{Dt+1} = K_{Dt} + d * T$$

$$r_{Dt+1} = r_{Dt} * e * T$$

The factor T, which stands for the occurrence of traumatic events, is a parameter that is either 0 (when no traumatic events occur) or 1 (when traumatic events occur). The parameters d and e moderate the effect of trauma, and, like all other parameters, are specific for a particular individual child in a particular environment. For instance, children with a high level of resilience will be less affected by a particular trauma than children with a low level. In a family, where one of the parents is highly supportive of the child, a trauma caused by the other parent might eventually have less effect on the growth of dissociation of the child in a family where the mother for instance tacitly supports the abuse by the father. Since all parameters are individual and environment specific, we obtain an entire space of possible parameter values that represent possible individual cases.

We can now use this dynamic systems model of coordination and dissociation skill growth to study the variety of individual trajectories that results from various combinations of parameters, including the various family support levels, growth rates that are dependent on individual personality characteristics, competition factors and factors influencing the effect of a particular traumatic experience.

Figure 15.8 shows the simulation of two trajectories of coordination and dissociation skills in a child who suffers from serious traumatic abuse from the age of about eight years on (the models step size is one month). The top graph shows a trajectory of dissociation following trauma at around the age of eight years which stabilizes well into adulthood and becomes the sole way of coping for the person in question. The bottom graph shows a trajectory after a similar trauma that shows a pattern of stabilization between coordination and dissociation, with coordination still active, but with dissociation as the dominant mode of adaptation. This latter pattern implies that there still exist enough contexts in which the person can use personality coordination skills, for instance in the context of therapy where the person is able to deal with the consequences of trauma in a healing way. Surprisingly enough, the only difference between these two scenarios is the value of the growth rate parameter for coordination in the second case, which is slightly bigger than in the first case. That is to say, the person's slightly bigger ability to build up coordination skills—which is represented by the value of the growth rate parameter—functions as a strongly protective factor, in that the situation is still maladaptive, but less so than the complete dissociation of the first example. This provides but one of the many illustrations of the nonlinear character of dynamic systems, where the effect

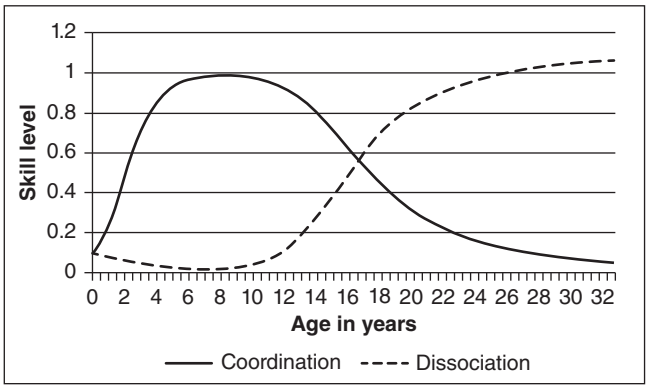


Figure 15.8 Modeling of two scenarios of dissociation-coordination after trauma occurring at 8 years of age; trajectories are determined by dynamic interactions between coordination and dissociation.

of changes in certain parameters strongly depends on the total constellation of the system including the values of the parameters.[3]

SELF-SUSTAINING LEARNING TRAJECTORIES IN CHILDREN WITH ATTENTION AND EMOTIONAL-BEHAVIORAL DIFFICULTIES

What is true for maltreated children is also true for other children who exhibit maladaptive patterns of thinking, feeling, and acting. Both adaptive and maladaptive patterns of psychological activity undergo development and assume different forms over time. Dynamic systems models contribute to understanding the ways adaptive and maladaptive patterns of thinking, feeling, and acting develop in children who exhibit attention and emotional-behavioral difficulties (EBD). In this section, we examine how dynamic systems models can be used to understand the processes by which learning fostered and thwarted in children with attention and emotional-behavioral difficulties.

Context Sensitivity of Attention Problems

Drawing upon the medical model, the concept of ADHD is typically understood as a fixed and trait-like property of individuals. Traditional models maintain that attention difficulties are products of primary deficits in the capacity to sustain attention, inhibit behavior, executive functioning, regulation of motor behavior, and related central deficits (Nigg, 2006). However, from a dynamic systems perspective (see Figure 15.2), all behavior must be analyzed in the context in which it occurs. Behavior—whether adaptive or maladaptive—is not a *thing* that a person *has*, but instead is an ongoing *process* that emerges from interactions between individuals and their contexts. Further, research supporting the idea that ADHD classified behavior is the direct product of central cognitive deficits has been mixed. Research suggests that primary deficits in the capacity to sustain attention, inhibit impulses, regulate motor action, etc., apply only to subsets of children exhibiting ADHD classified behavior (Sonuga-Barke, Wiersema, van der Meere & Roeyers, 2009).

Recently, theorists have elaborated alternatives to fixed deficit models of ADHD. For example, *delay aversion* (Castellanos et al., 2006) and *state regulation* deficit (van de Meere, 2005) models suggest that both adaptive and maladaptive behavior in children exhibiting ADHD behaviors are context-dependent products of relations between motivational resources and task demands. Among such children, overactivation of motivational resources occurs in the context of challenging tasks, whereas underactivation occurs in less challenging tasks. In structured contexts, underactivation can produce attentional drift and motivate stimulus seeking (e.g., fidgeting, heighted motor movement) accompanied by a preference for immediate rather than delayed forms of gratification, thus evoking impulsive behavior. Overactivation of arousal under high task demands can result in failure to inhibit prepotent behavior patterns (Sonuga-Barke, Wiersema, van der Meere, & Roeyers, 2009). Support for these ideas comes from studies in which children are asked to produce or inhibit simple responses (e.g., pressing or inhibiting a button press) under conditions that vary the speed with which children are required to respond. In comparison to controls, children with ADHD classifications make more errors under both

[3]To enable the reader to experiment with the complex interactions between the parameter values and the resulting effects on the developmental pattern, we shall provide a simple Excel model that can be downloaded at (http://www.paulvangeert.nl/articles_appendices.htm).

high (i.e., short deadline to respond) and low (i.e., long deadline to respond) task demands but not in response to moderate demands (Benikos, Johnstone, & Roodenrys, 2013a & b; van der Meere & Stemerdink, 1999; van der Meere et al., 1995).

Such findings suggest that task performance in children who exhibit ADHD behavior arises not simply as a product of general, trait-like deficits, but instead from the dynamic coupling of child and task demands. Children performed as well as controls in tasks that fall within an *optimal range* of difficulty; beyond that range, performance dissipated beyond that observed in controls. These studies suggest that inattentive, hyperactive and impulsive behavior are not linear results of central deficits but instead emerge through the self-organization motivational, affective and cognitive processes as they adjust to each other in response to local task demands.

The Strengths and Limitations of Neurobiological Approaches

Students with emotional and behavioral difficulties (EBD) are mainly known for problems involving so-called internalizing and externalizing behavior (Lane, Wehby, & Barton-Arwood, 2005). Many children with emotional and behavioral difficulties also exhibit difficulties in attention (e.g., ADHD). In recent years, however, increasing evidence also points to the negative academic outcomes typical for these students (Lane, Barton-Arwood, Nelson, & Wehby, 2008). Students with EBD continue to display significant academic delays across all placements (Reid, Gonzalez, Nordness, Trout, & Epstein, 2004) and do not seem to improve over time (Lane et al., 2008). These students thus require extra attention to support the development of academic performance. Unfortunately, the academic needs of this population continue to be unmet (Hayling, Cook, Gresham, State, & Kern, 2008).

Research assessing the academic needs of EBD children has focused on the neurobiological shortcomings that mediate, among other problems, lags and delays in their academic performances. In addition, research also examines how to ameliorate these shortcomings using pharmacological (and sometimes nonpharmacological) treatments (e.g., Hoekzema et al., 2010). Overall, neurobiological research about ADHD has yielded important insights (Castellanos & Tannock, 2002; de Zeeuw, Weusten, van Dijk, van Belle, & Durson, 2012; Tomasi & Volkow, 2012). Cortese (2012) provided an overview of anatomical, functional, neurophysiological, neurochemical, and genetic processes in the development of ADHD behavior. A primary conclusion consists of the finding that the brains of many children with ADHD differ from those of controls. Further, the processes that mediate ADHD behavior are both complex and heterogeneous, and are unlikely to be accounted for using simple pathophysiological models. As a result, there is a need to develop models that assess patterns of altered connectivity among multiple brain areas in individuals who exhibit ADHD behavior, rather than in terms of the localization of functional deficits in specific brain sites (Cortese, 2012).

Despite the importance of research assessing the neurobiologial contributions to attentional and emotional-behavioral problems, there are limitations to the neurobiological approach. First, until recently, findings from neurobiological research have produced few nonpharmaceutical interventions to address the behavioral and academic performance of ADHD and EBD classified children (Cortese, 2012). Teachers and practitioners face the task of interacting with whole children, and not simply their brains. As a result, there is a need to understand how neurobiological processes operate as but one important layer of functioning within the multinested epigenetic person–environment system. Second, within the neurobiological approach, neuro-biological deficits are often depicted as the primary causes of children's maladaptive actions. As a result, the complex dynamics that operate between child and context are excluded from theoretical and empirical consideration. This neglect is a problem, as child and social context (i.e., teachers, cultural tools, learning and motivation systems) are inseparable as causal processes in the development of children's attention and learning (Fabiano et al., 2013; Raver et al., 2008). An exception to this rule involves increasingly rich analysis of gene–environment interactions (G x E interactions) in the development of attentional and socioemotional problems (Nigg, Nilolas, & Burt, 2010; Pennington et al., 2009). A full accounting of the origins and development of attentional and emotional problems must build on to show how specific genes coact epigenetically with multinested environments to produce variation in attentional and behavioral problems.

Setting the Stage: The Dynamics of Teaching and Learning

Learning processes operate as socially situated, transactional processes (Steenbeek & Van Geert, 2013). To understand the process of teaching and learning involving children with attention and emotional difficulties, it is necessary to examine how learning is fostered or thwarted as a product of coactions that occur over time among aspects of the person–environment system. Such analyses

require examining the (1) structure of a student's attention and action as it arises (2) in coregulated exchanges that occur between (3) teachers and students (4) using cultural tools and practices as they operate (5) within particular sociocultural contexts. In this section, we elaborate a framework for understanding how teaching and learning operate as socially situated, transactional processes.

The Nature and Importance of Coactive Scaffolding

Students learn through their participation in sociocultural activities. Most often, successful learning occurs under the guidance and direction of more competent others who organize instruction, guidance, motivation, and emotion within a child's zones of optimal learning (Mascolo, 2013; Van Geert, 2008). An important means for teachers to help students to learn is to make use of coactive *scaffolding*. Scaffolding consists of the process of providing a student with external support and assistance, and optimally, discarding this support after learning has taken place (Granott & Parziale, 2002; Wood, Bruner, & Ross, 1976). Scaffolding is an intrinsically dynamic notion. We use the term to refer to any process that operates outside of the direct control of the individual over a given unit of behavior that functions to raise an individual's level of function beyond that which he or she is capable of performing him or herself (Mascolo, 2005). This principle is similar to the distinction made above between optimal and functional levels of skill that arise in contexts that provide high and low levels of contextual support. As discussed already, optimal level performance is that which a child can sustain under conditions of high contextual support; a child's functional level is the level at which he functions in everyday contexts in the absence of such support.

However, the process of *scaffolding* is different from the provision of *high support*. In contexts involving high support, a child performs a task on his own *with* contextual support but *without instruction or assistance during the actual execution of the task*. For example, a teacher may provide high support by *first* showing a child how to perform an addition problem that is beyond the child's ability, and *then* asking the child to perform the addition problem *on his own* without additional instruction or support. In contrast, when a teacher or adult scaffolds a child's performance, he or she often *performs part of the task for the child* (so the child can complete the remainder), or otherwise provides directives and cues to organize the child's actions as the child is actually carrying out the task. Scaffolding occurs, for example, when a teacher provides ongoing instruction (e.g., Now carry the one) or cues (e.g., What's next?) without which the child would be unable to complete the task himself.

