These volumes are dedicated to Marianne Gerschel in recognition
of her great vision and staunch support of the field
of developmental psychopathology.

Contents

Preface to Developmental Psychopathology, Third Edition xi
Dante Cicchetti

Contributors xiii

1 **DEVELOPMENTS IN THE DEVELOPMENTAL APPROACH TO INTELLECTUAL DISABILITY** 1
Jacob A. Burack, Natalie Russo, Cathryn Gordon Green, Oriane Landry, and Grace Iarocci

2 **FRAGILE X SYNDROME AS A MULTILEVEL MODEL FOR UNDERSTANDING BEHAVIORALLY DEFINED DISORDERS** 68
Annette Karmiloff-Smith, Brianna Doherty, Kim Cornish, and Gaia Scerif

3 **AUTISM SPECTRUM DISORDERS** 81
Raphael Bernier and Geraldine Dawson

4 **JOINT ATTENTION AND THE SOCIAL PHENOTYPE OF AUTISM SPECTRUM DISORDER: A PERSPECTIVE FROM DEVELOPMENTAL PSYCHOPATHOLOGY** 116
Amy Vaughan Van Hecke, Tasha Oswald, and Peter Mundy

5 **EXPLICATING THE "DEVELOPMENTAL" IN PRESCHOOL PSYCHOPATHOLOGY** 152
Sara J. Bufferd, Margaret W. Dyson, Iseli G. Hernandez, and Lauren S. Wakschlag

6 **THE DEVELOPMENT OF EMOTION REGULATION: IMPLICATIONS FOR CHILD ADJUSTMENT** 187
Susan D. Calkins and Nicole B. Perry

7 **INTERPERSONAL THEORIES OF DEVELOPMENTAL PSYCHOPATHOLOGY** 243
Karen D. Rudolph, Jennifer E. Lansford, and Philip C. Rodkin

8 **COGNITIVE RISKS IN DEVELOPMENTAL PSYCHOPATHOLOGY** 312
Benjamin L. Hankin, Hannah R. Snyder, and Lauren D. Gulley

9 **TRAUMATIC STRESS FROM A MULTILEVEL DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE** 386
J. Douglas Bremner

10 **CHILDHOOD EXPOSURE TO INTERPERSONAL TRAUMA** 425
Alicia F. Lieberman and Ann T. Chu

11 **CHILD MALTREATMENT AND DEVELOPMENTAL PSYCHOPATHOLOGY: A MULTILEVEL PERSPECTIVE** 457
Dante Cicchetti and Sheree L. Toth

12 **A DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE ON FOSTER CARE RESEARCH** 513
Philip A. Fisher, Leslie D. Leve, Brianna Delker, Leslie E. Roos, and Bryna Cooper

13 **MEMORY DEVELOPMENT, EMOTION REGULATION, AND TRAUMA-RELATED PSYCHOPATHOLOGY** 555
Gail S. Goodman, Deborah Goldfarb, Jodi A. Quas, Rachel K. Narr, Helen Milojevich, and Ingrid M. Cordon

14 **ATTENTION AND IMPULSIVITY** 591
Joel T. Nigg

15 **THE DEVELOPMENT AND ECOLOGY OF ANTISOCIAL BEHAVIOR: LINKING ETIOLOGY, PREVENTION, AND TREATMENT** 647
Thomas J. Dishion and Gerald R. Patterson

16 **NARCISSISM** 679
Sander Thomaes and Eddie Brummelman

17 **A MULTILEVEL PERSPECTIVE ON THE DEVELOPMENT OF BORDERLINE PERSONALITY DISORDER** 726
Peter Fonagy and Patrick Luyten

18 **ALCOHOL USE AND THE ALCOHOL USE DISORDERS OVER THE LIFE COURSE: A CROSS-LEVEL DEVELOPMENTAL REVIEW** 793
Robert A. Zucker, Brian M. Hicks, and Mary M. Heitzeg

19 **SUBSTANCE USE AND SUBSTANCE USE DISORDERS** 833
Laurie Chassin, Craig R. Colder, Andrea Hussong, and Kenneth J. Sher

20 **BIPOLAR DISORDER FROM A DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE: FOCUSING ON PHENOMENOLOGY, ETIOLOGY, AND NEUROBIOLOGY** 898
Bonnie Klimes-Dougan, Kevin P. Kennedy, and Kathryn R. Cullen

21 **CHILDHOOD SCHIZOPHRENIA** 950
Rochelle Caplan

22 **MULTILEVEL APPROACHES TO SCHIZOPHRENIA AND OTHER PSYCHOTIC DISORDERS: THE BIOBEHAVIORAL INTERFACE** 997
Elaine F. Walker, Arthur T. Ryan, Katrina C. Bridgman Goines, Derek M. Novacek, Sandra M. Goulding, Joy L. Brasfield, Allison Macdonald, and Hanan D. Trotman

23 **TOWARD A UNIFYING PERSPECTIVE ON PERSONALITY PATHOLOGY ACROSS THE LIFE SPAN** 1039
Jennifer L. Tackett, Kathrin Herzhoff, Steve Balsis, and Luke Cooper

24 **TOWARD A DEVELOPMENTAL PSYCHOPATHOLOGY OF PERSONALITY DISTURBANCE: A NEUROBEHAVIORAL DIMENSIONAL MODEL INCORPORATING GENETIC, ENVIRONMENTAL, AND EPIGENETIC FACTORS** 1079
Mark F. Lenzenweger and Richard A. Depue

Preface to Developmental Psychopathology, Third Edition

A decade has passed since the second edition of *Developmental Psychopathology* was published. The two prior editions (Cicchetti & Cohen, 1995, 2006) have been very influential in the growth of the field of developmental psychopathology. The volumes have been highly cited in the literature and have served as an important resource for developmental scientists and prevention and intervention researchers alike. In the present third edition, we have expanded from the three volumes contained in the second edition to four volumes. The increased number of volumes in this current edition reflects the continued knowledge gains that have occurred in the field over the past decade.

A not insignificant contributor to this growth can be found in the very principles of the discipline (Cicchetti, 1984, 1990, 1993; Cicchetti & Sroufe, 2000; Cicchetti & Toth, 1991, 2009; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). Theorists, researchers, and prevention scientists in the field of developmental psychopathology adhere to a life span framework to elucidate the numerous processes and mechanisms that can contribute to the development of mental disorders in high-risk individuals as well as those operative in individuals who already have manifested psychological disturbances or who have averted such disorders despite their high-risk status (Cicchetti, 1993; Masten, 2014; Rutter, 1986, 1987, 2012). Not only is knowledge of normal genetic, neurobiological, physiological, hormonal, psychological, and social processes very helpful for understanding, preventing, and treating psychopathology, but also deviations from and distortions of normal development that are seen in pathological processes indicate in innovative ways how normal development may be better investigated and understood. Similarly, information obtained from investigations of experiments of nature, high-risk conditions, and psychopathology can augment the comprehension of normal development (Cicchetti, 1984, 1990, 1993; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe, 1990; Weiss, 1969).

Another factor that has expedited growth within the field of developmental psychopathology has been its ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary and translational research (Cicchetti & Gunnar, 2009; Cicchetti & Toth, 2006). In keeping with its integrative focus, contributions to developmental psychopathology have come from many disciplines of the biological and social sciences. A wide array of content areas, scientific disciplines, and methodologies has been germane. Risk and protective factors and processes have been identified and validated at multiple levels of analysis and in multiple domains.

The increased emphasis on a multilevel, dynamic systems approach to psychopathology and resilience, the increased attention paid to gene–environment interplay in the development of psychopathology and resilience, and the application of a multiple levels of analysis developmental perspective to mental illnesses that have traditionally been examined nondevelopmentally (e.g., bipolar disorder, schizophrenia, and the personality disorders) not only have contributed to a deeper understanding of the dysfunctions but also have educated the public about the causes and consequences of mental disorder (see Cicchetti & Cannon, 1999; Cicchetti & Crick, 2009a, 2009b; Miklowitz & Cicchetti, 2006, 2010; Tackett & Sharp, 2014).

Advances in genomics, GxE interactions, and epigenetics; growth in our understanding of neurobiology, neural plasticity, and resilience; and progress in the development of methodological and technological tools, including brain imaging, neural circuitry, hormone assays, immunology, social and environmental influences on brain development, and statistical analysis of developmental change, pave the way for interdisciplinary and for multiple levels of analysis research programs that will significantly increase the knowledge base of the development and course of maladaptation, psychopathology, and resilience. Moreover, randomized control prevention and intervention trials are being conducted based on theoretical models and efforts to elucidate the mechanisms and processes contributing to developmental change at both the biological and psychological levels (Belsky & van IJzendoorn, 2015; Cicchetti & Gunnar, 2008).

Despite the significant advances that have occurred in the field of developmental psychopathology, much important work lies ahead. Undoubtedly these future developments will build on the venerable contributions of the past; however, as work in the field becomes increasingly interdisciplinary, multilevel, and technologically sophisticated, it is essential that even more emphasis be directed toward the process of development (Harter, 2006; Sroufe, 2007, 2013). It is not only genes and environments but also the cumulative developmental history of the individual that influences how future development will unfold (Sroufe, 2007, 2013).

Developmental psychopathologists have incorporated concepts and methods derived from other disciplinary endeavors that are too often isolated from each other, thereby generating advances in knowledge that might have been missed in the absence of cross-disciplinary dialogue. The continuation and elaboration of the mutually enriching interchanges that have occurred within and across disciplines interested in normal and abnormal development not only will enhance the science of developmental psychopathology but also will increase the benefits to be derived for individuals with high-risk conditions or mental disorders, families, and society as a whole.

DEVELOPMENTS IN THE DEVELOPMENTAL APPROACH TO INTELLECTUAL DISABILITY

The developmental study of intellectual disability is a long-established forerunner of developmental psychopathology with origins that predate the formal emergence of the latter discipline by decades, and yet is still in its early, and sometimes apparently regressive, stages of developmental emergence relative to other areas of work. It was largely shaped by scholars, such as Heinz Werner, Edward Zigler, and Dante Cicchetti, who were also seminal to the emergence of the scholarly discipline of developmental psychopathology, and yet it is often conceptualized as a separate unrelated entity. These complex relationships provide a lens through which we can understand the advances, and setbacks, in the study of intellectual disability, and its place in the domain of developmental psychopathology

"Make for yourself a teacher, acquire for yourself a friend, and judge everyone in a positive light . . . " Ethics of the Fathers (Pirkei Avot, 1, 6). We dedicate this chapter in honor of Ed Zigler for all his contributions to the science and welfare of so many children, including those with intellectual disability. He is the most inspiring teacher, loyal friend, and positive influence to all who know him. As with so much of his work, his articulation of the developmental approach to intellectual disability helped humanize our understanding of a population that for too long had been underserved and kept at the fringes of society. We are especially grateful to Dante Cicchetti for inviting us to contribute this chapter, on a topic about which we are so passionate and about which he was a visionary. His leadership both in the world of science and in making the world a better place for children is an example to us all.

We thank Jillian Stewart, Johanna Querengesser, Ashley Reynolds, Icoquih Badillo-Amberg, David McNeil, Eric Keskin, and Martina Tiberi as well as other members of the McGill Youth Study Team for their help in preparing the manuscript.

(and thereby in this volume). Within this framework, we highlight the thinking and research that led to and continue to maintain the developmental approach to intellectual disability and consider them with regard to developments in the study and understanding of intellectual disability since Hodapp and Burack's (2006) chapter in the last edition of this handbook (Cicchetti & Cohen, 2006).

As intellectual disability is essentially defined by the development of cognitive abilities and, to a considerably lesser extent, social skills that are so delayed and ultimately impaired that it only involves a small percentage of persons, it is a paradigmatic example of the construct of development at the extreme that is so essential to the field of developmental psychopathology (Burack, 1997; Cicchetti & Pogge-Hesse, 1982). In this way, intellectual disability also exemplifies Urie Bronfenbrenner's notion of an experiment of nature, which could never be replicated in an experimental setting but in this case is informative for understanding the course of typical cognitive and social development. Thus, consistent with Cicchetti's (1984) dictum that "you can learn more about typical functioning by studying its pathology and more about its pathology by studying its typical state" (p. 4), intellectual disability is a window into addressing issues and questions about cognitive and social development that cannot be fully answered when only considering typically developing persons (Burack, 1997; Cicchetti & Pogge-Hese, 1982; Hodapp, Burack, & Zigler, 1990). In providing the example of extreme delay, or impairment, intellectual disability would appear to allow us the opportunity to examine the integrity of the developmental system from the unique perspective of especially slowed or delayed development (Cicchetti & Beegly, 1990; Hodapp & Burack, 1990; Hodapp & Zigler, 1990). As is often the case in nature, this "slow motion" analysis of cognitive and social development allows for a particularly intense level of scrutiny that cannot be attained with events occurring at their typical speed.

The converse of Cicchetti's dictum is also particularly relevant to the study of intellectual disability as the theories and methodologies that have governed the study of development among typically developing persons have, during the past half century, transformed the way that persons with intellectual disability and their families are studied, understood, educated, and supported (for related collections, see Burack, Hodapp, Iarocci, & Zigler, 2012; Burack, Hodapp, & Zigler, 1998; Cicchetti & Beeghly, 1990; Hodapp, Burack, & Zigler, 1990). These advances are the focus of this chapter as we highlight the ongoing and evolving conceptual, methodological, and interpretive contributions of the so-called developmental approach to the study of persons with intellectual disability and the ways that they have led to a more precise and sophisticated science (Burack, Dawkins, Stewart, Flores, Iarocci, & Russo, 2012; Burack, Russo, Flores, Iarocci, & Zigler, 2012; Cicchetti & Ganiban, 1990; Hodapp, Burack, & Zigler; 1990).

THE DIAGNOSIS OF INTELLECTUAL DISABILITY AND ITS (LACK OF) MEANINGFULNESS

Although the diagnosis has far-reaching implications for the development and outcomes of the affected persons, intellectual disability cannot be considered at all tangible. Virtually unique among the phenomena addressed in this volume, the designation of intellectual disability is essentially based on a behavioral classification culled from scores on single measures used to operationalize each of two constructs—in this case, primarily the construct of intelligence but often also that of social adaptation. Typically, people who score in approximately the lowest 3% of the population, or two or more standard deviations below the mean, on standardized tests of intelligence and behavioral adaptation are considered to be intellectually disabled. However, the utility of this designation is compromised in two essential ways. One, the cutoff score is entirely arbitrary. Two, the low IQ, or behavioral, scores can be attained for different reasons and with different profiles as evidenced by the study of the handful of the most common of the more than 1,000 possible etiologies, each of which seems to differ considerably from the other conditions and situations associated with intellectual disability (for reviews, see Burack, 1990; Burack, Hodapp, & Zigler, 1988, 1990; Cornish & Wilding, 2010; Dykens, Hodapp, & Finucane, 2001). These group differences are especially apparent in developmental rates and trajectories as well as the profiles of relative strengths and weaknesses across the myriad of cognitive and social skills that are thought to impact intelligence and the many sub- and sub-sub-tests that make up the various different IQ tests and indexes of behavioral adaptation that are used for the diagnosis. Even given the usual within-group differences that are found in any population, the compelling and clearly demarcated group discrepancies on many aspects of functioning highlight the profound and complex developmental effects of the genes–brain–behavior relations associated with each syndrome that virtually swamp any generalized developmental effects of simply lower levels of intelligence and social adaptation (for relevant collections, see Burack et al.,

1998; Burack, Iarocci, et al., 2012; Howlin, Charman, & Ghaziuddin, 2011; Tager-Flusberg, 1999).

With these pervasive group differences across virtually all aspects of being and functioning, the notion of a population of persons with intellectual disability is a mirage. Thus, the phenomenon precludes a science or study of intellectual disability per se but rather would appear to necessitate the invocation of multiple sciences of identifiable populations that differ meaningfully from each other with regard to etiology, defining features, and developmental trajectories. In this framework, both the concept and the field of intellectual disability are inherently deconstructed from the monolithic framework of a single problem and population to more precise, albeit with the consequent of increasingly complex, conceptualizations and research (Burack, Russo, et al., 2012). This demise of a single science or framework of intellectual disability would seem to come at considerable cost. Prior so-called knowledge about persons with intellectual disability as a whole needs to be forsaken, while the alternative of the imposition of multiple fine-grained fields of study based on clearly differentiated populations inevitably entails considerably more work and would seem to signal the abandonment of any sense, or even hope, of a comprehensive and cohesive field of study. Yet, when the additional work is associated with the imposition of a developmental approach that is premised on the notion of a systemic, organized, and universal system, it provides both more precise information and a unifying framework with which the various fragments of information can be grouped into a meaningful area of scholarship (Burack, 1997; Burack, Iarocci, et al., 2012; Cicchetti & Ganiban, 1990; Cicchetti & Pogge-Hesse, 1982; Karmiloff-Smith, 2009; Zigler, 1969, 1973; Zigler & Balla, 1982; Zigler & Hodapp, 1986).

Diagnostic Criteria and Assessment

In one sense, intellectual disability is relatively easily conceptualized. Across the decades and even centuries of work with persons with intellectual disability, the basic notion has been that a certain percentage of persons function at such low levels of intelligence and social adaptation that they cannot survive or function independently in society, or at least need some intensive external support to do so (e.g., Luckasson et al., 2002; AAIDD, 2010; for reviews, see Rosen, Clark, & Kivitz, 1976; Zigler & Hodapp, 1986). However, intellectual disability is also an odd and elusive behavioral classification as it involves the grouping of an extremely heterogeneous population according to amorphous concepts, arbitrary criteria, and prevailing societal values, all of which have changed often during the past century (for recent discussions, see Bertelli et al., 2014; Salvador-Carulla et al., 2011; Schalock et al., 2010; Shulman, Flores, Iarocci, & Burack, 2011).

Diagnosis and Classification From a Developmental Perspective

Even as researchers and practitioners of intellectual disability discuss relevant issues, including the meaning of intelligence, the role of indexes of social competence in the classification, the measures that should be used for testing, and specific criteria for a diagnosis, the pragmatic reality is that the classification of intellectual disability has historically been entirely determined by IQ, a quantitative measure of the development of the elusive construct of intelligence. Despite the many concerns about IQ scores, they continue to be essential in the demarcation of persons with intellectual disability and in other strategies to identify persons at developmental risk because IQ scores in childhood are seen as reliable indexes of both a child's current rate of intellectual development and of future levels of functioning in relation to one's same-aged peers (Shulman et al., 2011).

The relative reliability among IQ scores at different points in the lifespan captures the developmental essence of intelligence testing and scores. Although IQ scores are typically discussed as measures of individuals' intellectual abilities in relation to those of other persons of the same age, they are historically and essentially indicators of the rate of development of intellectual abilities that is considered both to be consistent at least through adolescence and to be associated with relative level of functioning in adulthood. The developmental nature of IQ is evident in its formula, which involves dividing mental age (MA), the level of cognitive development attained by the individual, by *chronological age* (CA) and then multiplying that number by a constant (usually 100) (for discussions, see Hodapp, Burack, & Zigler, 1990; Zigler & Hodapp, 1986; Shulman et al., 2011). This is fundamentally a measurement of rate as, in this context, CA (the denominator) represents the amount of time taken to attain the level of abilities indicated by MA (the numerator). As a quick analogy, one might think of a common measurement of rate in our everyday lives, that of speed for which we commonly use the equation of kilometers (or miles) per hour. In this equation, the numerator is the specific distance travelled as indicated by the number of kilometers and the denominator is the length of time, as indicated by the number of hours, which has passed during the travels. Both the numerator and denominator grow in relation to each

other, although the ratio between them varies considerably as it serves both as an indicator of the speed of travel and as a point of comparison. And by definition of rate, faster speeds are associated with ratios in favor of the numerator over the denominator. For IQ, the numerator MA is the developmental distance traveled by the individual in their attainment of cognitive abilities and the denominator CA is the length of time that the individual has lived. In this case, a greater numerator, or more distance travelled, in relation to a smaller denominator, less time passed, indicates faster developmental growth. Clearly a child who attains the types of skills common to a 6-year-old in 6 years, and therefore has an IQ of 100 according to our developmental formula, is developing faster than a child for whom it takes 8 years and has an IQ of 75 but slower than one for whom it took only 5 years and who has an IQ of 120.

In terms of long-term consequences, these rates of development are highly correlated with IQ scores and related levels of functioning throughout the rest of the lifespan. Thus, slower development and, therefore, lower IQ scores in childhood are inevitably associated with lower scores on IQ tests and generally lower levels of functioning in adulthood. IQ scores are typically standardized in that they are normed across a representational sample, and, thereby reflect a statistically calculated average for a specific level of functioning at a given age or period in life. Within this context, the primary criterion for the designation of intellectual disability generally involves a cutoff score on a standardized IQ test that is associated with some statistical designation. This cutoff score is usually 70, which is two standard deviations below the mean for the general population for which a mean of 100 is statistically designated. According to this statistical designation, persons with intellectual disability should represent approximately the bottom 3% of the population in terms of IQ scores, although the number of persons who are actually diagnosed often varies in relation to income level of country (Carulla et al., 2011), age of the individual (Hodapp & Zigler, 1986), and the use of social adaptation criteria in addition to the IQ score for the diagnosis (MacMillan, Gresham, & Siperstein, 1993; Switzky & Greenspan, 2006).

The Arbitrary and Amorphous Nature of the Criteria for the Diagnosis of Intellectual Disability

This variability in the specific number of persons who meet this criterion might raise some concerns about the application of two standard deviations below the mean IQ as the cutoff point for the diagnosis, except for the fact that this designation is entirely arbitrary and has no inherent scientific significance with regard to differentiating functioning level among individuals. Rather, the most meaningful aspect of the score is its statistical convenience as the commonly used nomenclature of standard deviations allows for an easily described percentage of persons. As the standard deviations on common IQ tests represent 15 points, persons with IQs just above (i.e., 71, 72, 73) and below (69, 68, 67) the designated cutoff scores do not differ significantly, either statistically or pragmatically, from each other, whereas the differences among individuals within the range of either intellectual disability, with possible IQs of 0–70, or of so-called typical functioning, with possible IQs of 71 and above, are often vast and can encompass several standard deviations. If that is the case, why are IQ cutoffs imposed? The primary rationale is that some criterion is needed as a standard for social policy and decisions about who should receive specialized services. In this way, the designated score which is based on a statistical model of the real world distribution of IQ scores, and thereby level of functioning, offers a rough estimate of the number of persons who should be and are eligible for some combination of additional funding, resources, services, and supports from governmental and other service agencies. The delineation of intellectual disability then is not a scientific one, but rather one that is largely dependent on societal values and discourse, as well as the resources that are made available to support persons with intellectual disability.

The extent to which the designation of intellectual disability is an amorphous and arbitrary concept is evident in that the specific cutoff and the associated definition has been modified at least nine times over the past 100 years in the United States (AAMR, 2002; Harris, 2005; Zigler & Hodapp, 1986) and is once again revised in the newest versions of both the American-based, Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-5) (APA, 2013), and the International Classification of Diseases (*ICD*) (Bertelli et al., 2014; International Advisory Group for the Revision of *ICD-10* Mental and Behavioural Disorders, 2011; Salvador-Carulla et al., 2011). These changes in both the diagnostic criteria and the nomenclature are due to many different "real" factors including new knowledge regarding the causes and types of intellectual disability, the perceived significance of social competence and adaptive behaviors, perspectives on eventual outcomes and well-being of persons with intellectual disability, attitudes of societies and policy makers toward individuals' dignity and roles in the community, and pragmatically the resources available for services and intervention. Yet, they also highlight the arbitrariness of

the designation and the influence of factors external to the individuals with the diagnosis.

The most blatant example of the arbitrariness of the criteria was evidenced at the beginning of the 1960s. With the emerging zeitgeist of the time on the promotion of social justice and the desire to improve the lots and lives of those who were deemed less fortunate, the IQ cutoff score was changed from 70, two standard deviations below the mean of 100, to 85, one standard deviation below the mean, by the American Association on Mental Retardation (Heber, 1961). Accordingly, the percentage of persons diagnosed with intellectual disability grew from approximately 2–3% of the population to 16%. In the United States alone, with a population of approximately 200 million at the time, that meant a jump of about 26 million people, from around 6 million to approximately 32 million, who fell within the parameters of a diagnosis of intellectual disability (Zigler & Hodapp, 1986). The absurdity that so many people could go to sleep one night without a diagnosis and wake up the following morning meeting the primary criterion of a person with intellectual disability highlights the obvious arbitrariness in the designation and construct of intellectual disability that precludes any notion of some intrinsic condition that can be meaningfully quantified. These points are even further underscored by the subsequent reversion a dozen years later to the original IQ cutoff (Grossman, 1973), thereby shedding the same approximately 26 million people of their diagnosis—as if in a fairy tale in which they go to sleep one night and are magically relieved of their problem, which, of course, they had not suffered from prior to the change in diagnostic criteria a decade earlier (Zigler & Hodapp, 1986). These changes in the diagnostic criteria were certainly well meaning with the initial change occurring in an era of relative affluence and an emergent emphasis on social change with the intention of enabling services for those persons who typically did not meet the criterion of intellectual disability, but were still considered to be at risk as their intellectual functioning was at the low end of the average range. This course of events provides insight into the difficulties of conceptualizing intellectual disability and the extent to which it must be considered in relation to contemporary societal norms and values.

The Latest Incarnation of the Diagnostic Criteria for Intellectual Disability

In the latest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*; APA, 2013), the term *intellectual disability* (also referred to as intellectual developmental disorder [IDD]), intended to reflect deficits in cognitive capacity beginning in the developmental period, replaces the term *mental retardation*, which had long been used in classificatory schemes such as those of the American Association on Mental Retardation (AAMR) and the American Psychiatric Association for the *DSM*. This revised terminology brings the *DSM* into alignment with the World Health Organization's *International Classification of Diseases* (*ICD*) and other professional disciplines (Salvador-Carulla & Bertelli, 2008; Salvador-Carulla et al., 2011). Intellectual disability is also now the term of choice for public policy discourse by influential groups representing people with intellectual disabilities such as the American Association on Intellectual and Developmental Disabilities (AAIDD, formerly the AAMR; Schalock et al., 2011).

In addition to the revisions in the nomenclature, the changes and revisions to the *DSM* with regard to persons with intellectual disability stem from joint efforts of the American Psychological Association and the National Institutes for Mental Health to expand the scientific basis for psychiatric diagnosis and classification (http://www.dsm5.org/about/Pages/DSMVOverview.aspx). The revisions in the *DSM-5* are based on a comprehensive review of scientific advances, targeted research analyses, and clinical expertise. For example, one of the primary changes in the *DSM-5* involves a shift from a categorical to a more dimensional system. In the earlier versions of the DSM, disorders were described by category, with a specific list of symptoms within each domain (e.g., communication). In this categorical system, a person either displayed a symptom or they didn't, and the presence of a certain number of symptoms was required for a diagnosis. The newly published *DSM-5* involves dimensional assessments that allow clinicians to rate both the presence and the severity of the symptoms, such as very severe, severe, moderate, or mild.

As *DSM-5* is no longer based on a multiaxial classification system, intellectual disability is no longer listed as an Axis II disorder but rather is classified as a neurodevelopmental disorder of brain development. Both *DSM-5* and the AAIDD use the consensus definition of intelligence as a general mental ability that involves reasoning, problem solving, planning, thinking abstractly, comprehending complex ideas, judgment, academic learning, and learning from experience. However, the term "intellectual disability" as used by the AAIDD is a functional disorder, explicitly based on the WHO International Classification of Functioning (ICF). Within this framework, the extent of disability is evaluated within particular contexts for which the focus is on the supports needed to normalize

an individual's life to the extent possible (Schalock, Borthwick-Duffy, Bradley et al., 2010).

In previous versions of the *DSM*, the extent or severity of intellectual impairment was denoted by the levels of mild, moderate, severe, and profound. Whereas these levels of severity will likely remain as central to the new *ICD-11* system, specifiers (i.e., mild, moderate, severe and profound) are used in *DSM-5* instead of subtypes to designate the extent of adaptive dysfunction in academic, social, and practical domains. Within the AAIDD disability model, the focus is on assessment of the supports needed to accommodate to the specific setting (e.g., home, community).

The *DSM* criteria of an IQ score below 70 and low adaptive functioning do not change for the diagnosis of intellectual disability, but the diagnosis involves a greater reliance on adaptive functioning with greater consideration about how intelligence is applied to the functions of everyday life (*DSM-5*). The age of onset is no longer specifically defined as before 18 years and is replaced with onset during the developmental period. However, intellectual disability is distinguished from neurocognitive disorder, which involves a deterioration of cognitive functioning (e.g., dementia) with late onset. In addition, an overall adaptive functioning score of two standard deviations below the mean is no longer necessary, as the criteria is met when at least *one* domain of functioning—conceptual, social, or practical—is sufficiently impaired, based on an assessment of adaptive functioning, that ongoing support is needed. Under exceptional circumstances when standardized assessments cannot be used, as in the case of persons with sensory or physical impairments, a diagnosis of unspecified intellectual disability may be applied to individuals with significant adaptive functioning impairments (APA, 2013).

Even as the revisions to the *DSM* were welcomed by some stakeholders, they elicited criticisms from others. For example, the AAIDD raised the concern in an open letter to the president of the American Psychiatric Association (http://aaidd.org/docs/default-source/comments/aaidd-dsm5-comment-letter.pdf) that the new proposed changes to the criteria for intellectual disability would cause confusion, suggesting that the new boundaries are not as clear as in the *DSM-IV*. For example, the change in the criteria in *DSM* from necessitating that the IDD be present before 18 years of age, to the proposed revisions that all symptoms must have an onset during the developmental period, leaves the age at which the developmental period ends open to interpretation. The AAIDD suggests that this will result in the inconsistent use of developmental periods across jurisdictions. It also took issue with the use of the terms adaptive behavior and adaptive functioning as potentially confusing. According to the AAIDD, adaptive behaviors are the conceptual, social, and practical skills a person may have, whereas adaptive functioning is how well, or independently, the person is able to use those skills to handle common demands in life. Thus, in an appeal to John M. Oldham, the president of the *DSM-5*, the AAIDD argued that the *DSM-5*'s substituting of adaptive *functioning* for adaptive *behaviors* as "communication, social participation, functioning at school or at work, or personal independence at home or in community settings" was not consistent with the AAIDD position nor with the current psychometric literature, and was problematic because it did not adequately capture functioning but rather emphasized the individual's skills (http://aaidd.org/docs/default-source/comments/aaidd-dsm5-comment-letter.pdf). Similarly, the changes in the mutiaxial diagnosis also posed a concern for clinicians. For example, Harris (2013) highlighted the high prevalence of psychiatric disorders in people with a diagnosis of intellectual disability and suggested that both diagnoses are often warranted. However, the elimination of the multiaxial classification and removal of Axis II in *DSM-5* may result in clinicians overlooking diagnoses of mental health disorders, such as anxiety disorder or depression, among persons with intellectual disability.

The Application of the Diagnostic Criteria

The continual fine-tuning of the diagnostic criteria and system represents evolving synergy of professional and societal influences on the ever-changing ways that persons with intellectual disability are viewed, understood, and supported by those around them. As certain problems are addressed, other limitations in the process continue to be identified (Charman, Hood, & Howlin, 2008). For example, even into the twenty-first century, disproportionate numbers of minority children were still being diagnosed with mild intellectual disability as intelligence tests often underestimate the abilities of these children, who also typically fail to meet the dominant culture's expectations concerning academic performance (Hays, 2001; Valencia and Suzuki, 2001). In addition, other non-cognitive factors, such as child's health history, physical impairments, motivation levels, and social milieu must be considered when assessing intellectual abilities as they may inhibit performance on IQ tests or other cognitive tasks, especially among children from atypical or non-majority backgrounds. These types of concerns regarding the narrow focus of, and potential external influences on, intelligence

tests and their use as an exclusive vehicle for defining intellectual disability was the motivating reason for the initial insistence of the American Association of Mental Deficiency (AAMD) (later the AAMR and AAIDD) that low scores on adaptive behavior be included, along with low IQ scores, in its definition of intellectual disability (Borthwick-Duffy, 2007). Accordingly, traditional methods of examining cognitive and adaptive abilities are now supplemented with a thorough examination of the child's developmental history, family history, and social and cultural environment. A broader picture of the child's developmental status is obtained with parent and teacher interviews and evaluations of medical and school records. For example, information about the child's physical problems, peer interactions, social skills and emotional state can be productively used in conjunction with more formal assessment methods, despite their somewhat limited reliability and validity. Consequently, within the framework of a multifactorial model of assessment, the evaluation of intellectual disability is increasingly taking place within an interdisciplinary social developmental framework.

The emphasis is on providing a diagnosis as early as possible to identify the child's specific needs, to ascertain the required services, and to facilitate communication across the team of relevant professionals and among family members. However, this process is not without its problems especially as it can also stigmatize the child if it leads to unwarranted negative projections by professionals and parents about the child's potential. Thus, professionals need to be sensitive to the effects and limitations of the label and recognize that intellectual disability only captures specific aspects of the individual. As the manifestation and outcomes of the key symptoms of intellectual disability vary across the lifespan (Zigler & Hodapp, 1986), a comprehensive assessment program should be used to follow the individual through many of the key periods of development. Current social and behavioral models are characterized by an emphasis on the need for repeated assessments to evaluate the child's changing developmental status and needs, the impact of medical treatments, the appropriateness of educational placements, and the effectiveness of educational programming. This type of approach to assessment captures the dynamic and changing quality of development as well as its social nature. In addition to their discrepancies in cognitive functioning, persons with intellectual disability also differ with regard to their physical, social, and emotional characteristics as well as in their relations with their families and the broader environment.

THE ORIGINS OF THE DEVELOPMENTAL APPROACH TO THE STUDY OF INTELLECTUAL DISABILITY

As with virtually any aspect of scholarship, the developmental approach to intellectual disability has neither a clearly identifiable start date nor even a universally accepted origin. Thus, in a somewhat, but certainly not entirely, arbitrary fashion, we choose an auspicious event that both provided a conceptual link to the essential scholarly antecedents to the field and generated a foundational and vital body of research that transformed the research on persons with intellectual disability by grounding it in developmental theory and methodology. The event was Edward Zigler's 1967 publication of a conceptual piece, "Familial Mental Retardation: A Continuing Dilemma," which appeared in the prestigious general scientific journal, *Science*, at a time when the study of intellectual disability (or mental retardation as it was called at the time) was rapidly growing as a distinct, but largely circumscribed, field. Zigler used that article and a soon-to-follow sister article (Zigler, 1969), "Developmental Versus Difference Theories of Mental Retardation and the Problem of Motivation," which was published in the *American Journal of Mental Deficiency* as forums to challenge the prevailing (so-called) *defect approach* that characterized virtually all of the other research on intellectual disability at the time and continued to influence the field significantly into the 1980s and to some extent even until today (for a collection of pieces on the defect theories and early statements of the developmental approach, see Zigler & Balla, 1982).

The defect approach was largely characterized by a monolithic framework in which intellectual disability was seen as a single entity that was essentially caused by one or more of any number of proposed defects that were common to all persons with the diagnosis. Typically in this approach, cognitive and neuro-cognitive functions or abilities were the primary focus as the empirical work in the field was largely characterized by a race to identify the deficit that was the primary cause or marker of reduced intellectual functioning. Those who undertook this frantic search emphasized broad constructs of cognition that were considered to be essential across all domains of functioning, including cognitive rigidity, memory processes, discrimination learning, and attention–retention capabilities, among many others (for reviews of these approaches and their inherent problems from a developmental perspective, see Burack, 1990; Zigler, 1967, 1969; Zigler & Balla, 1982). With the use of experimental paradigms that were sophisticated for the time, researchers presented evidence

of deficient performance in virtually all of these areas of functioning, and each specific defect was touted as the central cause of intellectual disability. Unfortunately, the evidence was consistently *fatally* flawed as the researchers failed to consider essential and seemingly obvious conceptual and methodological issues, such as the inherent differences in developmental level of functioning between persons with and without intellectual disability of the same CA, the multiplicity of etiologies associated with intellectual disability, the uniqueness of each etiology with regard to phenotypic expression, and social factors related to the life experiences of persons with intellectual disability that could affect performance on experimental tasks (for reviews, see Burack et al., 2001; Burack, Dawkins, et al., 2012; Zigler, 1970, 1973; Zigler & Balla, 1982).

In critiquing and debunking the various claims of the defect theorists, Zigler and colleagues (e.g., Hodapp, Burack, & Zigler, 1990; Zigler & Balla, 1982; Zigler & Hodapp, 1986; Zigler, 1967, 1969) highlighted the conceptual and methodological concerns as the hallmarks of a nascent approach to intellectual disability that would be based on classic developmental theory. The fundamental principles of what would become known as the developmental approach to intellectual disability were based primarily in the previous few decades of developmental theorizing by Heinz Werner and Jean Piaget, but also in two centuries of relevant history of medical scholarship, more contemporary interpretations of statistical analyses of the plotting of IQ scores, and the social-political zeitgeist of the era. In their original and subsequent iterations over the past half-century, Zigler and others, including especially Dante Cicchetti, John Weisz, and Robert Hodapp, contributed immensely to a science and transformative understanding of intellectual disability that were both more precise with regard to the development and functioning of each individual and more humanistic in that they were framed within notions of development that are universal to all persons.

In his initial seminal papers, Zigler (1967, 1969) proposed four principles that both challenged the dogma of the time regarding persons with intellectual disability in one or more ways and that continue to be essential guidelines for current work almost a half century later, albeit in more nuanced and fine-tuned ways of thinking that have developed in the interim since their original articulation. One, the notion that functioning, development, and developmental trajectories differed according to etiology was consistent with centuries of evidence of meaningful differences in behavior in relation to the source (etiology) of the intellectual disability, but challenged the monolithic framework of intellectual disability as a specific disorder and of the population of persons with intellectual disability as a single population that prevailed in the 1960s–1980s and continues to be at the heart of even some contemporary research. Despite resistance from leaders in the field to any type of etiological differentiation (for a review of examples of the opposition to this innovation by leading scholars in the field, see Burack, 1990), Zigler's (1967, 1969) two-group approach involved the delineation between persons whose intellectual disability is due to familial factors such as genetic transmission of intelligence and those for whom it is due to some type of organic insult. This dichotomy would presage a multiple group, or even a 1,000+ group, approach fueled by evidence of differences in development across virtually all aspects of functioning (i.e., cognitive, language, social, emotional) (e.g., Burack 1990; Burack, Hodapp, & Zigler, 1988, 1990; Burack, Russo, et al., 2012; Dykens, Hodapp, & Finucane, 2000; Howlin, Charman, & Ghaziuddin, 2011; Tager-Flusberg, 1999). The need for this type of precision continues to grow as evolving technology continues to enhance our abilities to identify, highlight, and compare sub and sub-sub groupings of specific etiological groups (e.g., Romano et al., 2014; Dimitropoulos, Ferranti, & Lemler, 2013) as well as sub- and sub-subcomponents of the various domains of everyday functioning (e.g., attention, working memory, language, social skills) (Iarocci, Porporino, Enns, & Burack, 2012; Jarrold & Brock, 2012; Russo, Dawkins, Huizinga, & Burack, 2012; Vicari, 2012).

Two, grounded in the developmental theories of Jean Piaget (1970) and Heinz Werner (1948, 1957), Zigler's (1967, 1969) adherence to the traditional developmental principles of an organized, coherent, and systemic organism led to the delineation of universal patterns of developmental sequences and structures among persons with familial intellectual disability, those whose low IQ scores seem to arise from the genetic transmission of intelligence rather than any type of physiological or organic "insult" (for a discussion, see Zigler & Hodapp, 1986). According to Zigler, development, at least in this group which represents essentially the "purest" form of intellectual disability that is unaffected by specific organic insult, unfolds in a typical way but at a slower rate and with a lower asymptote. This view that the integrity of development is maintained even in the face of extreme delay contrasted markedly from the difference or defect approach in which persons with intellectual disability were discussed virtually always within the framework of differences rather than of similarities or universalities in relation to others. In the two decades following Zigler's initial articulation of the

developmental approach, the notion of intact but delayed development would be tested extensively by Weisz and colleagues (Weisz, 1990; Weiss, Weisz, & Bromfield, 1986; Weisz & Zigler, 1979) and extended conceptually to include persons with Down syndrome by Cicchetti and colleagues (Cicchetti & Beeghly, 1990; Cicchetti & Pogge-Hesse, 1982; Cicchetti & Sroufe, 1976, 1978; Wagner, Ganiban, & Cicchetti, 1990). This latter extension to include persons with Down syndrome within a developmental framework revolutionized the developmental approach to intellectual disability by the de facto inclusion of all persons with some type of organic etiology, whose impairments and profiles of functioning seem qualitatively different from the typical population. In an era of considerable debate and discussion about the integrity and legitimacy of developmental theory (for a discussion, see Bronfenbrenner, Kessel, Kessen, & White, 1986), it also would lead to an essential expansion of developmental theory to a more liberal approach that would include more variability, at least in terms of group differences, than was considered in the more conservative classic developmental approaches articulated by Zigler (Cicchetti & Pogge-Hesse, 1982; Cicchetti & Ganiban, 1990; Hodapp, Burack, & Zigler, 1990). This contribution can also be seen as essential to a more nuanced understanding of the extent to which various aspects of development are related to each other in an inherent versus a happenstance manner (Hodapp & Burack, 1990, 2006) and as the precursor to neuroconstructivism (Karmiloff-Smith, 1998, 2009) and other approaches focused on the trajectory of gene–brain–behavior relationships within specific etiological groups (for examples regarding Williams syndrome, see Elsabbagh & Karmiloff-Smith, 2012; Landau, 2012; for an example regarding *fragile X*, see Cornish, Bertone, Kogan, & Scerif, 2012).

Three, Zigler's emphasis on mental, rather than chronological, age in experimental and observational comparisons between persons with and without intellectual disability led to essential changes in the empirical study of intellectual disability with more fine-tuned questions regarding group differences in specific areas of functioning that could not simply be attributed to more general a priori differences in functioning between the groups. In noting that the finding that persons with intellectual disability perform worse than typically developing individuals of the same CA is circular, Zigler (1967, 1969) highlighted the futility and obvious methodological flaws of the defect approaches that unfortunately persist to some extent even until today. These approaches were derived largely from the inevitable finding of deficits among persons with intellectual disability who were compared with typically developing persons of the same CA—findings that simply confirmed the obvious conclusion that lower functioning persons perform at lower levels than higher functioning people. With the increased influence of developmental considerations, the matching of persons with and without intellectual disability has become increasingly fine-tuned as groups are often now matched on a measure related to the domain of functioning being studied, thereby further diminishing the possibility that findings of differences or similarities are a confound of the a priori relative strengths or weaknesses associated with specific etiological groups (for relevant discussions, see Burack, 1997, Burack et al., 2012; Burack Iarocci, Flanagan, & Bowler, 2004; Jarrold & Brock, 2004; Karmiloff-Smith, 2009).

Four, the inclusion of the social-motivational personality factors served to emphasize that the understanding of persons with intellectual disability needed to involve the whole person. Zigler (1967, 1969) highlighted that the life experiences of failure, exclusion, and segregation that are common to persons with intellectual disability (as well as to other commonly marginalized populations) have profound effects on each individual. Zigler even argued that apparent deficits found among persons with familial intellectual disability as compared with typically developing persons of the same MA could be the consequences of responding styles adopted by persons with intellectual disability because of their experiences (for reviews, see Merighi, Edison, & Zigler, 1990; Zigler & Bennett-Gates, 1999). These outcomes were most apparent among persons with intellectual disability who were institutionalized, a far more common occurrence when Zigler was writing than it is today although the implications of segregation and exclusion are still pressing issues.

These four transformative principles of the developmental approach, as initially articulated by Zigler (1967, 1970, 1973) and as developed over the years by him and others, comprise the guiding framework for our discussion both of persons with intellectual disability and of the science in which they are studied. We use these principles of the developmental approach as a framework for interpreting both essential historical and contemporary issues in the study of intellectual disability, and highlight ways that the approach has itself developed since its original articulation a half century ago to provide an increasingly fine-tuned and sophisticated science. Conversely, consistent with Cicchetti's (1984) premise that typical and atypical development are mutually informative, the challenges faced in the application of developmental principles to intellectual disability provide insight into essential ways that developmental theory can be adapted (Burack, 1997;

Cicchetti & Ganiban, 1990; Cicchetti & Pogge-Hesse, 1982; Hodapp & Burack, 1990).

THE TWO-GROUP APPROACH AND BEYOND

Zigler's (1967, 1969) original delineation of the two-group approach was ironic in that it hearkened back to even more precise medical and social classifications of intellectual disability that predated it by decades and even centuries, while challenging a contemporary field that was considerably less fine-tuned. Although Zigler's dichotomy between familial and organic intellectual disability was an essential enabler of the deconstruction of the field of intellectual disability, it can be seen as somewhat of a retreat from more fine-tuned, albeit not always accurate, diagnostic and classificatory schemes dating back centuries (for reviews, see Burack, 1990; Scheerenberger, 1982). As early as the end of the sixteenth and beginning of the seventeenth century, the Swiss physician Felix Platter identified two broad groupings of persons with intellectual disability. He described one group of individuals as simple-minded since infancy and the second as those persons born with identifiable physical anomalies that were the manifestations of underlying organic disorders that were the source of the intellectual disability. This differentiation between persons with intellectual disability born with and without observable physical and physiological problems continued to be highlighted in even more precise classification systems by later medical workers interested in intellectual disability. For example, in the latter part of the nineteenth century, both John Langdon Down (1887) and William Wetherspoon Ireland (1877) provided detailed early classification systems in which they distinguished between intellectual disability which appeared to be the consequence of some combination of familial, genetic, environmental, societal, and cultural factors and that which was the outcome of more obvious genetic anomalies or other types of organic insult. Down classified persons with intellectual disability into three general etiological groupings, which he referred to as congenital, accidental, and developmental. Ireland delineated ten categories, nine of which were associated with medical conditions that were linked with intellectual disability, whereas the tenth was labeled as idiocy by deprivation.

In the subsequent classification systems of the twentieth and twenty-first centuries, the number of genetic or organic conditions associated with neurological problems and intellectual disability grew rapidly as a result of increasingly sophisticated technologies and scientific advances. Current estimates include more than 1,000 organic conditions associated with intellectual disability (Hodapp & Burack, 2006), although the meaningfulness of that number is diminished by the realization that current technology increasingly allows us to identify the substantial effects on performance of even relatively subtle neurological or physiological differences across even persons with the same syndrome (e.g., for a discussion of within-group differences among persons with *fragile X*, see Romano et al., 2014; for a discussion of genetic subtype differences among persons with Prader-Willi syndrome, see Dimitropoulos, Ferranti, & Lemler, 2013).

Zigler's Emphasis on Familial Intellectual Disability

In delineating the two-group approach, Zigler's primary interest as a developmentalist was with the persons with intellectual disability, especially in the mild to moderate range, whose etiology could be considered cultural-familial (for the rest of the chapter we refer to this grouping as familial)—a classification conceptually similar to Platter's simple-minded from birth, Down's developmental in nature, and Ireland's idiocy by deprivation (for twentieth-century systems of classification by etiology, also see Kephart & Strauss, 1940; Lewis, 1933). Consistent with these earlier frameworks, Zigler argued that some combination of familial-genetic and environmental factors affect the development of intelligence and the occurrence of intellectual disability among this group (Hodapp & Dykens, 2001; Zigler & Hodapp, 1986). As predicted by Zigler and Hodapp, current conceptualizations provide increasingly complex but precise frameworks of the genetic transmission of intelligence and its relation to the environment in general and especially in relation to the occurrence of familial intellectual disability (for discussions, see Iarocci & Petrill, 2012; Shulman et al., 2011).

Persons with familial intellectual disability are characterized by IQ scores that are typically in the mild, or sometimes high moderate, range, as they represent a statistically expected downward extension of the typical IQ range and can be thought of as those who were simply at the low end of the normal distribution of IQ (Lewis, 1933; Pearson & Jaederholm, 1914; Penrose, 1963; Zigler, 1967). According to Zigler's conceptualization, familial intellectual disability is simply the case of development that occurs at a slower rate but along the normal continuum of intellectual development. This is consistent with the observation that both individuals with familial intellectual disability and persons with IQs in the lower end of the typical range are likely to have at least one parent with an IQ in or near the range

of intellectual disability (Broman, Nichols, Shaughnessy, & Kennedy, 1987; Hodapp & Burack, 2006; Zigler & Hodapp, 1986). The lack of clear genetic or physiological markers for the children who fit the criterion for familial intellectual disability was underscored a century ago as scores on the early Binet intelligence tests of school children showed neither a natural split nor any significant differences between the children at the lower end of the normal distribution of IQ and a group of typical school children (Pearson & Jaederholm, 1914). This point was reiterated shortly thereafter by Lewis (1933), who argued (in the terms of his time for the group of persons we refer to as those with familial intellectual disability) that there "seems to be a close biological kinship between the subcultural defective and the main body of normal persons . . . " (p. 300), and later by Tarjan (1960), who noted (in the terms of his day for the group of persons we refer to as those with familial intellectual disability) that the "socioculturally deprived" group of persons with intellectual disability blend "gradually into the continuum of the general population" (p. 60; see also Dingman & Tarjan, 1960).

The Politics of Eugenics in Conceptualizing Intellectual Disability Associated With Familial Transmission

The notion of the familial transmission of intelligence has been a historically essential, albeit stigmatizing, aspect of the work with persons with intellectual disability (see Rosen et al., 1976; Siperstein, Norkins, & Mohler, 2007; Zigler & Hodapp, 1986). This focus was highlighted by the advocates of the eugenics movement who, in the late nineteenth century and beginning of the twentieth century, reported on supposed family lines in which feebleminded-ness, criminality, and other forms of behavior that were considered to be generally immoral were linked across generations of families (for a discussion, see Shulman et al., 2011). In one particularly often cited example, Arthur Estabrooks (1916) used the sociologist Robert Dugdale's (1877; Dugdale, Harris, & Giddings, 1910) report on the criminal history of the so-called "Jukes" family from upstate New York to make the case that the procreation of persons with lower intelligence was detrimental to society. Ironically, Dugdale's report was originally intended to be used as evidence for the need for better social welfare and improved environments for persons from these backgrounds, but was twisted to support the argument for legal restrictions on their opportunities to reproduce.

The claim that allowing persons with intellectual disability to procreate was detrimental to society was particularly forcefully advocated by the twentieth-century eugenicist Henry Goddard (1912), who argued in his influential book *The Kallikak Family: A Study in the Heredity of Feeble-Mindedness* for the key role of heredity in feeblemindedness. In a post hoc recreation of the supposed genetic tree of an American Revolutionary War hero named Martin Kallikak Sr., Goddard compared Kallikak's descendants from an evidently feebleminded woman whom he met on his way home from the war and his descendants from his wife who was assumed to be typically intelligent. Goddard claimed that a particularly high percentage of Kallikak's 480 descendants from the feebleminded woman could be labeled as socially problematic as he identified that 36 were illegitimate, 33 were sexually immoral, 24 were confirmed alcoholics, three were criminal, three were epileptics, eight kept houses of "ill fame," 82 died in infancy. In contrast, he claimed that all but three of the 496 descendants from Kallikak's wife were considered to be intellectually normal, and generally prosperous and morally upstanding. With these supposed differences between these two lines of descendants from Kallikak as his evidence, Goddard concluded that levels of intelligence, sanity, and morality were hereditary, and preached that persons classified as "feebleminded" should be prohibited from procreating to prevent the spread of intellectual disability and its associated deleterious effects on society. The scientific integrity and merits of Goddard's work have certainly been questioned over the years. For example, factors other than inherited feeblemindedness, such as fetal alcohol syndrome, have been suggested as possible sources of the generally deleterious outcome of many of Kallikak's descendants (Karp et al., 1995). Yet, despite the criticisms of the obviously controversial focus and methodological problems of his work from contemporary perspectives, Goddard's message of hereditary transmission and intrinsic moral shortcomings of persons with familial intellectual disability was to influence the western world through much of the first half of the twentieth century.

Both Goddard's and Estabrook's views on eugenics and intellectual disability are cited as important contributing factors to the passing of sterilization laws in 25 states in the United States between 1907 and 1936 and in the Supreme Court decision that ruled in support of the sterilization laws in Virginia (for a discussion, see Zigler & Hodapp, 1986). Zigler and Hodapp note that the sentiment of the Supreme Court and that of much of the nation at the time was summed up by the eminent Supreme Court justice, Oliver Wendell Holmes Jr., who wrote the majority opinion in support of the forced sterilization of a young woman named Carrie Buck, who was forced by the courts in 1927 to undergo compulsory sterilization because she

was thought to be feebleminded. In his opinion, Justice Holmes wrote, "It is better for all of the world, if instead of waiting to execute degenerate offspring for crime, or let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind . . . Three generations of imbeciles are enough" (*Buck vs. Bell,* 1927). This pronouncement highlights the extent to which the notions of both the genetic transmission of intelligence and the link between lowered intelligence and criminal behavior were instilled in the American psyche in the first half of the twentieth century. Tragically, these pernicious American laws and attitudes would be copied in other places in the world and have even been cited by some as sources of inspiration for the sterilization and extermination practices of the Nazis toward Jews, Gypsies, homosexuals, and others (Kühl, 1994).

The Familial Inheritance of Intellectual Disability

Based on the notion that persons with familial intellectual disability represent a downward extension of the natural variation in intellectual ability, a variety of possibilities related to the interplay of the genetic transmission and environmental influences on intelligence in this population have been forwarded (for reviews, see Hodapp & Zigler, 1995; Iarocci & Petrill, 2012; Simonoff, Bolton, & Rutter, 1998; Zigler & Hodapp, 1986). These include attempts to fine-tune the understanding of both the genetic process in the transmission of intelligence and the interplay between intellectual heredity and environmental influences.

Consistent with the notion that persons with familial intellectual disability meld into the typically developing population, polygenic inheritance models are highlighted in the explanations of the transmission of intellectual disability within families (for a variety of relevant reviews from the past half century, see Gottesman, 1963; Iarocci & Petrill, 2012; Plomin, 1999; Zigler & Hodapp, 1986). According to this framework, many human traits are continuously distributed and are determined by a number of genes that work independently and additively to produce the particular trait whenever normal environmental conditions prevail. Within the framework of combined genetic and environmental contributions to phenotypic outcome, the primary goal is to identify the polygenes that additively accumulate genetic risk and, together with environmental risk factors, increase the likelihood of familial intellectual disability (Zigler & Hodapp, 1986).

In discussing intelligence in relation to familial intellectual disability, Iarocci and Petrill (2012) likened the nature of intelligence to an elastic band, for which environmental conditions may broaden or constrain inherent potential, but only within the limits of the elasticity, or integrity, of the structure (i.e., inherited familial genes). This is consistent with decades of evidence supporting the notions of the interplay between genetic and environmental factors in the developmental outcome of familial intellectual disability (Richardson, Koller, & Katz, 1985) as intelligence is classically thought to emerge through the coalescence of inherited developmental structures and the organism's ongoing and active engagement with the environment (Shulman et al., 2011). This relationship between familial transmission and environmental influence in intellectual disability was specifically examined by Broman et al. (1987) in a longitudinal study of pre- and perinatal causes of intellectual disabilities as they sought to differentiate the developmental trajectories of persons with familial intellectual disability from those with a clear organic etiology. Based on findings of a 12-fold increase in the frequency of intellectual disability among full siblings of children with mild intellectual disability, and significantly more affected relatives than among the siblings of children with severe intellectual disability, Broman et al. concluded that mild, but not severe, intellectual disability shows a familial link with normal variation in general intelligence. When the children were classified according to socioeconomic status (SES), SES level was associated with intellectual disability at 7 years. In the group of children in the bottom 25% of SES, 3.3% scored in the IQ range of intellectual disability, whereas only 1.3% of the children from middle 50% and 0.3% of the children from the highest 25% SES groups scored in that range. This is consistent with other evidence that mild, nonorganic, intellectual disability is found primarily at lower SES levels, whereas the prevalence of moderate to severe intellectual disability (IQ < 50) is generally distributed relatively evenly across SES levels (Tarjan, 1970; Richardson & Koller, 1996).

The clear link between the familial transmission of mild intellectual disability and low SES highlights the complexity of disentangling the relative contributions of the genetic transmission of intelligence and the environmental factors. This transmission of intelligence is not simply the case of the familial passing of genes, but involves a complex relation between the occurrence of low IQ in the family and the environment in which the family lives. For example, children of parents with intellectual disability are more likely to be raised in settings with fewer resources than typically found in contexts that are more conducive to optimal development (Simonoff et al., 1998). This may be particularly exacerbated among minority populations who already may have fewer opportunities to optimize child development because of linguistic, cultural, or other mismatches with the majority culture in educational and other settings. These qualifications

highlight the complexity of understanding either the unique contributions or the confluence of issues related to the genetic heredity of intelligence and environmental effects associated with familial intellectual disability.

Differentiating Among Organic Etiologies: Extending Beyond the Two-Group Approach in the Quest for Increased Precision

Although aware of the several different etiological groups that had been cited in the two to three centuries previously and that advancing technology would help delineate many more, Zigler simply proposed a two-group approach. This approach allowed him to highlight the group of persons with familial intellectual disability for whom he hypothesized that development unfolded in the same way as for typically developing persons, albeit at a slower rate, against the backdrop of persons with organic intellectual disability for whom Zigler argued that specific organic insult precluded any necessity of typical developmental patterns. Whereas familial intellectual disability represented a quantitative difference from so-called typical development because it simply represented the lower end of normal variation in IQ, the organic etiologies associated with intellectual disability reflected a qualitative break due to the physiological anomalies associated with each of them. Although Zigler would eventually collaborate with colleagues both on calls for more precise differentiation among persons with organic etiologies (e.g., Burack, Hodapp, & Zigler, 1988; 1990) and on attempts to apply developmental theory to specific etiological groups (e.g., Hodapp, Burack, & Zigler, 1990; Hodapp & Zigler, 1990), his primary emphasis continued to be on the developmental approach as applicable to persons with familial intellectual disability.

Burack et al.'s (1988; 1990; Burack, 1990) subsequent call for the precise differentiation among organic etiologies hardly seems revelatory from the perspective of today or even from the perspective of the time in which it was written as unique developmental trajectories and characteristics had already been identified, but it was in clear contradiction to the prevailing thinking of the time among the leading researchers of intellectual disability. Even as the defect theorists faded from the forefront of the study of intellectual disability by the 1980s, the prevailing leaders still refused to acknowledge the advantages of studying individual etiological groups (for some quotes by leaders in the field expressing the futility of differentiating by etiology, see Burack, 1990). Goodman (1990) expressed much of the spirit of the time in her argument against Burack et al. (1988) that "it is unhelpful and possibly detrimental to make etiology the cornerstone of a diagnostic system . . . " (p. 466), and that research and intervention would be better served by a focus on other factors, especially level of intellectual functioning. In the interim of the past quarter century, Burack et al.'s position has clearly been vindicated with the ever increasing precision in delineating both etiologies and unique profiles of functioning that are associated with at least those etiologies that are sufficiently common to be studied.

The contribution of differentiating among organic etiologies to the study of persons with intellectual disability is that of precision. And that quest for precision is characterized by the very undevelopmental process of deconstruction of the population of persons with intellectual disability. This process was central to the de facto breakdown of the field of intellectual disability per se, and the advent of essentially a conglomeration of many sciences (Burack, Russo et al., 2012). It involves the bottom-up process of grouping by etiology, in addition to other relevant factors such as age and gender, to better understand the functioning of each individual or group of individuals. Big stories, such as those once promulgated by the defect theorists concerning all persons with intellectual disability, are long abandoned in favor of more precise minutia—the research is focused on increasingly fine-tuned studies of components (and sub- and sub-sub-components) of functioning in specific etiological groups (and sub-groups). These sciences can be framed in at least one of two apparently orthogonal, but also overlapping strategies, with the emphasis on a specific aspect of functioning and the manifestation of its various components across various etiologies (e.g., for reviews on attention, short-term and working memory, executive functions and memory as manifested in different etiological groups, see respectively Iarocci et al., 2012; Jarrold & Brock, 2012; Russo et al., 2012; Vicari, 2012), or with regard to a specific etiological group in relation to their functioning within or across the many different domains, sub-domains, and sub-sub-domains of one or more specific areas (e.g., for extensive reviews of the abilities and impairments of persons with fragile X, Down syndrome, and Williams syndrome in the domain of language, see, respectively, Abbeduto, McGuffie, Brady, & Kover, 2012; Chapman & Kay-Raining Bird, 2012; Mervis, 2012).

The ultimate goals of this approach is to better understand the links among genes (loosely defined), brain functioning, and behavior in the pursuit of providing more information about the specified group, the contributors to specific aspects of functioning, and potential interventions at many different levels. The more precise the better, with improving technology in every aspect of the gene–brain–behavior relationship allowing us to

further deconstruct our understanding of each into even smaller more detailed units or sub-units. As these foci are syndrome-specific (or now even sub-syndrome-specific), the notion of a scientific field of intellectual disability is rendered essentially meaningless. Any attempts to discuss intellectual disability in terms of groups in which persons with different etiologies are included (often referred to as mixed-etiology) are futile as the syndrome-specific patterns offset each other in this hodge-podge, thereby obscuring any meaningful patterns—much like the flavors of the individual ingredients in stew are unrecognizable after they've been cooked together. And, as the flavor of a stew can be altered in relation to the ingredients, so too can the findings vary in relation to the makeup of the etiological mix. Thus, the notion that a so-called mixed etiology group reflects the general population of intellectual disability is fallacious, and the use of these groups as target groups or even as comparison groups must be seen as both study-specific and misleading. Rather, the more instructive approach to furthering our understanding of the significance of the gene–brain–behavior relations in these groups is to extend Cicchetti's (1984) dictum of the reciprocally informative relationship between typical development and atypical development to focus on the reciprocally informative relationship among various types of atypicality, in this case the specific syndromes.

One example of the ways that information from different syndromes can converge to inform both about each other and functioning more generally is exemplified in the study of multiple object tracking (MOT) among persons with Williams syndrome and Down syndrome. According to Pylyshyn (2001), the operations necessary to index and track multiple items at once in multiple object tracking are also necessary for deriving spatial relations. Concordantly, O'Hearn and colleagues (O'Hearn, Hoffman, & Landau, 2010; O'Hearn, Landau, & Hoffman, 2005) found poor tracking performance among persons with Williams syndrome that was consistent with their commonly reported problems on visuospatial tasks. Subsequently, Brodeur, Trick, Flores, Marr, and Burack (2013) hypothesized that if poor MOT performance is always associated with visuospatial deficits, then MOT should be relatively spared among individuals with Down syndrome who display strengths in visuospatial processing relative to other aspects of their cognitive functioning. However, contrary to their predictions, they found that the performance on a MOT task was worse among individuals with Down syndrome as compared with MA-matched typically developing children. In explaining these unexpected findings, Brodeur et al. suggested that tracking deficits may occur for different reasons in the two groups. For example, compared with individuals with Williams syndrome, persons with Down syndrome may display relatively intact object-based selection, but may nonetheless exhibit reduced tracking performance because the temporal resolution of the selection processes is poor, which would create particular difficulties when processing dynamic displays. Another possibility is that object-based selection may be preserved in persons with Down syndrome, but that limitations in executive function may reduce the ability to store information for later report while updating item positions. These post hoc explanations point to the need to specifically fine-tune our understanding both of the strengths in visuospatial functioning among persons with Down syndrome and of the extent to which MOT is generally associated with visuospatial performance. At a more conceptual level, they also highlight the necessity for greater nuance in understanding the abilities and factors that contribute to performance on tasks within a single etiological group and, more complexly, in comparisons across groups.

In retrospect from an era in which research is increasingly informed and fine-tuned by technology such that more and more groupings and subgroupings are defined and studied, Zigler's (1967, 1969) articulation of the two-group approach can be seen as a catalyst in transforming, or deconstructing, the field of intellectual disability into a more precise, albeit increasingly differentiated, science. As evident in the cutting-edge work by Romano et al. (2014) in delineating two biologically and clinically distinct phenotypic outcomes of fragile X using topological data analysis of variations in brain structure and by Dimitropoulos et al. (2013) in identifying differences in language functioning between the genetic subtypes of Prader-Willi, the level of precision and differentiation in the field will continue to increase dramatically. However, as discussed in the next section, Zigler and, to an even greater extent, Cicchetti provide a framework for the integration of these seemingly impossibly fractionated pieces—the fulfillment of Werner's orthogentic principle.

APPLYING DEVELOPMENTAL PRINCIPLES TO THE STUDY OF PERSONS WITH INTELLECTUAL DISABILITY: CLASSIC AND EXPANDED VERSIONS

Zigler and the Classic Developmental Approach

The defining developmental innovation in Zigler's approach to the study of intellectual disability was his imposition of essential classic developmental principles

to the study of persons with intellectual disability, who had previously virtually always been considered defective, impaired, or at least different in some specific way. In citing the organismic-developmental theories of Heinz Werner and Jean Piaget, Zigler (1967, 1969) invoked the notion of universality of the human organism, thereby including the previously excluded group of persons with intellectual disability, at least those with the familial form. Conversely, this approach was also essential to extending classic developmental theory to persons with intellectual disability and, thereby, to provide much needed tests of the theory from the context of atypical development. Even as classic developmental theory, in general, and Piagetian notions, in particular, were under siege throughout the 1960s and beyond as post- and neo- Piagetian scholars, among others, decried the lack of consideration of group and individual differences and even suggested the end of the age of development (Kessen, 1984), Zigler's framework provided compelling, if not sufficient, tests of the universality of classic developmental theory.

Zigler framed his notion of the applicability of the universality of development largely within the context of Werner's (1957) organizational principle of development that "wherever there is life there is growth and development, that is, formation in systematic, orderly sequence" (Werner, 1957, p. 125) and the Piagetian notion of universal sequences of development. These notions resonated especially with Zigler with regard to the population of persons with familial intellectual disability whose lower IQs represent simply a statistically expected downward extension of the typical IQ range as is consistent with the case of any hereditarily transmitted trait (e.g., height, weight). In contrast to the qualitative break that he suggested might be the case with persons with an organic etiology, Zigler hypothesized that the patterns of development of persons with familial intellectual disability should be indistinguishable from those of typically developing persons but that they would unfold at a slower rate and ultimately plateau below the general population mean. Zigler's approach led to two hypotheses of basic developmental similarities, similar-sequence and similar-structure, between persons with intellectual disability and typically developing persons that would be tested extensively by John Weisz and colleagues (e.g., Weiss, Weisz, & Bromfield, 1986; Weisz, 1990; Weisz & Yeates, 1981; Weisz, Yeates, & Zigler, 1982; Weisz & Zigler, 1979).

The Similar-Sequence Hypothesis

The similar-sequence hypothesis reflects the basic tenet of developmental theory that the development of a specific area of cognitive functioning necessarily follows a clear and universally prescribed order of attainment of the relevant abilities (Hodapp, 1990). The sequences can be thought of as the vertical aspects of development since they involve the trajectory of development in relation to the attainment of one or more specific functions, or abilities, over time. In an extensive review of relevant studies, Weisz and Zigler (1979) found that the integrity of typical Piagetian sequences seems well entrenched among all groups of persons with intellectual disability as it is among virtually all other groups of persons (for discussions, see Weisz, 1990; Hodapp & Burack, 2006).

In considering the inevitability of the universality of Piagetian and other developmental sequences, Hodapp (1990) proposed four possible reasons for their universality. One was that psychological, like biological, development involves a process that is consistent with Werner's (1957) orthogenetic principle, in which "wherever development occurs it proceeds from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration" (p. 126). The case of human fetal development is a classic case in the realm of biological growth as we all begin as a speck of a single cell that lacks any identifiable form, but unfolds with increasingly identifiable internal and external parts that continue to evolve into a complex human being in which all the parts are distinct and at the same time integrated in that they function in an organized coherent way. In an example of the orthogenetic principle in psychological development, children first use only sentences made of single words to communicate, but further along in development use more complex sentences composed of multiple different words combined in infinite combinations, giving rise to more complex communication. As psychological development is constrained and dependent on biological development that is universal, Hodapp suggests that it too must be universal. Hodapp's second argument is based in the logic that since behaviors are sequentially embedded in each other, a child is only able to perform a difficult or complex task by first attaining the necessary skills through the performance of more basic (earlier) tasks. Hodapp's third argument is based on universally shared information-processing capacities that are used to understand and experience the laws and relationships in nature that transcend culture, geography, or language. Hodapp's fourth argument is that the essential task of all cultures is to foster the development of its children and that this quest may involve universal aspects of the environment, regardless of culture or context.

The Similar-Structure Hypothesis

In contrast to the verticality of his similar-sequences hypothesis, Zigler's (1967, 1969) similar-structure hypothesis is relevant to the horizontal dimension of development as it concerns the relations across domains, or areas, of functioning at one or more given points in time. It is based on the classic developmental principle of an organized system, such as espoused by Piaget in his notions of cognitive structure and stage theory, in which aspects of development are meaningfully interrelated and therefore, despite individual variation, consistently emerge and unfold in some universally systematic and hierarchic way with consistent temporal patterns (also see Werner, 1957). In this manner, developmental profiles across domains should, with only minor differences, be consistent across the population of typically developing individuals for any given point in time (age) of development. Thus, also unlike the similar-sequence hypothesis, the similar-structure hypothesis was considered by Zigler to be specific to persons with familial intellectual disability for whom he considered the patterns of development to be the same as in typical development, but to just unfold at a slower rate and to ultimately reach a lower plateau—delayed rather than different (Zigler & Hodapp, 1986). In direct contradiction to the prevailing difference or defect theories of intellectual disability of the 1960s and 1970s, the similar-structure provided the framework for Zigler's expectation that persons with familial intellectual disability, as a group, would show the same level of performance on virtually every aspect of cognitive functioning when compared with typically developing persons at a similar general level of functioning (i.e., MA) (Mundy & Kasari, 1990; Weiss et al., 1986; Weisz, 1990; Weisz & Yeates, 1981; Zigler & Hodapp, 1986).

In a systematic and comprehensive review of empirical comparisons between the performance of persons with intellectual disability and that of typically developing children on Piagetian-type tasks, Weisz and Yeates (1981) found that the similar-structure hypothesis was supported in 90% of the 39 comparisons in the literature in which the appropriate developmental methodological strategies of matching the groups by MA and excluding persons with any indication of organic impairments or genetic anomalies were utilized. Thus, consistent with Zigler's hypothesis that familial intellectual disability is simply a slowed version of typical development, the findings across these studies indicated similar levels of performance by this group on Piagetian tasks in relation to typically developmentally children of the same level of functioning (i.e., MA rather than CA). However, the veracity of the similar-structure hypothesis was questioned by Weiss et al. (1986) in a subsequent analysis of evidence from studies of information-processing, as persons with familial intellectual disability displayed inferior performance as compared with appropriately MA-matched typically developing persons on some tasks of memory, discrimination learning, and learning set, but not on other aspects of information-processing such as concept usage and incidental learning.

Weiss et al.'s (1986) challenge to the similar-structure hypothesis highlights the need to consider the implications of findings of deficits in cognitive functioning among persons with familial intellectual disability as compared with typically developing persons, an occurrence that appears to be more likely with the more precise methodologies associated with study of information-processing (Mundy & Kasari, 1990). Both the areas of functioning and the specific tasks that are associated with the evidence of impairment may be informative about the specific source of the problems on the specific test and about broader issues regarding the general performance of persons with intellectual disability. For example, the number of domains in which differences were found were limited and may be due to extenuating, and potentially confounding, factors in the relevant paradigms as impaired performance only appeared to be found in situations in which the tasks were long and repetitive, lacked ecological validity, and occurred in situations in which certain motivational and personality characteristics can affect performance. This is consistent with Zigler's early conceptualization of the various ways that the effects of a lifetime of experiences of failure affects the performance on experimental and real-life tasks by persons with intellectual disability. In extending this notion of the influence of personality and motivational factors on performance to highlight a "helpless" style of behavior that arises from a lifetime of failure, Weisz (1990) suggested that the discrepancies in performance in the studies cited by Weiss et al. may have been a function of the approach to the task at hand, rather than inherent differences in cognitive processing. Thus, the finding of these group differences seem more of an opportunity to further fine-tune Zigler's point of the necessity of understanding the whole person with intellectual disability than a contradiction of Zigler's similar-structure hypothesis as applied to persons with familial intellectual disability.

Cicchetti's Expansion of the Developmental Approach to Persons With Organic Etiologies: A Focus on Persons With Down Syndrome

Barely a decade after Zigler's (1967) original articulation of the developmental approach to intellectual disability,

Dante Cicchetti and colleagues (Cicchetti & Serafica, 1981; Cicchetti & Sroufe, 1976, 1978) provided its most compelling and far-reaching extension by initiating a program of research with children with Down syndrome that was based in developmental theory and principles. Although their work was focused exclusively on persons with Down syndrome, Cicchetti and colleagues (Cicchetti & Ganiban, 1990; Cicchetti & Pogge-Hesse, 1982) raised the possibility that these principles and theories could be applied to all persons with an organic etiology rather than just to persons with familial intellectual disability as argued by Zigler. As was the case with Zigler's seminal work, Cicchetti and colleagues' innovations were largely based in Heinz Werner's (1957) organismic-developmental approach with its overarching and universal organizational principles that provide meaning to the patterns of development (for a discussion, see Cicchetti & Ganiban, 1990). However, their application of classic developmental theory to persons with Down syndrome and, thereby essentially, to all persons with organically based intellectual disability provided both a much expanded view of development and a more stringent test of the universality of developmental theory than did Zigler's iteration of the developmental approach.

Cicchetti and Pogge-Hesse (1982) designated Zigler's developmental approach to intellectual disability as a conservative one in that it only applied to persons with familial intellectual disability as he excluded those with organically based intellectual disability. The rationale for this exclusion was that "if the etiology of the phenotypic intelligence (as measured by an IQ) of two groups differs, it is far from logical to assert that the course of development is the same, or even that similar contents in the behaviors of two such differing individuals are mediated by exactly the same cognitive processes" (Zigler, 1969, p. 533). In contrast to Zigler's conservative application of developmental theory and principles solely to familial persons with intellectual disability and their apparent typical patterns of development, Cicchetti and colleagues' expanded theory was focused on the search for coherence even across patterns of development that did not conform either to the norm or to the classic developmental theories of Piaget, Werner, and others. This more liberal framework transformed the developmental study of intellectual disability with its de facto inclusiveness of essentially all persons with intellectual disability under the umbrella of universal developmental principles while maintaining the essential ingredient of differentiating among etiologies. The unique patterns of relative strengths and weaknesses across areas of functioning for each specific etiological group could be examined in relation to underlying patterns of development. Rather than delimiting the developmental approach and dismissing the unique development of specific etiological groups as different or impaired, Cicchetti and colleagues (Cicchetti & Ganiban, 1990; Cicchetti & Pogge-Hesse, 1982) sought coherence even as the developmental patterns diverged considerably from the typical (also, see Hodapp, Burack, & Zigler, 1990; Hodapp & Zigler, 1990; Wagner, Ganiban, & Cicchetti, 1990). For example, Cicchetti and Pogge-Hesse argued poignantly that the deficit approach "overlooks the possibility that the behavior and development of retarded children is organized, adaptive, and integrated—just as is the case for nonretarded children and infants. We know that they are retarded; the important and challenging research questions concern the developmental process" (p. 279). They concluded that "organically retarded persons are not only 'different' from nonretarded persons, they are organized in their own right . . . " (p. 313).

The centrality of this framework to the emergence of the developmental approach to the study of intellectual disability was highlighted by the inclusion of theoretically based review chapters by Cicchetti and colleagues (Cicchetti & Ganiban, 1990; Cicchetti & Pogge-Hesse, 1982) in the two initial edited volumes by Zigler and colleagues on the developmental approach (Hodapp, Burack, and Zigler, 1990; Zigler & Balla, 1982) and in a volume edited by Cicchetti and Beeghly (1990) devoted to the development of children with Down syndrome. Concordantly, Hodapp and Zigler's (1990) reframing of the conservative developmental approach to fit with the evidence from persons with Down syndrome (and, by extension, persons with other organic etiologies) in the opening chapter of the Cicchetti and Beeghly volume highlighted that the task of the expanded developmental study of intellectual disability was to seek developmental patterns across all etiological groups.

In broadening the cache of persons with intellectual disability to be studied within the context of the developmental approach, this more liberal developmental approach served to extend the relevance of classic developmental theories by implicitly challenging the common critiques of their deficiencies in accounting for group or individual differences (see Bronfenbrenner et al., 1986; Kessen, 1984). The study of Down syndrome and other etiological groups, with their own specific patterns of development, provides unique opportunities, or experiments of nature, to ask any number of essential questions such as which developmental patterns are necessary and which are happenstance? What skills are related to each

other throughout development and how closely need they be related? Where are alternative developmental pathways possible? Thus, Cicchetti and Pogge-Hesse (1982) argue that the orientation of the discussion about abilities needs to be changed so that "we should study not "does x have y" but rather "in what way does x use y" and does a particular mental structure interact with other mental structures in the same way in one . . . group as in another? (p. 313)"

One approach to this type of more complex, or liberal developmental, framework among persons with intellectual disability was initially suggested by Mundy, Seibert, and Hogan (1984) who borrowed the notion of local homologies, or developmental relationships across tasks that require underlying capacities, from the work on relationships across sensorimotor abilities among typically developing infants by Bates, Benigni, Bretherton, Camaioni, and Volterra (1979). Hodapp and colleagues (Hodapp, Burack, & Zigler, 1990; Hodapp & Zigler, 1990) proposed that this notion of local homologies may be essential to reconciling within an organizational developmental framework the apparent discrepancies, or lack of similar-structure (Weisz & Yeates, 1981), across areas of functioning that are found among persons with Down syndrome and other organic etiologies. Thus, this framework imposes some semblance of conceptual coherence across areas of functioning amid the apparent disconnectedness associated with the myriad of profiles of relative areas of strengths and weakness associated with the different etiologies.

In considering the various contributors to the complexity of the developmental approach to the study of persons with Down syndrome and other organic etiologies, Cicchetti and colleagues (Cicchetti & Ganiban, 1982; Cicchetti & Pogge-Hesse, 1982) highlighted that etiological groups could provide specific insights into the ways that both genes and organic function lead to behavioral outcomes. This notion is foundational to the contemporary notion of genes-brain-behaviors with specific etiological groups, each of which provides the opportunity for understanding the roles of specific genes and genetic structure as well as of organic function on behavior. As predicted by Cicchetti and colleagues, these endeavors would be enhanced by advances in technology and methodology that both allow for more extensive and precise groupings of persons with organic etiology and more sophisticated science with increasingly fine-tuned behavioral, physiological, and neuropsychological paradigms.

One particularly compelling expression of Cicchetti's vision was the "neuroconstructivist" approach that was promoted by Annette Karmiloff-Smith (1998, 2009; Mareschal et al., 2007; Westermann et al., 2007). Building upon the Piagetian notion of constructivism, with the child as an active agent in constructing his or her own cognitive structures through exploration and engagement with the environment, the neuroconstructivist model was developed and applied to children with organic etiologies associated with intellectual disability. Coined by Karmiloff-Smith (1998), neuroconstructivism brought together Piagetian constructivism with the emerging research on experience-driven neural plasticity. Karmiloff-Smith argued that to understand the cognitive profiles of organic etiologies, researchers needed to consider them within the context of the cascade of neural development. Using the example of Williams syndrome, Karmiloff-Smith et al. (1997) argued that rather than framing this syndrome as a modular disorder with spared language and impaired visual-spatial modules, the unique cognitive profile associated with it is the product of a unique developmental trajectory. As a corollary, Cornish and colleagues (Cornish, Cole, Longhi, Karmiloff-Smih, & Scerif, 2013; Cornish, Steele, Monteiro, Karmiloff-Smith, & Scerif, 2012; for a review, see Cornish & Wilding, 2010) highlighted that groups of persons with different organic etiologies might exhibit different attentional profiles and inhibitory control beginning in infancy, which in turn contribute to different developmental pathways. The neuroconstructivist framework then casts each of the organic etiologies as having genetically determined constraints, which manifest as subtle differences in preferences and biases early in development, steering the child down an etiology-specific developmental pathway that is nonetheless constructed by the child (e.g., for discussions regarding fragile X, see Cornish, Bertone, Kogan, & Scerif, 2012; Cornish, Scerif, & Karmiloff-Smith, 2007; for a discussion regarding Williams syndrome, see Elsabbagh & Karmiloff-Smith, 2012).