The level of functioning that children can sustain under conditions of scaffolding tends to be higher than their optimal level performance under conditions of high support. Social scaffolding functions by breaking down a child's unmanageable task into more manageable units, thus allowing a child to coordinate novel aspects of a task in vivo—during the process of learning by doing. Scaffolding thus has the effect of holding up novel configurations of a child's actions so that the child can coordinate those actions for himself even though he could not coordinate them by himself previously. Empirical studies have shown that the process of scaffolding (1) occurs on a widespread scale, (2) is effective in that it advances learning, and (3) has different forms (i.e., that it differs among individuals and contexts; see, e.g., an overview of scaffolding in the context of learning disabilities; Stone, 1998). In special education, the quality of scaffolding can be hampered by the ways behavioral problems interfere with the teacher's actions (Wehby et al. 2003). This tends to occur because teachers are insufficiently trained to cope with problems in their scaffolding activities.

Embodiment, Coaction, and the Initial Conditions of Learning

An important feature of our approach is that we conceive of learning as an embodied process. Representational development occurs within the medium of the brain and body and is organized by context sensitive interactions between cognition and affect (Figure 15.2, Point 3). In any given context, the development of higher order representational activities can occur only under conditions of optimal affective engagement (see Yun-Dai, 2012). Affective engagement, in turn, is maintained when representational content remains rich, varied and accessible over the course of the teaching process. Secondly, in our view, the quality of teacher-student interactions cannot simply be perceived as having a mere *influence* on the ADHD child's learning process but instead functions as a changing indicator of the types of dynamic influences that shape an ADHD child's learning—through both desired and undesired pathways. Over time, iterations in teacher-student interactions consolidate into mutually responsive relationships. In this way, interaction dynamics (direct, immediate, short-term processes) then become a proximal measure of many distant factors.

While research indicates that brain-related constraints on learning are present in children who exhibit ADHD behavior (Cortese, 2012), from a dynamic systems

perspective, such constraints should be viewed as the *initial conditions* for the learning process, and not necessarily fixed, stable, or deterministic factors. In principle, these starting conditions can be changed by designing interactions that focus on the neuropsychological strengths and weaknesses of particular children, and by providing cognitive and affective experience that falls within the optimal range of learning of individual children (Immordino-Yang & Damasio, 2007; Vinogradov, Fisher, & de Villers-Sidani, 2012). Over time, the consolidation of repeated short-term representational and affective experience yields long-term changes in the neural networks of the brain and corresponding changes in the child's skill repertoire (John, Bullock, Zikopoulos, & Barbas, 2013; Winkielman, Niedenthal, & Oberman, 2009). It is only through analysis of sequences of learning over time that we can understand the circumstances under which neurological and brain-based constraints remain stable, or eventually change for the better or the worse. To trace the developmental consolidation of such processes, it is necessary to have access to densely sampled serial indicators of learning and action that occurs between EBD children and their teachers.

Learning as an Interactive, Microdevelopmental Process. From our perspective, learning, which is often defined as a macrolevel variable operating over the long-term—is best studied as a microlevel process. That is, it must be studied during individual instruction sessions that occur within the learning triangle of teacher–material–learner (Figure 15.2). By tracking moment-by-moment teaching and learning over time, it is possible to identify how short-term triangular dynamics are consolidated into long-term learning trajectories. Toward this end, microgenetic methods have proved their value (Basseches & Mascolo, 2010; Siegler, 2006; Van der Aalsvoort, Van Geert, & Steenbeek, 2008) and are now broadly recognized as particularly suitable for studying learning as a transactional, coregulated process (Granott & Parziale, 2002; Mascolo, 2013; Siegler, 1995; Siegler & Stern, 1998).

An important mechanism of change in this microgenetic process is *iteration*, that is, the fact that learning takes place in the form of iterative steps, which can be modeled as a series of successive operations, in which the output of the preceding operation provides the input of the next one (Van Geert, 1991, 1994, 2008). In an iterative sequence, each previous action of the student has an influence on the subsequent action of the teacher, and vice versa, indicating the cyclic character of iterative causality. Teacher–student relationships evolve as successive iterations and tend to consolidate into stable structures (Bierman, 2011; Luckner & Pianta, 2011). The formation of mutually responsive teacher-student relations has a direct impact on student attitudes, which thereupon foster enhanced peer acceptance and positive peer reputations, which in turn promote increased student engagement. Especially at-risk students may have particular benefits from sensitively structured classroom climates (Bierman, 2011; Gazelle, 2006; Hughes & Chen, 2011).

When studying learning-in-interaction as a dynamic, complex process, it is fundamental to capture it by means of a variable that reflects the important characteristics of the dynamics of that process. This variable is called an *indicator variable*, in that it captures some of the most characteristic qualitative properties of the underlying process. Indicator variables are means of representing the dynamics of a system without aiming to approximate a complete or exhaustive description, which, in the case of complex processes often hampers our understanding. Instead of examining the roles of the interaction partners separately, it is important to take the iterative action–reaction responses of both partners together as defining variable (see also Fogel, 1993, 2009). One way to assess such dynamics is by focusing on scaffolding. By way of illustration, we present two studies on scaffolding dynamics in special education, involving individual math instruction with children exhibiting ADHD and related problems.

Scaffolding Dynamics During Arithmetic Lessons

We examined the dynamics of short-term interaction between teachers and students during arithmetic lessons. In particular, we focused upon the responsiveness of teachers and students over the course of one-to-one math instruction. Within any single initiation-response interaction, we defined responsiveness in terms of whether the responding utterance followed meaningfully from the content of the initiating utterance. Responses that connected meaningfully to initiating utterances (responsive utterances) were classified as matches, and those that were unrelated to initiating statements (unresponsive statements) were identified as mismatches. Matching and mismatching utterances could occur in either direction between teacher and student (i.e., teacher → student, student → teacher). Thus, response matches functioned as the indicator variable in this study. We also identified teacher and student self-iterations. Teacher self-iterations refer to statements made by the teacher subsequent to a self-initiated utterance (e.g., after a short wait, answering

a question that she had asked the student). We assumed that variations in scaffolding quality would be represented by variations in responsiveness over the course of teaching and learning. As it is difficult for even experienced teachers to provide clear instructions that maximize student self-regulation, we expected that the interaction dynamics between teachers and students would show evidence of disruption and mismatch over time. Participants included four primary school students exhibiting emotional and behavioral problems (mean age was 9.7 years) in a small town in northern Netherlands. The case focuses on one of these students (W) who exhibited behavioral problems as well as problems with attention, concentration, and impulse regulation. The data took the form of videotaped arithmetic lessons delivered biweekly over a 2-year period (32 lessons).

Figure 15.9 shows the number of matches, mismatches, student self-iterations, and teacher self-iterations expressed in the scaffolding dynamics of student W and his teacher over a 2-year period. As indicated in the figure, each variable showed substantial fluctuations over time. These patterns do not substantially differ from fluctuations that appear in the data of the other three EBD students. (This finding is based on an overall variability measure and Monte Carlo permutation analysis, $p = 0.66$.) Focusing on changes in the percentage of matches over time, two basic phases can be distinguished. Matches occurred more frequently in the first half of the observational period than in the remaining half. A change point analysis revealed that lesson 12 marked a discontinuity in the mean number of matches observed. A Monte Carlo permutation test shows that the difference is statistically significant ($p < 0.01$). In addition, the standard deviation of the matches became significantly reduced after fragment 17 ($p = 0.02$), marking a second transition point. Thus, the variable M showed a nonstationary pattern, with discontinuities around fragments 12 and 17. These discontinuities suggest changes in the attractor state of this student–teacher system.

Figure 15.10 represents the scaffolding dynamics between W and his teacher as reflected in changes in matches, mismatches, teacher self-iterations, and student negative responses over the 2-year period. Figure 15.10 shows that the drop in matches around Lesson 12 coincides with a gradual increase of mismatches and in the level and variability of the teacher's self-iterations. Thus, over the long term, relations among matches, mismatches, and teacher and student statements shifted from one attractor pattern to another. The shift is one from responsive, coherent, and contingent interactions prior to Lesson 12 to increasingly less responsive, coherent, and contingent interactions thereafter (see Steenbeek, Jansen, & van Geert, 2012).

Figure 15.11 identifies the number of math assignments that the child was successfully completing over the course of time. The figure provides a graphical illustration of the complexity of the relationships among response matches and self-iterations on one hand and the amount of productivity on the other. The patterns demonstrate a *decrease* in the quality of the scaffolding between child and teacher coincided with *progress* in math performance, as indicated by the number of assignments completed.

Our main question concerned what the short-term scaffolding dynamics would reveal about the different phases identified in the previous section. Figure 15.12 shows the sequences of the variables match, mismatch, teacher self-iteration, and student self-iteration in two prototypical instruction sessions between W and his teacher. The first session (left panel) occurred before the first change

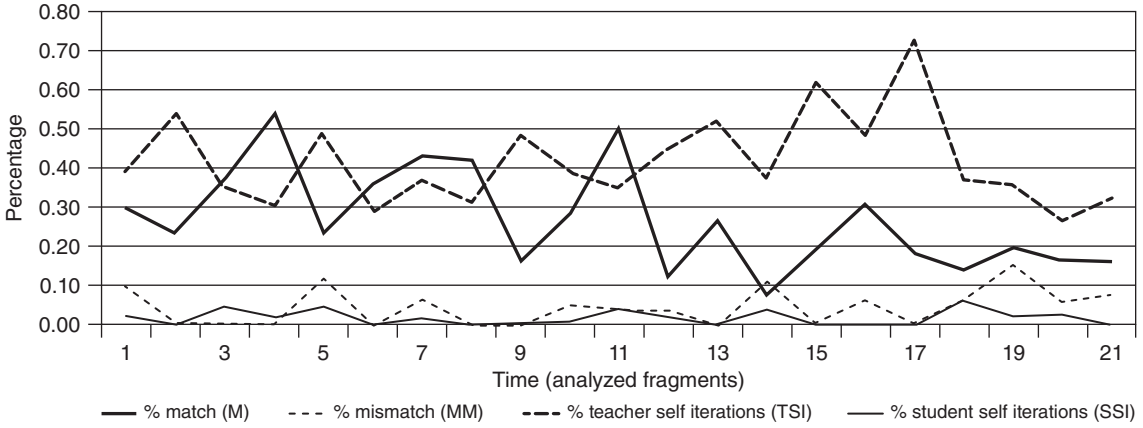

Figure 15.9 Changes in matches, mismatches and self-iterative utterances between a child and tutor in mathematics instruction.

point and represents a typical responsive session, the second session (right panel) occurred after the second change point, and represents a prototypical nonresponsive session. Figure 15.12 shows transition diagrams for both sessions. As indicated in Figure 15.12 (Session 4, upper left), in a prototypical responsive session, most of the self-iterations were produced by the teacher. This pattern was repeated in the prototypical nonresponsive session (Session 19, upper right). As indicated in Session 4 (Lower Left Corner), in the prototypical responsive session, when a match occurred (91% of the sequences), it was almost always followed by another match (93% of the sequences). In addition, the prototypical responsive session contained no mismatches. In contrast, in the proto-typical nonresponsive session (Session 19, lower right), when matches occur (41% of sequences), they were followed by a match in only 41% of the sequences, a mismatch in 41%, and by a neutral match in 15%. Thus, there were more vacillations among match, mismatch, and neutral sequences in the nonresponsive than in the responsive session ($p < 0.01$).

Thus, although the match–mismatch ratio differs substantially across the two lessons, the ratio of teacher self-iteration and student self-iteration stayed the same. This latter observation points to the stable and inactive role of the student during the instruction sessions. These findings support the idea that the interaction dynamics in EBD student–teacher dyads make it difficult, even for highly trained teachers, to motivate and enhance the use of self-regulatory strategies in EBD students.