In promoting the neuroconstructivist approach, Karmiloff-Smith and colleagues challenge the virtually exclusive dependence on cross-sectional methodologies, with their snapshots of performance at a specific moment in the lifespan, in the quest to better understand intact or impaired performance in the study of specific etiologies. This is consistent with the notion that performance is always relative—relative not only to another group but most important also to past and future performance. Ideally, developmental disorders (and development in general) should be examined longitudinally, although as Karmiloff-Smith (2009) acknowledges the measurement of change over time often needs to be simulated using regression-based approaches due to the pragmatic difficulties inherent in longitudinal studies. The extent to which our understanding of development is constrained by cross-sectional methodology is highlighted

by Cornish et al. (2013) who depicted both a trajectory mapping correlational study and a one-year longitudinal follow-up study of attentional control and working memory among children with fragile X. Whereas the data from the cross-sectional trajectory mapping suggested developmental arrest in working memory and a dramatically slower (relative to typical) but positive slope in relation to MA for attentional control, the longitudinal data indicated similar slopes of improvement for both skills in relation to the performance of the typically developing children.

Another example of the contemporary realization of the need for increasingly sophisticated methodology and precise understanding of the development of gene–brain–behavior relationship within a specific etiological group is Barbara Landau's (2012; Landau & Hoffman, 2007) work on the ways that developmental time is essential to the organization and development of spatial representations among persons with Williams syndrome as well as among typically developing persons. Landau argues that one of the ways in which, genetic etiologies contribute to intellectual disability is in the disruption of the rate of development, but emphasizes that the mapping of developmental timetables in these etiologies needs to be considered in relation to typical development. To illustrate this, Landau argues that the spatial capacities that are strong among persons with Williams syndrome are associated with the ventral stream, which emerges relatively early in the typically developing child, whereas the capacities that are weaker are associated with the dorsal stream, which develops later in typical development. For example, children with Williams syndrome (MA 4–6 years) perform at or above MA expectations on tasks used to measure aspects of spatial abilities that involve the ventral stream, which develops early in typical development (e.g., perceptual matching). Conversely, differences in performance emerge on dorsal stream tasks for which development is protracted in typical development. Based on this evidence, Landau hypothesized that the developmental trajectory of the dorsal stream is slower than that of the ventral stream for persons with Williams syndrome and that it is the exaggerated asynchronous development of the two streams that contributes to their unique profile of spatial abilities.

THE IMPORTANCE OF MENTAL AGE

Considering Developmental Level

In Zigler's (1967, 1969) critique of the prevailing defect approach of the time, the most obvious, and thereby the most troubling, of the essential methodological flaws that he cited as inherent to the defect theorists' research and findings was the emphasis on CA as the point of comparison between persons with and without intellectual disability. The defect theories were based largely on evidence from studies in which the performance of a group of persons with intellectual disability was compared with that of a group of typically developing persons who were matched, or deemed similar, to the first group on the basis of CA. Since persons with intellectual disability are, by definition, lower functioning than those without intellectual disability of the same CA, the outcome of such research is obvious. The persons with intellectual disability would always be expected to perform worse on any experimental task that is appropriate for the level of functioning of the participants and that is sufficiently sensitive to differentiate between groups of persons within the relevant range of level of functioning. Yet, despite their inevitability, findings of group differences based in this methodology were considered essential evidence by the defect theorists in their promulgation of the various impairments that were hypothesized as the core deficits of intellectual disability.

In highlighting one example of the extent to which CA matching research was integral to promoting the defect approach, Iarocci, Burack, and colleagues (Burack et al., 2001; Burack, Dawkins, et al., 2012; Iarocci & Burack, 1998; Iarocci et al., 2012) demonstrated that the commonly accepted notion of a core defect in attentional functioning, which was perpetuated from the 1960s even well into the 1990s, was based largely on empirical evidence in which matching was exclusively based on CA. In addressing this claim in a review of the rather limited empirical evidence available in which the group of persons with intellectual disability were homogeneous with regard to familial status and were matched to the comparison group of typically developing children on the appropriate basis of MA, Iarocci and Burack found no evidence for any attention deficit. Rather, they concluded that the defect approach researchers of attention had promoted "fatally" flawed research and had simply and inevitably found that lower functioning persons functioned at lower levels than higher functioning persons.

Iarocci and Burack (1998) acknowledged that the failure to find impairments in attentional functioning among persons with familial intellectual disability certainly does not rule out the possibility of finding deficits either among persons with familial intellectual disability on different components of attention, with different tasks, or at different ages; or among groups of persons with specific organic etiologies, some of which have been linked to preliminary developmental patterns of attention problems (for recent reviews, see Cornish & Wilding, 2010; Iarocci et al., 2012).

Yet, they and their colleagues highlight that the use of essentially problematic methodology of CA-matching led to the perpetuation of a myth of attention deficit in the study of intellectual disability (Burack et al., 2001; Burack, Dawkins, et al., 2012).

Given the obvious problems with CA-matching, what is the possible justification for the decades-long perpetuation for this fatally flawed methodology? One common argument for CA matching is that it allows for the identification of "spared abilities" in specific areas of functioning (for a discussion of the arguments in favor of CA matching and their fatal flaws, see Burack, Russo, et al., 2012). The proponents of CA matching argue that if persons with intellectual disability perform similarly to a CA-matched group of typically developing persons in a specific area of functioning then functioning in that area could be considered to be uniquely spared. Unfortunately, this reasoning is inconsistent with the basics of experimental developmental research. The failure to find differences between groups can rarely, if ever, be considered unqualified, or even strong, evidence that the groups perform similarly. Rather, this type of finding is more likely the consequence of one or more methodological constraints. In the case of research with persons with intellectual disability, the failure to find group differences is often because the participants do not function at the developmental levels at which differences in the specific area of functioning might optimally be found. For example, if an area of functioning emerges at age X, testing participants considerably prior to age X would not elicit group (or individual) differences since the area of functioning would not have yet developed for even the typically developing persons, and therefore both the typically developing children and children with intellectual disability would display apparently low levels of performance. Concordantly, differences would also be unlikely to be elicited with participants who are significantly older than X as the persons with intellectual disability would have had ample opportunity to attain the requisite skills even if their development in the specific area of functioning is slower as compared with the typically developing persons. Even in the case when the participants are all at the ideal age to study the emergent area of functioning, differences might not be found because of the lack of sufficient sensitivity of the task to differentiate level of performance among groups. Thus, without more evidence, the failure to find group differences tells us little about the relative abilities of the groups and the case for the sparing of abilities is more likely a consequent of problematic methodology than of any meaningful characteristic of the specific group (Burack, Russo, et al., 2012).

The most obvious matching strategy for comparing groups with different a priori levels of functioning, such as indicated by IQ, is to find a way to equate the groups on a general criterion that is relevant to the aspect of functioning that is being studied. In the study of cognitive and cognitive-related abilities among persons with intellectual disability as compared with those without intellectual disability, the relevant criterion is level of cognitive functioning, or MA, at the time of testing. In this context, the task of the researcher is to find groups of persons with and without intellectual disability that are similar on these measures, which can be accomplished only with groups that are considerably discrepant with regard to CA. Although the persons with intellectual disability are inevitably chronologically older, the strategy of matching by MA diminishes, or even eliminates, the potential criticism that findings of deficits among the persons with intellectual disability can simply be attributed to the generally lower levels of functioning. Rather, the case might be made that the deficit in the area of interest among the group of persons with intellectual disability is evident even when general functioning is equated. This is, of course, a much stronger argument than when the a priori level of functioning differs between the groups, as in the case of CA matching. Thus, the original call to match by MA (see Zigler, 1967, 1969; Zigler & Balla, 1982; Zigler & Hodapp, 1986), or general developmental level, was a meaningful improvement over the CA-matching strategies of yesteryear since the apparent deficits of persons with intellectual disability could not be simply attributed to a priori levels of development and functioning.

Although matching on the basis of MA represents an advance in the field, the process of matching is inherently flawed (Burack, Russo, et al., 2012; Jarrold & Brock, 2004) as the task of equating such different groups of persons is plagued by the fact that the groups are, in fact, essentially different. In highlighting this point, Burack, Russo et al. note that even in the imaginary scenario in which a person with intellectual disability and a typically developing child would have the exact same MA for a moment in time, they would differ from each other in so many different ways. By definition, the typically developing child would have attained the shared MA at a faster rate and at a younger age, whereas the person with intellectual disability would have lived longer and be more physically and physiologically mature. In addition to the age differences, the two would have had very different life experiences, especially with regard to support and encouragement, successes and failures, and the nature of familial and other relationships. Their futures would also diverge.

In the hypothetical case of an ideal test with perfect sensitivity and reliability in which the two children were perfectly commensurate with regard to level of functioning at a point in time, the typically developing child would surge ahead the moment after.

The inherent limitations in MA matching in the study of persons with intellectual disability are particularly exposed in the study of specific etiological groups, as the unique profiles observed for each of them relegate general scores of MA as insufficient to mitigate against claims of a priori differences between the groups (e.g., Karmiloff-Smih, 2009). In a relevant paper on matching in research with persons with autism, Burack et al. (2004) point out that "no choice of comparison group or matching strategy is perfect, but rather needs to be determined by specific research objectives and theoretical questions" (p. 65). In this context, they and others (e.g., for a detailed discussion, see Mervis & Klein-Tasman, 2004) highlight the need to utilize matching measures that are even more precise than general MA so that the matching is not by some general construct of developmental level but rather is linked to the development of abilities that are pertinent to the specific function or task. This strategy minimizes the chances that differences in performance between the groups might be an artifact of a specific relative strength or weakness in the area of functioning related to the experimental task for one of the groups. As an almost universal manifestation of this approach, researchers typically used measures of performance or nonverbal measures to match groups for studies that involve visuo-spatial processing, whereas verbal measures are most often used as the matching criterion for studies in which verbal abilities are central. However, this more precise strategy is still replete with problems as many experimental tasks involve both visual-spatial and verbal reasoning. Furthermore, the matching measures often lack precision, are often either particularly broad indicators of functioning, or are only tangentially related to the experimental task so that they are only minimally more relevant than general MA to the skills for which they are supposed to control. Despite the seminal methodological advances that arose from Zigler's articulation of MA, rather than CA, as the essential criterion for matching groups in studies with persons with intellectual disability and the subsequent imposition of increasingly precise indicators of matching, Burack, Russo, et al. (2012) suggest that the discussion should be less about "the way" or even "best way" to match, but rather, more humbly, the "least bad way" for the specific context of a given study. This acknowledgment of the inherent limitations with matching strategies is highlighted by the calls by some developmentally-oriented researchers to supplement, or even supplant, research methodologies based on the matching of groups with those involving regression or longitudinal paradigms (Cornish et al., 2013; Jarrold & Brock, 2004; Karmiloff-Smith, 2009).

THE STUDY OF THE "WHOLE PERSON" WITH INTELLECTUAL DISABILITY

The fourth of Zigler's (1967, 1969) primary contributions to the development of the developmental position best highlights the humanistic aspect of Zigler's developmental work (for a discussion, see Burack, 1997). Amid the field's obsessive focus on identifying a central, and inevitably cognitive-based, defect to explain intellectual disability, Zigler further distanced himself from his contemporaries by highlighting the need to focus on the persons with intellectual disability rather than on the phenomenon of intellectual disability and on all the domains of functioning that comprise the whole person rather than on just a specific area (or areas) of deficit. He argued that being a person with intellectual disability inevitably involved life experiences that would affect the way the person behaves and performs in all aspects of their life. However, true to his developmental outlook, Zigler even framed this apparently population-specific consideration within the context of universal developmental issues. The focus wasn't exclusively on the effects of intellectual disability or even on the life experiences of being a person with intellectual disability, but rather was framed within the context of a lifetime of failure, lowered expectations, and, in keeping with the times, institutionalization, all of which were relevant, but not exclusive, issues in the lives of persons with intellectual disability. As with other groups who shared some of these same life history backgrounds, such as persons from historically oppressed and particularly low SES groups, Zigler imagined that certain personality characteristics related to the motivation of the individuals with intellectual disability would develop in relation to the life circumstances and would permeate every aspect of the person's functioning. Although Zigler cited the personality-motivational characteristics as explanations for lower than expected performance for persons with familial intellectual disability on experimental tasks and how they could interfere with optimal task performance, these traits are as, if not more, relevant to virtually every aspect of any person's daily life.

These hypothesized interrelated traits include overdependency, low self-esteem, wariness of others, limited

mastery motivation, reinforcement-seeking, and outer-directedness (rather than innerdirectedness) (for reviews, see Merighi, Edison, & Zigler, 1990; Zigler & Burack, 1989; Zigler & Hodapp, 1986). Each of these styles of behaviors can be seen as a natural outcome for someone one who has lived with constant and consistent failure, little if any positive reinforcement, considerable criticism, lowered expectations, and other inevitable experiences of someone who functions outside the realm of society or fails to meet societal expectations. Yet they are also part of a more universal humanistic approach to understanding behavior as the same traits found among persons with intellectual disability or even others on the fringe are also found among persons in the mainstream society who have experienced failure. From a developmental perspective, the essential point of these characteristics is that they can even be adaptive in the appropriate context. For example, almost all of us utilize an outerdirected strategy in checking what others do when placed in situations that are particularly novel, dining in a restaurant of a different culture for the first time, or complex, dining at a particularly elegant event in which a multitude of dishes, glasses and utensils are provided. In these situations, we typically look around to see what is expected and act in relation to how others do in order not to embarrass ourselves, whereas in other more comfortable or common situations, we tend to behave in a more innerdirected way. In contrast, Zigler noted that persons with intellectual disability rely on the outerdirected approach even in more common situations in which they could perform well or at least accomplish what is expected without looking to others for cues as to how to behave. Bybee and Zigler (1992) highlighted this point with their finding that typically developing children used an outerdirected strategy in which they copied and otherwise looked to the experimenter's production of a picture using stickers for a novel or difficult task demand which they could not have otherwise fulfilled, whereas children with intellectual disability of the same MA used an outerdirected approach even on a simpler task that they should have been able to perform without external help (for a relevant review, see Bybee & Zigler, 1998).

The extent to which personality-motivational factors influence the lives of persons with intellectual disability, especially those with familial intellectual disability, is highlighted by findings that they are the best predictors of success and ability to integrate into mainstream aspects of society among persons within the range of mild intellectual disability (for reviews, see MacLean, 1997; Zigler & Hodapp, 1986). Consistent with the notion that mild intellectual impairment associated with familial intellectual disability simply reflects persons at the lower end of the natural continuum of the bell curve of intelligence, many persons in this grouping are able to hold jobs, live independently, and even start their own families (Bernheimer, Keogh, & Guthrie, 2006; Keogh et al., 2004; West, Wehman, & Wehman, 2005). As is the case with other persons, success is contingent primarily on extracognitive factors such as those related to personality and motivation (Merighi et al., 1990; Seltzer et al., 2009).

Although Zigler's (1967, 1969) initial broadening of the field of intellectual disability in the 1960s and 1970s to include extracognitive factors was focused almost solely on personality and motivational factors, it can be seen as the beginning of a more humanistic approach to research and scholarly understanding the whole person with intellectual disability. With the emphasis on the whole person, issues regarding the social and emotional lives of persons with intellectual disability became a priority for researchers, a timely occurrence in light of the relatively contemporaneous (and soon-to-follow) revelations of the atrocious conditions in which many persons with intellectual disability lived (e.g., in 1972, Geraldo Rivera exposed the conditions of the Willowbrook State School, a state-funded institution on Staten Island, New York, that housed 6,000 persons with intellectual disability) and the emergent emphasis on social adaptation in the essential (*DSM* and AAMD) diagnostic classification systems.

As with Zigler's other contributions to the developmental approach, the emphasis on personality and motivational factors and the whole person was expanded in many ways. The most notable is that Zigler's (1967, 1969) specific focus on these issues with regard to individuals with familial intellectual disability have since been applied to those with specific organic etiologies. Again, Cicchetti and colleagues provided early extensions of Zigler's dictum, as they focused on the temperament and socioemotional development specifically among children with Down syndrome (for extensive reviews, see Ciccheti & Beeghly, 1990; Cicchetti & Ganiban, 1990; Cicchett & Sroufe, 1978). This type of etiology-specific delineation is evidence of the advances in understanding the whole person in relation to essential issues that affect and are affected by development.

In this section, we highlight the advances and some of the difficulties in the specific study of three issues, social competence, language, and family relationships, that have been considered in relation to specific etiological groups and that reflect a commitment to understanding the social-emotional well-being of the whole person. Social competence represents the individual's abilities and

motivation to successfully interact in meaningful ways with others. Language reflects the case of a specific area of functioning that is essentially interrelated with social development. Family relationships involve issues of the reciprocal relationship between the presence of the child with intellectual disability and the family context. By disentangling these and related issues, we can better understand the transactions among the different systems that affect the whole person as well as between the individual and their immediate and broader systems (Bronfenbrenner, 1979). In the following sections, we consider the research on these components of the whole persons among individuals with the most commonly studied etiologies, Down syndrome, fragile X syndrome, Williams syndrome, and Prader-Willi syndrome.

Social Competence

Social competence is a key construct within the study of social development because it captures the dynamic relation between cognitive and social factors as they are applied to social adaptation (Iarocci, Yager, Rombough, & McGlaughlin, 2008). Although no operational definition of social competence is universally accepted, the term spans both socially adaptive behaviors as well as more basic social cognitive processes (Yager & Iarocci, 2013). It has been conceptualized as occurring at various levels of analysis—at the level of cognition (e.g., perspective-taking); overt behaviors/skills (e.g., use of eye contact); and outcome (e.g., social status, peer acceptance).

Developmental and contextual changes add further complexity to the study of social competence. It is both a developmental phenomenon that can be measured over the course of a child's development (i.e., ontogenesis) as well as a characteristic of a particular social encounter for which the time scale is in the order of seconds/minutes (i.e., microgenesis). Thus, continuities and discontinuities in the development of social competence are expected; children are better able to coordinate abilities and take advantage of resources with increasing age but may be less competent at certain developmental stages or in specific social contexts. What constitutes socially competent behavior changes depending on the age of the child as well as the context within which the child is evaluated (e.g., with parent or peers).

The same set of social skills are not available to the infant as they are to the adolescent. Thus, age-appropriate assessment in which the measure's focus is targeted to particular developmental periods are essential. For example, in infancy the quality of the parent–child interaction may be a particularly sensitive index of social competence as the interrelations between infant cues and parent sensitivity to the infant's cues improve the odds of survival as well as the social-emotional development of the infant. Peer interactions may be especially salient in middle childhood, whereas intimate relationships and community integration are paramount in adolescence.

In considering these aspects of social competence as well as other aspects of social development across populations, Yager and Iarocci (2013) note even persons with severe social impairment may be intensely aware of their social disconnectedness, experience distressing loneliness, and show a desire for greater social interaction. Accordingly, they emphasize that social motivation and social understanding may be relatively independent and measurable aspects of social competence. Within this framework, we use Rose-Krasnor's (1997) "prism model" to guide our understanding of the literature on social competence among persons with intellectual disability as it provides a useful framework for conceptualizing social competence and its levels of analysis. According to the model, social competence at a theoretical level is broadly defined as overall effectiveness in meeting short- and long-term social developmental needs/goals. Thus, social competence is viewed as a higher-order, organizing construct with transactional, context-dependent, and goal-specific characteristics. It cannot be reduced to any single index or skill but requires the active, skillful coordination of multiple processes as well as contextual factors to adequately meet the social demands of a particular situation (Iarocci, Yager, & Elfers, 2007; Iarocci, Yager, Rombough, & Mclaughlin, 2008). However, identifying and measuring a representative sampling of abilities/behaviors at the social motivation and skills level are useful in order to "tap into" the broader theoretical construct of social competence.

According to the prism model, social competence can be studied empirically at two distinct levels of analysis: the *index* level and the *motivation/skills* level (Rose-Krasnor, 1997). The index level represents real-life summary indicators of social competence (e.g., attachment security, peer acceptance, or employment success) that are considered to be situation/context-specific (e.g., with peers vs. with family). Although generally indicative of social competence, these indexes do not provide detailed information about the social presentation of an individual. Their utility in assessment is primarily as outcome measures or gross screening tools (e.g., identifying individuals who may be socially impaired). The *motivation/skills* level is comprised of the underlying dispositions and abilities that provide the "building blocks" of social interactions (e.g., social

motivations and social skills). Social skills include both social-cognitive abilities (e.g., perception and processing of social stimuli) and the more overt, observable social behaviors (e.g., eye contact, conversation ability). Any given social motivation or skill may be relevant across contexts or prove particularly valuable within a specific social context. In general, social motivations and skills tend to be more accessible to assessment methods (as compared with the indexes) and are commonly measured with performance-based laboratory tasks (e.g., tests of emotion recognition) or observation-based rating scales.

In this brief review of research on social competence among specific etiological groups of persons with intellectual disability, we include studies that are focused on the index level and those that are focused on the motivation/skills level. At the index level, the studies provide information about the individual's social behavior for adaptation, whereas those at the motivation/skills level contribute to an understanding of the socio-cognitive processes that underpin social behaviors.

Social Competence Among Persons With Fragile X Syndrome

Children with fragile X are often diagnosed with ADHD as they show poor attention span, impulsivity, and high motor activity. With age, hyperactivity and impulsivity subside yet attention deficits and inhibitory control problems persist (Cornish et al., 2008). High rates of autism spectrum disorder are also noted in this group along with considerable overlap of symptoms, although those with fragile X and autism display significantly less impairment on measurements of social response on the Autism Diagnostic Observation Schedule (ADOS), including the areas of Response to Joint Attention, Responsive Social Smile, and Facial Expressions (Wolf et al., 2012). For example, children with fragile X tend to show gaze avoidance, hyperarousal, repetitive activity, and motor stereotypy. Expressive language deficits are also common and include perseverative speech, echolalia, self-talking, and cluttering (Fletcher et al., 2007). Children with fragile X are also shy and at higher risk of developing social anxiety (Teisl, Reiss, & Mazzocco, 1999).

At the Index level, individuals with fragile X show relatively good adaptive skills and many are able to engage in occupational activities (Fletcher et al., 2007). However, they continue to show problems with temper outbursts as well as obsessional and aggressive behaviors well into adulthood (Howlin & Udwin, 2002).

At the motivation/skills level, children with fragile X are reported to show less approach, persistence, and adaptability in social interactions. Individuals with fragile X are described as socially anxious and withdrawn, and tend to avoid eye contact and have limited interaction with peers (Cornish et al. 2001; Kaufmann et al. 2004). In an analysis of scores on the Autism Diagnostic Observation Schedule (ADOS), Wolf et al. (2012) found that participants with both fragile X and autism were capable of appropriately responding to social bids made by others as indicated by their performance on the subtests of Responsive Social Smiling, Facial Expressions, Response to Joint Attention, but showed poor social initiative as indexed by the of Showing, Requesting, and Initiation of Joint Attention. Accordingly, Wolf et al. (2012) argued that the social difficulty in fragile X has more to do with a lack of prosocial initiative rather than any lack or impairment of social ability or social awareness. They speculated that the lack of initiative in making social bids was likely related to the high level of social anxiety in this group.

Initial evidence regarding the processing of emotions, faces, and other social information among persons with fragile X underscores the importance of considering developmental level, rather than CA, as patterns of performance which appear to reflect universal impairments or differences in relation to that of same-aged peers are considerably more nuanced in relation to MA-appropriate levels. For example, Shaw and Porter (2013) found that participants with fragile X (mean CA of 24.8 years and mean MA of 8.4 years) displayed specific emotion recognition deficits for angry and neutral, but not happy or fearful, faces as compared with both MA-matched (mean MA of 9.2 years) and CA-matched (mean CA of 24.5 years) typically developing persons, but developmentally appropriate visual scanning of emotional faces. Although the participants with fragile X displayed reduced attention to the eyes and different visual scan patterns of emotional faces as compared with the CA-matched typically developing individuals, their scanning patterns were commensurate with those of the MA-matched typically developing participants. The complexity in the relation between behavior and processes is highlighted by Hagan, Hoeft, Mackey, Mobbs, and Reiss's (2008) finding that 10 high-functioning females with the fragile X full mutation (mean CA of 16.4 years and IQ of 91) as compared with 10 typically developing girls matched on age but not IQ (mean CA of 15.2 and mean IQ of 106) showed intact emotion recognition despite a potentially disrupted neural circuit that modulates emotional responses to faces even when differences in IQ and accuracy of responses were statistically controlled. In a related study of visual scan paths, Williams, Porter, and Langdon (2013) found that

participants with fragile X (mean CA of 23 years and MA of 8.7 years) generally attended to social information overall to a similar degree as MA- (mean MA of 8.7 years) and CA- (mean CA of 23.2 years) matched typically developing participants, but were faster to disengage their attention away from social information in naturalistic static social scenes as compared with these groups as well as with a group of participants with Williams syndrome. Williams et al. concluded that the faster disengagement of attention away from social information was evidence of the avoidance of social stimuli among persons with fragile X.

In a study of higher order skills relevant to social understanding, Losh et al. (2012) examined theory of mind and pragmatic language skills among boys with fragile X-only, boys with fragile X and autism, boys with autism only, boys with Down syndrome, and typically developing boys. They found that both the participants with autism-only and the participants with both fragile X and autism performed most poorly, whereas the boys with fragile X-only did not differ significantly from the group of boys with Down syndrome or the MA-matched typically developing boys. Moreover, for all the groups, better theory of mind scores were associated with more pragmatic language competence as indexed by the Pragmatic Judgment subtest of the Comprehensive Assessment of Spoken Language. Losh et al.'s conclusion that the boys with fragile X-only showed relative strengths in theory of mind and pragmatic language and therefore that the deficits in these areas may be specific to those with both fragile X and autism highlights the social differences between the two subgroups of fragile X and suggests that any social problems associated with fragile X per se are not likely associated with higher-order cognition.

In summary of the work on social competence among persons with fragile X, the few preliminary studies on index level suggest good adaptive and occupational skills, but also behavioral problems that may interfere with overall social adjustment. At the motivational/skills level, social avoidance and anxiety appear prominent, yet unusual social attention processing is also present. Preliminary, but complex, profiles of both age-appropriate and impaired emotion recognition and theory of mind emerged, depending on what was being measured and with what task. Difficulties with theory of mind and pragmatic language tasks were specifically associated with fragile X, but only when co-occurring with autism.

Social Competence Among Persons With Down Syndrome

Children with Down syndrome typically fare better than children with other etiologies with regard to certain aspects of social competence. For example, at the index level they show generally good social adaptation and positive social outcomes (Rosner, Hodapp, Fidler, Sagan, & Dykens, 2004), whereas the profile is mixed at the motivation/skills level. Rosner et al. (2004) studied 177 persons with intellectual disability aged 4–49 years and found that the number and quality of social activities and relationships as measured by the Child Behavior Check List (CBCL; Achenbach, 1991) was significantly better among participants with Down syndrome compared with groups of children with Prader-Willi and Williams syndrome, after both age and IQ were covaried in all between-group analyses to account for the fact that the participants with Down syndrome were approximately 4–5 years younger and 12–16 points lower in IQ than the other two groups. In particular, the children and youth with Down syndrome were reported to behave well with others, show involvement in organizations, and demonstrate good job skills. In apparent contrast, Guralnick, Connor, and Johnson (2009) focused on more fine-grained analyses of peer social contacts, networks, quality of play, degree of control of play, and the characteristics of playmates, and found fewer well-developed peer networks in comparison to a MA-matched group of typically developing children. Specific areas of difficulties noted were the children's level of involvement in play with peers, linkages to other settings (e.g., school), and control of play. The seeming inconsistencies between the studies simply highlight two essential methodological points—the type of measure (global vs. fine grained) and the comparison group (typically developing vs. developmental disabled) need to be considered when interpreting findings.

With regard to the motivation/skills level, despite evidence of relatively good motivation and interest (e.g., face gazing and smiling behaviors) (Moore, Oates, Hobson, & Goodwin, 2002), difficulties have been noted in aspects of social cognition such as joint attention and theory of mind as compared with both MA matched typically developing children and children with nonspecific intellectual disabilities (for a review, see Iarocci et al., 2008). Children with Down syndrome were found to show fewer social referencing looks to their mothers in ambiguous situations (Kasari, Freeman, Mundy, & Sigman, 1995b) and make fewer attempts to direct their mother's attention across social situations (Fischer, 1987; Landry, Garner, Pirie, & Swank, 1994). Concordantly, Fidler (2005) found that toddlers with Down syndrome showed fewer nonverbal, instrumental requests than did typically developing and developmentally disabled toddlers matched on MA

and that these requests were related to the level of their problem-solving abilities.

Children with Down syndrome appear to show poorer emotion recognition relative to their cognitive abilities (Kasari, Freeman & Hughes, 2001; Kasari, Freeman & Bass, 2003), and appear to have particular difficulties with identifying and labeling fear and anger (Kasari & Freeman, 2001). Even when language demands were minimized with the use of nonverbal photo matching of expressions, Williams et al. (2005) found that children with Down syndrome had difficulty with fearful expressions. Concordantly, Wishart et al. (2007) found that persons with Down syndrome were particularly impaired on matching fearful expressions as compared with individuals with fragile X syndrome, those with nonspecific intellectual disability, and typically developing children. In addition to the difficulties recognizing emotions in others, children with Down syndrome have been found to show decreased emotional expressiveness. Early in infancy, they appear to have dampened smiles, shorter and less frequent displays of emotion, and longer delays to express emotion as compared with typically developing children (Emde & Brown, 1978; Thompson et al., 1985). Jahromi, Gulsrud, and Kasari (2008) found that children with Down syndrome generally showed more negative affect and difficulty regulating their emotions during challenging tasks as compared with typically developing children. The children with Down syndrome seemed to have a limited repertoire of behaviors to cope with frustration and, in fact, displayed more frustration and fewer cognitive self-soothing techniques. Consistent with the notion that personality-motivational characteristics can interfere with optimal performance among persons with intellectual disability, the children with Down syndrome oriented more to the experimenter without asking for help.

Despite the apparent difficulties in emotion recognition, expressivity and regulation, children with Down syndrome generally show more responsiveness to others (e.g., comforting) during distressing situations as compared with typically developing children. Although Kasari et al. (2003) found a poorer understanding of the concept of empathy among persons with Down syndrome, they reported an awareness of situations that are potentially distressing to others and the commission of appropriate actions to comfort others.

In adolescence and early adulthood, individuals with Down syndrome appear to become more withdrawn and show less pleasure or animation (Fletcher et al., 2007). The social withdrawal may be related to their higher risk of mental health problems such as the higher incidence of depressive disorder, anxiety, and obsessive compulsive disorder among the young adults (Dykens, Shah, Sagun, Beck, & King, 2002; Fletcher et al., 2007). Early onset Alzheimer's disease is also more likely in this group and possibly has adverse effects on social functioning (Prasher, Chung, Hague, 1998).

In summary, at the index level, children and youth with Down syndrome appear to show relative strengths in social competence as compared with other developmentally delayed youths. However, the type of measure and the comparison group need to be considered when interpreting as these findings of strengths may not be found in comparison to typically developing children. At the motivation/skills level, social motivation, interest, and responsiveness appear to be relative strengths, whereas social-cognitive abilities and emotion recognition, expressivity and regulation may be areas of relative weakness.

Social Competence Among Persons With Williams Syndrome

Children with Williams syndrome exhibit "hypersociability" and tend to be overly friendly, engaging, and responsive to others (Fidler, Hepburn, Most, Philofsky, & Rogers, 2007; Mervis et al., 2003). The social approach behavior appears to be compulsive since these children's approaches to strangers are typically indiscriminant even when the children have knowledge of the approachability of the other (Frigerio et al., 2006), and most report being scared of strangers (Dykens, 2003). Children with Williams syndrome show intense and prolonged attention to faces to the detriment of attention to other aspects of their environment (Mervis et al., 2003), yet their emotion recognition skills are delayed (Fidler et al., 2007; Gagliardi et al., 2003).

At the index level, individuals with Williams syndrome appear to show relative weaknesses in adaptive daily living skills (Hahn, Fidler & Hepburn, 2014; Mervis et al. 2001; Plissart et al. 1994), although they improve into adulthood (Howlin, Elison, Udwin, & Stinton, 2010). Howlin et al. used both cross-sectional and longitudinal designs and found no evidence of cognitive or linguistic deterioration overtime that could account for poor adaptive functioning among persons with Williams syndrome. Rather, adaptive functioning (as measured by the Vineland Adaptive Behavior Scales) generally improved until age 50 years. Specifically, Communication domain scores were consistently lower than scores in other domains and the relations between Socialization and Daily Living scores varied with age. However, parent reports suggest that these

individuals are dependent on family members and struggle with physical and mental health problems in adulthood. For example, 239 parents of adults (age 18–56 years) with Williams syndrome surveyed by Howlin and Udwin (2006) reported high rates of physical health problems as well as increases in rates of mental health problems (depression or anxiety) with age. Educational and employment attainments were generally low and self-help skills were relatively poor. Most (62%) of the adults with Williams syndrome were still living at home, some with quite elderly parents.

In Rosner et al.'s (2004) comparison of participants with Down syndrome, Williams syndrome, and Prader-Willi syndrome, those with Williams syndrome scored lower on social competency on the CBCL as compared with participants with Down syndrome, but higher as compared with participants with Prader-Willi syndrome. Most persons with Williams syndrome experienced difficulty with social interaction and were socially isolated (Davies et al., 1998). In one early study, 96% of all the individuals were described as experiencing difficulty in making friends and 76% were reported as having few to no friends (Udwin, 1990). With regard to occupational functioning, those with Williams syndrome scored lowest on job skills using the CBCL, which includes both household chores and jobs outside the home (Rosner et al., 2004). Problems with distractibility, social disinhibition and overfriendliness, as well as anxiety have also been noted (Davies et al., 1997; Udwin et al., 1998).

At the motivation/skills level, children with Williams syndrome have been found to show unusually intense social interest and processing of faces and eyes. For example, children with Williams syndrome fixate on faces longer than verbal IQ matched typically developing children and are slower to disengage their gaze once fixated on eyes (Porter et al., 2010) or a face (Riby et al., 2010). At an even more general level, Williams, Porter, and Langdon (2013) also reported difficulties disengaging attention rather than attentional capture among individuals with Williams syndrome, after they manipulated the location of socially salient information within visual scenes. These studies suggest that some aspect of selective attention may be impaired and implicated in the social perception behavior of children with Williams syndrome.

Despite the high social interest and intense attention to faces, individuals with Williams syndrome display significant impairments in recognizing emotions (Lacroix, Guidetti, Roge, & Reilly, 2009). Although they look longer at social stimuli they do not appear to process all relevant aspects but, rather, show a bias toward positive elements. In a study on autonomic responsiveness to emotionally laden images with social or nonsocial content, Plesa-Skwerer et al. (2011) found that the participants with Williams syndrome looked significantly longer at the social images as compared with images without social content and displayed reduced arousal to the negative social images as compared with the nonverbal MA-matched typically developing groups. Ironically, the awareness of emotional distress in others and heightened level of sensitivity to the emotional reactions of others (as evidenced by their high level of mimicry and imitation) does not appear to be applied to social decision making (Fidler et al., 2007).

Cognitive and language deficits seem to play a role in the social behavior of individuals with Williams syndrome. They appear to demonstrate difficulties in higher order social-cognitive functions such as atypical nonverbal communication, imagination, and problems in understanding the mental states of others (i.e., theory of mind; Plesa-Skwerer, Faja, Schofield, Verbalis, & Tager-Flusberg, 2006; Tager-Flusberg & Sullivan, 2000). Generally, people with Williams syndrome show about the same level of performance on various theory of mind tasks as other children with developmental disabilities (Plesa-Skwerer & Tager-Flusberg, 2006). Tager-Flusberg and Sullivan suggested that theory of mind functioning among persons with Williams syndrome is characterized by relative sparing in the social-perceptual component, the ability to make an immediate judgment of a person's mental state, but impairment on the social-cognitive component. The social-pragmatic aspects of language (e.g., sensitivity of the communicative partner's perspective, nonverbal and verbal cues, and conversational reciprocity, interpreting jokes) are poor and similar to those of persons with autism (Klein-Tasman, Mervis, Lord, & Phillips, 2007; Stojanovik, 2006; Stojanovik & James, 2006).

The social approach behaviors of people with Williams syndrome may be due to a reduced ability to inhibit the urge to socially interact with others, suggesting a general rather than a social deficit in inhibition (Porter et al., 2007). For example, in examining the variability in the social approach behaviors of children with Williams syndrome ranging from 6 to 15 years of age with a cluster analysis, Little et al. (2013) identified social approach behavior subgroups and found that the response inhibition ability of the children was the strongest predictor of the social approach behavior profiles. Similarly, Kirk, Kocking, Rigby, and Cornish (2013) found that heightened anxiety in some individuals with Williams syndrome was associated with attention allocation away from the eye regions of threatening facial expressions, whereas attention to eye gaze is typically overly fixated and prolonged.

This finding suggests that anxiety may play a role in biasing social attention in at least a subset of individuals with Williams syndrome.

In sum, persons with Williams syndrome show problems in social competence at the index level as well as an unusual pattern of intense social interest and attention to social stimuli coupled with social-emotional, social-communicative, and cognitive deficits. This profile of high social interest and poor social information processing likely contributes to the poor social outcomes (e.g., social isolation) but also makes these individuals particularly socially vulnerable in a variety of ways (e.g., bullying, abuse). In addition, despite relatively stable cognitive and linguistic functioning, and general improvements with age on adaptive skills, individuals with Williams syndrome remain dependent on family members and struggle with physical and mental health problems in adulthood.

Social Competence Among Persons With Prader-Willi Syndrome

Individuals with Prader-Willi syndrome eat excessively (may also ingest inedible items) and are typically morbidly obese. The pursuit of food is so extreme that in many cases they will resort to risk-taking and antisocial behavior such as lying, stealing, and exchanging sexual favors for the promise of food. These individuals exhibit poor social judgment and difficulty with interpreting social cues (Koenig, Klin, & Shultz, 2004). Rituals, tantrums, skin picking, and compulsive behaviors, such as hoarding and placing objects in a certain order, occur at elevated rates among persons with Prader-Willi compared with persons with other etiological syndromes (Greaves, Prince, Evans, & Charman, 2006; Holland et al., 2003). Clinically, the rates of autism and mood disorders are also elevated (Vogels et al., 2004).

Prader-Willi syndrome is caused by missing paternal chromosome 15 (q11–q13 region). Seventy percent of the cases are due to the deletion (DEL) of the region in the paternal contribution, 25% of the cases to the duplication of the region in the maternal contribution, referred to as uniparental disomy (mUPD), and the rest to either a methylation imprinting defect or a translocation microdeletion (Ledbetter et al., 1981; Nicholls et al., 1989). Individuals with the DEL subtype are more severely impacted than those with mUPD in several domains, including the characteristic facial appearance and hypopigmentation (Cassidy, 1984), maladaptive behaviors (Dykens et al., 1999), and self-injurious behaviors (Symons et al., 1999). However, individuals with mUPD are at increased risk for developing psychosis after adolescence (Verhoeven & Tuinier, 2006) and autistic-like symptoms (Descheemaeker et al., 2006; Dimitropoulos & Schultz, 2007)

At the index level, based on parent ratings on the CBCL, children with Prader-Willi syndrome were reported to show poor behavior with others, and to be less active in social organizations compared with those with Down syndrome (Rosner et al., 2004). Their overall social competence did not improve with age as it did for children with Down syndrome and those with Williams syndrome (Rosner et al., 2004). Individuals with Prader-Willi syndrome also display poorer adaptive skills than would be expected given their intellectual functioning (Holland et al., 2003), and are reported by their caregivers to exhibit rigidity, inflexibility, and great difficulty with changes in their routines (Benarroch et al., 2007).

At the motivation/skills level, unusual but discrepant perceptual processing of faces was found in both genetic subtypes of Prader-Willi syndrome (Halit et al., 2008). In a preliminary neurophysiological study of individuals with Prader-Willi syndrome, an attenuated response to faces was found among eight individuals with paternal deletions (DEL), whereas the participants with mUPD showed a more typical neural response to faces although their eye gaze processing was similar to those participants with autism (Halit et al., 2008). Emotion recognition, a related area of social competence, is considered to be atypical in Prader-Willi, and may be related to high rates of comorbid affective psychosis (mUPD subtype) and clinical depression (DEL; Soni et al., 2008). Although Soni et al. (2008) found that caregivers drastically underestimated the emotion recognition and response abilities of both children and adults with Prader-Willi syndrome, problems in facial emotion recognition factors is thought to contribute to the peer relationship difficulties that are common among persons with Prader-Willi syndrome (Whittington & Holland, 2011). This is consistent with Tager-Flusberg et al.'s (1998) findings that adults with Prader-Willi syndrome performed significantly worse than adults with Williams syndrome when selecting the correct labels to match to the photographs of mental state expressions in the eye region.

Theory of mind also appears to be an area of impairment among persons with Prader-Willi syndrome. However, performance may vary with the type of task used or aspect of theory of mind that was measured. For example, Tager-Flusberg and Sullivan (2000) found that children with Prader-Willi syndrome (mean age 6 years, 11 months and mean IQ of 63) performed better on the false belief component of theory of mind than children with Williams Syndrome (mean age of 7 years 2 months

and mean IQ of 68). However, Koenig, Klin, and Schultz (2004) found that participants with Prader-Willi syndrome (mean age of 19.9 years and mean IQ of 67) performed as poorly as those with autism (mean age of 15.7 years and mean IQ of 69) and below IQ-matched participants without autism (mean age of 20.8 years and mean IQ of 72). The difficulties may be especially apparent when tasks require an appreciation for more abstract mental states as Koenig et al. used a social attribution task involving ambiguous stimuli (moving shapes in a video). In this context, the group with Prader-Willi syndrome made simple cognitive attributions about the moving shapes but were less able to make inferences about affective states related to the scenario (e.g., envy, jealousy), elements that were critical to understanding the social story.

Using within-group subtype analyses, Lo, Siemensma, Collin, and Hokken-Koelega (2013) found that both persons with the DEL and with mUPD subtypes showed poorer than expected performance on several components of theory of mind including first order belief, false belief, and second order false belief. In this group, 36% of children also met criteria for autism; 29% of the DEL and 41% of the mUPD subtypes. The most common symptoms of autism in the Prader-Willi syndrome group were in the area of maladaptive behaviors and routines such as interrupting conversations, talking to strangers, and making literal interpretations of expressions. Whereas most individuals with Prader-Willi syndrome do not exhibit the severity of symptoms found in autism, the social deficits that are reported appear to fall on the same continuum (e.g., poor social reciprocity and peer relationships).

Conclusions About Social Competence

The distinction between studies on index level, real-life summary indexes of social competence (e.g., peer acceptance, or employment success) and motivation/skills level, the underlying dispositions and abilities that provide the building blocks of social interactions (e.g., social motivations and social skills) is helpful to identify which aspects of social competence are impaired and the implications for overall adaptation. More of the research on social competence among the various etiological groups associated with intellectual disability has been focused at the motivational/skills level than at the index level and no studies were found that were focused on the relations between the foundational social abilities (e.g., face and emotion recognition) and real-life indexes of social competence (e.g., friendships). Understanding this relation will be informative about the extent to which current interventions, which are typically designed to tackle specific social processes such as face and emotion perception can impact real-life social adaptation with all its complexity and many components. Thus, intervention studies designed to specifically target face or emotion processing in children with ID should also include outcome measures of indices of real-world social competence, such as peer and family relations.

Comparisons across syndromes point to unique profiles of social competence that further underscore the notion of multiple sciences of different etiologies rather than a single monolithic one in the study of persons with intellectual disability. Patterns of differences and similarities in sociability across syndromes would help us understand the contribution that sociability has on the overall social outcomes of persons with specific syndromes and provide further insight into gene–brain–behavior systems. For example, the hypersociability in Williams syndrome is clearly an extreme phenotype of a critical aspect of social competence. With increasing methodological sophistication, even more detailed analyses of within group subtypes and variation allows for more nuanced and precise genetic associations and markers with sociability. All of these extensions of the research must begin to be considered within a developmental framework to account for changes across syndromes across the lifespan rather than being based on extrapolations from studies with limited ranges of CAs or MAs.

Language Development

As with many areas of functioning, early accounts of language abilities among persons with intellectual disability were consistent with the defect theories. Various impairments were forwarded as characteristic of all persons with intellectual disability, regardless of etiology, and were generalized to involve all facets of language. This outlook has since evolved largely in relation to the emergence of the developmental approach to intellectual disability and the concordant increased specificity in the ability to measure different aspects of language. Accordingly, the discussion around language abilities among persons with intellectual disability has been transformed to include issues of development and abilities, rather than just impairment, and an emphasis on the etiology-specific developmental profiles of the many different components of language functioning. However, as with other areas of functioning, this more fine-grained and comprehensive approach only allows for the relatively extensive study of the most common etiological groups, and the intermittent study of a few others. Furthermore, statements about a general language skill

are misguided, as language is a multi-faceted process in which children often display multiple divergent trajectories that are largely dependent on foci of the research and the measures that are used.

To provide some insight into the role of language in understanding the whole person, we provide a brief review of current thinking regarding the disparate profiles of language processing as well as their interplay with cognitive and social development among the most commonly studied etiological groups, those of persons with fragile X syndrome, Down syndrome, and Williams syndrome. We also review language among persons with Prader-Willi syndrome as an example of current thinking in research on less studied syndromes. As with virtually all areas of functioning, the available evidence is piecemeal with only some areas of language functioning being considered within each etiological group, and with little consistency in the foci of research across groups.

Language Development Among Persons With Fragile X

Among children with fragile X, language is generally reported to develop along a consistent trajectory commensurate with MA, with the exception of pragmatics (Abbeduto et al., 2012). Individual differences within the syndrome are also reported as a function of gender, as males tend to be more affected overall than females, and as a function of autism comorbidity (which occurs in 20–30% of cases; Hatton et al., 2006; Rogers, Wehner, & Hagerman, 2001). In other aspects, inconsistent evidence leads to questions about language development in this group. In one example, Roberts et al. (2002) reported that receptive vocabulary lagged behind expressive vocabulary in a group of young boys whose MAs ranged from 12 to 28 months (CAs 21 to 77 months), whereas Abbedutto et al. (2003) reported that receptive vocabulary was at nonverbal MA expectations in a group of male and female adolescents. These findings suggest either that the rate of vocabulary acquisition increases more quickly than the rate of general cognitive development among individuals with fragile X over the course of development or that comparing receptive to expressive vocabulary (Roberts, 2002) leads to a different interpretation of strengths and weaknesses than comparing receptive vocabulary to MA (Abbedutto et al., 2003).

In a longitudinal study of boys with a mean MA of 5-years at entry, Martin, Losh, Estigarribia, Sideris, and Roberts (2013) found parallel gains on the Comprehensive Assessment of Spoken Language (Carrow-Woolfolk, 1999) among those with fragile X without autism, fragile X with autism, and Down syndrome over a 3-year period. In all three groups, language appeared to be below non-verbal MA expectations, and both the boys with fragile X without autism and those with Down syndrome showed a pattern of vocabulary > pragmatics > syntax, whereas the boys with fragile X with autism showed a pattern of vocabulary > pragmatics = syntax due to poorer pragmatic performance in the comorbid autism group. Given the frequent reports of gender differences and consequential exclusion of females from many studies, the pattern of findings reported by Abbeduto et al. (2003), which were inconsistent with other studies, might be related to the inclusion of females in their study (Abbeduto et al., 2012). This was supported by findings from a longitudinal study of boys and girls with fragile X, in which Pierpont, Richmond, Abbeduto, Kover, and Brown (2011) found that phonological and verbal working memory predicted gains in vocabulary and syntax for boys, but not girls, with fragile X. The evidence from the study of language among individuals with fragile X highlights the importance of taking into consideration both gender and the presence of a comorbid diagnosis of an autism spectrum disorder in understanding the development of skills in this group.

Language Development Among Persons With Down Syndrome

In a review of language development from childhood to young adulthood among persons with Down syndrome, Chapman and Kay-Raining Bird (2012) note that children with Down syndrome display a specific phenotype of language learning, including uneven impairments in language skills, yet they are one of few etiological groups in which impairments in pragmatics (the social use of language) are not identified. Combining evidence from cross-sectional and longitudinal studies of language acquisition, Chapman and Kay-Raining Bird (2012) painted a picture of changes in language functioning across development. In early childhood, children with Down syndrome display deficits in expressive vocabulary that are below nonverbal MA expectations (Fidler, Hepburn & Rogers, 2006; Miller, 1995). However, from age 2 to 4 years, the rate of expressive vocabulary growth falls further and further behind both receptive vocabulary knowledge and nonverbal development (Miller, 1995), with receptive vocabulary remaining commensurate with non-verbal development until early adolescence (Chapman, Schwartz, & Kay-Raining Bird, 1991). As the grammatical complexity of language skills among typically developing children increases, children with Down syndrome appear to fall further and further behind, even as language skills continue to grow (albeit unevenly).

In an attempt to study the relationship between language and cognition among individuals with Down syndrome, Chapman, Hesketh, and Kistler (2002) conducted a 6-year longitudinal study of grammar in which they found that receptive syntax at the beginning of the study predicted later expressive syntax. Furthermore, short-term memory skills (both auditory and visual) predicted the rate of receptive syntax growth, which in turn predicted the rate of growth in Mean Length Utterance. Auditory short-term memory has also been implicated in phonological development (Kumin, Councill, & Goodman, 1994; Laws & Gunn, 2004), the emergence of which appears to be delayed among infants with Down syndrome, although the pattern has been reported to follow a typical trajectory (Smith & Stoel-Gammon, 1983).

Consistent with the developmental approach, Chapman and Kay-Raining Bird (2012) caution that the manner in which we measure development plays a role in our understanding of language-related strengths and weaknesses of individuals with Down syndrome, and could lead to an under-evaluation of abilities. For example, researchers debate the relative strength of receptive vocabulary among individuals with Down syndrome during adolescence, with Chapman et al. (1991) reporting that receptive vocabulary surpasses general MA, and others reporting that receptive vocabulary is below MA expectations (Hick, Botting, & Conti-Ramsden, 2005; Price, Roberts, Vandergrift, & Martin, 2007; Roberts, Hennon, et al., 2007). However, this discrepancy in findings may have more to do with the use of different MA measures across studies, rather than actually reflecting conflicting patters of findings. Further, with respect to grammar, when assessments of language are based on conversational samples (e.g., question–answer or spontaneous comments during free play), expressive syntax appears to reach a plateau in adolescence among individuals with Down syndrome (Chapman et al., 1998; Fowler, Gelman, & Gleitman, 1994). Conversely, when assessments of language are based on narrative samples, the development of expressive syntax continues through young adulthood (Chapman et al., 1998; Chapman et al., 2002; Thordardottir, Chapman, & Wagner, 2002).

Language Development Among Persons With Williams Syndrome

Some early accounts of individuals with Williams syndrome focused on apparent strengths in expressive language, to the extent that in an early account, Bellugi, Marks, Bihrle, and Sabo (1988) described them as demonstrating a double dissociation between language and cognition or as having intact language abilities despite a general level of functioning in the range of intellectual disability. However, Mervis (2012) and Karmiloff-Smith (1998, 2007) argue that the expressive language abilities of individuals with Williams syndrome only appear to be so outstanding when they are considered in relation to the extremely impaired skills, such as visuo-spatial construction, in this group. With closer scrutiny, various aspects of language also appear to be delayed or impaired, and the development of language appears to be interdependent with, rather than independent from, general cognitive development (Mervis, 2012).

Karmiloff-Smith et al. (1997) argue that the entire trajectory of language development is altered in Williams syndrome, and that this may be linked to the syndrome's characteristic hypersociability. Beginning in infancy, infants with Williams syndrome seem to pay excessive attention to people at the expense of joint attention behaviors, which are necessary precursors to typical language development (Bloom, 2002). Despite, or perhaps consequential to, their hypersociability, atypicalities have been reported in virtually all areas of pragmatic language abilities, which include language related to social interaction such as turn taking, modulating content for the audience, and communicating wants and needs (Philofsky, Fidler, & Hepburn, 2007). Specifically, individuals with Williams syndrome exhibit a particular pattern of unusual conversation that tends to include features such as excessive idioms, overfamiliarity, evaluative comments, and emphatic markers, a cocktail party speech that is partly responsible for the reputation of strong language (Mervis, 2012). Individuals with Williams syndrome are quite verbose, but this verbosity appears to mask difficulties in the social aspects of language, the very skill that was initially considered to be their primary strength.

Language Development Among Persons With Prader-Willi Syndrome

The difficulties in providing a comprehensive understanding of less common etiological groups are highlighted in the literature on the development of language among individuals with Prader-Willi syndrome. Impairments in both expressive and receptive language have been cited, with greater impairment reported in expressive language (Branson, 1981; Dimitropoulos, Ferranti, & Lemler, 2013; Kleppe, Katayama, Shipley, & Foushee, 1990; Munson-Davis, 1988), although these findings are plagued by methodological problems regarding the comparison groups. For example, findings that expressive language appears to be particularly problematic in individuals with Prader-Willi syndrome, with specific problems with

morphosyntax and possible difficulties with vocabulary and pragmatics (Van Borsal, Defloor, & Curfs, 2006) are compromised as they are framed only in relation to the expected norms for CA. Although preliminary, areas of strength in language abilities among individuals with Prader-Willi syndrome have also been suggested in phonology (Van Borsal et al., 2006) as well as in vocabulary knowledge and decoding in the domain of reading (Dykens, Hodapp, Walsh, & Nash, 1992).

The differentiation among subgroups within Prader-Willi provides an opportunity to better understand the relation between aspects of the disorder and those of language abilities, although the evidence is mixed. For example, Dimitropoulos et al. (2013) reported that participants with maternal uniparental disomy (mUPD) genetic subtype of Prader-Willi syndrome only show higher expressive language abilities relative to their receptive abilities, whereas Lewis, Freebairn, Heeger, and Cassidy (2002) reported no differences in speech or language between individuals with Prader-Willi syndrome from either deletion or maternal uniparental disomy. If researchers are able to cobble together a more comprehensive literature on language processing among persons with Prader-Willi despite the difficulties, the subtle differences between subtypes may be essential to understanding the genetic mechanisms of intellectual disability in this population and their relationships to language abilities.

Language, Cognition, and Socialization

Although some language skills appear to develop independently of other cognitive abilities in some etiologies, the interdependence of language, cognition, and socialization is evident (Chapman & Kay-Raining Bird, 2012), albeit in different ways across groups. For example, Mervis (2012) notes that intact verbal working memory is important for grammatical comprehension among children with Williams syndrome, more so than for typically developing children. Among individuals with Down syndrome, Kay-Raining Bird and Chapman (2012) highlight the interdependence of language in literacy development, as vocabulary comprehension is reported to be the best predictor of their literacy skills (Kay-Raining Bird, Cleave, White, Pike, & Helmkay, 2008).

Syndrome-specific patterns in language development may also play a role in the acquisition of other higher order cognitive skills, such as executive functions. For example, Campbell et al. (2013) found that verbal development, independent of nonverbal development, predicted cognitive flexibility among persons with Down syndrome (Campbell et al., 2013), and Landry, Russo, Dawkins, Zelazo, & Burack (2012) found that it predicted working memory as well as cognitive flexibility among both persons with Down syndrome and those with Williams syndrome. This type of quest to understand the interrelatedness among skills across development exemplifies an essential task of the developmental approach, but is not sufficient. Rather, in addition to psychologically measurable intrinsic factors which impact the development of language, the complexity of genetic and environmental factors and their interplay must be considered in relation to the development of unique profiles of language, or any other type of, skills specific to the etiological groups. This was highlighted by Kay-Raining Bird and Chapman (2012) who describe how school, SES, and the home environment can affect the development of literacy skills among children with Down syndrome. For example, individuals with Down syndrome raised in a home environment display higher reading scores than those raised in an institution (Bochner, Outhred, & Pieterse, 2001; Carr, 2000), and those in integrated school settings and from higher SES backgrounds also display better literacy skills (Bochner et al., 2001; Sloper, Cunningham, Turner, & Knussen, 1990).

In delineating that genetics must also be considered when studying the relations among socialization, the environment, and language abilities, Abbeduto et al. (2012) reviewed evidence of links between language skills in fragile X and levels of FRMP, the protein produced by the FMR1 gene that plays a critical role in synapse maturation and functioning. Specifically, levels of FRMP are reported to be related to communication scores, verbal IQ, and story comprehension (Bailey, Hatton, Tassone, Skinner, & Taylor, 2001; Kuo, Reiss, Freund, & Huffman, 2002; Simon, Keenan, Pennington, Taylor, & Hagerman, 2001). Yet interactions with parents also affect the development of language skills in children with fragile X. For example, maternal responsivity is reported to be associated with communication in children with fragile X (Warren, Brady, Sterling, Fleming, & Marquis, 2010). Specifically, Warren et al. (2010) reported that level of maternal responsivity was related to the rate of total communication, receptive and expressive language development in 36-month-old infants with fragile X syndrome. These types of findings regarding the influence of parents underscore Abbeduto et al.'s call for an increased consideration of the complex role of genetics in language development. For example, mother carriers with the full or premutation of FMR1 gene may themselves experience cognitive deficits or affective disorders, which may inadvertently contribute detrimentally to their children's language development (Abbeduto et al., 2012).

The Impact of a Child With Intellectual Disability on the Family

Consistent with the notion of understanding the whole person, the study of aspects of development that are intrinsic to the individual need to be supplements with regard to the study of family relationships. At every moment, the unique development of the child influences the signals that he or she sends out to the world. Beginning with the simple characteristics in temperament, the child demands more or less attention from the caregiver, which may be easily accommodated or may stretch the limits of the caregiver. The caregiver then approaches the child with a positivity or negativity that is in part influenced by the child. For example, consistent with the notion that children with Down syndrome have the reputation of being easy babies, the caregivers of children with Down syndrome report lower levels of stress than caregivers of children with other diagnoses such as autism (Dabrowska & Pisula, 2010) and Prader-Willi syndrome (Lanfranchi & Vianello, 2012). This easier personality likely leads to more positive interactions with parents and siblings.

These findings highlight that, as with all persons, persons with intellectual disability both affect and are affected by the close relationships in their lives, such as those with family members. Clearly, having a child with intellectual disability can uniquely impact the well-being of parents, siblings, and the family as a whole. Just as obviously, different etiologies can be associated differentially with family well-being since differences in development and symptomology may exert different types of stressors on parents and may also affect the availably of certain resources or coping mechanisms. This effect is transactional, since the impact on parental, sibling, and family well-being continually shape parenting techniques and other factors which are, in turn, impacting the well-being of the child, all within the context of the larger, community, and society in which the child and family reside.

Negative Emotional Outcomes for Parents of Children With Intellectual Disability

Not surprisingly, having a child with intellectual disability can impose a negative emotional toll on parents. Depression has been the most common negative outcome studied in parents of children with intellectual disability (Glidden, 2012), which appears to diminish with time. High rates of parental depression are more often reported soon after the birth of a child with intellectual disability relative to years later during childhood and adolescence (Glidden & Jobe, 2006; Glidden & Schoolcraft, 2003; Keogh, Garnier, Bernheimer, & Gallimore, 2000; Singer, 2006). Anxiety, pessimism, and anger have also been reported (Glidden, 2012; Hall, Bobrow, & Marteau, 2000; Hodapp, Dykens, & Masino, 1997). These reactions are often in reaction to specific aspects of the child's specific condition. For example, increases in pessimism in parents are correlated with increases in maladaptive behavior in children with Smith-Magenis syndrome (Hodapp, Fidler, & Smith, 1998) and with Prader-Willi syndrome (Hodapp, Dykens, & Masino, 1997).

In addition to the negative emotional impact that having a child with intellectual disability has on the parents individually, it has also been reported to negatively affect the parental dyad (Glidden, 2012). Having a child with intellectual disability has been reported to slightly decrease marital adjustment (Risdal & Singer, 2004) and increase divorce rate (Reichman, Corman, & Noonan, 2004), although Hodapp (2007) reported a lower divorce rate for parents of children with Down syndrome relative to parents of typically developing children thereby indicating that the specific developmental profile of children with Down syndrome may uniquely protect against negative marital outcomes. Marital outcomes among parents of children with intellectual disability have been reported to be related to paternal involvement (Simmerman, Blancher, & Baker, 2001; Willoughby & Glidden, 1995), with more marital satisfaction reported in couples in which the father is involved in caring for the child (Willoughby & Glidden, 1995) or at least perceived by the mother as being involved (Simmerman, Blancher, & Baker, 2001). Coping style is also related to marital satisfaction among parents of children with intellectual disability. For example, the use of problem-focused coping by both parents in dealing with hassles has also been found to be related to higher marital adjustment (Stoneman & Gavidia-Payne, 2006).

Positive Outcomes for Parents of Children With Intellectual Disability

Despite the challenges often associated with raising a child with intellectual disability, many of the same positive life changes and emotions such as love, joy, and satisfaction that are experienced by parents of typically developing children are also reported anecdotally and in qualitative reports by parents of children with intellectual disability (see Hastings & Taunt, 2002). For example, Flahery and Glidden (2000) reported that lower levels of depression, positive marital adjustment, and increased family strength were found in both adoptive and non-adoptive parents of children with intellectual disability. In addition, mothers and fathers who felt optimism, contentment, and happiness

also had less stress and better family adjustment (Trute & Hiebert-Murphy, 2005).

Predictors of Parental Outcome

The stress of receiving a diagnosis is one factor often reported to elicit negative reactions and elicit symptoms of depression in parents soon after the birth of a child with intellectual disability (Glidden & Jobe, 2006, 2009; Glidden & Schoolcraft, 2003; Poehlmann, Clements, Abbeduto, & Farsad, 2005). Although this certainly can take an emotional toll, not receiving a specific diagnosis can be just as distressing for a family with a child who is not developing at the same rate as his/her peers (Glidden, 2012). A difference in the timing of when parents receive their child's diagnosis is thus one factor that has been reported to affect positive or negative outcomes depending on the etiology of the intellectual disability (Lenhard, Breitenback, Ebert, Schindelhauer-Deutscher, & Henn, 2005; Poehlmann et al., 2005). Specifically, parents report less anxiety, worry, and regret (Lenhard et al., 2005), and even relief (Poehlmann et al., 2005) when their children receive a diagnosis. Concordantly, Al-Yagon and Margalit (2012) highlight that early knowledge of a diagnosis was related to better parental adjustment among parents of children with Down syndrome. This is exemplified by findings that parents of children with Down syndrome generally show levels of anxiety, depression, and parental stress that are similar to those of parents of typically developing children (Hall, Bobrow, & Marteau, 2000), but not when they received a false negative diagnosis during prenatal screening (Hall & Marteau, 2003). In those situations, they display high levels of parenting stress, a negative attitude toward their child, and worse overall adjustment.

The type of coping mechanisms that are used and their availability to the parents also have been found to predict family well-being. Coping strategies that are focused more on problem solving and social support are related to more positive emotional outcomes than those using denial escape or avoidance of difficulties (Altshuler & Ruble, 1989; Levy-Shiff, Dimitrovsky, Shulman, & Har-Even, 1998; Reichman, Miller, Gordon, & Hendricks-Munoz, 2000). For example, mothers who use escape avoidance coping have been found to report higher levels of depression, whereas mothers who employ positive reappraisal report higher levels of subjective well-being (Glidden et al., 2006). Gender differences in coping styles have also been reported, as mothers tend to seek more emotional support whereas fathers seek more instrumental support and problem solving (Sullivan, 2002).

The children themselves, and especially their behaviors, impact considerably on parental well-being (Glidden 2012), as increases in child behavior problems are reported to contribute to more negative parental outcomes than the diagnosis of intellectual disability itself (Baker et al., 2002, 2003). Consistent with the findings that parents of children with Down syndrome experience a relative advantage as compared with parents of children with other etiologies, Al-Yagon and Margalit (2012) suggest that less severe behavior problems in children with Down syndrome may contribute to more positive outcomes for their families since less stress is associated with getting such behaviors under control.

Dyadic Interaction Between Mothers and Children With Intellectual Disability

One contributor to the parents' level of well-being that is affected by the child with intellectual disability is the parent–child dyad with that child. As with other aspects of social development and the family structure, the impact must be considered in relation to the relevant construct, task, and etiology (Hauser-Cram, Howell-Moneta, & Mercer-Young, 2012). In one example of an etiology-specific finding, Vaughn, Goldberg, Atkinson, Marcovitch, MacGregor, and Seifer (1994) found that young children with Down syndrome display an unclassified insecure attachment style relative to typically developing children who generally show a secure attachment to their mothers, as they are less reactive to their mothers and seek their mothers less for reassurance upon return. Esbensen et al. (2012) suggest that, in addition to deficits in cognitive functioning, the increase in the unclassified insecure attachment style among children with Down syndrome relative to typically developing children may be due to etiology-specific characteristics of Down syndrome that put strain on the mother–child relationship. Characteristics such as congenial heart defects, thyroid dysfunction and sleep problems, and ear infections can all limit the energy of children with Down syndrome and their ability to engage in sustained interactions with their mothers. Children with Williams syndrome display a similar attachment style as they show less intense facial and vocal distress when their parents leave the room and need less consoling upon being reunited with parents (Jones et al., 2000).

Mother–child interactions illustrate the etiology specific effects on parenting style. For example, parents of children with Williams syndrome were found to use more task directives than parents of children with Prader-Willi syndrome when playing with a puzzle, a style apparently adopted due to their childrens' poorer spatial skills (Ly &

Hodapp, 2005). In addition, the unique hypersocial personality style of children with Williams syndrome can be both beneficial and detrimental to the relationship (Jones et al., 2000). Accurate recognition of positive emotions creates a synergy of positive bi-directional affects in the dyad, although extensive interactions with others may diminish the child's interactions and relationship with their own mother (Järvinen-Pasley et al., 2008; Laing et al., 2002). With regard to Down syndrome, infants and toddlers appear to show less coordinated shared attention with their mothers as compared with typically developing children matched on MA (Legerstee & Fisher, 2008).

In keeping with Zigler's (1967; Zigler & Hodapp, 1986) argument for considering the ways that being a person with intellectual disability inevitably involves life experiences that affect the ways that people behave and perform in all aspects of their lives, the areas of social competence, language development, and family relationships are all essential to real lives lived. The simple cataloguing of the phenotypes as though the genotype is the only contributing factor to the eventual developmental path is clearly an erroneous strategy as features of different phenotypes present particular challenges for optimal functioning and relating within the context of the whole person in his or her family and environment.

NEUROSCIENCE AND THE DEVELOPMENTAL APPROACH: BENEFITS AND PITFALLS IN THE APPLICATION OF CUTTING-EDGE TECHNOLOGY

The advance of technology and the increase in the number of researchers who have access to cutting-edge tools like functional magnetic resonance imaging (fMRI), event-related potentials (ERPs), and magnetoencephalography (MEG) have led to a growing number of studies that involve mapping the relations between how an individual performs on a task and the brain regions that support that performance. The potential utility of these increasingly sophisticated and precise technologies along with the concomitant theoretical and methodological contributions of the field of neuroscience provide promise for yet a new stage in the development of the developmental approach to the study of persons with intellectual disability. Concordantly, as neuroscientists begin to delve into the study of intellectual disability, the history of the developmental approach can guide them in detecting theoretical and methodological landmines to avoid and directions of promise to pursue.

A Primer on What fMRI and ERP Measure

The study of brain function, which reflects modern techniques for linking behavior to brain, has generally involved either fMRI or ERP technology. Briefly, fMRI is based on the basic principle that any given region of the brain that is actively engaged in a task will draw more blood. This blood, rich in oxygen, is detected magnetically due to its iron content. fMRI is used to measure the so-called blood-oxygenated dependent level (BOLD) response, which serves as an indirect marker of neuronal activation during a cognitive operation. Namely, neural firing increases in a particular brain area as it is being engaged, which leads to both greater blood flow and release of oxygen to this area to satisfy local metabolic demands. By contrasting experimental conditions that differ only in the cognitive construct one is measuring or by comparing task based activations to rest, researchers can isolate the location of brain activity specific to a particular task or cognitive process. The major advantage of fMRI is that it has exquisite spatial resolution, allowing scientists to locate the specific areas of the brain that underlie task performance with millimeter precision. One of the disadvantages is that, because blood flow changes occur slowly, the temporal resolution of fMRI is on the order of seconds, which is much slower than the timing of brain processing in general, which is in the order of milliseconds.

In contrast to fMRI, event-related potentials (ERPs), offers the fine-grained temporal resolution researchers seek, but at the expense of spatial resolution. In order to relate brain activity to specific processes and behaviors, researchers isolate the continuous, ongoing electrical activity of the brain as measured by encephalography (EEG) into segments that are time-locked to a specific stimulus (Luck, 2005). ERPs display a stable time relationship to a discrete event (Luck, 2005). Because ERPs are small in size relative to other physiological events, many presentations of the evoking stimuli are necessary to average out the potentially unrelated events (Luck, 2005). For example, if a tone is played, the brain responds to that tone, but it also responds to other things that are present in the environment at that same time such as how a person is feeling, what they are looking at, and what they are thinking about. By time locking the physiological response to the presentation of the tone, and presenting the tone repeatedly, we can reduce the noise (the brain's response to things other than the tone) and extrapolate the brain's specific response to the tone itself (Luck, 2005). The brain's responses to a stimulus generate an ERP response that has specific peaks and troughs whose amplitude (height)

and latency (timing) can be compared either between conditions or between groups. The nomenclature of ERPs is based on the direction (positive or negative from 0) and time post stimulus onset, such that a P100 (or P1) represents a positive peak occurring 100ms post stimulus and an N170 represents a negative peak that occurs 170ms post stimulus. The meaning of each of these components have been isolated (with considerable disagreement) to reflect perceptual, attentional, or cognitive mechanisms and the stimulus factors to which they are sensitive.

An ERP represents only a sample of the electrical activity that is present in the brain when a specific event occurs (Luck, 2005). Since electrodes are located at the surface of the scalp, the activity of one single neuron is too small (and too far away) to record. Thus, ERPs are used to measure the integrated activity of many neurons that are recorded at the surface of the scalp. Specifically, neurons must have their dendritic trees oriented to one side (Coles, Gratton, Kramer & Miller, 1986) to be measured. ERPs are generally thought to reflect postsynaptic potentials (Luck, 2005) because these occur in the dendrites essentially instantaneously, while action potentials need to travel down the axon of a neuron (Coles et al., 1986; Luck, 2005). The advantage of this technique is that its temporal resolution is in the order of milliseconds, which reflects the speed with which our brain processes information. This allows researchers to examine different levels of processing such as perception and cognition by looking at early (first 250ms or so) and late (after 300ms) time frames of processing, which can reflect afferent (receiving input) or efferent (sending output) neural pathways. The disadvantage of ERPs is that because electrodes are placed at the surface of the scalp, which is far from the brain, the spatial resolution of ERPs is poor. Thus, fMRI is best suited to tell us *where* in the brain things happen, whereas ERPs allow us to know *when* things happen.

Neuroscience and the Developmental Approach: A Messy Meeting of Disciplines

The lessons learned from the developmental approach to intellectual disability which are particularly relevant to the emergence of the study of intellectual disability from a neuroscience perspective relate primarily to matching issues. One, comparing individuals with an intellectual disability to typically developing individuals who have normal cognitive function is problematic because it confounds general cognitive deficits with any specific skill or process being measured. Two, when matching on the basis of MA, the composition of the comparison group is particularly important and should be homogeneous (e.g., Down syndrome) as opposed to mixed (i.e., participants from different groups) such that (1) direct comparisons can be made between two groups that differ in only the cause of their intellectual disability, and (2) researchers can replicate findings by having similarly composed comparison groups. As will become evident from the review of studies that follow, these lessons, which form the basic tenets of the developmental approach to intellectual disability, are often ignored in studies of intellectual disability in which fMRI or ERP technology are used.

Generally, when reviewing studies on intellectual disability within the context of the developmental approach, papers in which the performance of individuals with intellectual disability are matched to the CAs of typically developing participants are discounted since performance differences are simply attributable to the a priori differences in level of functioning between the groups, reflecting the defect, rather than the developmental, approach. However, the notion of how best to apply the developmental approach to the study of brain processes still needs to be considered. For example, in the absence of a cognitively demanding task in which age-related differences would be expected, do we expect the neuroanatomical substrates (in the case of fMRI) or the neurophysiological components (in the case of ERPs) engaged or elicited by the presence of a stimulus to reflect physical or mental maturity? Would patterns of brain activation of a 12-year-old individual with Down syndrome whose MA is 6 resemble that of a 12-year-old or that of a 6-year-old, or somewhere in between? Does this vary as a function of the level of intellectual impairment? Is the answer to this question diagnosis-dependent? Task dependent? Answers to these questions will help to define and refine the reciprocal relationship, not only between typical and atypical development but also between developmental psychopathology and neuroscience.

Neuroscience and Intellectual Disability

As applied to the study of intellectual disability, the study of neurophysiology and neuroimaging are in their infancy. In applying the developmental approach to assessing the contributions of neuroscience (broadly speaking) research in the study of intellectual disability, we review all of the research studies that we could find in which functional magnetic resonance imaging or event-related potentials were the primary methodological tool. Consistent with the developmental approach, the discussion of these articles will be focused on both the main findings from these studies and how they contribute to our understanding of both

persons with intellectual disability and of typically developing persons, but also the implications of matching or non-matching practices for these findings and subsequently on advancing the field. Studies were selected for review according to the following course of action. An advanced PubMed search of the most common genetic disorders associated with intellectual disability—Down syndrome, Williams syndrome, fragile X, and Prader-Willi—was conducted with either the terms *event-related potentials* or *functional magnetic resonance imaging*. In addition, we looked through the reference sections of the articles generated through our original search and added additional relevant articles. This extended search yielded a total of 49 published research studies, 35 of which were studies that involved fMRI technology and 14 that involved ERPs as their main methodological tool. Abstracts of these studies were then read to exclude reviews and other non-empirical papers ($n = 6$), or papers that were irrelevant to perception, attention, and cognition very broadly defined (e.g., articles whose primary focus was on Alzheimer's disorder among persons with Down syndrome, or those looking at resting state fMRI were rejected; $n = 12$), or those for which full text articles could not be located ($n = 3$). This left a total of 28 articles that are reviewed here. The details of each study, including the chronological and mental ages of participants, and the matching strategies used by researchers are presented in Table 1.1, and are sorted as a function of etiology. Though the matching strategies used by researchers will be highlighted in the text, we refer the reader to the table for the specific participant and matching characteristics. Also included in the table are the relevant methodological factors, and the main research findings.

As the application of neuroscience techniques to the field of intellectual disability is nascent, we found little consistency in findings, or even in areas of study. The themes of sociability and food-related preferences represent the majority of areas of inquiry in the study of individuals with Williams and Prader-Willi syndromes respectively as these areas represent such consistent aspects of the phenotype for both of these disorders. However, no such consistency is to be noted across other areas of intellectual disability. Accordingly, few studies are replicated and no firm conclusions can be drawn regarding areas of strength or weakness or areas of the brain that are over or under active in response to specific types of stimuli. Although the main findings across studies will be reviewed, the main focus of this review is on the relationship between findings and the developmental approach to intellectual disability as it applies to neuroscience.

Matching in Neuroscience Studies. When reviewing the different studies, three broad matching classifications were used. The first category included studies with CA-matching alone. The majority of the studies ($n = 19$) fell under this umbrella of problematic methodology. The second category of studies ($n = 8$) involved the consideration of developmental level either directly with matching mental age or statistically by covarying IQ in the analyses. Finally, one study involved matching on a specific aspect of functioning (temperament) to assess the specificity of social approach among persons with Williams syndrome.

The publication of these papers in high-impact journals, despite the omission of any mention of such foundational issues in the developmental approach as the role of discrepant IQs or level of functioning, is particularly troubling. Conversely, many developmentalists are beginning to conduct research using cutting-edge technology without the necessary background training. As such, basic conventions in the ERP and fMRI literatures regarding methodology, such as compensating for multiple comparisons in fMRI and testing for assumptions underlying statistical tests such as sphericity in ERP data, which are common knowledge among basic neuroscientists in the field and essential to the acceptance for publication are often overlooked. One explanation is that due to the amount of effort required to develop meaningful tasks that can be completed by atypical populations and the difficulty involved in recruitment and testing, some of the methodological rigor of basic science papers gets overlooked (for information about basic considerations in fMRI research, see Bennett, Wolford, & Miller, 2009; Bennett, Baird, Miller, & Wolford, 2010; for considerations related to ERPs, see Picton et al., 2000). We review the available etiology-specific neuroscience-type studies within the context of the basic fundamentals of both the developmental approach and cutting-edge technologies.

Persons With Fragile X Syndrome. Due to the gender differences associated with the presence of an unaffected, protective X chromosome among females with fragile X syndrome, males and females are generally studied separately. Differences in their cognitive phenotypes are commonly associated with the lack of intellectual impairments noted among females with fragile X. We identified 10 neuroscience-based studies of fragile X, half of which involved fMRI to assess various aspects of functioning that included cognitive interference via the Stroop task, auditory discrimination, and emotional identification among females with fragile X, and the detection of eye gaze direction and inhibition using a go/no-go task among males, and

TABLE 1.1 Summary of Studies Using Neuroscience Tools Among Individuals With Developmental Disabilities

Citation	Diagnosis and comparison group (*N*, age, IQ)*	Matching*	EEG or fMRI	Stimuli and task	Findings (RT = Reaction time)
			Fragile X syndrome		
Watson et al. (2008)	FXS: *N* = 13. Age: M = 15.5, SD = 2.4. IQ: WISC III: M = 61, SD = 14.8. DD (developmental delay) group: *N* = 13. M = 16.1; SD = 3.3. IQ M = 62.4, SD = 9.4. TD: *N* = 13. Age: M = 15.0, SD = 2.5. IQ: M = 116.8, SD = 11.6.	CA matched to TD, IQ and CA matched to DD	fMRI	Color photos of faces with neutral expressions that were (1) forward facing with a direct gaze, (2) forward facing with averted gaze, (3) averted face with direct gaze, and (4) averted face with averted gaze. Button press for averted or direct gaze.	Aberrant neural processing during gaze perception and a lack of neural adaptation to successive gaze stimuli were found in the group with FXS. Functional brain correlates related to a decreased ability to adapt to direct eye gaze stimuli. Behavioral data: Task accuracy differed between the TD group and other groups (but not between the DD and FXS groups). FMRI Data: Within-group comparisons of the contrast DirectGz-AvertedGz revealed significant activation in distinct regions: (1) FXS group showed significant activation in the left anterior insula. (2) TD group in the right parahippocampal gyrus and the left medial frontal gyrus. (3) DD group in the right midfrontal and parahippocampal gyri. Whole-brain ANOVA for the DirectGz vs. AvertedGz contrast revealed a main effect of group in the right cingulate gyrus, right midfrontal gyrus, and left insula. ROI analyses: main effects of group in the left amygdala and in the right STG. FXS had significant sensitization in the left amygdala which correlated negatively with performance on successive trials in the FXS group.
Garrett et al. (2004)	FXS: *N* = 15 but 4 discarded; all female. Age: M = 16.4, SD = 4.09, Range= 10–22; IQ: (WISC III for children, WAIS II for adults); M = 93.7, SD = 10.4. TD: *N* = 15 all female. Age: M = 15.5, SD = 3.4, Range = 10–22. IQ: M = 107.0, SD = 11.2). TD group had higher full-scale IQ score than FXS.	IQ matched and gender	fMRI	Color photographs of faces in four categories: (1) face forward with direct gaze, (2) face forward with averted gaze, (3) face angled with direct gaze, (4) face angled with averted gaze. Task 1: Subjects pressed a button if the face in the photograph was looking at them or another button if the person was looking away from them. Task 2: Subjects were required to indicate direction of gaze for faces and to alternate pressing the first and second button in response to the scrambled pictures.	Results included 11 subjects in the FXS group and 11 subjects in the TD. (1) Task Accuracy: TD had greater accuracy (2) Full scale IQ: Scores were correlated with task accuracy for both groups combined but not within each of the groups. Subsequent between-group analyses were covaried for IQ, which also controlled for between-group differences in the task accuracy. (3) RT: No group differences. (4) Brain activation (direct-averted faces): No differences comparing forward faces with angled faces. Brain activation (direct-averted gaze)—Three clusters of greater activation were noted in the TD group including STS, lingual gyrus and cerebellum. Two clusters of greater activation were noted in FXS relative to TD group including the right insula and the cerebellum. Activation FG did not differ between FXS and TD. Interaction between group and hemisphere showed TD right > left FG activation to all stimuli.