Arithmetic Learning Among EBD and Typically Developing Students

Many studies suggest that EBD students show lags and delays in their academic performances, and that instructional practices can play an important role in reducing these delays. Several types of instructional behavior are effective for EBD students. These include providing clear and explicit instructions, enhancing opportunities to respond to questions, teaching the effective use of self-talk and self-regulation strategies (Kroesbergen & Van Luit, 2003; Sutherland, Alder, & Gunter, 2003). In addition, error correction, consistent feedback, individualized instruction, enhanced levels of instructional talk, and prompts for responding help increase student engagement and learning (Conroy, Sutherland, Snyder, & Marsch, 2008).

Steenbeek, Jansen, and van Geert (2012) examined the arithmetic performance of a group of five EBD students in comparison with that of a group of five typically developing students. Student performance on arithmetic

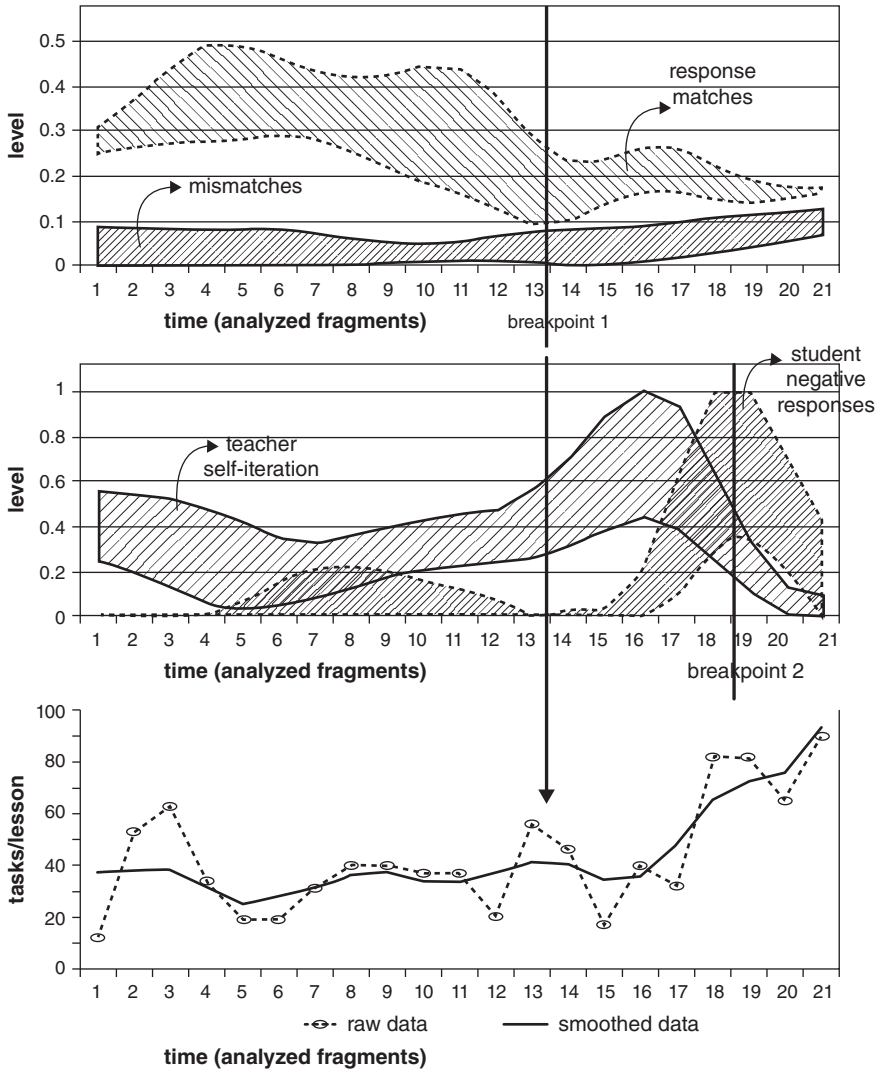

Figure 15.11 Relation between changes in matches, mismatches and self-iterations and the growth of mathematical performance.

assignments ordered with respect to increasing complexity over a 2-year period was assessed. We expected that EBD would exhibit lower levels of performance but higher levels of inter-individual variability than typically developing students. We also expected that typically developing students would make progress at a uniform pace consistent with the class-based nature of instruction. Figure 15.13 shows changes in arithmetic performance for each group over a one-year period. As expected, typically developing students successfully completed more assignments than the EBD students.

Further, as indicated in Figure 15.13, the growth curves for EBD children show greater inter-individual variability than those for the typically developing group. Although the growth curves for the typically developing group began at the same intercept, the pace of growth, as indicated by the slope of the curves, differed from individual to individual. In contrast, the growth curves for the four EBD students differed in terms of their intercepts (i.e., the level of complexity at which students began the instruction) but were similar in terms of their slopes (i.e., learning pace). Similar slopes for EBD students occurred even though these students followed individualized learning courses in the context of individualized scaffolding situations.

Self-Sustaining Trajectories in Suboptimal Learning Dynamics

These patterns of results point to the development of a self-sustaining dynamic of suboptimal educational

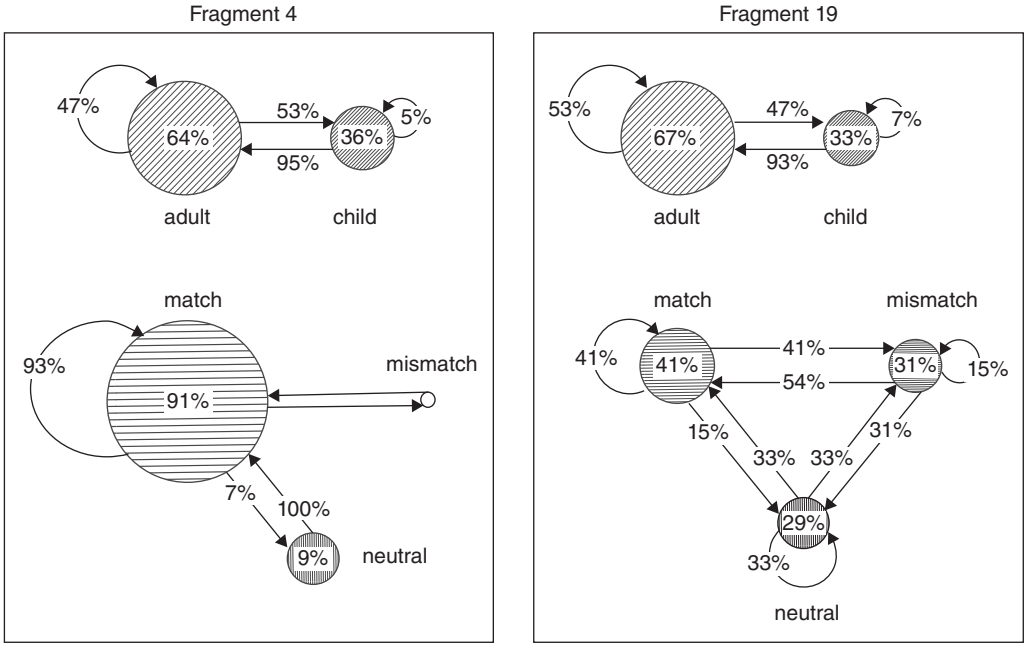

Figure 15.12 Interaction dynamics in prototypical responsive and nonresponsive learning sessions with a boy with emotional and behavioral difficulties.

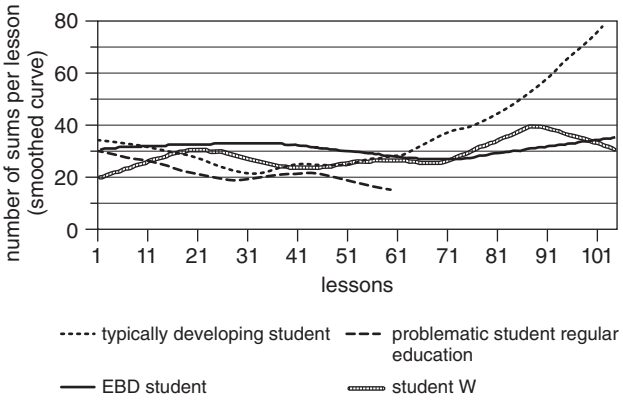

Figure 15.13 Growth of mathematical performance in EBD children.

functioning in which teacher's overinvestment and the student underinvestment support and maintain each other over time. Teacher overinvestment comes in the form of sustained patterns of scaffolding over time and through her willingness to bridge the gap between a series of assignments missed by the student. The student's underinvestment is indicated by poor effort and a lack of interest and motivation. This pattern is supported by a highly unbalanced surplus of self-iterations produced by the teacher in comparison to the student. The teacher continuously produced long utterances and tended to answer most of the questions she posed to the student. In contrast, the student maintained the strategy of responding with short answers (e.g., yes, no, or I don't know). Response matches—a measure of responsivity—had their origins in the teacher's effort to match the student, and not vice versa, and declined during the second part of the 2-year period.

This self-sustaining suboptimal pattern of teacher overinvestment likely has its origins in the teacher's desire to ensure *short-term* continuity in instruction, which, in the long term, proves problematic. Teachers know that students are easily distracted and tend to react to frustration in terms of negative emotion. Sensitive to the emotional reactions of their peers, negative emotions, and disorder easily spread through the class. Hence, there was a strong desire of the teacher to orient students toward their work without too much frustration in order to create room for another student to receive individual instruction. Teachers were well aware of this self-sustaining dynamic. In this way, suboptimal teaching and learning processes had their origins in the ways children's difficulties influenced the classroom dynamics, and not by a lack of quality among the teachers. These suboptimal interactions reflect a dynamic process in which student difficulties reciprocally affect teacher activities in ways that perpetuate and amplify a downward spiral in teaching and learning (Van Geert & Steenbeek, 2005).

Modeling School Performance in EBD Students

It is possible to describe the performance of EBD students using a dynamic model of learning and teaching called the dynamic scaffolding model (Van Geert & Steenbeek, 2005). The model starts with the assumption that a student's learning and a teacher's teaching can be represented by means of the same ruler. For instance, a particular student's current level in math can be represented on a measurement scale that specifies mathematical ability. The student's teacher provides instruction and scaffolding in the form of assignments, explanations, questions and so forth. The teacher's instruction will target a particular level of mathematical ability from the student. The level of teaching can, in principle, be represented on the same developmental ruler, (e.g., a dynamic skill ruler) as the child's mathematical ability.

While the student's progress strongly depends on the teacher's instruction, a teacher's instruction can be effective only if it operates on a level that is slightly higher than the level currently achieved by the student. As the student learns, the teacher should adapt his level of instruction to the new skill level of the student. Learning and teaching are dynamically coupled processes. Thus, changes in learning depend, among other factors, on the level of teaching provided, whereas changes in teaching depend on the amount of learning accrued from preceding teaching activities. For the teacher to adapt, on the one hand, his teaching to the level of the student, and, on the other hand, to the progress made by the student, the teacher must be able to assess the student's level and progress in real-time. Thus, if the student's progress is observed as being low, the teacher will hardly, if at all, modify the teaching level.

Students differ in terms of the distance between their actual levels of functioning and the levels of teaching under which they optimally learn. In comparison to intellectually advanced students, students with learning difficulties will exhibit smaller distances between their actual levels of functioning and the levels of teaching under which optimal learning occurs. Hence, while teaching, a teacher must not only assess the students' levels of functioning and their degree of progress, she must also estimate the optimal distance between their levels of functioning and the level of teaching under which students can make optimal progress.

The general mathematical properties of this teaching-learning model rely on the logistic change model. In so doing, they also rely on couplings between a student's level of skill, a student's progress in learning, and the level and progress in the teacher's instruction (see van Geert & Steenbeek, 2005; see also Van Dijk et al., 2013). As far as EBD students are concerned, we may assume EBD students profit more from a relatively small distance between their actual level of functioning and the level of instruction. In the studies described above, we have also seen that the teachers of EBD tend to avoid strong challenges and in general stay rather close to the students' actual levels of functioning. As a result, student learning remains suboptimal. EBD students are "under-challenged," as student and teacher get stuck in a mutually influencing process of underachievement and under-challenge.