Hall et al. (2009)	FXS: *N* = 10, females; Age: (M = 18.7 years, SD = 3.81 years). IQ (test not specified) M = 86.3, SD = 16.41). TD: *N* = 10, female; Age (M = 14.7 years, SD = 2.95 years). IQ (M = 110.2, SD = 10.84)	MA matched.	fMRI	Two tones (standard and comparison); determine by button press whether the comparison tone was longer or shorter than the standard tone. In control task the stimuli were of equal duration.	Accuracy and RT did not differ between the groups. Brain Activation: FXS activation was more diffuse and distributed over a large number of regions. No greater activation in TD compared with FXS. IQ and age—no correlation with activated brain regions; in FXS only the left pons showed a significant (positive) correlation with mental age. Percent correct correlated with activation in the cerebellum in the TD group, and performance was significantly correlated with activation in middle temporal gyrus in the FXS group. In the FXS group, no significant correlation with FMRP level.
Hagan et al. (2008)	FXS: *N* = 10, female. Age: M = 16.4, SD = 4.9, range = 9.7–24.0 years. IQ: (WISC-III for children, WAIS III for adults) M = 91, SD = 16.2, range 75–124; TD: *N* = 10, female. Age: M = 15.6, SD = 4.2, Range = 8.4–22.9; IQ: M = 106.1, SD = 15.7, range 79–128. No age differences; trend for FSIQ differences between groups.	CA matched.	fMRI	Color photographs: happy, sad, neutral and scrambled faces. Press the left button if the person in the photograph appeared happy, a middle button if the person appeared sad, and a right button if a neutral or scrambled face appeared.	Accuracy: FXS participants were less accurate at recognizing neutral and scrambled faces relative to TD. No differences in the identification of happy or sad faces. RT: no differences. No correlation for either group between RT and FSIQ. Brain activation: increased left hemisphere activation in left medial frontal gyrus and left superior and middle temporal gyrus, left cerebellum and left pons among participants with FXS relative to TD. Overall more activation in FXS than TD.
Hoeft et al. (2007)	FXS: *N* = 10, all male. Age: M = 15.4, SD = 2.7; IQ (WISC-III for children, WAIS III for adult): M = 59.2, SD = 9.8). Idiopathic (DD)- *N* = 10, male. Age: M = 14.6, SD = 2.7; IQ: M = 65.3, SD = 13.8. TD: *N* = 10, male. Age: M = 16.7, SD = 4.2; IQ: M = 125.6, SD = 11.5. The three groups were matched for age and race/ethnicity. IQ of TD > DD = FXS	FXS and DD matched on IQ; FXS, DD, TD were matched for age and race/ethnicity.	fMRI	Visual go/no-go task: Press the button to every letter except X which occurred 50% of the time; Control task—press a button to every letter but no x's were presented.	No RT differences. Accuracy: DD sig lower go% correct, and a lower no-go% correct and overall task performance than TD and FXS (post hoc). No accuracy difference between TD and FXS. Brain Activation- task performance in FXS was associated with left VLPFC, and not by right fronto-striatal region activation. Interactions between FMRP and right striatal dysfunction are associated with this putative compensatory left VLPFC activation in FXS. The extent of right fronto-striatal dysfunction in FXS is correlated with FMRP levels.
Tamm et al. (2002)	FXS: *N* = 14, female. IQ WISC-III or WAIS: M = 84.43, SD = 15.79; TD: *N* = 14, female IQ: M = 117.93, SD = 13.21; Child Behavior Checklist (CBCL) scores: TD had lower attention and thought problem subscale score. Participants ranged in age from 10–22 (M = 15.43, SD = 3.79). IQ higher in TD.	CA matched while IQ was controlled.	fMRI	Two kinds of Stimuli conditions: Neutral condition: the word *fish* was presented 1, 2, 3, or 4 times on the screen (15 trials). Interference condition: Subjects were presented the words *one*, *two*, *three*, and *four*, presented one, two, three, or four times on the screen (15 trials). TASK (Stroop): Press a button that corresponded to the number of words on the screen.	Behavioral results: FXS more affected by the interference condition (slower RT). Evidence that individuals with FXS sacrificed speed for accuracy, while the controls did not. Brain activation: Both groups recruited the prefrontal cortex (middle and inferior gyri) during the interference condition, for FXS this activation was bilateral, while controls' activation was primarily in the left hemisphere. Between-group comparisons indicated that FXS did not show greater activation than controls in any brain area.

(*continued*)

TABLE 1.1 (*Continued*)

Citation	Diagnosis and comparison group (*N*, age, IQ)*	Matching*	EEG or fMRI	Stimuli and task	Findings (RT = Reaction time)
Van der Molen et al. (2012)	FXS: *N* = 16 males, Age: M = 29.6, Range= 18–42 years; Raven Standard Progressive Matrices RAW SCORES: M = 19.88, SD = 8.15, Raven IQ was equivalent to an average mental age of 7.73 years (SD = 1.59). TD: *N* = 20 males, Age: M = 29.2, Range = 19–47; Raven Standard Progressive Matrices M = 55.65, SD = 3.76; Raven Standard Progressive Matrices Raw scores were sig. lower in FXS than TDs.	CA matched.	EEG	75 ms 1000 Hz and 1500 Hz sinusoidal tones with 5 ms rise and fall time, presented through headphones, at 80 dB SPL. The interstimulus interval was 1,000 ms. To counterbalance which tone was deviant/standard for each participant, half of the participants were presented with the 1000 Hz tone as standard and the 1500 Hz tone was deviant (and vice versa for the other half). Task: All participants watched a silent movie and were told that the auditory stimuli were irrelevant.	N1: amplitudes to standard tones were larger in FXS males than in controls but larger for deviant tones than standards for the comparison participants. N1 Habituation): In controls, amplitude of the N1 elicited by late standards was significantly smaller than the amplitude elicited by early standards (mean difference = −1.20 P2: amplitudes were significantly larger in FXS than in control group to both standard and deviant stimuli). P2 amplitudes were largest at Cz and smallest at Fz in controls and largest at Cz and Oz in FXS males.
Van der Molen et al. (2012)	FXS: *N* = 16 males, Age: M = 29.6, Range = 18–42 years, Raven Standard Progressive Matrices RAW SCORES: M = 19.9, SD = 8.2. IQ couldn't be calculated but performance was equivalent to an average mental age of 7.7 years (SD = 1.6), PPVT 3rd edition (average verbal mental age of 9.1 years, SD = 2.7. TD: *N* = 22 males. Age: M = 29.2, Range = 19–47, Raven Standard Progressive Matrices: M = 55.65, SD = 3.8; Raven IQ: M = 121.5, SD = 25.8). Raven Standard Progressive Matrices Raw scores were sig lower in FXS than TD.	CA matched.	EEG	Acoustic stimuli: 1000 Hz and 1500 Hz sinusoidal tones with a duration of 100 ms, including 5 ms rise and fall times. Visual stimuli: blue and yellow colored smiley faces that were viewed from 70 cm distance and presented on a black background in the center of a 17-inch laptop. TASK: A target (deviant) or a nontarget stimulus (standard) was presented for 100 ms (similar in both auditory and visual tasks). Participants were required to respond to the target stimulus (blue or yellow smiley face; 1,000 Hz or 1,500 Hz tone). Responses were registered within the 100–1200 ms response window after stimulus onset. Yellow smiley faces and 1000 Hz tones were used as target stimuli. Participants were instructed to responded as quickly and accurately as possible to the onset of a deviant stimulus by pressing a button on the computer.	Behavioral data: FXS males showed more false alarms, and were slower on both the visual and auditory tasks than controls. FXS males committed significantly more false alarms on the auditory than on the visual task suggesting that selective attention is more compromised in the auditory than in the visual modality in FXS. N1 auditory: N1 amplitude was larger for both stimuli in FXS males compared with controls; no group differences in P2 auditory amplitude were noted. N1 visual: peak amplitudes were maximal at Oz in control participants and at FCz in FXS males. N1 amplitudes were significantly larger in FXS males than in controls for both stimuli, but only at FCz. No differences in Visual P2 were noted between groups. Visual P3b: P3b component was larger in controls than in FXS males, in both auditory and visual modalities. For FXS males, the P3b component was significantly larger in the visual modality as compared with the auditory modality.
Castren et al. (2003)	FXS: *N* = 4 boys. Age: M = 11.6, SD = 2.8, Range = 7–13; and one 21 years old. TD- *N* = 4 boys, Age: M = 10.6, SD = 0.6	CA matched.	EEG	(1) Random stimulus sequence of tones consisting of 85% standard (800 Hz) and 15% of deviant (560 Hz) tones. (2) Trains of four identical standard tones. The recordings were performed while the children were watching a silent cartoon on a TV screen, and they did not attend to the tones.	(1) N1 amplitude is larger in children with FXS than in controls. (2) The first half of N2 component for controls is significantly more negative than that of FXS. (3) A significant difference between groups was present in the global-field-power waveforms implying differences in the total brain activity. (4) The topographic distribution of the N1: the N1 peak in children with FXS was well defined when compared with that of controls, maximum amplitude was located frontocentrally. The N1 scalp distribution in FXS patients was similar to controls, whereas the N2 in FXS was located more centrally than controls.

			Down syndrome		
Wetter et al. (1999)	DS: *N* = 20 Adults, Age: M = 26.0, SD = 10.0; IQ: M = 52.5, SD = 7.1; Dementia was assessed using the Dementia Rating Scale-DRS: M = 99.1, SD = 17.9. TD= *N* = 20, Age: M = 25.7, SD = 10.3. IQ was not administered to TD group	CA matched; Within group DS assessing relationship between olfactory ERP and dementia.	EEG	Olfactory stimuli (banana odor) were presented via an olfactometer. 2-alternative (odorant and blank), forced choice, ascending method of limits (increased concentration of banana odor) ERP measured at the Fz, Cz, Pz sites for 2000 ms (500 ms prestimulus and 1,500 ms post).	OERP components: the amplitudes and latencies of the OERP components N1, P2, N2, P3, and the interpeak amplitudes N1-N2, N1-P3 were analyzed. Latency: DS demonstrated delays in initial sensory processing. DS demonstrated longer latencies at all components compared with TD. In addition, N2 latency showed a significant effect of age ($F(1,37) = 6.64$, $P < 0.005$), with latencies increasing from adolescence to adulthood. OERP amplitude—not sig. Odor Threshold: DS group had higher thresholds (poorer sensitivity) than TD. Negative correlation between smell threshold and the latency of early OERP components (N1, P2 and N2). Dementia rating scale—negative correlation between DRS scores and P3 latency at all electrodes.
Yoder et al. (2006)	DS: *N* = 10 children (6 males). Age: M = 5.9, SD = 1.4, range 4.33–8.25 years. Nonverbal MA- Leiter-R age equivalency M = 3.5, SD = .8, Nonverbal IQ: M = 66.7, SD = 8.7, Grammatical morphology comprehension: M = 3.7, SD = 1.9; Percentile ranking on Grammatical Morphology subscale of the Test of Auditory Comprehension of Language-TACL-3 (M = 5%, SD = 4.6%) indicated that the sample was quite impaired as a whole (M = 5%, SD = 4.6%), with all but 1 participant falling below the 10th percentile. No control group.	DS split into two subgroups based on their performance on the TACL-3. Then DS was compared based on age, IQ and MA.	EEG	A passive task with three contrasts of consonant-vowel syllables were selected: (1) ga vs. da; (2) ga vs. ba; (3) da vs. na.	ERP difference waves to two consonant-vowel syllables were strongly associated with the degree of impairment in morphological comprehension. Results demonstrated a greater differentiation between event-related potential waves for the less impaired subgroup than the more impaired subgroup within the targeted latency range indicated by the temporal principal components analysis factor of interest. Age, IQ, and MA were nonsignificantly correlated with TACL-3.
Lalo et al. (2005)	DS: *N* = 20 Adults (10 males). Age: 18–31, M = 24.10 years, SD = 49 months. TD: *N* = 20 adults (10 males), Age 19–31; M = 25 years, SD = 44 months.	CA matched.	EEG	3 conditions: passive, simple—required to press a button on the armrest chair when detecting target tones and complex—required to aim with their dominant hand from the armrest at a target fixed on their chest when detecting target tones; presented as oddball.	(1) Passive condition: N1 and P2 components were reliably present in all participants. TD: infrequent stimuli usually triggered a MMN under the passive condition. In addition, a P3a component was elicited in about half of the participants, while a P3b was observed in 70%. In comparison, these three components were observed in only 10–25% and their latency tended to be longer in the DS group. (2) Active condition: TD- components N2b and P3b were usually seen under the active conditions, whereas in the DS group the N2b was often missing or delayed. The P3b was present in most participants with DS (55–65% compared with 75–85% in the TD group), albeit with a latency longer than the TD. RT = was shorter in TD than in DS. In addition, RT was significantly longer under the simple > active condition for the DS group only.

(*continued*)

TABLE 1.1 (*Continued*)

Citation	Diagnosis and comparison group (*N*, age, IQ)*	Matching*	EEG or fMRI	Stimuli and task	Findings (RT = Reaction time)
Jacola et al. (2011)	DS: *N* = 8, 5 female. Age: 18, SD = 3, Range =12–26. IQ: Stanford-Binet Intelligence Scale, 5th Edition (SB-V). Full scale IQ: M = 44, range = 40–50. Peabody Picture Vocabulary Test (PPVT-III): M = 57, range =40–83. TD: *N* = 12, 5 female. Age: M = 19, range = 12–26 years. SB-V full scale IQ, M = 106, range 88–124. PPVT-III: M = 107, range = 95–133.	CA matched.	fMRI	Experimental condition: press a button for pictures of farm animals. Control condition: Scrambled animal images were presented and participants pressed a button for each image.	Qualitatively and quantitatively different pattern of activation for DS in comparison age-matched TD. Increased activation in DS bilaterally for middle frontal gyrus and regions of the left parietal lobe. An overall reduction in spatial extent of neural activation and atypical patterns of activation were found in individuals with DS.
			Williams Syndrome		
Haas et al. (2009)	fMRI Study: *N* = 27, 13 TD, 5 males; 14 WS, 7 males. EEG Study: *n* = 70, 25 TD, 11males; 30 WS, 11males; 15 with developmental delay, 8 males. Both fMRI and EEG: 11 WS participated in both, 4 males. Age: M = 31.13, (SD = 7.55). Williams Syndrome: *N* = 33, 13 males. Age, M = 31.01 (SD = 8.80). Comparison Group 1(TD): *N* = 38, 18 males. Age, M = 29.71, SD = 9.52. IQ: M = 106 (SD = 11.8). Comparison Group 2 (idiopathic ID but not autism): *N* = 15, 8 male. Age: M = 28.07, SD =8.8; IQ: M = 62, SD = 8.8). WS and DD were matched on full-scale IQ (WS: M = 65, SD = 6.8, DD: M = 62, SD = 8.8).	CA matched to TD, IQ matched for DD. No significant between groups' ages or proportion of females to males.	Two separate studies, 1 fMRI and one EEG.	Color images of males and females with: happy, fearful, or neutral expressions. Participants identified if each face was male, female, or scrambled by button press.	Behavioral findings: Williams syndrome slower and less accurate compared with age-matched participants but equal to MA matched participants. fMRI and EEG findings: participants with Williams syndrome exhibited heightened amygdala and cortical responses to happy/neutral. WS—exhibited greater right amygdala in happy condition compared with neutral condition. TD—did not exhibit greater left or right amygdala activation to happy condition compared with neutral condition than the WS group. WS exhibited significantly greater right amygdala reactivity to happy compared with neutral. TD: No significant left or right amygdala activation in response to happy compared with neutral was observed. Fearful/neutral group differences: TD exhibited greater right amygdala activation than WS. TD exhibited greater right amygdala reactivity to fearful compared with scrambled faces (nonsocial) at the corrected statistical threshold. There was no significant difference in amygdala reactivity to neutral relative to scrambled faces between the WS and TD groups. *Amygdala with IQ, RT and accuracy:* (1) IQ as a covariate with BOLD signal extracted from the right amygdala yielded no significant correlations between IQ and amygdala activity either in response to happy ($p = 0.57$) or fearful ($p = 0.48$) facial expressions within the WS group. (2) RT and accuracy as covariates with BOLD signal extracted from the right amygdala yielded no significant correlations

					between either RT or accuracy and activity either in response to happy or fearful facial expressions within the WS group. ERP happy condition: P300–500-condition × group interaction indicated that the P300–500 response to happy versus neutral facial expressions was significantly different between the three groups. Happy minus neutral facial expressions was larger for the WS than for the TD group and the DD group (but did not differ between the TD and DD groups). ERP fearful condition: P500–700-condition × group interaction indicated that the N200 to fearful versus neutral facial expressions was significantly different between groups in mean amplitude. No condition × group effects for peak latency. Between-group comparisons showed that the N200 difference wave to fearful minus neutral facial expressions tended to be greater (more negative) for the WS than for the TD group over the left hemisphere and was greater (more negative) for WS than for the DD group. In contrast, the effect was smaller (more positive) for the DD than for the TD group. TD group: The N200 did not differ in mean amplitude to fearful versus neutral expressions or peak latency. DD showed increased N200 amplitudes to fearful relative to neutral faces.
Hass et al. (2010)	WS: $N = 12$ Adults (8 Female, 4 Male) Age: M = 29.46, SD = 8.07, Range = 18.03–43.58	No comparison group.	fMRI	Colored pictures of headshots of young adults displaying fearful, happy or neutral expressions and scrambled images. Stimuli presented using an event-related design with the four experimental conditions and a resting baseline. Subjects were instructed to judge if each face was either male or female or scrambled by responding with their index finger.	(1) Behavioral data: Mean RT: 981.46 ms and accuracy rates- 72.16%. No condition differences (fearful, happy, neutral and scrambled) in RT($F = .47$, $P = .70$) or accuracy ($F = .08$, $P = .97$). In addition, no relations between either RT or accuracy and the sociability measures were found. (2) Indiscriminate sociability and amygdala response to facial expression: Social approach scores were regressed against amygdala response to facial (fearful, happy and neutral combined) expressions compared with scrambled images. No significant positive or negative relationships between social approach scores and either left (group averaged ROI: R2 = .33, $p = .40$; standardized ROI: R2 = .27, $p = .30$) or right (group averaged ROI: R2 = .11, $p = .70$; standardized ROI: R2 = .04, $p = .61$) amygdala response to facial expressions compared with scrambled images, even when age, sex, and handedness were entered as covariates. Furthermore, no significant relationships were observed between social approach scores and either hippocampus and parahippocampal gyrus response to facial expressions.

(*continued*)

TABLE 1.1 (*Continued*)

Citation	Diagnosis and comparison group (*N*, age, IQ)*	Matching*	EEG or fMRI	Stimuli and task	Findings (RT = Reaction time)
Thornton-Wells et al. (2011)	WS: *N* = 10, 6 females. Age: M = 21.8, SD = 1.0 IQ: Kaufmann Brief Intelligence Test-2: M = 79.20, SD = 17.84; 2 control groups of TD: selected cutoff scores (inhibited (IT) ≥ 2.6, uninhibited (UT) ≤ 1.9) Temperament (IT)-*N* = 10, 6 females. Age: M = 24.3, SD = 1.93 IQ: Kaufmann Brief Intelligence Test-2: M = 117.30, SD = 13.49. 2-Uninhibited Temperament (UT)-*N* = 10, 6 females. Age: M = 24.5, SD = 1.98; IQ: M = 108.33, SD = 9.03.	TD from each temperament group, based on the traits of IT and UT were matched on gender to WS group.	fMRI	Social and nonsocial images across three emotions (happy, fear and neutral) in a passive viewing task.	WS-IT: Fear nonsocial images: WS > IT controls in left amygdala relative to the IT control group even in relation to neutral expressions. No differences for other comparisons WS (neutral and happy nonsocial images). WS-UT: when viewing social images (faces). Larger left amygdala responses in WS group for neutral social images, compared with the UT control group. When comparing the happy faces to the neutral faces, the UT group had significantly greater left amygdala response than the WS group.
Golarai et al. (2010)	WS: *N* = 13, Age: M = 29.9, SD = 2.6,TD: *N* = 13, Age: M = 30.0, SD = 2.3. IQ (WAIS-R or WAIS-III) WS: performance IQ: M = 71.08, SD = 2.3, Verbal IQ: M = 64.92, SD = 2.5: FSIQ: M = 66.3, SD = 2.6. TD: performance IQ: M = 117.9, SD = 3.5, Verbal IQ: M = 115.6, SD = 4.6; FSIQ: M = 119.0, SD = 4.2. Benton recognition test on upright face: WS: *N* = 13; M = 20.8, SD = 0.7. TD: *N* = 9 of 13; M = 22.63, SD = 1.05.	CA matched and matched Benton face recognition scores.	fMRI	Passive viewing of grayscale images of faces (male, female, various ages, races, expressions and views), objects (abstract sculptures), places (indoor and outdoor), textures (created by randomly scrambling object pictures into 225, 8 x 8, pixel squares).	(1) Average rFFA (right Fusiform Gyrus) volume was two times larger and left FFA volume was 2.5 times larger among WS than TD. The proportional volume of the FFA relative to the anatomical volume of the FUS (fusiform) gray matter was also significantly higher in WS than in TD even when matched on total volume. (2) Variation in the absolute volume of the FFA within each group did not correlate with the anatomical volume of the FFA, gray matter content, or subjects IQ or age.
Mimura et al. (2010)	WS: *N* = 7, all females. Age: M = 34.0, SD = 12.17, All were ELN negative on chromosome 15 by FISH. All exhibited the medical or clinical features of the WS phenotype including cognitive, behavioral, and physical profiles. IQ Wechsler Adult Intelligence Scale third edition (FSIQ: M = 68, SD = 8.7; VIQ: M = 74, SD = 8.7; PIQ: M = 65, SD = 8.8). TD: *N* = 7, all females. Ages (M = 35.7, SD = 11.1). IQ: FSIQ: M = 115SD = 12.0; VIQ: M = 112, SD = 14.5; PIQ: M = 114, SD = 8.2.	CA matched.	fMRI	(1) Match Affect Paradigm (MAP): consisted of 90 achromatic face stimuli presented in an event-related FMRI paradigm: Two faces were presented that were either congruent for negative or positive affect or incongruent. Participants determined whether the faces matched or not. (2) Control task: Subjects matched gender (male, female) of neutral faces rather than emotions.	(1) Behavioral performance: No difference in accuracy between WS and TD when controlling for FSIQ. (2) Brain Imaging: (a) WS < TD for negative compared with positive valance face stimuli in both right amygdala and right lateral OFC but WS > TD for right medial OFC for negative compared with positive emotional face stimuli. (b) Medial OFC, WS to TD showed significantly reduced activation to negative face stimuli relative to positive stimuli and greater activation to negative stimuli. (c) No correlations between IQ and whole brain activation for either group; significant positive correlation between right lateral OFC activation and IQ for the positive vs. negative valance contrast in the WS group. (d) Control gender matching task showed nonsignificant effects in all these regions and analysis.

Mobbs et al. (2007)	WS: *N* = 10, 8 females. Ages: M = 31.10, SD = 9.7, Range = 15.5–48.4), IQ: VIQ: M = 71.6, SD = 7.6; PIQ: M = 65.6, SD = 8.1; FSIQ: M = 67.3, SD = 7.5. TD: *N* = 8, 7 females. Ages: M = 35.2, SD = 10.10, Range = 24.0–54.7. IQ: VIQ: M = 113.5, SD = 14.7; PIQ: M = 111.2, SD = 8.1; FSIQ: M = 114.2, SD = 9.8	CA matched.	fMRI	A nonverbal global processing task was used: (1) 72 experimental stimuli were either a large concentric triangle or square consisting of smaller triangles or squares; (2) 72 control stimuli consisted of a large, single-lined triangle or square of the same dimensions.	There were significant IQ differences between the groups. WS were less accurate but not slower than TD. No correlation between IQ and global task RT or accuracy. FMRI: between group analysis—greater activation in WS than TD in right MFd. significantly increased activation in WS was seen in hippocampus and parahippocampal gyrus, right lateral geniculate, insula, thalamus, superior temporal gyrus, middle temporal gyrus, orbital frontal cortex, middle frontal gyrus and medial aspects of the precuneus. No significant correlation was found between activation and either IQ or performance accuracy in WS.
Key and Dykens (2011)	WS: *N* = 21, 12 males. Age: M = 26.24, SD = 8.26. IQ: Kaufmann Brief Intelligence Test-2 = M = 74.25, SD = 17.19; TD: *N* = 16, 7 males. Age: M = 29.64, SD = 11.77. IQ scores for TD participants assumed to be in the normal range but not tested.	CA matched.	EEG	Oddball paradigm with letter stimuli that could appear as a global form (big letter) or a local element (small letter) but never in same trial. Participants responded yes/no regarding the presence of a target (H) that could occur at either the global (20% probability) or the local level (20% probability).	RT: TD showed global targets associated with shorter RT than standard stimuli or local targets and no RT differences between local targets and standard stimuli. However, WS RT data failed to identify any differences among the conditions. Accuracy rates for TD across all three conditions were near perfect. WS detected global targets more accurately than local targets. ERP: TD: trend for reduced P1 amplitude P1 amplitude for global targets compared with standard stimuli). WS: relative to the standard stimuli, global targets elicited a smaller P1 peak with shorter latency. TD condition differences were present for the centro-parietal P3b amplitude while WS showed no significant effects for the centro-parietal P3b amplitude.
Levitin et al. (2003)	WS: *N* = 5, 2 males. Age: M = 28.8, SD = 14.6; IQ = M = 63.0, SD = 17.2. TD: no information provided	Age, handedness, gender, and musical experience matched depending on what they measured.	fMRI	Passive listening of noise, music, and silence.	TD: consistent bilateral activation in the superior temporal gyrus and middle temporal gyrus which were not present in WS. WS activations were more widespread and diffuse, recruiting regions in the amygdala and cerebellum. Both groups displayed bilateral temporal lobe activation for music compared with noise and rest. However, these activations were decreased for WS than TD.
Paul et al. (2009)	WS: *N* = 17, 10 females. Age: M =30.6 years. IQ: Wechsler: Full Scale IQ M = 67.5, SD = 11.3 range 47–82. Verbal IQ M = 72.8, SD = 7.8, range 59–89. Performance IQ: M =64.4, SD = 10.3, range 44–83. Peabody Picture Vocabulary Test age equivalents: M = 12.6, SD = 4.5, range 5.8–22. Visuomotor Integration (VMI) Nonverbal: Figure Drawing Age Equivalent: M = 5.69, SD = 1.6, range 4.1–11.3. TD (CA matched group): *N* = 17. Age: M = 31.0, SD = 11.2. TD: MA-matched: *N* = 17, 9 females. Age: M = 8.8, SD = 0.7.	CA and MA (two different comparison groups).	fMRI	Visual matching of facial identity of black and white photographs appearing in one to 12 possible positions. Two faces sequentially, followed by a delay 500 or 1750 ms delay. A 3rd face appeared and participants indicated whether the test stimulus matched either of the two reference stimuli by hitting the yes or no button.	Behavioral Findings: WS slower and less accurate that CA but not MA comparison participants. Functional neuroimaging: FMRI responses were generally similar in WS participants and MA controls with both groups displaying less robust activations than CA controls. Amygdala response in WS participants showed no activation in contrast to both CA and MA comparison participants.

the other half involved ERPs or MEGs to assess basic auditory processing. Although there is very little overlap with respect to tasks across studies, both the Stroop task and the go/no-go tasks can be considered measures of executive function (specifically inhibition), while the emotion identification task in females and the eye-gaze direction detection task in males with fragile X can be considered as assessing the social-cognitive correlates of the disorder. The auditory ERP studies allow researchers to assess the integrity of the auditory pathway as well as the ability of individuals with fragile X to habituate to sounds and respond to auditory novelty. These three areas are all considered to be fundamentally impaired in the phenotypes of both males and females with fragile X syndrome (e.g., Hagerman, 1996; Turkstra, Abbeduto, Meulenbroek, 2014).

Auditory Processing Assessed by ERP and fMRI Individuals with fragile X demonstrate sensory difficulties, and specifically auditory hypersensitivity, as measured by parent report. These behavioral findings have been partially substantiated by both MEG (Rojas, Benkers, Rogers, Teale, Reite, & Hagerman, 2001) and ERP studies (for a recent review of electrophysiological findings among individuals with fragile X syndrome in which developmental level is considered in the interpretation of findings, see Knoth & Lippé, 2012). Findings are consistent for certain ERP components which include an overall increased amplitude of the N100, an automatic component elicited by the onset of a sound (Castren, Paakkonen, Tarkka, Ryynanen, & Partanen, 2003; St Clair, Blackwood, Oliver, & Dickens, 1987; Rojas et al., 2001; Van der Molen, Van der Molen, Ridderinkhof, Hamel, Curfs, & Ramakers, 2012, 2012), albeit with findings of decreased habituation of the N100 (Castren et al., 2003; Van der Molen et al., 2012) in relation to chronologically age-matched participants. In addition, a consistent attenuation of the P300, which indexes attention and/or orientation to novelty, has been noted in relation to typically developing CA-matched comparison participants (St Clair et al., 1987; Van der Molen et al., 2012, 2012) but not in relation to MA-matched individuals with Down syndrome (St Clair et al., 1987), indicating that the physiological responses of individuals with fragile X are of similar amplitude to those of individuals of a similar MA. These findings suggest that individuals with fragile X overrespond to sound, and do not habituate (decrease in response to the repeated presentation of a sound) to auditory stimuli in the same manner as typically developing individuals, although the P300 findings of differences relative to CA- but not MA-matched participants highlight that matching strategies need to be considered in all interpretations and conclusions.

In addition to findings of consistent atypicality in early physiological responses to auditory stimulation, inconsistent findings are noted for other ERP components, including the P2, a physiological response that is greater for infrequent simple targets than frequent targets or frequent distractors, and the N2, which is greater for attended versus unattended stimuli and can index the detection of novelty, stimulus identification, or shifts in attention. St Clair et al. (1987) found increases in P2 but no difference in N2 in relation to typically developing comparison participants using a passive oddball task in which the participants watched a silent movie while two different sounds (one, the frequent, occurring on 80% of the trials and the other, the oddball, occurring on 20% of the trials) were played in the background. In contrast, Van der Molen et al. (2012) found an increased P2 and an increased N2 using a similar passive task. In a subsequent study, Van der Molen et al. (2012) required participants to actively detect oddball targets, and found no P2 differences but an increased N2 in relation to CA-matched typically developing comparison participants. These findings suggest that processing differences depend on whether participants are actively engaged in an experiment or passively listening, which may or may not be related to MA. The implications of these studies are diminished by small groups and the use of CA matching (with the exception of St Clair et al., 1987, who compared individuals with fragile X to both CA-matched typically developing peers as well as MA-matched peers with Down syndrome).

In the only MEG study conducted with participants with fragile X, the participants watched a silent movie while pure tones were played, thereby allowing for the assessment of basic auditory processing (Rojas et al., 2001). (Briefly, MEG is a technique that combines some of the temporal resolution of ERPs with the some of the spatial resolution of fMRI.) Rojas et al. compared 11 participants with fragile X (six female, five male) to typically developing peers matched on CA and reported an increased amplitude of the mN100 component, the MEG analogue of the auditory N1 in EEG studies, among the participants with fragile X, suggesting greater neuronal activation in response to sounds. However, these findings need to be qualified due to the differences in developmental level between the groups, as the IQs of the typically developing comparison participants were more than double that of the participants with fragile X, and well above the average range. Given these vast differences in IQ between the groups and the notion that CA affects the amplitude of ERP responses (Gomes et al., 2001), we need

to consider whether the amplitude differences between the groups might reflect meaningful phenotypic differences or are a confound arising from the significant differences in developmental level of functioning (i.e., MA) between the groups. Also given the IQ differences between males and females with fragile X, whose ERPs were averaged together into one group, gender differences may have confounded the findings. If MA affects the magnitude of ERPs, then averaging females with high MA (and their characteristic ERPs) with males with low MA (and their characteristic ERPs) may have led to an average ERP response that is characteristic of neither the males nor the females in the sample. Accordingly, the group-level analyses comparing typically developing and fragile X groups may not reflect any meaningful differences.

In spite of these major caveats, other evidence has also supported the notion that auditory processing in fragile X is atypical. For example, Castrèn, Paakkonen, Tarkka, Ryynanen, and Partanen (2003) found higher N100 amplitudes using a similar passive paradigm and ERPs among a small sample of children with fragile X compared with CA-matched typically developing children, providing further support for the notion that basic auditory processing appears to be atypical among individuals with fragile X. However, these findings must be considered in light of the difference in level of functioning between the participants with fragile X and the typically developing participants and very small group sizes. Nonetheless, ERP and MEG findings of basic auditory processing in fragile X are consistent with those of the FMR1 knockout mouse, an animal model of the disorder, which also suggest auditory hypersensitivity. In addition, the knockout mouse also shows deficits in cerebellar learning that are temporally sensitive, a key factor in auditory processing (Chen & Toth, 2001).

Based on these links between ERP findings of basic auditory differences and mouse models of fragile X, Hall, Walter, Sherman, Hoeft, and Reiss (2009) sought to assess the ability of females with fragile X and MA-matched typically developing female participants to make auditory temporal discriminations and measured the relationship between this ability and activations in sensory areas using fMRI. Although no differences in behavioral performance as measured by response time and accuracy were noted between the participant groups in their ability to assess whether a comparison tone was longer or shorter than a standard tone, fMRI activations differed between the groups.

The activation differences were compared by subtracting activations to the task condition described above with a control condition in which the participants were asked to respond to a button press after the presentation of two identical tones. Hall et al. (2009) noted that these two conditions were identical in every way, except that in the control condition the participants did not have to make temporal discriminations (the tones were always of equal duration, though participants were not told this). The primary finding was that subtracting activations between the discrimination and control tasks yielded more diffuse areas of activation in frontal, temporal and limbic regions for the participants with fragile X, whereas for the typically developing participants, the subtraction led to focal activations in parietal and occipital regions. This latter finding is somewhat surprising as Hall et al. were trying to isolate an auditory temporal discrimination but report activations in both the parietal lobe which is related to tactile processing, number knowledge, and multisensory integrations and in the occipital lobe which houses the visual regions, neither of which should have been involved in the task processing. Direct group comparisons yielded increased left hemisphere activations for the participants with fragile X in the frontal (left medial frontal gyrus) and temporal (left superior and middle temporal gyrus, left cerebellum and left pons) regions. No areas of the brain were more active among the typically developing than among the participants with fragile X, suggesting that the participants with fragile X used more processing resources than the typically developing participants. Hall et al. examined the associations among IQ, age, and activation levels and noted that their findings could not be attributed to these potentially confounding variables because the correlations among age, IQ, and activated cortical and subcortical regions were not significant.

Hall et al. (2009) also found that task performance correlated with cerebellar activations in the typically developing group but with middle temporal gyrus for the fragile X women, and that contrast values of the significantly activated brain regions did not correlate with levels of FMRP among the females with fragile X. These findings suggest differences in activation patterns on this simple task despite similar behavioral performance, and that these differences were related neither to IQ, age, nor the severity of fragile X, as genetically defined. However, the lack of significant correlations could also be due to a restricted range in these variables, the small sample size, or the lack of correction for multiple comparisons in their fMRI results, a problem which plagues fMRI research and which some authors suggest will always lead to increases in false positive discovery rates and subsequent difficulties in interpreting findings (see Bennett, Wolford, & Miller, 2009; Poldrack, 2012).

Overall, simple temporal discrimination abilities among females with fragile X syndrome appear commensurate with MA, although task performance seems supported by different brain regions, which could reflect either increased mental effort or some sort of compensatory processing.

Gaze Processing as Assessed by fMRI Garrett, Menon, MacKenzie and Reiss (2004) and Watson, Hoeft, Garrett, Hall and Reiss (2008) conducted similar studies of gaze processing among females and males with fragile X, respectively. Gaze avoidance is a hallmark symptom of fragile X even in the absence of a comorbid diagnosis of ASD, and generally occurs across both males and females with the disorder. Both studies involved similar stimuli, task, and methods in which participants were presented with pictures of faces (angled or forward facing) whose gaze was either direct or averted. The participants responded by button press as to whether the face was looking at them or away from them. Garrett et al. compared females with fragile X with IQs in the average range to typically developing females matched on age. However, despite the attempt to include only females with fragile X with average IQs, the IQs of the typically developing comparison participants were significantly higher than those of the fragile X participants. In a different approach, Watson et al. compared boys with fragile X to both typically developing children of the same CA and individuals with a developmental delay (DD; group composition not mentioned but specified as not autistic) matched on the basis of both age and IQ. With respect to task performance (RT and accuracy), the typically developing groups in both studies performed better than the individuals with fragile X. The boys did not differ in performance from the IQ matched group of DD participants, but the importance of this finding is negligible due to the problems in methodology and interpretation associated with the use of mixed etiological comparison groups. A significant correlation between IQ and task performance was noted for females, but not for males when compared with participants of equivalent MAs. That is, both males and females with fragile X appear to display a relationship between performance and developmental level. In neither study were RT differences found across the groups.

Group differences in the processing of direct versus averted gaze between individuals with fragile X and their respective comparison participants were noted in both the Garrett et al. (2004) and Watson et al. (2008) studies. Activations were similar between the participants with developmental delays and the typically developing participants, but activation patterns differed across studies with the exception of the superior temporal sulcus (STS), which showed greater activation in the typically developing groups as compared with the fragile X boys (Watson, 2008) and girls (Garrett, 2004). The finding of completely different activation patterns, even among the typically developing participants, is puzzling as essentially identical tasks yielded very different findings. The most we can conclude from these fMRI findings is that individuals with fragile X showed a relatively consistent decrease in activation in the STS, an area generally associated with the perception of other's gaze (Campbell, Heywood, Cowey, Regard, & Landis, 1990) and biological motion (Grossman & Blake, 2002).

Overall, the findings from the neuroscience studies of individuals with fragile X suggest both that auditory processing appears atypical in relation to CA-matched participants but not in relation to MA-matched participants (at least for the P300) and that gaze processing appears atypical in fragile X in relation to both CA- and MA-matched comparison participants. MA among persons with fragile X was, as expected, consistently linked to behavioral performance, but less so in relation to brain activations related to behavioral tasks.

Persons with Down Syndrome.

Simple Sensory Processing in Down Syndrome Using ERPs Many ERP studies of participants with Down syndrome have involved no-task paradigms in which participants just passively listen to sounds or view pictures while brain activity is recorded. This allows for the assessment of basic sensory function and is generally used to assess afferent (bottom-up) rather than efferent (top-down) pathways without requiring participants to complete an experimental task. The advantage of these studies is that they can be conducted in lower functioning individuals and are not tied to cognitive functioning. The disadvantage, of course, is that they are not informative about cognitive, or any other aspect of, functioning. Briefly, evidence from passive studies of auditory and visual functioning suggests that basic auditory processing of tones among individuals with Down syndrome is atypical, with reports of longer N1 latencies and higher P2 amplitudes in infants relative to CA-matched typically developing infants (Barnett & Lodge, 1967; Seidl, Hauser, Bernert, Marx, Freilinger, & Lubec, 1997), as well as an attenuated habituation to visual stimuli in frontal regions (but habituation was observed in other regions as well as behaviorally; Karrer, Karrer, Bloom Chaney, & Davis, 1998; Karrer, Wojtascek, & Davis, 1995). These findings appear to be consistent across childhood with findings of an attenutated P3 response during repeated auditory stimulation.

In addition to the studies involving responses to simple tones, Yoder, Camarata, Camarata, and Williams (2006) assessed the relationship between standardized measures of grammatical morphology and ERP responses to different consonant-vowel syllable pairs among individuals with Down syndrome. They divided a group of participants with Down syndrome into high and low grammatical morphology skill sub-groups (although the majority of participants fell below the 10th percentile) and found increased differentiation between syllables in the ERP waveforms among participants in the less-impaired group than among those who were more impaired, suggesting a relationship between grammatical abilities and brain responses. These findings suggest that increased mental effort is required for individuals with Down syndrome in the processing of basic sounds relative to their same-aged peers; that this finding is sustained over age, and that grammatical skills can reliably be differentiated among persons with Down syndrome using ERP technology. No studies of passive processing involved MA matching strategies and so, again, the meaningfulness of these findings are difficult to evaluate.

To assess whether the need to prepare a motor response influences the speed of perceptual auditory processing among individuals with Down syndrome, Lalo, Vercueil, Bougerol, Jouk, and Debu (2005) examined auditory processing and its relationship to movement complexity among adults with Down syndrome and CA-matched typically developing comparison participants. They used passive, simple active (button press responses) and complex active (motor movement to a spot on their chest) versions of an auditory oddball task. Lalo et al. noted RT differences between the groups as the responses under the simple task conditions were longer than the complex task condition among the participants with Down syndrome, but did not differ among the typically developing participants. Auditory N1 latencies were longer and auditory P2 responses were larger for the participants with Down syndrome than for the comparison participants when comparing simple versus complex tasks (with the passive task serving as the baseline). Inconsistent with Lalo et al.'s hypotheses, motor complexity did not appear to affect the ERPs for either group of participants. In addition, the identifiable ERP peaks were noted less reliably overall (for peaks such as the MMN, N2b, and P3b) for the adults with Down syndrome in relation to the typically developing participants, suggesting that the reliability of even simple sensory processing peaks might fundamentally differ between persons with Down syndrome and typically developing people of the same chronological age. The lack of reliable ERP peaks in this population suggests either a fundamental alteration of processing or could be related to the young mental ages of the participants, as the MMN continues to develop through middle childhood and adolescence (Bishop, Hardiman, & Barry, 2011), as do auditory ERPs more generally (Bishop, Anderson, Reid, & Fox, 2011). Furthermore, the lateralization of ERP components also changes with age, with auditory ERPs become more visible in central scalp locations with increasing age. Since Bishop et al. only recorded ERPs at midline central locations (Cz and Pz), their findings may be related to differences in the location of ERPs among individuals with Down syndrome whose cognitive abilities are less mature than among typically developing participants and whose ERPs would perhaps be larger at lateral electrodes than at central scalp location.

In the one study of olfactory ERPs among adults with Down syndrome in relation to CA-matched comparison participants, Wetter and Murphy (1999) found that individuals with Down syndrome had lower olfactory thresholds (poorer sensitivity to smell), as well as longer latencies to process smell in relation to typically developing participants. For both groups, detection threshold and ERP latency were correlated, and specifically in the group of participants with Down syndrome, higher ratings of dementia were related to longer latencies of the P3b component, suggesting that individuals with Down syndrome who had poorer cognitive functioning had a slower brain response to smell. Overall, sensory processing (visual, auditory and olfactory) appears to be more effortful for individuals with Down syndrome than CA-matched typically developing comparison participants.

Higher Order Processing Among Persons With Down Syndrome Despite the numerous studies of resting state fMRI, which provide information about brain anatomy and the brain's functional organization in the absence of task demands, we only found one fMRI study in which participants actively listened to speech and one in which individuals with Down syndrome completed some sort of experimental task that relates to cognition. Losin, Rivera, O'Hare, Sowell, and Pinter (2009) assessed brain activation patterns using fMRI while participants with Down syndrome and age-matched typically developing adolescent participants rested (control condition), or passively listened to speech presented forward and backward. The contrast of interest was between forward and backward speech, which would allow researchers to isolate the language-specific aspects of receptive language. The main finding was a significant difference in brain activations between forward and backward speech among the typically developing participants (temporal

language regions), but not for the participants with Down syndrome, suggesting that the latter group did not process the linguistic elements of the task.

In contrast to the passive listening approach of the previous study, Jacola et al. (2011) compared brain activations of adolescents and adults with Down syndrome and CA-matched typically developing participants while the participants completed a basic categorization task in which they were presented with pictures of animals one at a time and were asked to respond by button press to farm animals. Jacola et al. compared activations elicited by the categorization task to a control condition in which the participants pressed a button in response to the appearance of a scrambled image (simple detection) to isolate visual object recognition and semantic classification regions of the brain. In addition to the experimental task, the participants also completed the Peabody Picture Vocabulary Test (PPVT; a standardized measure of receptive vocabulary) as well as the Stanford-Binet V (SBV), a measure of IQ. The SBV scores reported reflect only scores on a composite of verbal and nonverbal visual-spatial subtests, which were correlated to the BOLD responses. Correlational analyses between the BOLD responses and the PPVT scores were not computed because of "more variability in the scores for the individuals with Down syndrome compared to those for the typically developing individuals" (Jacola et al., 2011, p. 349). Overall, the mean IQ of the typically developing participants was double that of the participants with Down syndrome, and, as might be expected, the performance of the participants with Down syndrome was much worse than that of the typically developing participants. However, these differences in performance were not correlated with PPVT or SBV scores suggesting that task performance was not related to underlying cognitive abilities. On the basis of these findings, Jacola et al. suggest that individuals with Down syndrome activated different brain areas than the typically developing participants to complete the task, that the relationships between SBV scores and areas of activation differed between the groups, and that activation differences could also reflect performance differences. The findings from this study are difficult to interpret because of small sample size, differences in cognitive abilities between the groups, as well as differences in thresholding requirements for inclusion of BOLD activations between the two groups of participants—for no specified reason, the inclusion practices were more liberal for the participants with Down syndrome than for the typically developing participants. Although a first step in the quest to understand differences in brain activations involving a task that requires cognitive processing, the findings from this study do not really provide any information other than to say that individuals with Down syndrome are different than CA-matched typically developing individuals.

This review highlights that we are only at the beginning stages of utilizing neuroscience approaches to complement the study of cognitive processing among persons with Down syndrome. Very few studies involved placing any cognitive demands on the participants, and none involved MA-matching. This is particularly troubling as Down syndrome is one of the most common etiologies of intellectual disability, with one of the better-understood cognitive phenotypes. In addition, the findings from all of these studies suggest that the defect approach permeates the literature on Down syndrome. As such, activations in the case of fMRI and neurophysiological responses in the case of ERPs are always considered defective, if they differ from that of typically developing participants who generally have double their IQs. Only Jacolo et al. (2011) even acknowledged that MA matching might help further our understanding of how and whether individuals with Down syndrome process information in different ways than typically developing individuals.

Persons With Williams Syndrome. As persons with Williams syndrome are characterized by a hypersocial phenotype and common visuospatial deficits that appear related to a difficulty integrating parts into wholes, neurobased studies of individuals with Williams syndrome have been focused on global-local stimulus processing ($n = 2$) or amygdala responses to different facial expressions ($n = 6$). Five of the studies reported here were completed by the same research group, headed by Ursula Bellugi and Allan Reiss, who have provided an extensive understanding of both Williams syndrome and of the role of the amygdala more generally. Their group seemed to consistently consider issues related to matching participants, either by assessing the effect of IQ on task performance and regions of interest, by directly matching participants on the basis of MA, or at the very least by acknowledging a lack of a comparison group as a limitation.

Global-local Processing in Williams Syndrome Both studies of global-local processing in Williams syndrome involved the presentation of Navon-type stimuli (Navon, 1977), composed simultaneously of global and local levels. The global level stimuli, typically letters or shapes, are made up of smaller, local level letters or shapes, which could either be congruent or incongruent with the global level (e.g., a large S made up of small s's or small o's respectively). Typically developing individuals generally show a

global precedent on these tasks, as they are faster and more accurate at detecting stimuli at the global level as compared with the local level, although this may vary as a function of stimulus characteristics (e.g., Enns & Kingstone, 1995; Kimchi et al., 2005). Mobbs et al. (2007) used fMRI to assess global–local processing of shapes among participants with Williams syndrome and CA-matched typically developing participants. The participants were asked to attend only to the big shapes and to press one button if the big shape was a triangle and a second button if the big shape was a square. Thus, in this case, the local level of the stimulus was never mentioned to the participants. Comparisons were made between BOLD and performance responses on this experimental task with a control task in which shapes were presented without local elements (e.g., a big triangle and a big square). Mobbs et al. found that the participants with Williams syndrome were less accurate and marginally slower than the typically developing participants, but these results did not seem to be linked to IQ. Activation differences were diffuse, with areas of larger activation among the participants with Williams syndrome in the dorsolateral prefrontal cortex, which Mobbs et al. linked to increased effort required to perform the task. Less activation was seen in parietal and early visual cortical areas among the individuals with Williams syndrome, suggesting disruptions in the dorsal-stream pathway.

Key and Dykens (2011) compared the performance of participants with Williams syndrome with typically developing participants matched on the basis of CA. The participants were asked to respond yes or no (by button press) with respect to the presence of the letter H, which could appear either at the local level (an S made up of small h's) or the global level (an H made up of small s's) with equal probability (20% each) during concurrent ERP recordings. The remaining 60% of trials were non-target standards (which did not contain the letter H). The presentation of only 30 target trials (30 global and 30 global stimuli) is problematic as it is a very low number of trials for an ERP study, which requires multiple repetitions to reduce the signal to noise ratio. Four components of interest were tested for between and within group effects. Early components included the occipital P1 (between 70 and 150 ms) and the N150 (between 150 and 220 ms), whereas later components of interest included the centro-parietal P3b (between 300–600ms) and the frontal P3a (between 200 and 400 ms) based on other ERP studies of global-local processing.

As expected, the typically developing participants demonstrated a global precedent behaviorally as evidenced by faster responses to the global stimuli than both the local and the distractor stimuli, but were equally accurate across stimulus types. ERP components were significantly different among the standard, local, and global level stimuli at the N150, and P3a and b components. Global and local targets elicited more negative N150s than standards, and more positive P3a and b amplitudes. No differences were noted between the physiological responses to global and local targets. Among the participants with Williams syndrome, no global precedent was noted although the global targets were detected more accurately than the local targets (75% vs. 31% approximately). ERP differences were noted for the early N150 and P1 components. P1 amplitudes were lower for the global versus the standard targets and had a shorter latency. The N150 component was more negative (larger) for the global versus the standard stimuli. Further, later in the processing stream, the global targets elicited a larger and earlier P3a component relative to standard stimuli. Although these findings suggest that individuals with Williams syndrome detect the global configuration of Navon stimuli similarly to typically developing participants early in the processing chain, additional analyses would have allowed for stronger conclusions. One, the groups were never compared with one another, so group differences or interactions between the conditions and group were never assessed. Two, the processing of local targets was not compared directly with the processing of global targets, which would have also allowed for an understanding of the relative physiology underlying global–local processing. Three, the participants with Williams syndrome were compared with college students who, even if their IQs were not assessed, can be assumed to function at a significantly higher cognitive level. Key and Dykens made no attempt to correlate task performance with IQ as a function of condition, nor did they take into account the obvious IQ differences between the groups in their analyses of ERPs or in their discussion (other than to say that IQ matching might be a useful future direction). Although this study provides evidence that early visual processing of global configurations seems typical in Williams syndrome, this study, as with the one by Mobbs et al., does not allow for an examination of the relations between global and local processing. Without actual comparison of these levels of processing, much remains to be learned about the nature of global-local processing among persons with Williams syndrome.

Facial Expression Processing and Face Processing in Williams Syndrome To better understand the hypersociability in this group, Haas et al. (2010) used fMRI to assess the relationship between amygdala responses to different facial expressions (happy, fearful, neutral and control images that were scrambled) among adults with Williams

syndrome. The participants' parents completed a questionnaire used to assess their adult child's sociability across three scales (global sociability, approach strangers, and approach familiars). In the experimental task, the participants who were in the fMRI portion of the experiment were asked to respond by a button press as to whether the image they were presented was male, female, or scrambled (three buttons). The goals were to look at the associations among task performance, BOLD responses in the amygdala, and parental reports of sociability. Behavioral findings indicated no relationship between task performance (reaction time and accuracy) and the parental reports of sociability. However, consistent with the notion that the increased social approach of individuals with Williams syndrome is related to a decreased response to social fear, Haas et al. found that a diminished amygdala response to fearful faces was associated with a greater tendency (as reported by parents) to approach strangers. This is initial evidence of a neural correlate of behavioral observations of hypersociability, and provides a developmental pathway that may lead to this behavioral phenotype.

In a further attempt to understand the relationship between hypersociability and amygdala responses, Paul, Snyder, Haist, Raichle, Bellugi, and Stiles (2009) compared the performance and associated BOLD responses of individuals with Williams syndrome as well as a group of typically developing participants matched on CA and a group of younger typically developing children matched to the participants with Williams syndrome on the basis of MA on a facial expression matching task. The participants completed an experimental task in which they were required to determine whether a target face matched either of two faces presented just prior to the target. This task was completed both in and out of the scanner with slight modifications. Behaviorally, prior to the scanning, the performance of the individuals with Williams syndrome was as fast and as accurate as the MA-matched typically developing children, and both of these groups were slower and less accurate on the task than the CA-matched typically developing participants. However, while performing the task in the scanner, the MA- and CA-matched participants outperformed those with Williams syndrome with respect to both reaction time and accuracy. With respect to BOLD responses, the physiological responses to the task were in many ways similar between the participants with Williams syndrome and the MA-matched group, whose activation patterns were less robust than the CA-matched participants. The exception to this was the amygdala, which was more active in both the MA and CA groups than among the participants with Williams syndrome. The finding of an underactive amygdala is consistent with Haas et al.'s (2010) finding that decreased amygdala responses to fearful faces are associated with a greater tendency to approach strangers.

Haas, Mills, Yam, Hoeft, Bellugi, and Reiss (2009) used both ERPs and fMRI to test the neural basis of social responsivity among individuals with Williams syndrome in response to emotionally valent facial expressions (happy and fearful). In both the ERP and the fMRI studies, the participants were asked to detect whether the images that were presented were male, female or scrambled by pressing one of three response buttons. The face stimuli depicted happy, fearful or neutral facial expressions. Fourteen participants with Williams syndrome completed the fMRI study and their performance was compared with that of typically developing individuals matched on the basis of CA, while 30 participants with Williams syndrome completed the ERP study (11 overlapped) and their performance was compared with typically developing participants matched on CA and to a smaller group of participants with idiopathic developmental delay (participants who had an intellectual disability of unknown origin and were not autistic) matched on the basis of full scale IQ (test unspecified). The age range of the IQ-matched participants groups were similar, though the authors did not mention that they specifically match on CA. Behaviorally, the performance of the participants with Williams syndrome was slower and less accurate than the CA-matched typically developing participants but did not differ from the IQ-matched participants with idiopathic developmental delay. The fMRI findings indicated that compared with CA-matched participants, the participants with Williams syndrome showed increased right amygdala activation for happy as compared with neutral facial expressions, and lower right amygdala activation than the typically developing participants when the fearful facial expressions were compared with the scrambled images. Neither IQ, reaction time, nor accuracy accounted for their findings.

With regard to the ERP paradigm, Haas et al., (2009) compared differences between happy and neutral facial expression as well as fearful-neutral facial expressions in three time periods (N200, P300–500 and P500–700). At 200 ms, they found that the participants with Williams syndrome showed a larger difference between fearful and neutral facial expressions than the MA-matched participants and a trend for the same finding among the CA-matched participants (but only the participants with Williams syndrome showed a smaller response to fearful facial expressions relative to neutral ones). Between 300 and 500 ms, the participants with Williams syndrome

demonstrated greater physiological responses (larger differences between happy and neutral expressions) relative to both the CA- and MA-matched groups (which did not differ from each other). Between 500 and 700 ms, there was a larger difference between physiological responses to fearful—neutral facial expressions in the CA-matched participants relative to the participants with Williams syndrome. The Williams syndrome and MA-matched groups did not differ in their responses at this time point. Together, these findings corroborate the notion that individuals with Williams syndrome show a decreased response to fearful facial expressions, which is visible early in the processing stream and which appears to be maintained in more cognitive time frames (between 500 and 700 ms). The participants with Williams syndrome also showed increased reactivity to happy facial expressions as measured by both fMRI and ERPs. These findings map well onto the behavioral phenotype of individuals with Williams syndrome who are often very socially driven but also approach others indiscriminately, although the significance of these findings are diminished considerably due to the use of two problematic groups—CA-matched typically developing persons and an etiologically unspecified group of persons with intellectual disability.

Another explanation of the unique social characteristics of persons with Williams syndrome is linked to the finding that they rate pictures of faces as more approachable than MA-matched comparison participants (Frigerio et al., 2006), a phenomenon that Bellugi, Adolphs, Cassady, and Chiles (1999) termed a positive attribution bias. In an attempt to understand this positive attribution bias, Mimura et al. (2010) assessed activations of the amygdala and the orbitoprefrontal cortex (OFC), which are involved in facial affect recognition among seven participants with Williams syndrome and seven typically developing participants matched on CA. The participants completed a facial expression-matching task by responding with a button press as to whether two faces presented side by side had matching or mismatching facial expressions while in the scanner. Specifically, Mimura et al. attempted to assess the role of both the medial and lateral portions of the OFC, which play different roles in facial expression recognition. The medial regions of the OFC are involved in monitoring the reward value of reinforcers, whereas the lateral OFC is involved in the monitoring of punishers. Mimura et al. hypothesized that among typically developing individuals, positive facial expressions would activate the medial OFC while negative facial expressions would activate the lateral OFC. In contrast, they expected that among individuals with Williams syndrome, facial expressions depicting both positive and negative facial expressions would activate medial regions as a result of their positive attribution bias. Accuracy on the task did not differ between the groups despite IQ differences (although *p*-values increased when FSIQ was used as a regressor).

Mimura et al.'s (2010) fMRI findings indicated that the participants with Williams syndrome had decreased activation in the right amygdala and right lateral OFC relative to the typically developing participants for negative facial expressions but the right medial OFC showed greater activation than the typically developing participants in response to negative stimuli (compared with positive stimuli). Although no relationship between task performance and IQ were found at the level of the whole brain, when region of interest analyses were repeated in the participants' native space, a correlation was found between right lateral OFC activation and IQ for the positive versus negative contrast among the individuals with Williams syndrome, suggesting that those individuals with higher IQs also had larger activation differences between positive and negative facial expressions in this region than those with lower IQs. These findings are consistent with previous evidence of decreased amygdala responses to negative facial expressions among persons with Williams syndrome as compared with typically developing individuals, but are novel with regard to the finding that that negative facial expressions activate regions of the brain associated with reward gating in individuals with Williams syndrome compared with typically developing participants. This suggests that these two regions might work in tandem to explain why individuals with Williams syndrome tend to approach strangers. That is, individuals with Williams syndrome view negative facial expressions as rewarding, and also show a decreased fear response to negative facial expressions.

Thronton-Wells, Avery, and Blackford (2011) also attempted to dissect the role of the amygdala among individuals with Williams syndrome by comparing BOLD responses to social and non-social images among participants with Williams syndrome relative to comparison participants with an inhibited temperament group (who have high non-social fear responses, which is consistent with the Williams syndrome phenotype) and those with an uninhibited temperament who are characterized (similarly to individuals with Williams syndrome) as being highly sociable. Thus, they attempted to determine whether the typical findings related to amygdala responses among persons with Williams syndrome are unique and specific to this group or rather more characteristic of the personality traits associated with the phenotype. Their findings indicated that individuals with Williams syndrome had

larger BOLD responses to non-social fear images than the typically developing individuals with a similar level of fear. With respect to social images, the BOLD response in the amygdala of individuals with Williams syndrome was commensurate with that of typically developing individuals who are highly social, suggesting that high sociability personality traits might explain more generally the heightened amygdala responses rather than being unique to individuals with Williams syndrome.

In addition to the role of the amygdala and the OFC in facial expression processing, and thus in the hypersociability of individuals with Williams syndrome, the fusiform face area is also an important region associated with the identification and recognition of faces. As individuals with Williams syndrome have been found to have face-identity recognition abilities that are commensurate with CA and better than would be expected for MA (Bellugi, Lichtenberger, Jones, Lai, & St George, 2000), the fusiform face (FFA) area might be involved in Williams syndrome. In one example, Golarai et al. (2010) systematically deconstructed the role of the FFA (and the relationship between task performance, IQ and FFA activation) among individuals with Williams syndrome and CA-matched typically developing comparison participants on a passive viewing task in which the participants were presented with grayscale images of faces, objects, textures and places. They sought alternative explanations to their finding that the FFA of individuals with Williams syndrome is almost double the volume of the FFA of typically developing participants by using different thresholds, clustering and spatial smoothing techniques, and comparing their FFA results to other brain areas associated with face processing. The participants also completed a face recognition task outside of the scanner and, consistent with previous findings, performance on the task did not differ between typically developing participants and those with Williams syndrome, although a significant correlation between size of the right FFA and task performance was found among the participants with Williams syndrome but not among the typically developing participants. This correlation remained significant even after IQ was controlled (despite task performance being correlated with IQ), thereby providing a neural anatomical correlate that might explain why individuals with Williams syndrome have better facial recognition abilities than would be expected for their MA.

Summarizing Neuroscience Work Across Etiologies. Our review of neuroscience-based studies across etiological groups highlights that we are in the most nascent stages of work in this area. The studies were generally characterized by essential methodological problems either in their execution, or in their consideration of cognitive level in their findings, thereby considerably diminishing the conclusions that can be made.

Although the study of intellectual disability within the context of neuroscience is still a new area of inquiry, several foundational questions have been raised, especially with regard to the roles of developmental level, CA, and specific etiology on ERP and fMRI findings. We have no methodological consensus regarding how best to treat IQ, or cognitive development more generally, nor do we have a real understanding of their relation to brain physiology. Further, the difficulties in recruitment and retention of participants with an intellectual disability for studies involving fMRI and ERPs necessitate that the most of the studies involve adult participants, which represents the endpoint of development, leaving open an important chicken-egg problem. That is, what is the degree to which neural differences are causes or consequences of the behavioral phenotype? Nonetheless, as more researchers with different areas of expertise work together, we hope that these questions as well as those regarding the relationship between brain and behavior in intellectual disability will be addressed.

The current advancement of technology and the related increased access and funding available to researchers using neuroscience tools to study persons with intellectual disability are certainly welcome contributions to this field, but have given rise to a new generation of defect theorists who, in their frantic pursuit to identify key neurological problems, lay waste to many of the tenets of developmental theory and methodology. Thus, decades after its apparent demise, the defect approach appears to be rearing its head again. We are a long way from being able to consider the whole person from a neuroscience perspective but we hope that by promoting the importance of developmental theory and methodology that we will accelerate the developmental legitimacy of neuroscience research in the study of intellectual disability.

CONCLUSIONS

From Genes to Brain to Behavior in Intellectual Disability: Future Directions in Research

More than 10% of the human genome has been implicated in intellectual disability, both organic and familial (Schuurs-Hoeijmakers et al., 2013). The number of well-known syndromes associated with intellectual disability is quite small, however a major advancement of the

twenty-first century is the mapping of these known genetic disorders to neural consequences. This approach has led to breakthroughs in understanding exactly how specific genes work together to build a brain. The burgeoning field of epigenetics is also beginning to shed light on the subtle influences of external factors, from diet and the prenatal environment, to parenting. Each child enters their individual world, with their unique epigenome, acting upon and eliciting experiences from the world that combine to carve the child's unique developmental path, like water carving a stream in the sand. Just as every child carves out a unique developmental pathway, some are more functionally adaptive than others. Thus, the orthogenetic principles and similar-sequence/similar-structure hypotheses are still relevant to understanding both familial and organic intellectual disability, as are Piagetian constructivism, and the neo-Piagetian neuroconstructivist (Karmiloff-Smith, 1998) models in which the child, typically developing or otherwise, is the unique product of cumulative and self-driven experiences. Via general and universal developmental principles, the unique child constructs his or her own path through the selection of experiences and evocations from the environment. The biology of the child presents merely a set, albeit often a powerful one, of constraints.

Summary

Throughout this chapter, we highlight, that, as with all developmental processes (Werner, 1957), the development of the developmental approach to intellectual disability led to an essential deconstruction, in this case of the commonly applied theories and methodologies in the field, as part of the progression toward a more precise but comprehensive understanding. Thus, this deconstruction is not one of a Humpty Dumpty who can never again be put together. Rather it is one of a chrysalis in which the ideas are even more beautiful and lofty than the original. This optimism is based in the advances in the almost half century since Zigler's original articulation of the developmental approach to intellectual disability and in the twenty-first century sophistication in experimental technology and empirical methodology in the study of genetics, brain functioning, behavior, social and interpersonal functioning, and emotional well-being, as well as in the study of the complex developmental trajectories and relations among them. Through this synergy, the key to understanding the development and functioning of the heterogeneous grouping of persons labeled as intellectually disabled is with the paradoxical top-down imposition of developmental theory on the bottom up process of piecing together a mosaic based on fine-tuned and precise empirical evidence from relatively precise homogeneous groupings. Despite, and because of, the abandonment of the big stories of the defect and related approaches to intellectual disability, we now know much more about persons with intellectual disability than we have in the past, but are also painfully aware of the extent to which we only tap the surface of all there is to know. As we (Burack et al., 2012) noted elsewhere, the outcome of this process might best described by yet two more paradoxes, that the more we know, the less we know, and that is still progress, because, the less we know we know, the more we (really) know. Accordingly, despite all the advances in research on persons with intellectual disability since the Hodapp and Burack (2006) chapter in the last edition of this handbook, we can make the same claim that we are only in the early stages of the development of the developmental approach to intellectual disability and are still just becoming more aware of the immensity of the task ahead of us—but that is the nature of a developmental process.

INTRODUCTION

Neurodevelopmental disorders of known genetic origin, like fragile X, Williams, and Down syndromes, can serve as multidisciplinary, multilevel models for understanding the neurodevelopmental mechanisms and the origins of other disorders that are currently defined only at the behavioral level (e.g., dyslexia, attention-deficit/hyperactivity disorder [ADHD]; autism spectrum disorder [ASD]), with one critical proviso: they are considered within a truly developmental framework. Indeed, special emphasis will be given throughout this chapter on the importance of the developmental perspective on neurodevelopmental disorders. It is crucial for researchers always to recall that early genetic modifications—whether deletions, translocations, duplications, or mutations—are likely to affect neurocognitive functioning from the very outset of development and to have complex interactions and widespread cascading effects over time on the resulting phenotype. For example, research on infants with disorders of known genetic origin has highlighted the importance of investigating empirically the very early developmental profile of each syndrome during infancy, rather than assuming a priori that the cognitive profile in adults is representative of earlier deficits and abilities (Karmiloff-Smith, 1998; Paterson, Brown, Gsödl, Johnson, & Karmiloff-Smith, 1999). So, researchers always need to keep in mind a clear distinction between the mature, developed, relatively stable brain and the dynamically changing developing brain (Karmiloff-Smith, 2010). Thus, while genetic disorders can provide unique insights into how relatively well understood genetic modifications, molecular pathways, and systems neuroscience influence cognition, these complex interactions cannot be fully understood outside their developmental context (Doherty, Shimi, & Scerif, 2015).

In this chapter, we take the case of one such neurodevelopmental disorder of known genetic origin, fragile X syndrome (FXS), to discuss a number of broad issues that emerge from the comparison with disorders that are behaviorally defined (see Farran & Karmiloff-Smith, 2012, for a similar approach using Williams syndrome as the model disorder). First, we provide a short summary of the genetic, neurocognitive, and behavioral characteristics of FXS, with special emphasis on the complex interplay between developmental stability and developmental change. Second, using longitudinal data, we discuss the ostensibly surprising fact that despite being a monogenetic disorder, there are wide within-syndrome individual differences in the phenotypic outcomes of individuals with FXS. The longitudinal findings highlight the existence of within-syndrome developmental trajectories that diverge over time as well as the importance of identifying both risk and protective environmental factors that influence these outcomes. Then we focus on cross-syndrome comparisons

of the similarities and differences in social and cognitive problems of children with FXS with those of children with two behaviorally defined disorders, ADHD and ASD. We conclude with a strong emphasis on the usefulness of cross-syndrome comparisons and a discussion of how this approach can be used as a model for understanding other genetic disorders in which within-syndrome variability has not been as thoroughly investigated, particularly within a longitudinal framework.

THE FRAGILE X GENOTYPE AND PHENOTYPE

Genetically, FXS is caused by the silencing of a single gene on the X chromosome, and in males who are carriers of the full mutation it results in an almost complete absence of the protein product linked to this gene in typical development. Phenotypically, the syndrome is associated with significant attentional, memory, and sociocognitive deficits that turn out to be more severe than would be predicted given levels of overall developmental delay. This therefore makes FXS an ideal model in which to study the effects of protein networks on the developmental trajectories of attentional control and memory at multiple levels, from the cellular to the systems and cognitive neuroscience, and how they impact on specific cognitive domains such as social cognition (see Belmonte & Bourgeron, 2006; Bourgeron, 2009; Scerif & Karmiloff-Smith, 2005, for a discussion of this interdisciplinary approach). Nonetheless, at all levels, scientists must take into account the developmental constraints acting over time if we are to reach a full understanding of the resulting phenotype. In the following paragraphs, we characterize FXS at these different levels.

Constituting the most common inherited form of intellectual disability, FXS has a prevalence of approximately 1 in every 4,000 males and 1 in every 8,000 females, although more recent figures estimate a general prevalence closer to 1 in 2,500 (Crawford, Acuña, & Sherman, 2001; Hagerman, 2008). It results from a large trinucleotide CGG repeat expansion in the 5' untranslated region of the *FMR1* gene at site Xq27.3. While typically developing individuals usually have approximately 30 CGG repeats at this site, premutation carriers present with around 55–200 repeats, and individuals with the full mutation have over 230 repeats (Maddalena et al., 2001). In this chapter, we will concentrate on full mutation carriers because of the greater wealth of developmental findings to date (but see Bourgeois et al., 2009; Cornish, Kogan, Li, Turk, Jacquemont, & Hagerman, 2009; Cornish et al., 2008; for fascinating research that now reveals unsuspected impairments also in premutation carriers, and their developmental progressions from childhood into young and late adulthood). The extensive CGG repeat expansion in full mutation carriers gives rise to epigenetic changes, such as methylation of the *FMR1* gene promoter, and thus transcriptional silencing of the *FMR1* gene itself, which then results in a reduction of FMRP, the fragile X mental retardation protein (Verkerk et al., 1991). Because of the location of the *FMR1* on the X chromosome, males are usually more severely affected than females, the latter being more resilient because they have two X chromosomes, only one of which is randomly inactivated (Grigsby, Kemper, Hagerman, & Myers, 1990).

Phenotypically, individuals with FXS present with a number of physical features: prominent ears, a long narrow face, flat feet, joint laxity, and macro-orchidism (Hagerman, Van Housen, Smith, & McGavran, 1984). However, while these features are not especially obvious in early development, they become more evident with growing maturation. By contrast, developmental delay in cognitive and motor milestones is more obvious during the early stages of development, and is often what alerts clinicians to the possibility of a neurodevelopmental disorder in families with newly diagnosed children and no previous FXS births (Bailey, Skinner, Hatton, & Roberts, 2000). By contrast, given the inherited nature of the syndrome, if there is already an older child with FXS in the family, babies are screened for FXS during fetal or early postnatal life even in the absence of overt physical signs.

In terms of cellular modifications, FXS results in numerous anatomical and functional changes at the level of synaptic connectivity. Post-mortem studies have identified immature dendritic spines in neurons (Hinton, Brown, Wisniewski, & Rudelli, 1991; Rudelli et al., 1985). Interestingly from an evolutionary perspective, the *FMR1* gene has high conservation across species (Verkerk et al., 1991), which has made it possible for animal models to investigate in greater depth the changes that arise from the loss of FMRP. For example, *Fmr*1 knockout mice develop dense, immature dendritic spines that are very similar to those observed in human patients (Comery et al., 1997; Grossman, Aldridge, Weiler, & Greenough, 2006). Additional murine research has revealed that FMRP binds selectively to mRNA in the postsynaptic spaces of dendritic spines, thereby repressing synaptic translation by stalling ribosomal translocation. In typical development, FMRP derepresses translation in response to synaptic activity, making the synthesis of crucial synaptic plasticity proteins possible. The FXS loss of FMRP thus constrains this response and, because deficits in synaptic plasticity

correlate with memory and learning problems, it has been argued that such deficits are the main cause of the resulting FXS phenotype. In particular, mGluR dependent long-term depression (LTD), a major form of synaptic plasticity, is thought to constitute the impaired neurological pathway involved in the FXS behavioral symptoms (Bear, Huber, & Warren, 2004). Furthermore, it has been demonstrated that mGluR LTD is indeed altered in *Fmr1* knockout mice (Huber, Gallagher, Warren, & Bear, 2002), and that mGluR antagonists can indeed enhance cognitive and behavioral outcomes (Yan, Rammal, Tranfaglia, & Bauchwitz, 2005), as well as rescuing immature dendritic spine morphology (Michalon et al., 2012; Nakamoto, Nalavadi, Epstein, Narayanan, Bassell, & Warren, 2007). The successes of the murine intervention studies with these antagonists have now resulted in relatively successful clinical trials with human patients using drugs to target the mGluR LTD pathway (Berry-Kravis et al., 2009). However, while atypical synaptic function and anatomy are characteristic of most animal models of FXS, an examination of different studies that have used *Fmr1* knockout mice reveals that these synaptic phenotypes are in fact transient and appear developmentally only within short time windows. This means that their effects are dependent upon the temporal expression of *Fmr1* (Meredith, Dawitz, & Kramvis, 2012), stressing again the importance of a developmental perspective on such questions. In sum, although there is a single and well-understood genetic cause of FXS, there is wide variation in phenotypic outcome in this population. This is likely to be due to a combination of individual temporal expression dynamics together with differing timing of environmental impacts, something to which we will turn our attention in a subsequent section.

BRAIN–BEHAVIOR RELATIONS IN FRAGILE X

The investigation of human patients with FXS at the systems level has yielded interesting links between genes, brain, and behavior. For example, memory impairments, particularly working memory, correlate with FMRP levels in FXS as well as with abnormal brain activation in regions that are critical for memory functions (Menon, Kwon, Eliez, Taylor, & Reiss, 2000). Moreover, during attention and impulse control tasks, FMRP also has been shown to correlate with the atypical recruitment of dorso-striatal networks (Hoeft, Hernandez, Parthasarathy, Watson, Hall, & Reiss, 2007; Menon, Leroux, & White, 2004). These studies tend to lend support to the hypothesis that FMRP is required for the brain to react rapidly in the service of executive function and working memory tasks (Lightbody & Reiss, 2009). Additionally, evidence is accruing to suggest that reduced FMRP is associated with reduced amygdala volume as well as reduced amygdala activation during emotion processing tasks (Hessl et al., 2011). Furthermore, recent research with mouse models suggests a general neural imbalance between excitation and inhibition across the whole brain in FXS (D'Hulst et al., 2006; Gibson, Bartley, Hays, & Huber, 2008). An exciting area of open research would be to investigate such an imbalance in humans by measuring the levels of excitatory and inhibitory neurochemicals, such as GABA and glutamate, in individuals with FXS using magnetic resonance spectroscopy. These findings point to a serious problem in individuals with FXS, because it is known that the excitatory/inhibitory balance is critical for optimal functioning at the neural level, both in terms of region specificity and across developmental time.

Much of the early research on the FXS brain was done on older children and adults, but recently structural imaging studies have targeted very young children with the syndrome (Haas et al., 2009; Hoeft et al., 2008, 2010, 2011). This should in time make possible the much earlier diagnosis of FXS, identifying in infants precocious neural markers of atypical brain development. For example, in a longitudinal study by Hoeft and collaborators (2010) on 1–3-year-old boys with FXS, gray and white matter volumes were measured over a 2-year period. The researchers identified areas of the brain in which gray matter volumes were either enlarged (caudate, thalamus, and fusiform gyri) or reduced (cerebellar vermis), and this held across both time points, thereby highlighting from a very early point in development quite stable regional effects in the brains of individuals in this population. Interestingly, other brain regions revealed initial gray matter volume that was similar to that of typically developing controls (orbital gyri, basal forebrain, and thalamus), but which subsequently increased in size in FXS, again stressing the need for a developmental perspective when considering the atypical brain (Karmiloff-Smith, 2010). In contrast to gray matter volumes, white matter volumes of fronto-striatal regions were greater in FXS compared with typically developing controls at the first time point, and, in this case, the differences did not remain stable but increased over time. In general, then, these results underscore how structural (and probably functional) abnormalities within different brain regions develop differently over time in FXS, reflecting again time-dependent effects of *FMR1* silencing. Such effects are very similar to those already highlighted in the context of murine models of FXS.

COGNITIVE AND BEHAVIORAL PATTERNS IN FRAGILE X

Individuals with the full FXS mutation present with a very characteristic cognitive and behavioral profile across development, despite the existence of strong individual variation. Males are usually severely impaired intellectually, with an average IQ as low as 41, whereas those males with incomplete *FMR1* inactivation can turn out to be less affected (Merenstein, Sobesky, Taylor, Riddle, Tran, & Hagerman, 1996). Males also have quite severe communication difficulties, including significant language delay coupled with social awkwardness alongside hyperactivity, inattention, impulsivity, and anxiety. By contrast, females—even those with the full mutation—tend to present with less deficits (due to their unaffected second X chromosome), often having only moderate and in some cases no intellectual impairment at all. However, social problems are frequently part of the female FXS phenotype, but unlike the co-occurring symptoms in males with FXS, social impairments in girls and women are more likely to be accompanied by anxiety or depression (Freund, Reiss, & Abrams, 1993).

Noteworthy is the fact that subtle behavioral and cognitive delays and deficits are evident in infancy, with parents becoming concerned about their children's symptoms on average as early as 9–13 months of age. However, clinical confirmation of the atypical developmental pathways often has to wait until the child is considerably older, that is, on average around 21–24 months of age, with in many cases a full diagnosis of FXS not happening until as late as 32–35 months of age (Bailey, Skinner, Hatton, & Roberts, 2000; Bailey, Skinner, & Sparkman, 2003). The early signs at around 9–12 months of age include decreased object play, increased leg stereotypies, and atypical postures. In fact, these quite subtle symptoms have been shown actually to be able to yield a FXS diagnosis in infancy with some 73% accuracy (Baranek et al., 2005). Furthermore, scientific research has revealed that already in infancy, those with FXS demonstrate poor response inhibition (Scerif, Cornish, Wilding, Driver, & Karmiloff-Smith, 2004, 2007), poor saccadic eye-movement control (Scerif, Karmiloff-Smith, Campos, Elsabbagh, Driver, & Cornish, 2005), and prolonged visual attention to objects or what is known as sticky fixation (Roberts, Hatton, Long, Anello, & Colombo, 2012). In subsequent FXS development, school children and adolescents also display poor response inhibition (Sullivan, Hatton, & Hammer, 2007) and atypical patterns of visual attention (Hooper, Hatton, & Baranek, 2000; Munir, Cornish, & Wilding, 2000a, 2000b). Finally, executive function is clearly deficient in FXS in childhood, with concomitant memory impairments (Lanfranchi, Cornoldi, & Drigo, 2009). All of these characteristic problems continue into adulthood; nonetheless, the most serious cognitive impairments have been shown to reside in executive function and visual-spatial attention in this syndrome (Cornish, Munir, & Cross, 2001).

INSIGHTS FROM LONGITUDINAL STUDIES OF FRAGILE X

Attentional control has been a particular area of FXS research, but hitherto mainly only in cross sectional designs. Here, we provide data from a longitudinal approach that yielded deeper insights into the FXS phenotype. It is indeed longitudinal research that has highlighted two crucial factors affecting the cognitive phenotype of individuals with the full mutation. The first concerns differences in attentional biases that tend to alter cognitive development from the very outset for children with this genetic disorder. One important way of targeting the attentional domain is to compare younger and older individuals with FXS (Cornish et al., 2007; Scerif et al., 2004, 2005, 2007), and especially to do so within a longitudinal design (Cornish, Cole, Longhi, Karmiloff-Smith, & Scerif, 2012; Cornish et al., 2013; Scerif, Longhi, Cole, Karmiloff-Smith, & Cornish, 2012). The second resides in the fact that, as we mentioned earlier, even in seemingly simple monogenic disorders like FXS, the resulting phenotype displays significant phenotypic variability across individuals, as for instance demonstrated by studies of individual differences in saccadic eye-movement control in young children with FXS between 12 and 36 months of age (Scerif et al., 2005). Moreover, variability also exists in how abilities actually change longitudinally over developmental time in FXS (Cornish, Cole, Longhi, Karmiloff-Smith, & Scerif, 2013; Cornish et al., 2012; Scerif et al., 2012). There is clearly no simple one-to-one mapping between the mutated gene and the resulting phenotype.

Noteworthy is that fact that studies of neurodevelopmental disorders have produced a new emphasis on theory development, highlighting the need to go beyond group comparisons and trace instead domain-specific or even task-specific developmental trajectories, by plotting, say, numerical or linguistic functioning against individuals' verbal or nonverbal ability levels (e.g., Thomas, Annaz, Ansari, Scerif, Jarrold, & Karmiloff-Smith, 2009). Basically, this involves a new focus on within-syndrome individual differences. There is indeed a glaring absence

of studies tracking change over developmental time, that is, longitudinally. For example, even though striking attentional difficulties had already been demonstrated in children with FXS, even when compared with a much younger typically developing group of children matched on overall developmental level (Cornish et al., 2007; Scerif et al., 2004, 2005, 2007), the cross sectional design did not make it possible to ascertain whether the severity of attentional difficulties increased over developmental time or remained stable. This was because the experimental instruments available to measure attention in younger and older individuals were often very different in nature and the outcomes across age were difficult to compare directly. Moreover, although the FXS cognitive phenotype has been extensively examined via cross sectional research, far fewer studies have probed longitudinal changes not only within attention but also in terms of other sensory and cognitive domains (e.g., Baranek et al., 2008; Roberts et al., 2009; Skinner et al., 2005). In other words, studies that simultaneously target the FXS phenotype both longitudinally and in a cross-domain design have been sadly lacking.