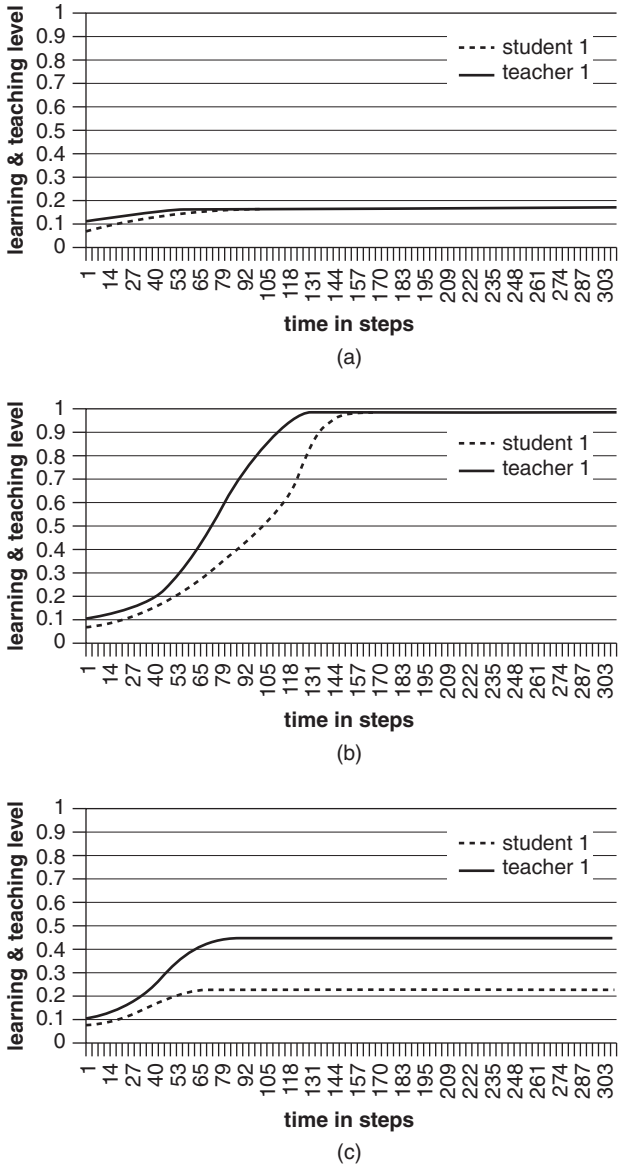

Figure 15.14 Modeling growth in teaching and learning with children with attentional and emotional problems.

The dynamic model predicts that if teachers tend to stay too close to the student's actual levels of performance, the process will lock itself into a pattern where no real learning progress is made (Figure 15.14a). If the teacher attempts to force learning by presenting challenges above a student's optimal level, there will be a similar self-sustaining process of suboptimal learning (Figure 15.14c). However, the model also predicts an intermediary window where the level of teaching and challenge provides an opportunity for optimal learning (see Figure 15.14b). The simulations based on the model show that the rate of student learning (which, along with other factors, is a function of the student's effort and motivation) is also a critical factor. Lower rates of learning destroy the window of possible opportunities and create self-sustaining processes of underachievement that are difficult to change. In short, what the model deductively demonstrates is that among EBD students, learning opportunities are fragile and dependent on the teacher's capacity for sensitive adaptation. The fragility of the teaching-learning dynamics, which the dynamic model clearly demonstrates, can explain why so many children in special education perform at lower intellectual levels than might be expected on the basis of their actual intellectual abilities.

THE DEVELOPMENT SOCIOEMOTIONAL ADJUSTMENT IN CHILDREN WITH EMOTIONAL AND BEHAVIORAL DIFFICULTIES

Thus far, we have examined idiosyncratic pathways in the macro-development of dissociative structures among maltreated individuals as well as microdevelopmental trajectories of teaching and learning involving children with attention difficulties. In this section, we extend our discussion of the dynamics of development to an analysis of developmental pathways taken by different groups of individuals from childhood through adulthood. In particular, we examine the development of socioemotional functioning among children who exhibit emotional and behavioral difficulties. A common way to understand emotional and behavioral-regulation difficulties involves the *internalizing–externalizing* dichotomy. According to Merrell and Walker (2004):

> Externalizing problems include behavioral characteristics that are considered to be undercontrolled and other-directed, such as antisocial and aggressive behavior, conduct problems and delinquency, destructive and harmful behavior, and the hyperactive impulsive manifestations of ADHD. Internalizing problems include "overcontrolled" or self directed behavioral and emotional characteristics such as depression, anxiety, social withdrawal, and somatic problems. It is important to recognize that in some cases, a child's behavioral characteristics can be of a 'mixed' variety, manifesting important aspects of the both the internalizing and externalizing broad bands (p. 907).

Despite its prominence in developmental research, the internalizing–externalizing dimension raises several problems. First, the dimension is broad. As a result, there is considerable heterogeneity in the behaviors to which the terms *externalizing* and *internalizing* apply. Second, given its breadth, assessments of internalization and externalization tend to involve aggregations across a broad range of behavior collapsed across context, time, and domain of functioning. Third, the practice of representing externalization and internalization as polar opposites implies that the co-occurrence of behaviors named by these terms should be low. However, research, shows dramatic comorbidity between so-called internalizing and externalizing behavior.

Most important, the internalizing–externalizing dimension seems to have limited descriptive value. While it is clear how everyday concepts like *acting out* or *aggression* can reflect forms of externalizing behavior, it is not clear why anxiety or depression reflect internalization. The externalizing–internalizing contrast has its origins in the distinction between over- and undercontrol (Block & Block, 1980). From this view, problems of aggression, attention regulation and impulsivity reflect an underdeveloped capacity for regulation (undercontrol), whereas anxiety, depression, and related states reflect a tendency toward overcontrol (Block & Block, 1980). While a large literature suggests that many (but not all) externalizing problems are linked to poor behavior regulation (Rubin, Burgess, Dwyer, & Hastings, 2003), relations between overregulation and internalization are less clear. Kagan's (2003, 2008) work on behavioral inhibition is an exception. Kagan and his colleagues have demonstrated a degree of stability in the emotional development of children who exhibit a bias toward *behavioral inhibition*. They have also shown that a tendency toward behavioral inhibition is related to the development of social anxiety, alcoholism, and related conditions (Smoller et al., 2003). The concept of *behavioral inhibition*, however, is different from the concept of *overcontrol*. Behavioral inhibition reflects an emotional disposition to withdraw from novelty, whereas overcontrol implies a more controlled and self-directed process.

The Dynamics of Adaptive and Maladaptive Socioemotional Adjustment

Instead of representing maladaptive emotional processes along a single externalizing-internalizing dimension, Figure 15.15 depicts a multidimensional space-state representation of socioemotional adjustment in motive-inconsistent contexts. The horizontal dimension reflects variation in the *direction* of emotional action from *moving toward* to *moving away* from motive-inconsistent events. The vertical dimension reflects degree of activation, ranging from *activation* to *immobilization*. In any given motive-inconsistent situation, a person confronts a series of *affective choices*—alternative modes of emotional responsivity within or between situations (de Rivera, 1991). Figure 15.15 shows affective channels that avail themselves in motive-inconsistent situations. These include (1) anxiety under uncertainty; (2) moving against others in response to moral violations (e.g., anger, rage); (3) moving away from others under conditions of danger or powerlessness (e.g., fleeing in fear; hiding in shame); and (4) immobilization under conditions of hopelessness or helplessness (e.g., depression; freezing in fear).

Within and between contexts, emotional functioning fluctuates dynamically throughout this state-space. Within this state-space, some affective movements may be more likely than others. For example, theorists have long postulated dynamic relations between *shame* and *anger* (Hejdenberg & Andrews, 2011; Scheff & Retzinger, 1991). Research suggests that angry aggression (moving against) is often motivated by the invocation of shame-related challenges to identity (e.g., insults, criticism; Ferguson, Eyre, & Ashbaker, 2000; Scheff, 2010; Shanahan, Jones, & Thomas-Peter, 2011; Tangney, Wagner, Fletcher, & Gramzow, 1992; Wright, Gudjonsson, & Young, 2008). Conversely, children who exhibit reactive aggression (moving against others) are more likely to experience peer rejection (Morrow, Hubbard, McAuliffe, Rubin, & Dearing 2006) and shame-related feelings that result from rejection (Ji, Wei, Chen, & Zhang, 2012). Movements between anger and shame can thus foment a mutually sustaining anger ←→ shame dynamic.

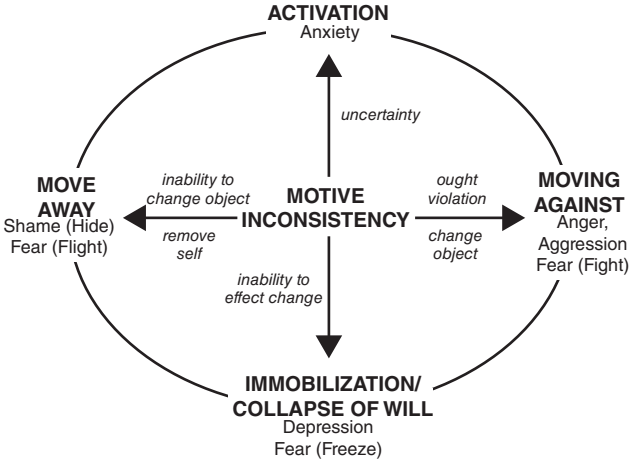

Figure 15.15 The dynamics of socioemotional adjustment for negative emotions.

Several points arise from this example. First, emotional life is rarely organized around single emotional states. As a result, it is not helpful to think of socioemotional development as organized around any single class of emotions or around *any single pole* of a bipolar dimension. Instead, emotional life involves dynamic movements between and among different emotional states throughout the state space. Second, some emotional dynamics may be more probable than others (e.g., shame ←→ anger vs. fear ←→ shame). Third, some emotional dynamics (e.g., shame ←→ anger) may involve movement between opposite poles within the multi-dimensional state space. As a result, thinking of emotional life in terms of dynamic movements within a state space provides a framework for understanding how emotional functions self-organize into heterogeneous, fluctuating, and comorbid patterns over time.

Pathways in the Development of Adaptive and Maladaptive Patterns of Socioemotional Adjustment

Patterns of socioemotional adjustment are epigenetic products of the mutual interplay among (not always obvious) nested processes that orient development in particular directions (Gottlieb, Lickliter, & Wabash, 2005; Mascolo, 2013). Given a set of initial conditions (e.g., a child's genotype and temperament), variations in local conditions can move development along a variety of different pathways. Development, however, is an iterative process; as development occurs, developmental changes at one moment create the conditions that canalize movement in the next moment (Cox, Mills-Koonce, Propper, & Gariepy, 2010; Witherington, 2011; Van Geert, 1994). As conditions of development organize into stable, mutually strengthening patterns, developmental changes can cascade in particular directions. As development advances, deviations from particular pathways are possible, but tend to require more systemic changes in developmental conditions. Such changes can often be initiated by modifying the functioning of key developmental variables—sometimes called control parameters (Fogel & Thelen, 1987)—which then

iterate and ripple over time, creating novel opportunities for development in alternative directions.

Figure 15.16 displays a developmental web describing pathways in the development of adaptive and maladaptive patterns of socioemotional adjustment. The figure identifies patterns of converging, diverging, and overlapping trajectories in patterns of socioemotional adjustment within groups of individuals. The bottom portion identifies the temperamental starting points of development in terms of patterns of affectivity and attentional control (Evans & Rothbart, 2009). Each pathway is defined in terms of a series of movements toward or away from the varied socioemotional outcomes identified at the top of the figure. Within the figure, statements in shaded boxes refer to the influences of socialization agents (caregivers and peers); unshaded statements refer to developmental steps along a socioemotional trajectory.