However, very recent research using the longitudinal approach has yielded new insights. For example, although we know that significant delays in attentional control are present in boys with FXS, this turns out not to be a case of developmental arrest. Instead, dynamic trajectories of delayed development have now been identified. For example, using a combined cross sectional and prospective longitudinal design, we examined early profiles of attention and working memory impairment in FXS (Cornish et al., 2013). When investigated only in cross sectional designs, significant weaknesses emerged for boys with FXS, with no clear improvement over chronological age. By contrast, when we examined the same issues in a longitudinal design, we were able to reveal that, although clearly impaired, the improvements that occurred over time in boys with FXS paralleled the slope of improvement that we witnessed in typically developing children. In other words, while cross sectional approaches would have called on an interpretation of developmental arrest, the longitudinal studies yielded developmental improvements, albeit delayed compared with TD controls, in both attention and working memory. While confirming previous cross sectional findings of deficits in attentional control and working memory compared with what would be expected given their general level of developmental delay, the Cornish and collaborators' longitudinal study (2013) additionally revealed improvements over developmental time that a simple cross sectional comparison would have masked. The longitudinal study also measured other aspects of the FXS cognitive profile (i.e., nonverbal intelligence) and revealed unique insights that would again have been missed in cross sectional approaches. For instance, cross sectional studies of nonverbal IQ scores, measured by the Leiter International Performance Scale–R (Roid & Miller, 1997), had tended to point to a potential plateau or even decline with age, whereas our longitudinal trajectories measured with growth scores (an analogue of raw scores that takes into account repeated presentations and item difficulty) highlight instead an albeit small yet significant improvement over developmental time (Cornish et al., 2012).

What about lower level perceptual rather than cognition-level functions? Are these unimpaired in FXS? Studies with adults (Van der Molen et al., 2012) and also with infants with FXS (Farzin, Whitney, Hagerman, & Rivera, 2008) suggest that visuospatial attention impairments may in fact be underpinned by atypical lower level perceptual abilities. Again, longitudinal data are crucial in evaluating whether low level perceptual processing differences do in fact lead over developmental time to atypical higher level processing. This yet again highlights the need for more longitudinal approaches to understanding the complexities of neurodevelopmental disorders like FXS.

In addition to the aforementioned striking group-level deficits, clinicians working with individuals with FXS tend to identify striking individual differences in attention outcomes, with some individuals much more seriously affected by inattention than others, even when they have equivalent levels of IQ. Again, longitudinal studies following sufficiently large samples could start to dissect the within-syndrome FXS variability, because they enable researchers to go beyond correlational measures, and ask instead how within-syndrome variability predicts subsequent outcomes. This was indeed our approach in the longitudinal study referred to above. We measured visual, auditory, and multimodal attention in young boys with FXS, aged between 4 and 10 years of age at time 1 and again 12 months later at time 2 (Scerif et al., 2012). We also assessed behavior in these boys through standardized teacher questionnaires targeting dimensions that are relevant to symptoms of ADHD (e.g., Conners Teacher Rating Scales; Conners, 1997). The results showed that the children with FXS attended less well than mental-age matched typically developing boys and had greater difficulties with auditory stimuli than with visual ones. In addition, unlike typically developing children, the boys with FXS did not benefit from multimodal information. Importantly from the perspective of individual differences, early visual attention markers in boys with FXS were significant predictors of their later ADHD symptomatology, highlighting the

need to identify the drivers of differing developmental trajectories for individual children within this seemingly homogeneous group if measured cross sectionally. Interestingly, while visual attention was a significant longitudinal predictor of ADHD symptoms in the boys with FXS (Scerif et al., 2012), it was auditory attention that predicted later symptoms related to ASD (Cornish et al., 2012).

THE CHALLENGES OF COMORBIDITY

Individuals with FXS present with a particularly high risk for comorbid symptoms, which are found in autism spectrum disorder (ASD) and attention-deficit/hyperactivity disorder (ADHD). Indeed, some 50–90% of patients with FXS have autistic-like traits such as tactile defensiveness, poor eye contact, hand flapping, hand biting, and speech perseveration (Bailey et al., 1998; Baumgardner, Reiss, Freund, & Abrams, 1995; Kerby & Dawson, 1994). Strikingly, about 25–47% of individuals with FXS actually meet the diagnosis for ASD (Bailey et al., 1998; Demark, Feldman & Holden, 2003; Rogers, Wehner, & Hagerman, 2001). Moreover, FXS has been identified as the most common known genetic cause of ASD, with between 1 and 2% of individuals with ASD having the full FXS mutation (Devlin & Scherer, 2012).

A similar situation obtains for ADHD. Some 74% of individuals with FXS meet the criteria for an ADHD diagnosis (Backes, Genç, Schreck, Doerfleur, Lehmkuhl, & von Gontard, 2000), making ADHD the most common comorbid condition diagnosed alongside FXS (Tranfaglia, 2011). Despite these high risk factors for ASD and ADHD, we have consistently noted in earlier sections that behavioral outcomes across individuals with FXS are highly variable, making the investigation of the factors causing individual differences in these symptoms of both theoretical and clinical importance. What factors are involved in the developmental trajectories in many children with FXS to cause them to present with social and cognitive control problems similar to those experienced by children diagnosed with ASD and ADHD, while at the same time there exist other children with FXS who do not display these particular socio-cognitive problems? One research advantage stems from the fact that both FXS and ASD are diagnosed around the same age and substantially earlier than the diagnosis of ADHD (usually only diagnosed in the early school years), making FXS an ideal model for assessing high risk early in development. Indeed, comorbidity in disorders of known genetic origin can serve as models for understanding other disorders that are diagnosed only on behavioral measures, because the genetic disorders can be diagnosed much earlier in development. This is not unique to FXS, of course. Genetic disorders such as Williams syndrome are also characterized by high risk for ADHD symptoms (Rhodes, Riby, Matthews, & Coghill, 2011) and also receive very early diagnosis, often at or shortly after birth. The same holds for infants with Down syndrome. Given the early, and possibly perinatal diagnoses, neurodevelopmental disorders like FXS, Williams syndrome and Down syndrome can be considered models of high risk for those behaviorally defined disorders. However, given the developmental unfolding and variability of these difficulties within and across syndromes, understanding high risk requires moving away from static snapshots, even of individual differences, to developmental trajectories. Furthermore, systematic longitudinal comparisons across these genetically distinct groups with commonly high risk for those behavioral symptoms could lead us to understand the differing developmental trajectories leading to those symptoms.

Nonetheless, the promise of insights from genetic disorders that, like FXS, are diagnosed early and carry a high risk for ASD or ADHD is not necessarily straightforward.

Comorbidity With ASD

A first set of questions that obviously must be raised are the following: are the comorbid autistic-like traits in FXS really the same as those existing in individuals with idiopathic ASD? Or do they constitute instead the severe end of a continuum of cognitive impairment and behavioral difficulties present in more affected individuals? Separating these two interpretations is not an easy endeavor, yet is clearly critical for the development of behavioral and pharmacological treatments that address the core impairments in ASD, ADHD, and FXS. Several researchers have attempted to address this question using behavioral measures. While some have identified similar profiles of autistic traits in both individuals with FXS and those with idiopathic ASD (Bailey et al., 1998), others argue that behavioral profiles are in fact distinct in the two populations (Hall, Lightbody, Hirt, Rezvani, & Reiss, 2010; Kaufmann et al., 2004; McDuffie, Thurman, Hagerman, & Abbeduto, 2014). For example, McDuffie and colleagues (2014) designed a study whereby groups of individuals with idiopathic ASD and individuals with FXS were matched on three different criteria: (1) on chronological age regardless of comorbidity (i.e., some members of the FXS group met and others did not meet the ASD diagnostic criteria); (2) on diagnosis (chronological age matches, taking all

the participants with FXS who had received a comorbid ASD diagnosis); and (3) on severity (chronological age together with severity levels of the ASD diagnosis). The three groups were then compared on the basis of their scores on the ADI-R, a tool commonly used in the diagnosis of ASD, which yields a variety of scores within three categories: reciprocal social interaction, communication, and restricted interests/stereotypical behaviors. Comparing idiopathic ASD and comorbid FXS/ASD, the study identified a number of significant differences in scores, for instance, for social smiling and complex behaviors. However, studies based solely on behavior can be problematic, because they tend to match individuals according to ASD severity, or ASD diagnostic criteria, which themselves are behaviorally defined, and then compare groups based on behaviorally defined ASD symptomatology and measures of adaptive behaviors. The risk of circularity is obvious.

Circularity can be surmounted by opting for a different level of analysis, i.e., neurobiological and molecular variation between FXS and ASD or ADHD, using both human and animal models. Taking again the example of ASD, researchers need to raise the very question of why genetically defined FXS would lead to ASD-like symptoms. Here, the major response stems from research that has found that many of the targets of FMRP are indeed the products of genes that have also been implicated in ASD (Darnell et al., 2011). This has caused scientists to argue that FXS leads to ASD or autistic-like symptoms via downstream mechanisms of FMRP. Recent modeling studies have lent support to this claim by modeling how FMRP targets not only contribute to an ASD outcome, but they do so via a number of distinct etiologies. These include single, rare, highly penetrant disruptions in a subgroup of embryonically expressed FMRP targets, as well as multiple less penetrant disruptions with cumulative effects in a subgroup of FMRP targets up-regulated in adolescence and adulthood (Steinberg & Webber, 2013). Such an explanatory framework suggests that *FMR1* silencing would put individuals with FXS at higher risk for comorbid ASD if accompanied by other downstream hits that are also involved in ASD risk factors. This gives rise to a further question: why does non-idiopathic ASD, which may or may not result from genetic disruption downstream of FMRP, share symptoms with genetically defined FXS? This is where animal models become critical. Indeed, molecular work on mice is beginning to shed light on this issue. Research using a common ASD mouse model, the *Nlgn3* KO mouse, has succeeded in creating the same synaptic phenotype as in FXS (Baudouin et al., 2012). Thus, despite distinct etiologies, FXS and at least one example of genetically defined ASD share a core neurobiological phenotype, opening the doors to explore shared therapeutic intervention studies. Moreover, scientists have argued that the notion of shared genetic and neural mechanisms is actually supported also by behavioral findings. For example, Rogers and collaborators (2001) studied two subgroups of young children with FXS between the ages of 21 and 48 months, one of which performed similarly to children with developmental delay but not ASD, and the other whose performance was similar to a group with idiopathic ASD. To explain the subgroup findings, the authors argue that these differences occur because the FXS mutation represents high risk for all individuals, but it is not determinist; additional mutations are likely to work synergistically with the FXS mutation to result in comorbid ASD. In spite of the demonstration of shared genetic and neural mechanisms, there are numerous other functional and anatomical differences between individuals with FXS and those with idiopathic ASD, which supports a contrasting view, that is, that comorbid ASD in FXS may be distinct from those in nonsyndromic, idiopathic ASD (Hazlett et al., 2009). Further in-depth research is clearly necessary to decide between these competing theories. Although variation in the behavioral profiles of individuals with FXS alone, FXS together with comorbid ASD, and idiopathic ASD obviously complicates the picture, the investigation of the genetic and cellular mechanisms of ASD risk in FXS may yield a better understanding of comorbidity in general as well as of the heterogeneous presentation of symptoms across individuals, ultimately resulting in targeted therapeutic interventions based on biological differences.

Comorbidity With ADHD

Very similar approaches need to be taken to understand the mechanisms responsible for the presence of hyperactivity and inattention mechanisms in ADHD and comorbid FXS/ADHD (Scerif & Baker, in press). Idiopathic ADHD is associated with both functional and structural abnormalities of a distributed right lateralized corticostriatal network implicated in inhibitory control. Interestingly, these atypicalities overlap significantly with those implicated by functional imaging studies of inhibitory control problems in FXS (e.g., Hoeft et al., 2007). Early reports of localized structural abnormalities have since been complemented by large-scale studies of cortical development over time (Shaw et al., 2007). Such longitudinal studies have also pinpointed the differences in prefrontal cortical thickness across patients with ADHD that tend to predict

later clinical outcome (Shaw et al., 2006). Functional abnormalities of these circuits in ADHD have also been clearly established: fMRI studies using classical inhibitory control tasks (e.g., go/no-go task, stop-signal reaction time) yield reduced activation of inferior prefrontal cortex and caudate nucleus compared with healthy age-matched controls (Durston et al., 2003), a finding that mirrors the abnormalities found in FXS (Hoeft et al., 2007). Electrophysiological studies also indicate that children with ADHD differ from controls at multiple time points in the information processing cascade leading to the inhibition of a response or when resolving conflict (Liotti, Pliszka, Perez, Kothmann, & Woldorff, 2005). Again, very similar findings have emerged from electrophysiological studies of adolescents and adults with FXS (van der Molen et al., 2012).

At the level of neurotransmission, the involvement of striatal circuits in ADHD is strongly supported by the fact that methylphenidate (MPH), a dopamine reuptake inhibitor, alleviates symptoms in the majority of affected cases (Volkow, Wang, Fowler, & Ding, 2005). Interestingly, MPH has been shown also to be the most effective pharmacological intervention for treating ADHD-like symptoms in individuals with FXS (Roberts et al., 2011). Intriguingly, recent findings from genome-wide association studies have considerably changed prevailing views on which key genes might be associated with risk for ADHD (Franke, Neale, & Faraone, 2009). Rather than the expected dopaminergic candidates, it is genes involved in neurodevelopmental networks for neurite outgrowth that seem to be more heavily implicated (Poelmans, Pauls, Buitelaar, & Franke, 2011). This turns out to be consistent with recent evidence from the study of rare copy-number variants in ADHD, suggesting that intrinsic neurotransmitter systems, and more specifically metabotropic glutamatergic pathways, are likely to be involved in ADHD risk (Elia et al., 2012). Importantly, these very pathways overlap with those compromised in FXS, suggesting at least one neural pathway of risk for hyperactivity/inattention that is shared between idiopathic ADHD and FXS.

In summary, the high risk for ADHD- and ASD-like symptoms in FXS has attracted the attention of scientists studying those behaviorally defined neurodevelopmental disorders, because multilevel studies of FXS could contribute to a much earlier understanding of the developmental trajectories in the normal population that lead to compromised outcomes in confirmed diagnoses of ADHD or ASD. The longitudinal assessment of very young children with FXS, before their behavioral problems become consolidated, would be especially helpful in this respect, in that it could lead to the identification of potential modifiable protective factors (e.g., environmental inputs such as parent-child interaction and teaching practices). However, this again puts us squarely in the important debate as to whether ADHD and ASD symptoms in FXS are similar to or different from those in idiopathic cases of ADHD and ASD. We argue that a focus on both overlapping and distinct neural mechanisms may advance this debate, especially if it also takes into account potential differences in developmental timing.

RELATIONSHIPS TO THE PRINCIPLES OF DEVELOPMENTAL PSYCHOPATHOLOGY

Throughout this chapter, we have focused in particular on a specific neurodevelopmental disorder and its comparison with other genetic disorders. However, because of their identified etiology, disorders like FXS, WS, and DS offer inroads into the broader and more general principles of developmental psychopathology as a whole (Cicchetti & Toth, 2009). First, their study is increasingly interdisciplinary, bridging scientists who work at complementary levels of enquiry: from cellular neuroscience to systems neuroscience, developmental and cognitive psychology, as well as clinical implementation (e.g., see Fung, Quintin, Haas, & Reiss, 2012, for a review of mechanistic comparisons between FXS and WS). Second, work on specific genetic disorders and their comparison identifies new challenges for developmental cognitive neuroscientists working with neurotypical individuals: if they play such an important role in shaping atypical development (e.g., Karmiloff-Smith et al., 2012), how do typical low-level mechanisms such as attentional biases impact memory and learning trajectories over developmental time (see Scerif & Wu, 2014, for emerging implications in the field of typical attention research)? Third, because the early genetic diagnosis increasingly precedes the emergence of childhood difficulties and it is clear that not all children with disorders like FXS, WS, and DS develop full-blown ADHD or ASD, may offer insights into pathways to protection and resilience. Fourth, in addition to discovering multilevel processes leading to maladaptive and adaptive life span outcomes, researchers in this area now have a range of interdisciplinary tools to ameliorate poor outcomes. Although recent efforts have focused on pharmacogenetics (e.g., Jacquemont et al., 2014), there is also growing interest in complementary effective and syndrome-specific psychosocial therapies (Turk, 2011). We turn to these translational implications in a later section.

FUTURE DIRECTIONS: THE IMPORTANCE OF LONGITUDINAL COMPARISONS ACROSS SYNDROMES OF KNOWN GENETIC ORIGIN

Throughout this chapter, we have argued for the importance of taking a syndrome of known genetic origin to gain a deeper understanding of those neurodevelopmental disorders which are currently only defined in terms of patterns of behavioral deficits. Yet, cross-syndrome comparisons amongst genetic syndromes themselves also turn out to be particularly useful. For example, it is frequently the case that individuals with different genetic syndromes end up with the same behavioral scores on a task. Can we take it that the underlying cognitive and/or neural processes are the same? Not necessarily. Indeed, in a series of cross-syndrome comparisons of genetic syndromes including FXS, Down syndrome (DS) and Williams syndrome (WS), we have revealed different cognitive and neural processes even when scores fall within the normal range on standardized tasks such as the Benton or Rivermead face processing tasks (Karmiloff-Smith et al., 2004). Other studies, e.g., examining sensitivity to numerical displays in infants with genetic syndromes such as DS and WS, revealed different trajectories of saccadic eye movements even though total looking time scores were equivalent across the two syndromes (Karmiloff-Smith, 2012). In comparisons of FXS and WS (e.g., Scerif et al., 2004), we demonstrated the existence of different patterns underlying equivalent behavioral scores. Such subtle differences are crucial to inform both theory and intervention, and underline the importance of syndrome-specific treatment schedules. In general, comparisons across syndromes yield subtle impairments that a focus on a single syndrome would not necessarily reveal. Ultimately, future research in developmental psychopathology should target prospective longitudinal designs that directly compare dynamically changing profiles and trajectories across disorders of identified genetic etiology, at all their interacting levels. Detailed prospective work on developmental dynamics at each level will need to be increasingly complemented by interdisciplinary collaborations bringing together clinicians and researchers working on animal models, systems neuroscience, and developmental psychology.

TRANSLATIONAL IMPLICATIONS

Translational research has been defined as "research designed to address how basic behavioral processes inform the diagnosis, prevention, treatment and delivery of services for mental illness and, conversely, how knowledge of mental illness increases our understanding of basic behavioral processes" (National Advisory Mental Health Council, 2000, p. iii). The convergence between basic scientists and clinicians in the area of genetic disorders is still in its infancy. However, we believe that a cross-syndrome developmental cognitive neuroscience approach will be pivotal in devising intervention attempts that are truly syndrome-specific, rather than focused on a collection of individual behavioral symptoms. To take hyperactivity and inattention, until now the most commonly used approach to treat them in the context of FXS has been stimulant-based treatment (Roberts, Miranda, et al., 2011). A similar approach has characterized the treatment of hyperactivity in WS (Rhodes et al., 2011). In contrast, researchers and clinicians alike have been calling for a mechanism- and syndrome-specific approach to treatment, and one that is sensitive to individual and developmental differences within the spectrum of individuals with FXS (Jacquemont et al., 2014; Turk, 2011). We believe that similar translational implications apply to other neurodevelopmental disorders of identified genetic etiology and high risk of behavioral difficulties. If these difficulties continue to be treated as disparate symptoms, rather than the complex outcomes of multilevel developmental dynamics, treatment approaches will not be optimized to the specific needs of individuals with genetic disorders.

CONCLUDING THOUGHTS

In this chapter we have highlighted the importance of both cross-syndrome comparisons and within-syndrome variability. Indeed, despite very high risk, FXS is not of necessity associated with impairment. In fact, some children with the full FXS mutation function quite well. This is true in the case not only of females, who have the additional unaffected X that may act as a protective factor, but also of some males. So, something protects a limited number boys from risk, which is why we believe that the case of young children with a diagnosis of FXS constitutes an interesting more general model in which to assess early predictors of risk and resilience, as well as early predictors of declining or improving neurocognitive trajectories (Hernandez et al., 2009; Rogers, Wehner, & Hagerman, 2001). This is particularly true of comorbidity with ASD- and ADHD-like symptomatology. Other syndromes of known genetic origin (e.g., Williams syndrome) have also been used as models for a more general consideration of neurocognitive disorders (D'Souza et al.,

2014; Farran & Karmiloff-Smith, 2012; see also Scerif & Wu, 2014). Cross-syndrome comparisons can also be rich sources of information at multiple levels of description (Karmiloff-Smith et al., 2012).

Here, we used the example of fragile X syndrome to illustrate a number of broad points that emerge from the study of genetic syndromes. We overviewed what is known about the FXS genotype and phenotype in terms of cellular, neural, cognitive, and behavioral aspects of the syndrome, in particular emphasizing its developmental nature. Critically, we discussed how recent longitudinal data emphasize the need to focus on variability in outcomes for affected individuals, even in the face of a monogenic disorder. As mentioned above, there is indeed no one-to-one mapping between genetic mutation and phenotypic outcome, but rather a complex, time-dependent pathway across developmental time. The findings on FXS highlight the need to understand diverging developmental trajectories, predictors of greater risk, mechanisms of resilience and environmental protective influences. In summary, we argue that, because they present biologically well-dissected information about genetic origin, syndromes like FXS lend themselves particularly well to study of the high risk of impairment for common behaviorally defined disorders, like ADHD and ASD (see Scerif & Baker, in press, for a review of how this approach might inform an understanding of ADHD risk). However, to understand trajectories leading to good or poor outcomes, as well as their overlap or differences across disorders, a developmentally inspired approach is critical and needs to go beyond behavioral outcomes and be underpinned by knowledge of the developmental cognitive neuroscience of each disorder.

HISTORICAL CONTEXT

In the early twentieth century Dr. Eugen Bleuler used the term *autism* to describe individuals with schizophrenia who were disconnected from reality ushering in the word into the scientific literature (Bleuler, 1911/1950). Decades later, Dr. Leo Kanner used the term to describe 11 individuals with a pattern of behaviors involving social withdrawal that he felt was distinct from schizophrenia (Kanner, 1943). He referred to this group of patients with challenges in the social and language domains and repetitive behaviors as having early infantile autism. He reported that the patients demonstrated an inability to relate to others as well as social communication challenges including language delays, echolalia, pronominal reversals, and concrete language use. Additionally he described elaborate rituals and routines reflecting a significant insistence for sameness (Kanner, 1943).

During the same time period, Dr. Hans Asperger, working in Europe, described a group of boys with similar challenges in social communication (Asperger, 1944/1991). He described a pattern of difficulties in social interaction including impaired use of eye contact, affective expression, and conversational abilities, similar to Kanner's report. However, in contrast to Kanner's patients, the patients Asperger described had well developed language abilities and often spoke pedantically like adults (Asperger, 1944/1991). Although their vocabulary and grammatical skills were intact, these children had significant impairments in conversational skills and had an unusual use of the volume, tone, and rhythm of speech. Finally, Asperger commented on their tendency to become excessively

preoccupied with singular topics of interest, referring to them as little professors because of their tendency to discuss these interests in great detail.

Early theories on the etiology of autism were based on the prevailing atmosphere of psychological understanding of the middle of the twentieth century. At the time psychoanalytic theory was the prominent perspective on the development of mental illness, and although there are many schools of thought within the field, in general, psychoanalytic theory is based on the notion that mental illness arises from unconscious conflicts resulting from early childhood experiences—most often experiences with parental relationships. As such, based on this perspective, if unconscious conflicts resulting from early development are believed to be the root cause of a childhood disorder and if parents, particularly mothers, are the key component of a child's early development, then parents could be considered the causal factor in the development of disorders for which no clear etiology has been identified. Such was the case with autism.

Following his contemporary theorists, Bettelheim (Bettelheim, 1967) proposed that children with autism withdrew from social interaction and turned inward in response to cold, aloof parents—particularly mothers. However, empirical work in the 1970s and 1980s provided evidence counter to this refrigerator mother theory. Parents of children with autism demonstrated personality measures within the normal range and reported similar levels of marital satisfaction and family cohesion relative to parents of children without disabilities (Koegel, Schreibman, O'Neill, & Burke, 1983; McAdoo & DeMyer, 1978). Early scientific leaders arguing against the refrigerator mother theory proposed that the disorder was due to a neurological impairment (Rimland, 1964) and had a strong genetic component (Folstein & Rutter, 1977), and also proposed that involving parents as part of the treatment was more appropriate and beneficial than treating the parents (Schopler & Reichler, 1971).

In the years since Kanner first reported on 11 children who had an "inability to relate themselves in the ordinary way to people and situations from the beginning of life" (Kanner, 1943, p. 242), there have been tremendous gains in our understanding of the core impairments, etiology, and intervention of autism spectrum disorder.

CORE CHARACTERISTICS

The saying "if you've met one child with autism, you've met one child with autism" speaks to the significant variability in presentation of autism. While each individual with autism presents with a unique constellation of symptoms and corresponding challenges, there are several characteristics that fall within the domains of social communication and repetitive and restrictive behavior and define the ASD diagnosis.

Social Attention

From the first days of life typical infants show preferential attention to their social world, attending to faces, voices, and body movements from very early in life. In contrast, young children with autism pay less attention to people and their actions and movements, instead directing their attention to nonsocial objects (Shic, Bradshaw, Klin, Scassellati, & Chawarska, 2011). A primary feature of ASD that emerges by 12 months of age is impaired eye contact (Werner, Dawson, Osterling, & Dinno, 2000; Zwaigenbaum et al., 2005). Toddlers (between the ages of 14 and 42 months of age) with ASD prefer geometric images to images of other children (Pierce, Conant, Hazin, Stoner, & Desmond, 2011), and as opposed to toddlers with either typical development or developmental delays, toddlers with ASD do not show any difficulty disengaging from looking at a face when presented with another stimulus (Chawarska, Volkmar, & Klin, 2010). Two-year-old children with ASD orient to nonsocial contingencies as opposed to biological motion (Klin, Lin, Gorrindo, Ramsay, & Jones, 2009), and preschool-age children with ASD do not show normal preferences for speech sounds (Klin, 1991, 1992; Kuhl, Coffey-Corina, Padden, & Dawson, 2005). Similarly, Ruffman, Garnham, and Rideout (2001) observed intact anticipatory looking during a story task involving nonsocial objects but decreased looking during a story involving human characters in children with ASD compared to children with learning disabilities. This reduced social attention and the observed failure to orient to social stimuli has been termed a *social orienting impairment* and has been noted in preschool-age children with autism and in children as young as 10 months old who go on to develop autism (Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998; Werner et al., 2000). In early work in this area, Osterling and Dawson (1994) viewed videotapes of first birthday parties for children who later went on to develop autism and typically developing children and observed that 1-year-olds with autism oriented less often to social stimuli (faces, speech sounds) in their natural environments. In an experimental effort to characterize social attention abilities in ASD, Dawson et al. (Dawson, Meltzoff, Osterling, Rinaldi, et al., 1998) compared rates of orienting to social stimuli (name calling, clapping) and

nonsocial stimuli (rattle, jack-in-the-box) in children with ASD, and receptive language mental age matched children with Down syndrome and typical development. They found that children with ASD more frequently failed to orient to both types of stimuli but this failure was more pronounced for the social stimuli. This body of literature highlighting deficits in social attention suggests that children with ASD may have reduced sensitivity to reward value of social stimuli. As such, these deficits early in development could subsequently result in other, broad downstream social impairments as the child would have reduced opportunities for social learning as a result of the decreased attention and resources devoted to the social world. Indeed, as described later, disruptions to brain circuitry related to reward mechanisms, such as the anterior cingulate cortex (ACC) and orbitofrontal cortex (OFC), have been noted in imaging studies of individuals with ASD indicating differences in neurological functioning of reward related neural networks (Dichter et al., 2010; Haznedar et al., 2000; Schmitz et al., 2008; Scott-Van Zeeland, Dapretto, Ghahremani, Poldrack, & Bookheimer, 2010).

Joint Attention

Joint attention is defined as the ability to "coordinate attention between interactive social partners with respect to objects or events to share an awareness of the objects or events" (Mundy, Sigman, Ungerer, & Sherman, 1986, pp. 657). By about 9 months of age, typically developing infants begin to look between an object and caregiver and learn to share attention (Walden & Ogan, 1988). This is followed by the incorporation of gesture. By about 12 months of age, infants learn to direct another's attention to an object of interest through gestures such as pointing and also learn to follow another's point (Hannan, 1987). These early emerging joint attention skills are a critical step in the development of spoken language (Bruner, 1975).

Systematic study of joint attention abilities in ASD reveals marked impairments in initiating joint attention, but less so for initiating requests and responding to others' joint attention bids. Children with ASD show less spontaneous sharing or directing of others' attention to an object or action of interest, but less impaired abilities to follow others' gaze and gestures to jointly attend to a point of reference (Mundy, Sigman, & Kasari, 1994; Mundy et al., 1986). Impairments in joint attention, assessed through medical screening visits at 12 and 18 months of age, are present in children later diagnosed with ASD (Baron-Cohen et al., 1996). These joint attention impairments remain consistent over development (Mundy, Sigman, & Kasari, 1990), are linked with later language abilities (Mundy et al., 1990), and are predictive of subsequent diagnosis and degree of social impairment (Mundy et al., 1994; Sigman et al., 1999; Yoder, Stone, Walden, & Malesa, 2009). Given the prominence of these impairments, a deficit in joint attention is considered a core social impairment in ASD (Charman, 2003; Dawson, Toth, et al., 2004; Loveland & Landry, 1986; Mundy et al., 1986; Sigman et al., 1999; Wetherby & Prutting, 1984). Indeed, joint attention deficits correctly classify 94% of children with ASD in relation to children with intellectual disability (Mundy et al., 1986). Considered in a developmental context, the role of joint attention ability is critical to social and language learning. Indeed, the deficits in this social cognitive ability observed in ASD, as demonstrated in the research literature, predict further downstream impairments later in development.

Face Perception

At birth infants show a preference for face-like stimuli (Goren, Sarty, & Wu, 1975), and within the first few days of life typical infants are able to recognize their mother's faces (Bushnell, Sai, & Mullin, 1989). Individuals with ASD have consistently shown impairments in face processing abilities. A failure to look at others was the single best discriminator between 12-month-old infants who were subsequently diagnosed with ASD and those going on to develop typically (Osterling & Dawson, 1994), and as such this lack of attention to faces may be one of the most reliable early indicators of ASD risk (Dawson, Webb, & McPartland, 2005). By middle childhood, children with ASD perform worse than mental-age and chronological-age matched peers on tasks of face recognition (Boucher & Lewis, 1992; Boucher, Lewis, & Collis, 1998; Gepner, deGelder, & deSchonen, 1996) and face discrimination (Tantam, Monaghan, Nicholson, & Stirling, 1989). In a controlled study of face processing in ASD, Klin and colleagues (1999) observed impaired face recognition that could not be accounted for by cognitive delays or impairments in spatial memory. In contrast to typical children, children with ASD are better at recognizing isolated facial features and partially obscured faces (Hobson, Ouston, & Lee, 1988; Tantam et al., 1989) show better face memory performance when focusing on the lower half of the face (Langdell, 1978), but show less attention to the core features of the face such as the eyes and nose (Chawarska & Shic, 2009; Klin, Jones, Schultz, Volkmar, & Cohen, 2002; Pelphrey et al., 2002; Trepagnier, Sebrechts, & Peterson, 2002).

This reduced attention to faces may be the downstream effect of reduced social motivation (Chevallier, Kohls, Troiani, Brodkin, & Schultz, 2012; Dawson, Webb, & McPartland, 2005; Klin et al., 1999). Dawson and colleagues proposed that reduced social motivation results in decreased attention to faces that subsequently results in a failure to develop expertise in the perception of faces. Without this experience expectant environment, the brain systems needed to process faces in a typical pattern do not develop (Dawson, Webb, & McPartland, 2005).

Indeed, several studies indicate atypical neural functioning in face perception in ASD. Young children with ASD show an atypical faster neural response using neurophysiological assessment to objects than to faces as opposed to the opposite pattern observed in typical children (Webb, Dawson, Bernier, & Panagiotides, 2006). Preschool-age children with ASD show neural responses to familiar and unfamiliar faces similar to typically developing toddlers, suggesting delayed development in face processing circuitry (Webb et al., 2011). Slower neural responses to faces have been observed in adolescents and adults with ASD (McPartland, Dawson, Webb, Panagiotides, & Carver, 2004; O'Connor, Hamm, & Kirk, 2007), parents of children with ASD (Dawson, Webb, Wijsman, et al., 2005), and 10-month-old infants at risk for ASD (McCleery, Akshoomoff, Dobkins, & Carver, 2009), suggesting that the neural systems underlying face processing may be less efficient and lack specificity to faces. However, not all results have been consistent (for a review, see Dawson, Webb, & McPartland, 2005).

Emotion Perception

By 6 months of age typical infants differentially respond to the emotional displays of those in their environment (Trevarthen, 1979). That is, they smile more and direct more attention to happy faces relative to neutral or sad expressions (Rochat & Striano, 1999; Tronick, Als, Adamson, Wise, & Brazelton, 1978). By the time infants are between 9 and 12 months of age they have learned to utilize others' facial expressions to guide their own behavior when in unfamiliar situations or presented with novel stimuli (Feinman, 1982; Moore & Corkum, 1994). The ability to empathically respond to another's distress also begins to emerge within the first years of life, and is reflected by demonstrations of concern, sharing, helping, and comforting (Rheingold, Hay, & West, 1976; Zahnwaxler & Radkeyarrow, 1990).

In his initial report in 1943, Kanner noted that individuals with ASD are impaired in the recognition of affective cues. A number of empirical studies have demonstrated this observation through carefully controlled experimentation. Studies have shown that children with ASD fail to attend to others' affective displays normally (Bacon, Fein, Morris, Waterhouse, & Allen, 1998; Blair, 1999; Charman et al., 1998; Dawson, Meltzoff, Osterling, & Rinaldi, 1998; Hall, Szechtman, & Nahmias, 2003; Sigman, Kasari, Kwon, & Yirmiya, 1992) and show deficits in recognizing emotional expressions (Bormannkischkel, Vilsmeier, & Baude, 1995; Braverman, Fein, Lucci, & Waterhouse, 1989; Hobson, 1986a, 1986b; Macdonald et al., 1989). Pioneering work in which a familiar examiner pretended to hurt himself or herself by hitting one finger with a plastic hammer and then displayed facial and vocal expressions of distress without using words demonstrated differential response to distress. Sigman and colleagues (1992) observed the behavioral responses of 3- to 4-year-old children with ASD, intellectual disability, and typical development and found that children with ASD often failed to notice or ignored the examiner's affective displays, while the comparison groups were very attentive to the examiner's affective display regardless of the type of emotion displayed. However, employing a similar design, Dawson and colleagues (1998) found that although still attending less than controls, the children with ASD were able to distinguish between emotions; they were more likely to observe and attend to distress relative to a neutral expression. This reduced attention to emotional expressions has also been noted in children with ASD as young as 2 years old (Charman et al., 1998).

The behaviorally observed differences in emotion perception are reflected in observed neurophysiological differences as well. Dawson and colleagues (Dawson, Webb, Carver, Panagiotides, & McPartland, 2004) assessed neural responses to images of a fear face and a neutral face in 3–4-year-old children with ASD as well as typically developing, age matched peers, and chronological and mental aged matched children with developmental delay using event related potentials. During passive viewing of facial expressions the toddlers with ASD failed to demonstrate the increased amplitude to the fear face that was observed in the typical children. Importantly, delays in neural processing of the fear face were associated with reduced social attention assessed through experiments conducted on a different day. Specifically, greater delays in processing the emotional expressions were associated with decreased attention to an experimenter expressing distress, fewer joint attention bids, and reduced social orienting. Importantly, these affective processing delays were not correlated with task performance involving attention to

nonsocial stimuli, such as orienting to nonsocial sounds. This study suggests that children with ASD show deficits in basic aspects of emotion perception by at least 3 years of age and that these challenges are associated with poor social abilities more broadly.

Imitation

Imitation is an early emerging social ability. Newborns as young as 42 minutes old can imitate facial expressions (Meltzoff & Moore, 1977, 1979, 1983) and from there, these early skills develop rapidly over the first years of life with the imitation of actions on objects and imitation of simple gestures, such as waving, emerging around one year of age. Imitation skills progress from simple and familiar actions to increasingly complex, novel, and sequenced behaviors (Meltzoff & Moore, 1994; Piaget, 1962) with the application of imitative actions in novel contexts, emerging between the first and second year, although some researchers suggest the skill emerges earlier (see Bauer, 1996, for review).

It has been proposed that imitation serves as a foundation for social reciprocity and connectedness with others as well as the child's ability to differentiate self from others (Eckerman, Davis, & Didow, 1989; Meltzoff & Gopnick, 1993; Nadel, Guerini, Peze, & Rivet, 1999; Trevarthen, Kokkinaki, & Fiamenghi, 1999; Uzgiris, 1981), developing symbolic play (Piaget, 1962), peer relationships (Trevarthen et al., 1999), language (Avikainen, Wohlschlager, Liuhanen, Hanninen, & Hari, 2003; Charman et al., 2003), and emotional sharing (Hatfield, Cacioppo, & Rapson, 1994). It has also been proposed to play a role in understanding about other's intentions and goals (Kugiumutzakis, 1999; Uzgiris, 1999). In showing that 18-month-old children can imitate others' intended but not completed actions, Meltzoff (1995) proposed that imitation allows a child to understand others' internal states and through the process of learning that the child can produce the same action sequence as what he or she has just observed is a precursor for the development of a theory of mind (Meltzoff & Gopnick, 1993; Rogers & Pennington, 1991).

DeMeyer and colleagues (1972) first reported imitation deficits in ASD after studying nine children with ASD and 12 age-matched children with intellectual disability. The individuals with ASD performed significantly poorer on a large battery of tasks assessing imitation of body movements and actions on objects. The children did not differ in their ability to perform non-imitated actions on objects, suggesting it was imitation and not motor deficits accounting for the observed differences.

Despite the varied testing methodologies, sample characteristics, and comparison groups employed in the studies conducted in the years since DeMeyer and colleagues' report, imitation impairments in ASD have consistently been noted (Williams, Whiten, Suddendorf, & Perrett, 2001). Impairments in the ability to imitate the others' movements, including simple body movements and actions with objects have been observed in young children with ASD (Curcio, 1978; Dawson & Adams, 1984; Dawson, Meltzoff, Osterling, & Rinaldi, 1998; DeMeyer et al., 1972; Sigman & Ungerer, 1984; Stone, Ousley, & Littleford, 1997). Deficits in both immediate and deferred imitation have been noted (Dawson, Meltzoff, Osterling, & Rinaldi, 1998) as well in both *procedural* imitation (i.e., the imitation of actions on novel objects) and *gestural* imitation (i.e., the imitation of meaningless gestures), although gestural impairments were much greater for the autism group (Roeyers, Van Oost, & Bothuyne, 1998). Hobson and Lee found no differences between teens with ASD and age matched peers with intellectual disability in imitation of goal directed actions. However, fewer adolescents with ASD accurately imitated the style with which the experimenter performed the observed action than the control group. They concluded that imitation impairments in ASD reflect a deficit in "the coordination of the representation between the self and other" (Hobson & Lee, 1999). Using a manualized coding system, Bernier and colleagues (Bernier, Dawson, Webb, & Murias, 2007) enlisted trained raters naïve to subject diagnosis to code imitation ability across single step and sequenced behavioral movements in adults with ASD and normal cognitive ability. The adults performed worse on imitative tasks and made more errors in completing the imitative tasks relative to typical peers suggesting imitative deficits are not simply the result of delays in development.

Although there is a general consensus that imitation ability is impaired in ASD, the underlying etiology of particular deficit is still under debate. Theories have attributed imitation impairments to motor praxis impairments and to planning, sequencing, and executing intentional motor movements, although individuals with motor deficits perform better on imitative tasks than ASD (Green et al., 2002; Rogers, 1998). Others have proposed that difficulties in understanding the intersubjective experience of others leads to impairments in matching the movements of self and others (Hobson & Lee, 1999; Meltzoff & Gopnick, 1993). Another theory suggests inadequate procedural learning and inefficient cerebellar-basal ganglia-parietal circuitry contribute to the imitation impairments (Mahone et al., 2006; Mostofsky, Goldberg, Landa, & Denckla,

2000) while neurophysiological and brain imaging studies suggest that a dysfunctional mirror neuron system may play a critical role in imitation deficits (Bernier, Aaronson, & McPartland, 2013; Bernier et al., 2007; Dapretto et al., 2006; Iacoboni & Mazziotta, 2007; Martineau, Cochin, Magne, & Barthelemy, 2008; Oberman et al., 2005; Oberman, Ramachandran, & Pineda, 2008; Rizzolatti & Craighero, 2004; Williams et al., 2006). Regardless of the etiology of the imitation impairments in ASD, given the prominent role of imitative ability to subsequent social cognitive abilities, it is clear that early disruption to imitation can result in deviations from the normal social cognitive developmental tract and result in further downstream developmental challenges for children with ASD.