There are multiple pathways to the development of adaptive, prosocial, behavioral outcomes. Three socially adaptive pathways are identified in Figure 15.16. The empathic–prosocial pathway (1) involves development toward adaptive, empathy-based prosocial action. Prosocial outcomes are most probable among children who (1) exhibit an emotional bias toward positive affect and

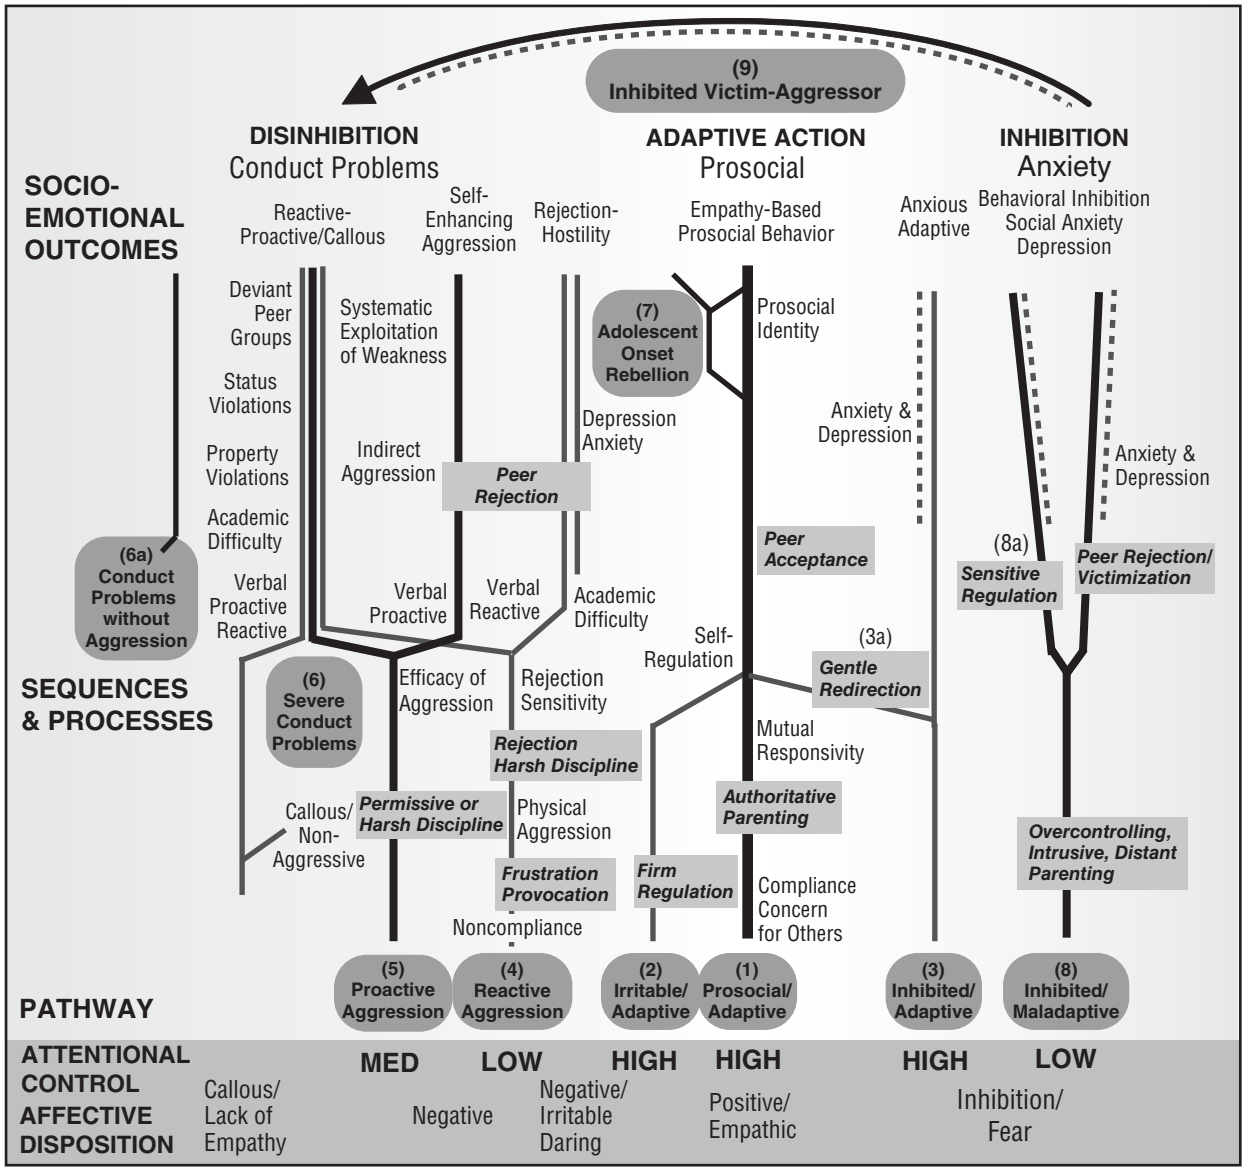

Figure 15.16 Pathways Toward Adaptive and Maladaptive Socioemotional Adjustment. Phrases along individual trajectories indicate order of developing skills or deficits; gray boxes indicate social effects on developmental pathways; dashed lines indicate co-morbidity of anxiety and depression.

concern for others; (2) exert high dispositional levels of effortful control over action and emotion (Eisenberg, Hofer, & Vaughan, 2007); and (3) are cared for by sensitive and authoritative parents (Kochanska & Akzan, 2006; Kochanska & Kim, 2013). Such infants and their caregivers mutually influence each other's actions over time, and quickly self-organize into mutually responsive and emotionally attuned interactions (Kochanska & Aksan, 2004). Children who develop along the adaptive–prosocial path tend to demonstrate affective concern for others from an early age (Roth-Hanania, Davida, & Zahn-Waxler, 2011) and begin to regulate their actions in terms of parental rules during the second year of life (Kochanska & Aksan, 2006). The form of intersubjectivity established within mutually responsive relationships mediates the joint production of positive affective affect (Bornstein, 2013), the development of emotional-regulation skills (Ursache, Blair, Stifter, & Voegtline, 2013), a concern for others (Roth-Hanania, Davida, & Zahn-Waxler, 2011), and the appropriation of sociomoral standards to regulate social conduct (Kochanska & Kim, 2013). The development of prosocial action in children both fosters and is reciprocally facilitated by peer acceptance and the formation of increasingly stable peer relationships (Clark & Ladd, 2000).

Figure 15.16 identifies two additional pathways toward adaptive prosocial behavior. These occur among children who exhibit emotional biases toward negative or irritable (Pathway 2, irritable–adaptive) and inhibited (Pathway 3, inhibited–adaptive) affect. These children are protected from maladaptive development by virtue of their capacity for high levels of behavioral and emotional control, coupled with parenting styles that are sensitive to children's emotional needs. The prosocial development of children with irritable temperaments is facilitated by the use of firm but affectively positive behavioral regulation. In contrast, because less arousal is needed to motivate inhibited children, they benefit from gentle redirection in regulatory contexts (Kochanska & Aksan, 2006).

Pathways in the Development of Aggression and Conduct Problems

Figure 15.16 identifies four pathways in the development of conduct problems. Conduct problems encompass a broad range of rule violating behavior, including noncompliance, aggression, property violations (e.g., stealing, vandalism), status violations (e.g., running away, truancy, substance abuse), and delinquency (e.g., arrest; incarceration; Barry, Golmaryami, Rivera-Hudson, & Frick, 2013; Wakschlag, Tolan, & Leventhal, 2010). Aggression is among the more important and widely studied conduct problems. Figure 15.16 identifies four pathways in the development of problems involving physical aggression. Researchers have differentiated between adolescent-onset and child-onset pathways in the development of aggression (Barry et al., 2013; McMahon & Frick, 2005). Figure 15.16 identifies three pathways in the development of child-onset aggression: reactive aggression (Pathway 4), proactive aggression (Pathway 5), and severe conduct problems and aggression (Pathway 6). Adolescent-onset aggression (Pathway 7) tends to be limited to adolescence and arises as the product of comparatively few risk factors. It tends to arise as an amplification of the normative process of autonomy seeking (Moffitt, 2003).

Reactive aggression refers to defensive or retaliatory attempts to harm others in response to real or perceived provocation; proactive aggression involves deliberate, nonemotional, and unprovoked attempts to harm others for the purpose of instrumental gain (Kempes, Matthys, de Vries, & van Engeland, 2005). Research assessing the reactive-proactive dimension has produced considerable debate. On the one hand, research shows that reactive and proactive aggression have different origins and developmental courses (Hubbard, McAuliffe, Morrow & Romano, 2010). Reactive aggression is associated with irritable/angry infant temperament (Vitaro, Barker, Boivin, Brendgen, & Tremblay, 2006), lower dispositional capacities for effortful and attentional control (Connor, Chartier, Preen, & Kaplan, 2010), and poor impulse regulation (Connor, Chartier, Preen, & Kaplan, 2010). Children and adults who exhibit reactive aggression are more likely to develop a hostile attribution bias—a tendency to interpret ambiguous emotion in others as indicating hostile intent (Bailey & Ostrov, 2008)—and heighted sensitivity to rejection (Jacobs & Harper, 2013). Such biases may arise from a history of reciprocal provocation by parents and peers, maltreatment or other forms of threat (Dodge, Lochman, Harnish, Bates, & Pettit, 1997). These biases also tend to feed forward into later romantic relationships (Canyas, Downey, Berenson, Ayduk, & Kang, 2010) and play a role in dating violence (Brendgen, Vitaro, Tremblay, & Lavoie, 2001).

In contrast, as a form of deliberate provocation, proactive anger is less likely to be accompanied by anger (Hubbard et al., 2002). It tends to be associated with lower basal physiological arousal and may be associated with high levels of dispositional sensation seeking (Wilson & Scarpa, 2011). Children who display proactive anger tend to hold beliefs about the social legitimacy of aggression and its efficacy as a means to instrumental ends (Arsenio, Adams & Gold, 2009). Teens who exhibit high levels of proactive aggression show higher levels of delinquency

(Brendgen, Vitaro, Tremblay, & Lavoie, 2001) and lower levels of psychosocial adjustment than those who exhibit high levels of reactive aggression (Card & Little, 2006).

On the other hand, researchers have noted that reactive and proactive aggression tend to co-occur (Vitaro & Brendgen, 2005) with correlations that range between .40 and .70 (Poulin & Boivin, 2000). In an important study, Barker, Tremblay, Nagin, Vitaro, and Lacourse (2006) identified three trajectories of aggressive behavior between the ages of 13 and 17. The vast majority of teens (.93) were classified as either low aggressors or moderate aggressors. A small minority (.06) exhibited high levels of aggression that peaked at age 15. However, regardless of group membership, children who aggressed exhibited similar levels of *both* proactive and reactive aggression. Given the massive co-occurrence of reactive and proactive aggression, some theorists have suggested abandoning the distinction (Bushman & Anderson, 2001).

Recent research has produced findings that may help account for these seemingly contradictory findings. Researchers have demonstrated that early-onset aggression is often associated with the presence of callous and unemotional affective dispositions in children (Frick & Viding, 2009; McMahon & Frick, 2005). Callous and unemotional behavior includes a lack of empathy and concern for others, an absence of guilt upon wrongdoing, and the intentional manipulation of others for personal gain (Frick & Viding, 2009; Muñoz, Qualter, Padgett, 2011). Children who show early-onset aggression tend to score high on measures of callous and unemotional social engagement (Dandreaux & Frick, 2009). Frick and White (2008) reviewed research showing that children exhibiting callous emotionality are more likely to show fearless and thrill-seeking behaviors, deficits in processing emotional information, less sensitivity to punishment cues, and positive beliefs about the use of aggression. Children who exhibit callous and unemotional dispositions are more likely to exhibit conduct problems, bullying (Fanti & Kimonis, 2012) and delinquent behavior (Edens, Campbell, & Weir, 2007) that carries forward into adulthood (Frick & Viding, 2009).

Aggression and conduct problems are not the results of single causes or risk factors. Risk and protective processes combine in complex ways in the probabalisitc self-organization of developmental trajectories. Fanti, Frick, and Georgio (2009) found that adolescents showing higher levels of callous and unemotional dispositions were more likely to exhibit combined proactive and reactive aggression and not pure forms of either proactive or reactive aggression (see also Thorton, Frick, Crapazono, & Terranova, 2013). Similarly, in a large sample of Greek-Cypriot adolescents, Fanti (2013) found that teens who exhibited both high levels of conduct problems and high levels of callousness exhibited higher levels of bullying, substance abuse; inattentiveness, impulsivity, and narcissism, as well as less robust family support than teens rated as high in either conduct problems or callousness.

Together, these findings support the proposition for the three child-onset pathways identified in Figure 15.16. While research suggests two distinct but overlapping pathways involving reactive (4) and proactive (5) aggression, children who exhibit these forms of aggression in the absence of callous and unemotional dispositions are less likely to be involved in severe conduct problems. Thus, severe antisocial outcomes (6) involve the co-occurrence of callous and unemotional affective disposition with a combination of both proactive and reactive aggression. As indicated in Figure 15.16, in addition primary pathways toward conduct problems, research suggests an additional path toward conduct problems without aggression (Burt, 2009; Eley, Lichtenstein, & Moffitt, 2003).

Pathways in the Development of Inhibition and Social Anxiety

Inhibited patterns of socioemotional adjustment are those that are organized around avoidance as a style of affective coping (Rapee, Schniering, & Hudson, 2009). Such individuals tend to approach events with a disposition toward fearful or anxious affect, show avoidance toward unfamiliar people and events, and exhibit heightened vigilance in novel contexts (Lahat, Hong, & Fox, 2011). Research suggests that children exhibiting fearful/inhibited biases early in life are more likely to develop problems related to anxiety in adolescence and adulthood (Lahat, Hong, & Fox, 2011; Muris, Brakel, Arntz, & Schouten, 2011; Schwartz, Snidman, & Kagan, 1999; Sportel, Nauta, Hullu, Jong, & Hartman, 2011). For example, Prior, Smart, Sanson, and Oberklaid (2000) found that 42% of children who were rated as shy across multiple observations in childhood exhibited anxiety problems in adolescence. In contrast, only 11% of the children not previously classified as shy exhibited anxiety problems in their large sample. Thus, while not all children classified as inhibited develop anxiety problems later in development, a sizable proportion do.

Figure 15.16 identifies four pathways in the development of inhibited patterns of socioemotional adjustment. Severe social anxiety problems develop through the inhibited/maladaptive pathway (8). Children who pass through

this pathway tend to experience fearful/inhibited temperament and a diminished capacity for attentional control (Sportel et al., 2011) coupled with parenting styles that can be classified as overprotective, overcontrolling, or intrusive or distant (Lahat et al., 2011; Lindhout, Markus, Hoogendijk, & Boer, 2009). Such parenting styles are unlikely to operate as static properties of individual parents. Instead, it is most likely such parenting styles are emergent, coregulated products of a parent's attempt to respond to an inhibited child (Evans & Porter, 2009, 2012). While over-protective parenting fails to promote strategies regulating emotional arousal in the context of novel events, over-controlling or intrusive parenting is likely to amplify inhibited emotion and restrict a child's capacity to master novel situations. Emotionally distant parents may foster the development of anxious attachment relationships, which increase the probability of anxiety problems in children (Warren, Huston, Egeland, & Sroufe, 1997).

Anxiety problems in children who display inhibited temperaments and diminished capacities for attentional control can be mitigated by parents who introduce children to novel events with persistence and sensitivity (Pathway 8a). Conversely, although the capacity for high levels of attention control acts as a protective factor in the development of anxiety problems in children with inhibited temperament (Lahat et al., 2011; Sportel et al., 2011) insensitive or intrusive parenting can channel development away from a prosocial path and in the direction of social anxiety (Pathway 3a). While inhibited temperament biases socioemotional development toward the direction of social anxiety, it is important not to view inhibited temperament simply as a risk factor for maladaptive behavior. Shyness and behavioral inhibition is often viewed negatively, at least among Westerners (Aho, 2011). The work of Kochanksa, Aksan, and colleagues suggest that behavioral inhibition may serve important developmental functions. For example, children with inhibited temperament do not require strong arousal induction in moral socialization (Kochanska & Aksan, 2006). In an insightful study, Aksan and Kochanska (2004) showed that children who exhibited inhibited temperament and inhibition to novelty in infancy (9, 14, and 22 months) showed an increased capacity for voluntary inhibitive control at 45 months). Aksan and Kochanska (2004) suggested that the involuntary reactive inhibition (inhibited temperament) functions to decreases the speed of approach to novel situations early in life. This decrease, in turn, provides the opportunity for additional attentional focus on novel events, thus facilitating the development of voluntary effortful control. These findings illustrate the ways nonobvious relations between developing systems promote psychological development. In the case of Aksan and Kochanska's (2004) findings, involuntary relations between inhibition and novelty earlier in development operate iteratively to set up conditions for the development of the capacity for voluntary control. The resulting developing of voluntary control then buffers against developmental movement in the direction of social anxiety.

As is the case with the development of aggression, the development of social anxiety is also accompanied by experiences of depression (Epkins & Heckler, 2011; Sportel et al., 2013). Peer rejection, victimization, social isolation, and loneliness play important and cumulative roles in the development of depression and anxiety in children, adolescents, and adults (Dempsey & Storch, 2008; Epkins & Heckler, 2011). Briggs, Nelson, and Sampino (2010) reported evidence that depression among adolescents who experience social anxiety was mediated over time by experiences of peer rejection and victimization. Silk, Davis, McMakin, Daahl, and Forbes (2012) reviewed evidence suggesting that the codevelopment of anxiety and depression in adolescence is mediated by a heightened sensitivity to self-evaluative social threat (fear of negative evaluations of the self by others) coupled with modifications in the proclivity to seek out wanted outcomes. Research indicates, for example, that anxious adolescents show a heightened attentional bias to social threat, and are more likely to interpret socially ambiguous situations in terms of threats to one's self-evaluation (Silk et al., 2012). These same processes are also implicated in the development of depression. Silk et al. (2012) suggest that in an attempt to adapt to social threat, adolescents revise their expectations for social acceptance, ultimately resulting in increasing depression. These findings suggest that experiences of rejection, exclusion, loneliness, and related social threats to self-evaluation play cumulative roles as risk factors in the codevelopment of anxiety and depression (Epkins & Heckler, 2011). The codevelopment of anxiety and depression as a product of peer exclusion and rejection is represented in terms of the double lines associated with the inhibited pathways depicted in Figure 15.16. For some children, the anxiety-rejection link not only results in depression, but also evokes aggressive reactive and proactive attempts to lash out against rejection. The *inhibited-victor aggressor* pathway (Pathway 9) occurs in children with inhibited temperaments who are recipients of harsh discipline or consistent patterns of humiliation by peers. Research shows that in some circumstances (e.g., when children are humiliated or raised in violent homes) temperamentally

inhibited children become highly aggressive in later childhood and adulthood (Watson, Fischer, Andreas, & Smith, 2004).

Trajectories of Development: Making a Path by Walking

Developmental pathways are the outcomes of constructive processes. Pathways should not be viewed as inherent, preformed, or predestined roads that anyone with a particular precondition must take. Unlike highways that have been planned and pre-structured by a central authority, developmental paths are more like trails that that are formed through the active process of walking (Thompson, 2007). A developmental pathway emerges slowly as if one were walking through a thicket. As each step is taken, part of the path is formed. Each step provides the conditions that orient the next step. Each movement is constrained and channelized by the obstacles and clearings that one encounters along the way. Obstacles, however, can turn into clearings with the thrash of a sickle, while clearings can invite movement away from desired destinations. Thus, pathway representations of development are like prototypical images that researchers have imposed upon an enormous variety of individual trajectories. In this way, the notion of pathway provides a particular way of summarizing large numbers of individual, self-organized trajectories that show sufficient similarity to be treated as members of common idealized class.

BEYOND BEST PRACTICES AND EVIDENCE-BASED INTERVENTION: TRANSLATING DYNAMIC SYSTEMS INTO PREVENTION AND PRACTICE

How can dynamic systems approach inform the goals of preventing and redirecting maladaptive behavior? Perhaps the most important—and most difficult—task is a conceptual one—namely the task of helping practitioners and policy makers think systemically about the origins and treatment of maladaptive behavior. Many current approaches to intervention and prevention continue to adopt a static, discrete state approach to the problem of maladaptive behavior. From this view, maladaptive behavior is understood as a reflection of more or less fixed pathologies located within individual persons; interventions (e.g., medication, therapy, skill development) are focused on effecting change within the individual child. With exceptions (e.g., family systems therapy; coordinated intervention teams), interventions tend to be focused on the individual child viewed as separate from the contexts in which she acts. However, treatments (e.g., drugs, psychotherapy) are often administered in an unsystematic (or loosely connected) fashion, with different treatments administered and assessed independent of one another. Still further, therapeutic interventions—psychotherapy, social skills training and so forth—tend to occur in contexts that are isolated from everyday life (e.g., the four walls of a therapist's office). If one thinks of psychological maladaption as a kind of pathology that resides within individuals, it makes sense to focus interventions on processes that occur *within* persons. However, if one understands patterns of maladaptive behavior as *emergent* products of individuals in social contexts, this argument begins to lose its force.

In the past decades, the quest for evidence-based interventions and prevention programs based on best practices has occupied the attention of policy makers, practitioners and clinically oriented researchers. Evidence-based interventions are those that can cite scientific support for their effectiveness (Gullotta & Blau, 2008). The call for evidence-based therapies had its origins in dissatisfaction with therapeutic approaches that had long been untested, that had been based primarily on anecdotal testing, or that were judged impervious to testing. Interest in evidence-based therapies is not simply a product of scientific motives; insurance companies make evidence of the effectiveness of an intervention a requisite for the compensation of practitioners; federal agencies make funding of mental health research and programs contingent upon empirical demonstrations of therapeutic effectiveness. Evidence-based research has demonstrated the efficacy of different modes of therapy for various broad classes of maladaptive behavior. The requirement that practitioners garner empirical evidence supporting the effectiveness of psychological interventions has positive value. However, calls for evidence-based prevention and treatment tend to be based on the assumption that certain intervention and prevention strategies for particular classes of problems have universal application across contexts. That is, they tend to assume that (1) patterns of maladaptive behavior reflect more or less fixed types of problems (i.e., pathologies) that (2) lend themselves to standardized, generalized and even manualized modes of treatment. They also assume (3) that change is the result of a causal force—a property of the treatment as such, exerting an influence on every individual client similar to that causal force—plus random individual influences—that may increase or decrease the observed effect. This view reflects a continued reliance on models of science developed in the early twentieth century that seek to identify universal laws and relationships that transcend the context and content of

target phenomena. Prevention and intervention programs that fail to acknowledge the dynamic, heterogeneous and nonlinear origins of maladaptive behavior are unlikely to have high levels of effectiveness. Further, they may mistakenly identify group-based average effects with real effects on individuals, without taking into account that some interventions might also have a causal negative effect on some clients who are compensated in the group averages by positive effects in other clients.

Dynamic systems approaches seek to move beyond the limits imposed by linear ways of thinking about prevention, intervention, and assessment. Dynamic systems approaches maintain that effective prevention and intervention must be organized around a foundational appreciation of the nature of complexity (Gorman et al., 2006; Schensul, 2009). One cannot seek to understand the contextualized dynamics of maladaptive activity using principles and methodologies designed to assess relations among decontextualized variables. Systems thinking requires nothing less than a shift in mind-set:

- The unit of prevention and intervention should not be the individual child separate from its social context; instead, it should focus on the multiply nested child–environment system as a whole (Antonishak & Reppucci, 2008). Maladaptive patterns of action are not fixed forms or linear expressions of inner pathologies; instead, they are emergent products of individuals (with their dispositions and histories) operating within a complex person–environment system.
- A complex system is not defined as one that is composed of a simple set of multiple processes acting in isolation; instead, a complex system is one in which component processes mutually influence each other over time. If this is so, then prevention and intervention programs organized around discrete sets of uncoordinated interventions that are insensitive to local context are unlikely to be effective. Instead, prevention and intervention should focus on seeking transformations in the system as a whole. This can be accomplished by exerting control over central variables (sometimes called *control variables*) that, through their coactions with other variables in the system, modify the functioning of the whole.
- Complex systems are not steady states. They are sensitive to the initial conditions of their component processes (Kelso, 1995; Thelen & Smith, 2006). This means that minor variations in the initial conditions of two different complex systems can, over time, produce dramatic variations in the operations of those systems. If follows that efforts at prevention and intervention that are based on generalized or standardized procedures that are insensitive to the dynamics of local systems are unlikely to be effective. Instead, interventions must be organized around particular dynamics of local child–environment systems. Further, because small changes in local variables within a system can modify system functioning, changes introduced by prevention and intervention programs are often unforeseen and unpredictable. As a result, prevention and intervention programs must be sensitive to concrete changes in target systems as they evolve dynamically over time.

Instead of seeking to produce standardized remedies intended to have broad application across diverse contexts, dynamic systems approaches maintain that the tasks of prevention and intervention become ones of seeking to exert control over the dynamics of local complex systems. In the language of dynamic systems theory, the goal of prevention and intervention would be to produce phase shifts in functioning of the system—namely, a series of cascading or rippling effects that transform relations among variables throughout the child–environment system.

To illustrate, consider the simple child–environment system shown in Figure 15.17. This system describes the structure of a particular social interaction (Tseng & Seidman, 2007) between a child and a staff member in a group home for children who exhibit emotional and behavioral problems. At this school, staff members are trained in the use of time-out techniques for managing rule violations among children (8–11-year-olds) in the unit. A product of behaviorist thinking, the time-out technique was initially proposed as a way to provide a child with time out from the reinforcing contingencies assumed to be operative during the production of rule breaking behavior (Bostow & Bailey, 1969). Many practitioners, educators, and parents, however, misuse the time-out technique as a form of punishment (Kemp, 1996). Instead of operating as a break from reinforcing contingencies, the technique is used as an unpleasant consequence for a child's misdeed. As a result, time-out procedure often has effects

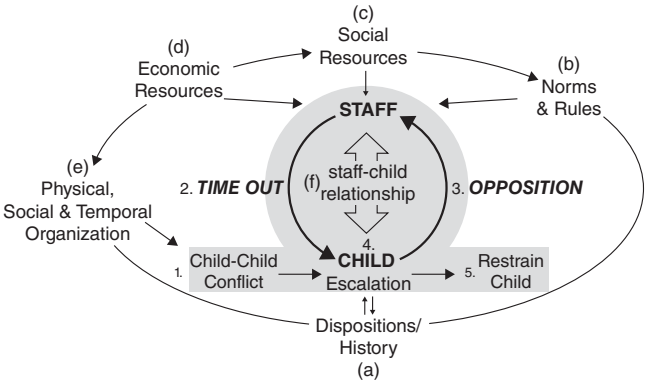

Figure 15.17 Dynamics of staff–child interaction in a group home.

that are opposite to their intended ones. For example, in an interview study with children enrolled in a special education program, Visser, Singer, van Geert, and Kunnen (2009) found that some children experience a time-out as a moment in which they can better reflect on and prepare a negative reaction to the behavior of the other child. In the interaction depicted in Figure 15.17, two boys were engaged in a conflict while watching television together (Point 1). As a result, (2) a staff member ordered one of the boys to a time-out. The boy responded by (3) mouthing off to the staff member, who then (4) increased the amount of time that the boy was asked to spend in time-out. Over time, the boy's oppositional behavior escalated out of control, and (5) the boy was physically restrained.

In this example, the child's unwanted behavior emerged as a product of coactive processes that operated within a complex child–environment system. The components of this simple system affect and constrain each other over time. In Figure 15.17, the shaded area indicates coregulated activity between a staff member and a child over time. The nonshaded elements indicate processes and resources that constrain child–staff interaction. The most obvious example of the mutual interplay among system components involves the positive feedback cycle that arose between the staff member and the child over the course of the encounter. In this interaction, the child's unwanted behavioral escalation was the emergent product of coregulated processes that occurred between the child and the staff member. While this was the most proximal source of the child's behavioral escalation, other elements of the system played an important if less obvious role. The (1) rules and norms of the group home stipulated that staff were to use the time-out technique to regulate misbehavior. Interactions between students and staff were constrained by the (2) social and (3) economic resources available to the group home—namely limits on the availability of funds and the capacity to recruit and retain qualified staff members. Further, the (4) physical (i.e., close quarters), social (i.e., the particular children involved in the conflict; the relationship between the target child and the staff member) and temporal (i.e., the placement of quiet TV time after homework and before bedtime) place constraints on the ways children can respond to each other and to the staff member.

However, changes in one or more core components of this child–environment system would likely produce dramatic changes in the capacity of staff to regulate the behavior of the children who lived there. The most obvious source of transformation would involve implementing appropriate uses of the time-out procedure. This would involve training staff to use time-outs as an opportunity to break behavior sustaining contingencies and to provide an opportunity for reflection and problem-solving, and also to talk with the children about how they experience the meaning of time-out, what it does to them emotionally, physically and rationally (Visser, Singer, van Geert, & Kunnen 2009). Success in the use of the time-out procedure—especially if coupled with sensitive emotional regulation and scaffolded behavioral redirection—would likely create a cascade of reciprocally influencing transformations. These could include the emergence of a shared ethos of improved intervention strategies among staff; increased capacity for behavioral and emotional regulation among children; increased cooperativeness between and among staff and children; and improved staff–client relationships. Over time, such subtle changes would settle into a stable and organized system of functioning. Participation in the system would have the effect of organizing children's capacity for effective social engagement and emotional regulation within the context of the unit.

It is also possible that similar results could be achieved by seeking to influence less central components of the child–environment system. For example, it is possible that misuse of time-outs in this particular organization was a product of difficulty in recruiting and retaining staff with suitable levels of experience and education. It is possible that the misuse of the time-out procedure arises from difficulties in training less qualified staff, or in retaining qualified or trained staff. If this were the case, it might be possible to transform the child–environment system by enhancing economic resources and using those resources to improve the quality of the social resources available to the organization, perhaps by recruiting and retaining more highly qualified staff who would require less intensive training in basic procedures. It is also possible that the aggressive behavior within a group of children prevails as a product of reciprocal imitation or retaliation that originates its in the aggressive activity of a minority of students. Simply changing the context often improves the behavior quite substantially (Visser, Kunnen, & Van Geert 2010).

We propose a series of general principles that can guide efforts at prevention and intervention at multiple levels of functioning. Efforts at prevention and intervention can be organized around several loosely organized steps:

1. Understand the dynamics of the local nonlinear systems in question. Efforts at prevention and intervention must begin with contextualized understandings of the nature of the local systems of psychological adaptation or maladaptation under consideration (Gorman et al., 2006; Schensul, 2009). This may require access to local data related to the functioning of particular child–environment systems of interest. Efforts at prevention and intervention can be focused on systems that operate at multiple levels. These may include the level of the individual child at home or at school; of multiple children interacting with each other and

with adults within organizations; or groups of children functioning within larger communities (Tricket & Schensul, 2009; Visser, Kunnen, & Van Geert 2010; Yoshikawa & Hsueh, 2001). Success in assessing the nature of nonlinear systems is facilitated by cooperation among interdisciplinary teams of practitioners who can coordinate their expertise relative to understanding a problem (Aiken & Hanges, 2012). For example, to assess a problem of aggression within a school system, it is important to bring together teams that can assess a broad range of variables related to the problem of aggression. These may include identifying (1) forms of observed aggression and the contexts in which they occur; (2) students at risk of being perpetrators or targets of aggression; (3) student culture and student-student relationships; (4) teacher–student interaction that arise during aggressive encounters; (5) demographics and values and of the families; (6) school culture; and (7) school–home–community relations. Varieties of methods are available to collect and analyze data for conducting such assessments, from dynamic mathematical modeling to ethnographic observation (Aiken & Hanges, 2012; Schiepek, 2003; Steenbeek & van Geert, 2013; Tricket & Schensul, 2009).

2. Identify core control variables. Having gained an understanding of the dynamics of the local system of interest, identify major control variables whose manipulation can have effects on the operation of other components in the system. For example, studies suggest that parental involvement and moral climate and children's personal interpretive socioemotional biases are important variables in mediating the level of aggression observed in middle schools (Farrell, Henry, Mays, & Schoeny, 2011; Foà, Brugman, & Mancini, 2012). Such variables may function as important control variables that, when modified, can produce cascading changes in a multiple variables related to the production of aggression within a given school system.
3. Coordinate attempts to regulate core control variables in relation to each other. It is not enough simply to seek to modify parameters of a dynamic system in isolation of one another. Instead, research suggests that prevention and intervention programs that seek to coordinate interventions and resources in relation to each other are more able to produce systemic change than those that do not (Eron et al., 2002; Farmer, Farmer, Estell, & Hutchins, 2007). The process of coordinating possible control variables during prevention and intervention increases the likelihood of fostering synergy among the coacting variables that compose a dynamic system.
4. Monitor and respond to changes in the system continuously over time. Traditional approaches to intervention tend to assess target functioning of individuals both prior to and subsequent to an intervention. Pre- and posttest designs yield insufficient data to allow assessment of the change dynamics in a complex system. To gain sufficient information to provide a clear understanding of the developmental course of intervention, it is necessary to assess the status of an evolving system at multiple points over the course of an intervention. A mindset of continuous assessment provides an important corrective to static pre- and posttest designs. Without multiple assessments, it is not possible to identify the types of nonlinear changes that result from coactions among system variables. Further, nonlinear systems often exhibit instabilities and fluctuations that result from minor changes in component processes. As a result, modifications in any given control variable can produce both wanted and unwanted effects (Gorman et al., 2006). Continuous monitoring of changes in system dynamics is necessary to know when and how to regulate the fluctuation of system parameters to produce optimal effects. Still further, understanding how manipulation of control parameters produces patterns of wanted and unwanted change over time is important for the development of prevention programs. The capacity to identify core control parameters provides practitioners with the ability to know where and how to allocate limited resources to produce optimal gain.

CONCLUSIONS: THE SELF-ORGANIZATION OF ORDER, VARIABILITY, AND DISORDER IN STRUCTURES OF THINKING, FEELING, AND ACTING

The way we conceptualize a problem affects how we study it. In the case of deviant behavior, our conceptualizations affect how we approach people who exhibit patterns of action that we classify as maladaptive. The study of deviant behavior raises difficult issues that have long captured the attention of psychologists, sociologists, philosophers, physicians, and practitioners. Although the medical model of psychopathology remains dominant, recently, it has weathered its share of controversy (Frances, 2013). From our perspective, the medical model influences theory and research in developmental psychopathology by representing psychological dysfunction as fixed structures that reflect an underlying pathology. In what follows, we discuss how dynamic systems thinking can address limitations of the psychopathology of fixed forms.

From Fixed Forms to Emergent Structures

When we think of psychological problems in terms of the concept of disorder, we run the risk of treating behavior and psychological problems as if they were entities or

things. The psychopathology of fixed forms leads theorists and researchers to think of psychological problems as trait-like entities that exist within individuals. When this occurs, researchers seek to investigate the nature of the presumed trait or form: What is the nature of the trait? Where is it located? What causes it to come into being? However, from a dynamic systems perspective, behavior is not a thing that a person has; behavior is a process that occurs over time within particular social contexts. It is necessary, therefore, to study how behavior emerges over time in particular contexts and social interactions. An inhibited child is not shy all the time; a child who withdraws at school is often noisy and rambunctious at home (Kagan & Snidman, 1990).

Further, when we treat psychological problems as trait-like entities, we tend to direct our attention to behavior that fits our a priori conception of the nature of the entity, and ignore behavior that does not comport with those preconceptions. For example, by focusing on the so-called trait rather than on the dynamic production of behavior in context, we fail to observe how patterns of both maladaptive and adaptive behavior arise as individuals adjust to the demands of local contexts. By studying individuals in contexts, systems approaches seek to understand the origins of order and variability, adaptive and maladaptive action, consistency and inconsistency. Similarly, if we think of patterns of maladaptive activity as discrete and trait-like forms, we are likely to be surprised when we find evidence that presumably fixed categories of disorder in fact fade into one another and assume a variety of diverse and overlapping forms. In contrast, if we seek to understand how patterns of psychological adaptation and maladaptation develop over time in individual children and contexts, it would not be surprising to find adaptive and maladaptive variation in behavior as individuals with different psychological resources and histories adjust to the contextual demands.

Conceptualizing Dysfunction: From Pathology to Adaptive Conflict

In medicine, pathology refers to a discernible deviation in the structure and functioning of the body. Drawing on this concept, the term psychopathology is typically employed in two ways. The first uses the concept of pathology as a metaphor for deviant behavior. From this view, psychopathology is to healthy behavior as a disease is to a healthy organ. Problems arise when one treats this metaphorical construction as a literal statement. Unlike the body, psychological functioning (or mind) is not an entity or thing. As a result, it is not the kind of thing that can be diseased. Treating psychopathology as a disease obscures the social, scientific, and pragmatic processes through which psychological processes are identified as deviant or maladaptive. The standards we use to identify psychological dysfunction are different from those used to determine physical pathology (Banner, 2013). Judgments that any given set of psychological processes is dysfunctional or disordered can be made only against the backdrop of some framework for identifying what is functional or ordered. Such judgments are ultimately normative and evaluative in nature. While many seek to define psychological dysfunction in neutral or nonevaluative terms, this is not possible. Judgments of human action necessarily operate against the backdrop of inescapable evaluative frameworks (Boysen, 2007; Taylor, 1989).

The second use of the term psychopathology is arguably less metaphorical, but nonetheless troublesome. From this view, psychological problems are regarded as symptoms of an underlying pathology located outside of the sphere of behavior itself (e.g., in the brain or body). This view is less metaphorical in the sense that it holds that psychological problems are actually products of bodily (brain) pathology. Several problems arise from this view (Banner, 2013). First, this approach suggests that there should be some correspondence between an underlying biological pathology and psychological symptoms. However, as indicated throughout this chapter, research shows patterns of psychological dysfunction are highly variegated and multiply determined. Patterns of psychological dysfunction emerge over time and function as dynamic systems. However, the proposition that psychological problems are caused by brain disorders begs the question of how to discriminate psychological dysfunction from psychological health. Whatever the role of biological disorder in psychological dysfunction, judgments of psychological dysfunction can only made by invoking standards for defining psychological functioning as optimal or nonoptimal. The identification of biological dysfunction does not in and of imply that any concomitant psychological processes are dysfunctional.

From a dynamic systems perspective, persons—like all organisms—are complex adaptive systems (Lickliter & Honeycutt, 2013; Masten, 2007; van Geert, 1994). A person's psychological processes operate as modes of adapting to their environs. Adaptation reflects the capacity of an organism to adjust its behavior to environmental demands. From this view, it might be better to think of modes of psychological dysfunction as systemic difficulties in adaptation, rather than as distinct forms of pathology, disorder, disease, or illness. The concepts of adaptation and maladaptation are relational concepts; they make reference to the goodness of fit between the resources of the organism and the demands of its environment (Gottlieb & Halpern, 2002; Lerner, Hess, & Nitz, 1990). Thus, maladaptive behavior is behavior that causes problems for an

individual, dyad, or community. The concept of dysfunction as adaptive conflict reflects a more person-centered rather than pathology-centered understanding psychological dysfunction (von Eye, 2009). Instead of seeking to understand the essence of a given category of psychological disorder, emphasis is placed upon the processes by which individual develop adaptive and maladaptive ways of relating to their worlds over time.

From Aggregates to Individual Trajectories

From a dynamic systems perspective, human behavior self-organizes through the dynamic coupling of person-in-context. Thus to understand the process of psychological development, it becomes necessary to examine how novel psychological structures arise through the moment-by-moment coactions among aspects of the person–environment system. This requires moving beyond methods based primarily on aggregate judgments collapsed across time and context and toward direct observation of integrative patterns of behavior during the process of their developmental formation. Traditionally, much research in developmental psychopathology has been variable centered rather than person centered (von Eye & Bergman, 2003). Research directed toward identifying relations among abstract variables using aggregated data tends to be nonergodic and thus fails to capture the nature of processes that occur at the individual level of functioning (Molenaar & Ram, 2010). Further, much research is conducted using participant judgments on rating scales and checklists without actually observing the activity of individual persons. Such methods fail to examine the data that is most essential to understand the process by which order and variability develop over time: the dynamic coupling of individual and social context over time. The use of direct observation of individual-context interaction allows researchers to track how complex patterns of adaptive and maladaptive functioning codevelop in single individuals (Granic & Hollenstein, 2006; Kagan, Snidman, McManis, Woodward, & Hardway, 2002).

The Challenges Ahead

Over the past 20 years, dynamic systems approaches to maladaptive development have themselves undergone considerable development. Nonetheless, dynamic systems models of development are only beginning to show their promise. There remain important challenges to be overcome.

The Importance of Psychological Theory in Dynamic Systems Analyses of Development

Dynamic systems theory has its origins in the fields of physics, mathematics, biology, and chemistry. Since then, it has proliferated in virtually all areas of scientific inquiry. The principles of dynamic systems theory are broadly applicable to the study of any system that demonstrates complexity. Over the past 20 years, there has been an astonishing proliferation of work in many areas of psychology and developmental science. While the principles of *dynamic systems theory* are broadly applicable, it is perhaps misleading to speak of dynamic systems thinking as a theory. Dynamic systems theory operates more as a meta-theory that provides principles and methods for understanding and modeling dynamic phenomena (Witherington, 2007). If this is so, meaningful dynamic systems modeling—mathematical or otherwise—requires a solid foundation of psychological theorizing (Cowan, 2003; Spencer, Austin, & Schutte, 2012; Van Geert, 1994). This is not to say that dynamic systems approaches should necessarily work from a hypothetico-deductive framework. Dynamic systems models of development are still in their infancy. Much work remains in developing dynamic system methods that are capable of representing the overwhelming complexity of human psychological functioning as it unfolds over time. As this work ensues, researchers are producing extraordinarily rich analyses of the dynamic coupling of local psychological processes as they unfold and develop in a wide variety of psychological domains (e.g., Ferrer & Helm, 2013; McAssey, Helm, Hsieh, Sbarra, & Ferrer, 2013). Such studies, even when they do not proceed from a specific theoretical model, are providing an extremely rich matrix of findings that can inform the development of psychological theory. Thus, while dynamic systems theory provides meta-theoretical and meta-methodological tools for developmental science, to exploit the promise of dynamic systems thinking, it is important to wed systems meta-theory more closely with genuinely psychological theorizing.

Elaborating Quantitative and Qualitative Methods for Assessing Complexity in Normative and Nonnormative Development

The task of studying dynamic complexity in development raises obvious methodological questions. Traditional methods that focus on parsing variance at the level of populations typically fail to shed light on the dynamic processes that operate at the level of the development individual action (Molenaar & Campbell, 2009; Ong & Zautra, 2009). Dynamic systems researchers have developed a multiplicity of methods that track dynamic change in ways that are sensitive to the individual development. These methods include mathematical modeling (Ferrer & Steele, 1982; Kunnen, 2012); state space grids (Hollenstein, 2013); microdevelopment of individual and dyadic activity (Mascolo & Fischer, 2015; Thomas, Hopwood, Woody, Ethier, & Sadler, 2013); analyses of alternative developmental pathways (Mascolo & Fischer, 2015); self-report

and diary methods (Navarro, Arrieta, & Ballén, 2007); thick description (Fogel, Garvey, Hsu, & West-Stroming, 2006); and qualitative analyses (Haggis, 2008; Sommerfeld & Hollenstein, 2011). Traditional methods—including experimental design (Gottlieb, 2001) and factor analysis (Ram, Brose, & Molenaar, 2013)—are also applicable to the dynamic analysis of complex systems. These approaches are sensitive to issues relating to developmental timing (Granic, 2005); synchronicity of unfolding psychological processes (McAssey, Helm, Hsieh, Sbarra, & Ferrer, 2013); multiple levels of analysis (Van Geert & Lichtwarck-Aschoff, 2005); sequence (Molenaar & Goode, 2013); and structural transformation (Mascolo & Fisher, 2015).

While there has been enormous progress made in the elaboration of dynamic systems methodology, a series of challenges remain. First, most of this work has been performed with normative populations. There is a need to apply and develop these methods further for the study of the dynamic development of maladaptive behavior patterns. Second, despite the impressive progress in the development of dynamic systems methods, the issue of representing developmental complexity remains. For example, in pursuing ergodic methods that are sensitive to individual development, researchers are increasingly performing longitudinal analyses of multiple single individuals. This raises the question of the extent to which it is desirable and possible to use idiographic methods to make nomothetic generalizations (Fisher, Newman, & Molenaar, 2011). Further, given the enormous complexity of normative and nonnormative development, the question of how to differentiate core control variables from other variables relevant to the development of any given system or systems of activity remains a central challenge. Third, as research comes to address increasingly complex units of behavior, there will be a need to find ways to assess developmental complexity at multiple levels of analysis in ways that are accessible, meaningful and intelligible but not overly simplistic. Toward this end, there is a need to explore ways to coordinate quantitative and qualitative research methods. Similarly, it is essential to keep in mind that the study of developmental complexity does not always require complex designs. We should never lose sight of the principle that *methods* are driven by problems (Bergman & Vargha, 2013). Simple (but not simplistic) methods can often reveal vast complexity. Examples of these include but are not limited to the use of experimental designs to study the effect of variations in rearing conditions on behavioral development (Gottlieb, 1991, 2002; Jablonka & Lamb, 2006); thick description of historical-relational trajectories of development (Fogel, Garvey, Hsu, & West-Stroming, 2006; Piaget, 1952); and the microdevelopmental tracking of developmental complexity in real time (Mascolo & Fischer, 2015).

Accounting for Structural Change in Dynamic Assessments of Development

While dynamic systems approaches have produced powerful methods for the quantitative analysis of nonlinear trajectories of development, it is equally important to understand the structural aspects of developmental change. Many attempts to identify trajectories of maladaptive development focus on quantitative changes in the frequency of or rate of maladaptive activity over time. While useful, such analyses fail to account for the patterns of differentiation and integration that define a sequence as a genuinely developmental one. The concept of development is not simply a synonym for change over time or age-related change. Development is a directional and transformational concept (Bibace & Kharlamov, 2013; Raeff, 2011; Van Geert, 1986). To say that a psychological structure is developing implies that it is undergoing successive structural changes defined with reference to some actual, hypothetical, or idealized developmental outcome (see Basseches & Mascolo, 2010; Sroufe, 2007; Van Geert, 1986, 1987). For example, the structure of indirect aggression in adolescence is different from the reactive aggression of a preschooler (Arnocky, Sunderani, Miller, & Vaillancourt, 2012; Card & Little, 2006); the dynamics of shame, worthlessness and rage experienced among adult victims of early sexual abuse differ from the raw unarticulated experiences of victimization in childhood (Isely, Isely, Freiburger, & McMackin, 2008; Rahm, Renck, & Ringsberg, 2013). To measure structural change, there is a need to invoke some type of developmental yardstick to measure the transformations in the structure of normative and nonnormative patterns of thinking, feeling and acting over time. Dynamic skill theory (Fischer, 1980; Mascolo & Fischer, 2015) provides one such yardstick. Fischer's analysis of developmental transformations in dissociative splitting (described earlier in this chapter) provides but one example of how researchers can account for structural transformations in nonnormative patterns of thinking, feeling, and acting over the course of development.