Symbolic Play

Symbolic representation through pretend play is an important precursor to language development that gradually emerges in the second year of life (Riguet, Taylor, Benaroya, & Klein, 1981; Ungerer & Sigman, 1984). By approximately 20 months of age most children can engage in play in which they attribute animate characteristics to inanimate objects (e.g., pretending that a doll can talk) and can use one object as if it were another (e.g., pretending that a block is a car).

Early reports indicate impairments in symbolic play in ASD. Wulff (1985) stated "the autistic child's play is striking in its lack of fantasy or all other aspects of symbolic play" (pp. 146). Indeed, a key indicator for children who went on to develop ASD noted through a prospective medical screening study was the absence of pretend play at 18 months of age in (Baron-Cohen et al., 1996). Importantly, as their language develops, individuals with ASD show increases in their symbolic play (Amato, Barrow, & Domingo, 1999), and targeted interventions focusing on improving symbolic play yield promising results (Kasari, Freeman, & Paparella, 2006). In scaffolded situations children with ASD can engage in symbolic play (McDonough, Stahmer, Schreibman, & Thompson, 1997), but spontaneous symbolic play is limited, mechanical and repetitive (Wing & Gould, 1978), more akin to learned routines than elaborate, complex, pretend stories (Williams, Reddy, & Costall, 2001). It is unclear if the deficits in symbolic play are the result of a metarepresentational impairment in attending, understanding, and imitating others' actions on objects, that is, a function of joint attention impairments or a function of a generalized cognitive deficit in symbolic thinking, along the lines of an executive function deficit (see (T. Charman, 1997), for a review). Regardless of the cause of the symbolic play deficits, the child with ASD who lacks the opportunity for language and representational learning practiced through play will miss out on the needed opportunities for learning in this arena, resulting in challenges that will only compound with development.

Language and Communication

Given the deficits in the above mentioned early-emerging social communication abilities that are precursors to language development (e.g., joint attention), it is not surprising that many children with ASD have significantly language delays and atypical language development. In fact, language delay is often cited as the initial concern for many parents whose children are later diagnosed with ASD (Chawarska et al., 2007; De Giacomo & Fombonne, 1998; Siklos & Kerns, 2007).

Although it has been historically reported that approximately 50% of individuals with ASD remain nonverbal throughout their lives (Rutter, 1978), this estimate has decreased considerably with advances in earlier diagnosis and intervention. Anderson and colleagues (2007) assessed 9-year-old children with ASD and found that approximately 25% of the children were effectively nonverbal, and another 25% were fluent speakers using complex sentence structure. Findings from longitudinal studies suggest that variability in language ability increases over time, possibly due to responses to intervention (Charman et al., 2005).

Pioneering work in early social communication found that those children with ASD who developed gestural, nonverbal joint attention skills were more likely to develop language (Mundy et al., 1990; Sigman et al., 1999) and a prospective study following high-risk infants who later went on to develop ASD fewer joint attention and gestural behaviors indicating that these early social communicative abilities may be key behavioral indicators of ASD and later language ability (Landa, Holman, & Garrett-Mayer, 2007).

The presence of atypical language is often noted in individuals ASD and limited language. Many individuals with ASD have atypical language characterized by immediate or delayed echolalia (e.g., verbatim repetition of previously heard words or phrases; Rydell & Mirenda, 1994), atypical prosody (e.g., abnormal rhythm, stress, intonation, and loudness; Peppe, McCann, Gibbon, O'Hare, & Rutherford, 2007), neologisms or idiosyncratic language (e.g. the use of made of words; Volden & Lord, 1991), and pronominal reversal (e.g., use of "you" instead of "I" when referring to the self; Cantwell, Baker, Rutter, & Mawhood, 1989; Kanner, 1943).

Despite the presence of language delays and atypical use of language, the most pronounced language impairments in ASD fall in the pragmatic, or social, aspects of language use (see Tager-Flusberg, 1999, 2001, for reviews). Noted characteristics of conversational exchanges with individuals with ASD include the use of irrelevant detail in conversations (e.g., providing dates and ages when discussing a particular event or person), perseveration of particular topics, pedantic speaking on a particular topic of conversation, inappropriate shifts to a new topic without context or consideration of the listener, and a lack of responsiveness to conversational topic initiations introduced by another person (Eales, 1993; Paul, Orlovski, Marcinko, & Volkmar, 2009; Tager-Flusberg, 1999, 2001). These challenges, along with reduced responses to questions and fewer spontaneous offerings of information disrupt the sense of reciprocity in conversational exchanges (Capps, Kehres, & Sigman, 1998). These difficulties with the social aspect of language are also observed among highly verbal adults with ASD (Lord & Paul, 1997). It has been proposed that these pragmatic deficits are the result of impairments in understanding another's intention during conversations (Eales, 1993) or because individuals with ASD have difficulty taking the listener's perspective into account (Tager-Flusberg, 1993, 1996). This difficulty is reflected in atypical language use such as abnormal pronoun use (e.g., saying "You want a drink" when meaning "I want a drink") and inaccurate application of questions and statements (e.g., saying "Want milk?" instead of stating "I want milk").

Language comprehension difficulties have been noted in ASD as well. Many individuals have difficulty understanding non-literal language such as irony, sarcasm, and metaphor (Happe, 1995; MacKay & Shaw, 2004; Martin & McDonald, 2004). Studies also suggest that individuals with ASD also struggle to understand vocal utterances based on stress patterns (Peppe et al., 2007) or identify affective content in a voice (Korpilahti et al., 2007; Rutherford, Baron-Cohen, & Wheelwright, 2002). Rapin (1996) noted that many individuals with ASD seem to have greater challenges in understanding other people's language than they do in learning the specific language structures necessary to produce language (Rapin, 1996). For example, in a study of children with ASD compared to children with specific language impairment, the children with ASD tended to rely on a syntactically based word order strategy rather than relying on the semantic content to determine the meaning of a sentence (Rhea Paul, Fischer, & Cohen, 1988).

It is becoming clear that the language delays and atypical language observed in ASD often result from and interact with other deficits such as comorbid language processing deficits (Bishop & Norbury, 2002; Rapin & Dunn, 2003; Tager-Flusberg, 2004); difficulties in theory of mind (Paul et al., 2009; Tager-Flusberg, 2000); and repetitive behavior being reflected in stereotypical speech patterns (Bodfish, Symons, Parker, & Lewis, 2000; Gabriels, Cuccaro, Hill, Ivers, & Goldson, 2005).

Restricted and Repetitive Interests and Behaviors

Restricted and repetitive interests and behaviors (RRBs) are considered a core diagnostic feature of ASD (Lord & Luyster, 2006; Lord et al., 2006) and were identified as part of Kanner's initial report on ASD. RRBs include repetitive, stereotypic motor mannerisms such as hand flapping, finger flicking, or complicated whole body movements such as posturing or spinning and repetitive use of objects, such as lining things, spinning the wheels of a toy car, playing with strings, repeatedly dropping something from the same height. RRBs also include interests that are unusual in their focus, such as an interest in street signs or toilets, or in their intensity, such as a focused preoccupation on a particular topic typically involving the memorization of facts (e.g., train timetables). An insistence on sameness, reflected in difficulties with transitions or changes to routines or by the presence of ritualized sequences of actions or the precise arrangement of space also falls under the category of RRBs. Finally, sensory interests, such as interests in the sight, sound, smell of things or people (e.g., interest in hair) and aversions (e.g., aversions to specific sounds or particular textures, sound sensitivities necessitating removal from stimuli or situation) are also components of this category.

The observed sensory related challenges can be subdivided to reflect sensory over-responsivity (e.g., negative responses to specific sensory stimuli such as lights or sounds), sensory underresponsivity (e.g., reduce responsiveness to various sensory stimuli), and sensory seeking (e.g., actions performed to increase sensation) (Dunn, 1997; Miller, Anzalone, Lane, Cermak, & Osten, 2007). All three of these sensory processing profiles have been observed in individuals with ASD (Baranek, David, Poe, Stone, & Watson, 2006). Rates of sensory overresponsivity in ASD range from 56 to 70% (Baranek et al., 2006; Ben-Sasson et al., 2007) with common manifestations including distractibility because of the noise emitted by fluorescent lights or a distant siren. However, the same

children with overresponsivity can at times show underresponsivity such as in the form of insensitivity to pain. It has been suggested that impaired ability to modulate sensory information underlies these challenges observed in ASD (Ornitz, 1989).

It has been proposed that RRBs in ASD fall in two distinct categories: lower level behaviors including repetitive motor movements and higher level behaviors that are characterized by insistence on sameness and circumscribed interests (Turner, 1999). The lower level behaviors appear to occur more often in younger children with ASD or children with comorbid intellectual impairments (Wing, 1988; Wing & Gould, 1979), while the higher level behaviors are observed in children without significant intellectual impairments. Both forms of RRBs appear by 2 to 3 years of age (Bishop, Richler, & Lord, 2006; Honey, McConachie, Randle, Shearer, & Le Couteur, 2008; Militerni, Bravaccio, Falco, Fico, & Palermo, 2002; Mooney, Gray, & Tonge, 2006) and longitudinal studies suggest that they persist into adolescence and adulthood (Piven, Harper, Palmer, & Arndt, 1996; Rumsey, Rapoport, & Sceery, 1985).

No specific type of repetitive behavior is specific to ASD as RRBs are observed in typically developing infants and young children (e.g., Evans et al., 1997; Thelen, 1979), and in other neurodevelopmental and psychiatric disorders (Frith & Done, 1990). For example preferences for routines and distress from changes to expectations are observed in typically developing young children (Evans et al., 1997) and in individuals with psychiatric disorders, such as obsessive-compulsive disorder, and repetitive mannerisms are often seen in individuals with intellectual disability. However, relative to typical development in which these behaviors happen fleetingly and to other disorders, in ASD these behaviors occur more frequently (Matson, Dempsey, & Fodstad, 2009). Indeed, the observed pattern of multiple types and severity of RRBs can aid in the discrimination of ASD from other disorders (Bartak & Rutter, 1976; Bodfish et al., 2000; Charman & Swettenham, 2001).

More research is needed to elucidate the relationship between RRBs and the social communication impairments characterizing ASD. Historically, studies examining early emerging ASD characteristics suggested that social communication impairments were the first indicators to emerge in ASD (Baron-Cohen et al., 1996; Cox et al., 1999; Osterling & Dawson, 1994; Robins, Fein, Barton, & Green, 2001); however, recent prospective studies of at risk infant siblings of children with ASD suggest that RRBs, including spinning and spending more time attending to objects observed at 12 months of age are predictive of subsequent ASD symptoms and diagnosis (Ozonoff, Heung, Byrd, Hansen, & Hertz-Picciotto, 2008; Zwaigenbaum et al., 2005). While some argue for an underlying continuous factor of ASD symptoms rather than distinct domains of impairment (Constantino et al., 2004), others cite twin studies showing that these ASD domains are only modestly correlated and conclude they are likely distinct (Happe, Ronald, & Plomin, 2006). The presence of circumscribed interests may provide insight. These intense, perseverative interests usually involve memorization of facts about a specific topic (e.g., cameras, trains) that are nonsocial in nature (South, Ozonoff, & McMahon, 2005) and appear to be common to ASD (one study found that approximately 88% of children with ASD had circumscribed interests) regardless of intellectual functioning or symptom severity (Lam, Bodfish, & Piven, 2008). The nonsocial focus of these interests could diminish motivation and opportunities for social experiences, such that decreased reward salience for social stimuli and increased valence for non-social stimuli could result in the sequelae of impairments observed across both domains in ASD.

DIAGNOSIS AND ASSESSMENT OF ASD

There is currently no biological marker or medical test for making a diagnosis of ASD. The diagnosis is made through careful evaluation of developmental history and caregiver report of symptomatology and observation of the presence (or absence) of behaviors across the two domains of ASD: social communication and repetitive and restricted behavior. The two widely used systems for diagnosing ASD include the *Diagnostic and Statistical Manual of Mental Disorders,* 5th ed. (*DSM-5*; American Psychiatric Association, 2013) and the *International Classification of Diseases,* 10th ed. (*ICD-10*; World Health Organization, 1992). The specific criteria are described in Table 3.1.

Changes in the Diagnosis

The *DSM-5* was revised in 2013 following nearly two decades of research into ASD (American Psychiatric Association, 2013). With the revised *DSM*, the previous diagnostic umbrella term *pervasive developmental disorders* is no longer used, and the three diagnostic subtypes of autistic disorder, Asperger's disorder, and pervasive developmental disorder–not otherwise specified are collapsed into one term: autism spectrum disorder. Although controversial, the *DSM* committee's decision to collapse all three diagnostic subtypes under one diagnosis was

TABLE 3.1 ***DSM-5*** **Diagnostic Criteria for Autism Spectrum Disorder**

(A) Clinically significant, persistent deficits in social communication and interactions across multiple settings, currently or by history, as manifested by all of the following:
  1. Deficits in social-emotional reciprocity
  2. Marked deficits in nonverbal communication used for social interaction
  3. Failure to develop, maintain, and understand relationships

(B) Restricted, repetitive patterns of behavior, interests, and activities, currently or by history, as manifested by at least two of the following:
  1. Stereotyped or repetitive motor movements, actions on objects, or speech
  2. Insistence on sameness and excessive adherence to routines or ritualized patterns of behavior
  3. Highly restricted, fixated interests
  4. Hyper- or hyporeactivity to sensory input or unusual sensory interests

(C) Symptoms must be present in early childhood (but may not become fully manifest until social demands exceed limited capacities)

(D) Symptoms must cause clinically significant impairment in social, occupational, or other areas of functioning

based on findings that no specific etiology was tied to the subtypes, no treatment was specific to each subtype, and even experienced clinicians were unable to agree on which children should be diagnosed with each subtype (King, Navot, Bernier, & Webb, 2014; Lord et al., 2011). Other changes included the collapse of three domains of impairment (social, communication, and restricted/repetitive behaviors) into two domains (social communication and restricted/repetitive behaviors). The collapsing of the domains was to reflect that all communication is social in nature and that certain symptoms under the previous system could be counted in both the social domain and the communication domain giving additional weight to a particular symptom (King et al., 2014). Finally, qualifiers, a severity rating system, the inclusion of sensory sensitivities to the RRB domain, and the removal of the requirement that deficits be observed by 3 years of age were all changes made during this revision process.

Domains of Impairment, Qualifiers, and Severity

As shown in Table 3.1, to meet diagnostic criteria for ASD, a child must have deficits in three areas in the social communication domain, at least two of the four possible symptoms in the RRB domain. These impairments may not become evident until the social demands exceed the capacities of the individual and to reflect that there has been a shift from the previous requirement of symptoms present prior to three years of age to an allowance for diagnosis later in life and even adulthood.

With the adoption of the *DSM-5* criteria, qualifiers have been appended to the diagnostic description for an individual. Due to the commonality of the behaviors seen across the *DSM-IV* ASD subtypes, the *DSM-5* committee concluded that the constellation of impairments observed in ASD are best represented as a single yet multidimensional disorder that manifests it uniquely for each individual due to differing cognitive and language abilities, and comorbid disorders (Rutter, 2011). As such, qualifiers to the ASD diagnosis include the presence of co-occurring intellectual or language impairment and association with a known medical or genetic condition or environmental factor. Severity levels have also been incorporated into the *DSM-5* diagnostic process with three levels of support defined for each ASD domain. The levels range from level 1, requiring support, which reflects a severity level such that if a child were without supports, the child's deficits in social communication would cause noticeable impairments spanning level 2, requiring substantial support, and progressing to level 3, requiring very substantial support, which for the social communication domain is defined as deficits in verbal and nonverbal social communication skills that cause severe impairments in functioning (American Psychiatric Association, 2013).

RELATED SYMPTOMS AND COMORBID DISORDERS

Intellectual Disability

Current estimates of the rate of intellectual disability (i.e., IQ below 70) in individuals with ASD are at approximately 40% with higher rates of comorbidity observed in girls with ASD (Baird et al., 2000; Centers for Disease Control and Prevention, 2009, 2012; Chakrabarti & Fombonne, 2001). These estimates differ from earlier estimates published between 1966 and 1999, reviewed by Fombonne (1999), which ranged from 44 to 100% with rates of individuals without intellectual disability estimated at 25.4%, mild to moderate impairment at 23.2%, and severe to profound mental impairment estimated at 55.5%. The decline in the rate of comorbid intellectual disability among individuals with ASD is likely a function of increased diagnostic rates of individuals with intact cognitive abilities along with the effectiveness of early intervention (Chakrabarti & Fombonne, 2005; Fombonne, 2003a, 2003b; Matson & Shoemaker, 2009; Newschaffer, Falb, & Gurney, 2005a).

The diagnostic differential between intellectual disability and ASD lies most clearly in the display of specific impairments in joint attention, motor imitation, symbolic play, theory of mind, and expressive versus receptive language skills (Maljaars, Noens, Scholte, & van Berckelaer-Onnes, 2012; Poon, Watson, Baranek, & Poe, 2012; Wong & Kasari, 2012) observed in ASD. Although some investigators report a specific pattern of intellectual abilities such that individuals with ASD perform better on nonverbal visual–spatial tasks relative to verbal tasks (Fombonne, 2003b; Happe, 1994; Lockyer & Rutter, 1970; Matson & Shoemaker, 2009), others have failed to observe this (Mayes & Calhoun, 2003; Minshew, Turner, & Goldstein, 2005; Siegel, Minshew, & Goldstein, 1996; Szatmari, Tuff, Finlayson, & Bartolucci, 1990), or note that this cognitive profile is not consistent across the age span (Ankenman, Elgin, Sullivan, Vincent, & Bernier, 2014).

Communication Disorders

Given the previously reported deficits in language and communication, communication disorders are often diagnosed at some point in the diagnostic journey for an individual with ASD. Many of the language impairments observed in ASD are reflected in the diagnosis of language disorder, characterized by deficits in comprehension or production of language, although the early emerging social deficits and presence of stereotypic interests or behaviors can readily differentiate language disorder from ASD (American Psychiatric Association, 2013). Speech sound disorders, defined by persistent deficits in speech sound production can also be diagnosed in many children with ASD and may be linked to common underlying etiologies. For example, as described already, many individuals with 16p11.2 deletion have speech sound disorders, but this also one of the most common risk factors for ASD, such that many children with 16p11.2 deletion have both ASD and speech sound disorders (Hanson et al., 2014).

The *DSM-5* also includes a new diagnostic classification related to communication impairment: social communication disorder (SCD). The *DSM-5* defines SCD as persistent difficulty with verbal and nonverbal communication, such as difficulties with spoken and written language and conversational impairments, that is not better accounted for by cognitive impairments. These social communication impairments overlap with many ASD symptoms rendering the differential diagnosis difficult; however, the SCD diagnosis specifies the absence of repetitive or stereotyped behaviors. The lack of repetitive or restricted behaviors differentiates ASD and SCD. As such, ASD must be ruled out before making a diagnosis of SCD.

Attention-Deficit/Hyperactivity Disorder

Prior to the *DSM-5*, attention-deficit/hyperactivity disorder (ADHD) and ASD were considered exclusive of one another and a diagnosis of ASD precluded a diagnosis of ADHD (American Psychiatric Association, 2000). However, some individuals do show symptoms of ADHD, including inattention, hyperactivity, and impulsivity, and the *DSM-5* now allows for the presence of both conditions in one individual (Mayes, Calhoun, Mayes, & Molitoris, 2012). Over the past 10 years, study of the overlap between the two disorders has expanded considerably with a focus on common etiology, similar neurological origins, the evidence for comorbid occurrences, and the implications of a dual diagnosis. Common genetic events have been identified between both disorders (Williams et al., 2010) and decreased prefrontal cortex activation has been reported in both ASD and ADHD (Happé, Booth, Charlton, & Hughes, 2006), providing putative biological bases for the overlap in symptom presentation. Indeed, rates of comorbidity across ASD and ADHD range from 33 to 78% (Gargaro, Rinehart, Bradshaw, Tonge, & Sheppard, 2011; Goldstein & Schwebach, 2004; Sinzig, Walter, & Doepfner, 2009). Interestingly, for those individuals dually diagnosed with ASD and ADHD, oppositional behavior, but not anxiety or ADHD symptom severity is more often reported (Grzadzinski et al., 2011).

Anxiety and Mood Disorders

Co-occurring anxiety and mood disorders are commonly reported in individuals with ASD (Strang et al., 2012; Whitehouse, Durkin, Jaquet, & Ziatas, 2009; Whitehouse, Watt, Line, & Bishop, 2009), however, it is sometimes difficult to identify these symptoms, especially in individuals with ASD who have poor ability to report their internal states. For example, social phobia and social withdrawal may be manifestations of anxiety and depression, respectively, or the result of social impairments related to ASD. Given the clinician's reliance on self-report of symptoms in the assessment of anxiety and mood disturbances and the observation that individuals with ASD often have difficulty identifying and describing their own emotions and feelings (Gillott, Furniss, & Walter, 2001), the ability to detect these symptoms is sometimes challenging. The clinician often must rely on parent or supplemental reports

(Stewart, Barnard, Pearson, Hasan, & O'Brien, 2006), which are known to be less reliable than self-report for both disorders. Further, it is difficult at times to determine if these symptoms are actually distinct diagnoses or rather a characteristic of the disorder (e.g., obsessive compulsive symptoms). Importantly, both anxiety and depression are both responsive to pharmacological and behavioral intervention in individuals with ASD.

Depression in ASD often manifests as an increase in agitation, social withdrawal, and compulsions along with changes in sleep and appetite. Rate estimates for comorbid depression and ASD range from 1 to 58% (Lainhart, 1999; Mayes, Calhoun, Murray, Ahuja, & Smith, 2011). Studies suggest that symptoms of depression are often observed during adolescents in individuals with ASD who have greater insight into their social communication challenges, behavioral differences show an increase in wanting to develop friendships (Kim, Szatmari, Bryson, Streiner, & Wilson, 2000; Mayes et al., 2011).

Research in depression and ASD suggests that even though an individual with ASD may not meet full diagnostic criteria for a comorbid depressive disorder, the manifestation of depressive symptoms can still significantly impact his or her quality of life (Leyfer et al., 2006a; Simonoff et al., 2008). Interestingly, it has been noted that the rate of suicidal ideation is less likely in individuals with ASD and depression such that suicidal ideation is 2.6 times more likely to occur in children with depression alone than in children with both disorders (Mayes et al., 2012; Stewart et al., 2006). A systematic review of several large-scale studies, however, indicated that individuals with ASD comprised 7.3–15% of suicidal populations. This is a substantial subgroup. Several risk factors for suicide among individuals were also reported including peer victimization, behavioral problems, Black or Hispanic ethnicity, lower socioeconomic status, and lower level of education (Segers & Rawana, 2014).

Difficulties with the assessment and characterization of anxiety in ASD have made establishing the prevalence of co-occurrence challenging and as a result study estimates have varied considerably (Leyfer et al., 2006a; Mayes et al., 2012; Simonoff et al., 2008). Studies report ranges from 7 to 84% with the most commonly co-diagnosed disorders being generalized anxiety disorder, agoraphobia, and simple phobia (Gillott et al., 2001; Lainhart, 1999; Leyfer et al., 2006b). Challenges in the symptom overlap make disentangling the disorders difficult. For example, symptoms of obsessive-compulsive disorder (OCD) can resemble the ritualized and repetitive behavior observed in ASD. Although OCD can be differentiated from ASD in that individuals with OCD are more often fixated on a single compulsion than individuals with ASD (Russell, Mataix-Cols, Anson, & Murphy, 2005; Russell & Sofronoff, 2005; Wakabayashi, Baron-Cohen, & Ashwin, 2012), this requires careful clinical investigation. And, similar to depression, certain subgroups of ASD may be more prone to anxiety disorders such that adolescents with intact cognitive abilities may be more likely to have comorbid anxiety than others (Kim et al., 2000; Mattila et al., 2010; Mayes et al., 2011).

Self-Injurious Behaviors

Self-injurious behaviors can include head banging, head slapping, hair pulling, and finger or hand biting and have been observed in individuals with ASD. However, the presence of these behaviors may be more linked to cognitive and language deficits in ASD, rather than ASD itself (Dawson, Matson, & Cherry, 1998). It has been suggested that self-injurious behaviors can be the expression of frustration in individuals with limited communication ability to express feelings or needs (Donnellan, Mirenda, Mesaros, & Fassbender, 1984; Lainhart, 1999). Regardless of the origin, self-injurious behaviors are associated with increased perceived stress in families (Bishop, Richler, Cain, & Lord, 2007); however, behavioral treatments can prove effective in reducing these behaviors.

Seizures

Epilepsy is diagnosed in 6–50% of individuals with ASD depending on the study source with population-based studies reporting lower rates of 5% and epilepsy specific clinics citing rates of 15–30% (Clarke et al., 2005; Matsuo, Maeda, Sasaki, Ishii, & Hamasaki, 2010). Seizure onset most often occurs either early in childhood or in adolescence (Parmeggiani et al., 2010) with early onset seizures associated with poorer outcomes (Saemundsen, Ludvigsson, & Rafnsson, 2008). Given the increased likelihood for seizures in ASD, it is recommended that individuals with ASD suspected of having seizures be promptly evaluated (Filipek et al., 2000).

Gastrointestinal Problems

Gastrointestinal (GI) problems, including constipation, abdominal pain, bloating, diarrhea, and nausea, are estimated to impact between 9 and 70% of children with ASD (Buie et al., 2010). The relationship between GI

impairments and ASD is unclear, but recent work suggests a shared genetic etiology for atypical neuronal development in both the central nervous system, impacting brain development and the enteric nervous system, impacting gut motility, that might lead to comorbid challenge in a subset of children with ASD (Bernier et al., 2014). Another avenue of investigation suggests anxiety may be playing a role. Studies indicate significantly higher rates of anxiety in children with GI problems (Mazurek et al., 2013; Nikolov et al., 2009).

Sleep Problems

Sleep problems are commonly reported in children with ASD with reports indicating that between 44 and 83% of children with ASD have severe sleep problems (Allik, Larsson, & Smedje, 2006a, 2006b; Goldman, Richdale, Clemons, & Malow, 2012; Goldman et al., 2009; Krakowiak, Goodlin-Jones, Hertz-Picciotto, Croen, & Hansen, 2008; Owens, Spirito, McGuinn, & Nobile, 2000; Patzold, Richdale, & Tonge, 1998; Richdale, 1999; Richdale & Prior, 1995). Reported sleep problems include difficulty falling and staying asleep, early-morning waking, and overall shortened sleep times. These problems are most often reported in children under 5 years of age, but sleep problems persist for many despite age related improvements. The cause of sleep disturbances in ASD remains unknown, but disruptions to melatonin synthesis (Richdale, 1999), alterations in melaton regulation (Rapin & Katzman, 1998), disruptions to arousal (Richdale & Prior, 1995), and anxiety (Wagner, 1991) have been proposed as possible etiologies. Regardless of the origin, actigraphy, an objective measure of sleep, indicates that children with ASD sleep shorter amounts than children with typical development or developmental delays (Goodlin-Jones, Tang, Liu, & Anders, 2008). Treatment for sleep disturbances in ASD, including supplemental melatonin, has been shown to be effective through both actigraphy and parent report of sleep and behavior (Doyen et al., 2011; Malow, Adkins, et al., 2012; Malow, Byars, et al., 2012; Rossignol & Frye, 2011). Further, treatment for sleep difficulties appears to also improve related symptoms such social interaction, repetitive behaviors, affective problems, oppositional and aggressive behavior, and inattention/hyperactivity symptoms (Goldman et al., 2009, 2012; Malow, McGrew, Harvey, Henderson, & Stone, 2006). Given the frequent concerns regarding sleep problems in ASD, the effectiveness of treatment, and the associated improvements in other behaviors following sleep treatment, it is important that assessment and management of sleep concerns be a routine part of clinical care for children with ASD.

Regression

While development can progress atypically from very early in life in ASD, symptoms may also appear following a loss of skills previously developed. This regression is estimated to occur between 20% and 47% of children with ASD (Goldberg et al., 2003; Lord, 1995; Rapin & Katzman, 1998; Rutter & Lord, 1987) with typical regression onset between 18 and 24 months of age (Davidovitch, Glick, Holtzman, Tirosh, & Safir, 2000; Fombonne & Chakrabarti, 2001; Kurita, 1985, 1996; Rapin & Katzman, 1998; Rutter & Lord, 1987; Shinnar et al., 2001; Wilson, Djukic, Shinnar, Dharmani, & Rapin, 2003). Some reports suggest that individuals with regression have poorer outcomes (Luyster et al., 2005) while others have found that there are no differences between children with and without regression on language, cognitive, or behavioral outcomes at age 3 to 4 years (Werner & Dawson, 2005). Loss of language skills is most often reported but can include social engagement, cognitive ability, and adaptive skill loss. Any loss of skills warrants immediate evaluation (Filipek et al., 1999).

EARLY IDENTIFICATION

Most parents report concerns with their child with ASD's development by 18 months of age (Howlin & Asgharian, 1999; S. Rogers, 2001), but the mean age of diagnosis across the United States ranges from 38 to 120 months (Daniels & Mandell, 2013) with an average age of 3.1 years (Mandell, Novak, & Zubritsky, 2005). However, the age at which a child receives a diagnosis is decreasing as a result of increased awareness, improved screening techniques, and more expertise; earlier identification is important for intervening earlier and therefore improving outcomes.

Established practice parameters have helped to improved screening of ASD in young children. In 2000, the American Academy of Neurology issued practice parameters outlining a two-tiered screening approach for ASD. The first level focuses on the identification of children at risk for atypical development (followed by identifying those specifically at risk for ASD) through routine developmental surveillance conducted at all well-child visits. The second level entails formal diagnostic procedures conducted by expert evaluators focusing on the diagnosis

TABLE 3.2 Red flags indicating need for further evaluation for ASD

Further developmental evaluation is warranted if a child fails to meet any of the following:
Babbling by 12 months
Gesturing (e.g., pointing, waving bye) by 12 months
Using single words by 16 months
Using spontaneous (not echoed) two-word phrases by 24 months
OR if there is a loss of language or social skills at any age

of ASD (Filipek et al., 2000). Importantly, these parameters stipulated that should a child fail to meet certain milestones or demonstrate a loss of language or social skills at any time, then further evaluation is warranted (Table 3.2). The American Academy of Pediatrics clarified that in addition to routine level 1 surveillance to identify children at risk for developmental delay, specific screening using an autism specific screening tool should be utilized at 18 and 24 months of age regardless of any identified risks (Johnson, Myers, & American Academy of Pediatrics Council on Children With Disabilities, 2007).

Several screening measures for infants at level 1 screening have been developed that meet the American Academy of Pediatrics' recommendations. Some of these include the modified CHAT (M-CHAT), the Pervasive Developmental Disorders Screening Test, and the First Year Inventory and Infant Toddler Checklist. The M-CHAT (Robins et al., 2001) and Pervasive Developmental Disorders Screening Test (Siegel, 2004) are both level 1 questionnaire-based screening instruments designed to quickly capture parent report of their toddlers. The First Year Inventory (Baranek, Watson, Crais, & Reznick, 2003) lowers the age boundary to 12 months for parent report in level 1 screening. The Screening Tool for Autism in Toddlers (Stone, Coonrod, & Ousley, 2000) and the Communication and Symbolic Behavior Scales Developmental Profile (CSBS; Wetherby & Prizant, 2002) are both interactive tools for use in level 2 screening. Through 20-minute, play-based interactions, clinicians can gather information regarding the presence of ASD and generate targets for intervention. The CSBS also includes a general developmental screener, the Infant Toddler Checklist, and a follow-up caregiver questionnaire in addition to the play based interaction.

There is a considerable increase in the ability to diagnose autism at younger ages and research to indicate a diagnosis can be reliably diagnosed by 20 to 24 months of age (Baron-Cohen et al., 1996; Rogers, 2001). Further, studies suggest that early diagnoses remain stable over time such that diagnoses made in the first two years of life are retained by age 3 (Baron-Cohen et al., 1996; Lord, 1995; Stone et al., 1999). These findings underscore the importance of early detection, followed by diagnosis so that intervention can begin as early in development as possible.

EPIDEMIOLOGY

Prevalence

Once thought to be a rare disorder, ASD is now one of the most common developmental disorders. In the 1980s, the prevalence of ASD was estimated to be 4 per 10,000 individuals (Ritvo et al., 1989), but estimates currently suggest more than 1% of children in the United States (1 in 68) are affected (Centers for Disease Control and Prevention, 2014). Multiple studies have reported an increase in prevalence of ASD diagnosis (Cavagnaro, 2009; Centers for Disease Control and Prevention, 2009, 2012; Hertz-Picciotto & Delwiche, 2009; King & Bearman, 2009; Newschaffer, Falb, & Gurney, 2005b) although it remains unclear if the increase in diagnosis is strictly related to improved identification and broadening definitions or if there is a true increase in prevalence (Rice et al., 2012). A meta-analysis spanning 20 studies between 1966 and 1997 revealed that the prevalence rate for children born before 1970 was 4.7 cases per 10,000 while the rate for those born in 1970 or later was 11.2 per 10,000 (Gillberg & Wing, 1999). Similar to the recent CDC studies, this analysis yielded an estimated annual increase in autism diagnoses of 3.8 percent per year, mirroring rising international prevalence rates (Fombonne, 2009). Current research examining the multiple ASD risk factors, including genetic and prenatal and early postnatal environmental factors and their interaction, that contribute to risk for autism may illuminate the cause of the changing diagnostic rates (Newschaffer et al., 2007).

Gender

Males are diagnosed at approximately a 4:1 rate relative to females (Fombonne, 2009). A variety of mechanisms have been proposed, including endogenous hormones (Knickmeyer & Baron-Cohen, 2006; Knickmeyer et al., 2006), intrauterine exposures that impact male but not female growth (Hertz-Picciotto et al., 2006), and X-chromosome inactivation (Nagarajan et al., 2008). More recently it has been demonstrated that females have a higher mutational burden, more deleterious structural mutations in autosomal chromosomes, than males, suggesting increased numbers of genetic events, not linked to variants on the X chromosome, contribute to the development of ASD in females (Jacquemont et al., 2014).

Finally, it has been suggested that the diagnostic tools may be biased toward identifying ASD in males (Rivet & Matson, 2011), which underscores the limited research on the diagnosis of females with ASD (Rutter, Caspi, & Moffitt, 2003).

Sociocultural Influences

Socioeconomic status (SES) and race have both been associated with ASD diagnosis. In European countries supporting population wide surveillance and universal health care, SES does not appear to be a factor in the prevalence of ASD; however studies conducted in the United States indicate an underascertainment of families with low SES backgrounds (Baird et al., 2006; Fombonne, Du Mazaubrun, Cans, & Grandjean, 1997; Larsson et al., 2005). Race is also associated with ASD. Differential prevalence rates of ASD have been observed based on ethnicity with the odds of having an ASD being 57% lower for non-Hispanic, African American children, than non-Hispanic, Caucasian children (Kogan et al., 2009). The age at which a child is diagnosed also varies with ethnicity. One study suggested that on average, Caucasian children are diagnosed 1.5 years earlier than African American children, and $2\frac{1}{2}$ years earlier than Latino children (Mandell, Listerud, Levy, & Pinto-Martin, 2002). The association between SES and ASD is likely due to reduced availability of diagnostic and treatment resources for families with lower SES (Kogan et al., 2009) as opposed to an association with etiology. Similarly, it is likely other factors driving the association between race and ASD. For example, it has been suggested that parents of certain ethnic backgrounds may emphasize disruptive or other behaviors during assessment rather than social oddities, leading to a reduced likelihood of an ASD diagnosis (Mandell et al., 2002). Alternatively, it has been proposed that general prejudices held by the clinician can lead to misguided expectations about the probability of ASD occurring in different ethnicities (Balsa, McGuire, & Meredith, 2005). Ultimately, the existing literature suggests that ASD does not discriminate based on racial or socioeconomic background.

ETIOLOGY

No one clear cause of ASD has been identified, although significant advances have been made toward genetic susceptibility factors and potential environmental triggers. It is generally considered that ASD has a variety of contributors including genetic and environmental factors.

Genetic Risk Factors

Twin Studies

The first clear indication that ASD had a strong genetic component was from Folstein and Rutter's (1977) study of twins with ASD. In their same-sex epidemiological study they found a 36% concordance rate for MZ twins and a 0% rate for DZ twins. Subsequent twin studies have replicated these findings with concordance rates ranging from 60–96% in MZ twins compared to 0–23% in DZ twins (Bailey et al., 1995; Ritvo, Freeman, Mason-Brothers, Mo, & Ritvo, 1985; Steffenburg et al., 1989). However, a recent California based population study of twins with ASD observed that common environmental factors may contribute approximately 55% of the ASD risk with genetic heritability accounting for less than 40 percent (Hallmayer et al., 2011). This recent study highlights that while genetic factors play an important role, the role may be lower than previously estimated.

Family Studies

The study of family members of an individual with ASD has illuminated the potential role common genetic variation in the susceptibility to ASD. The broader autism phenotype has been observed in family members of individuals with ASD. Defined as having similar traits to ASD (such as aloofness, rigidity of thought, repetitive interests), but to lesser degree, the broader autism phenotype was identified in a large-scale study in 7.5% of relatives of in individuals with ASD while in only 2.5% of relatives with Down syndrome (Pickles et al., 2000). Similarly, the broader autism phenotype has been observed in 12–20% of siblings of children with ASD but in only 2% of siblings of children with developmental delays and observed more often in parents of children with ASD relative to parents of typical children or children with delays (Bailey et al., 1995; Baron-Cohen & Hammer, 1997; Bernier, Gerdts, Munson, Dawson, & Estes, 2012; Dawson, Webb, Wijsman, et al., 2005; Gerdts, Bernier, Dawson, & Estes, 2013; Losh et al., 2009). The observation of a broader phenotype suggests that relatives of individuals with ASD may be demonstrating a lesser variant a result of shared genes (Baron-Cohen & Hammer, 1997).

A large study of infant siblings of children with ASD indicated that 18.7% of younger siblings of individuals with ASD went on to develop ASD with risk increasing the more older siblings with ASD in the family (Ozonoff et al., 2011). In contrast, only approximately .18% of second-degree relatives and .12% of third-degree relatives of an individual with ASD also have ASD (DeLong & Dwyer, 1988;

Jorde et al., 1991; Pickles et al., 1995; Szatmari, Volkmar, & Walter, 1995). The differential rates of ASD in extended family members relative to siblings suggest that many genes may contribute to ASD (Pickles et al., 1995).

Genetic Findings

Early molecular studies of ASD focused on linkage analysis to identify potential genomic regions harboring ASD susceptibility gene or genes. Through these studies many chromosomal regions were identified, yet few were replicated reflecting the heterogeneity in genetic contributions (e.g., Barrett et al., 1999; IMGSAC, 1998; Philippe et al., 1999; Risch et al., 1999) and no single gene region has been reliably identified (Abrahams & Geschwind, 2008).

Research suggests that there is no single gene that accounts for ASD, but rather that there are multiple genes and structural rearrangements, each one a risk factor that may alone or in concert with other genetic variation, contribute to ASD (Folstein & Rosen-Sheidley, 2001). Indeed, approximately 10–30% of ASD cases have an identified genetic cause through an observable chromosomal structural rearrangement, called copy number variation (CNV), or gene mutation (Abrahams & Geschwind, 2008; Krumm, O'Roak, Shendure, & Eichler, 2014). Among individuals with an identified genetic contributor, the most common contributors are CNVs in regions 15q11–13 and 16p11.2, CNVs at each region accounting for only approximately 1% of cases (Miles, 2011). However, complicating the picture is that individuals with CNVs in these regions, such as 16p11.2, ascertained for the presence of the event, do not always develop ASD. In fact, ASD is only observed in 23% of individuals with 16p11.2 deletion (Hanson et al., 2014). With the advent of exome and targeted sequencing the discovery of disruptive gene mutations has advanced the understanding of genetic risk factors. Indeed, exome sequencing has yielded findings that close to 1,000 different genes may contribute to ADS (O'Roak, Vives, Girirajan, et al., 2012; Sanders et al., 2012). Among the most prominent are CHD8, DYRK1A, GRIN2B, PTEN, TBR1, TBLXR1, with mutations to these 6 genes likely contributing to 1% of all ASD cases (O'Roak, Vives, Fu, et al., 2012). Indeed, CHD8 appears to be the most common single gene mutation contributing to ASD and represents a distinct subtype of ASD with characteristic facial features, macrocephaly, and gastrointestinal disturbances (Bernier et al., 2014). Many other genes have been linked to ASD including ADNP (Helsmoortel et al., 2014), SCN2A (State & Sestan, 2012), SHANK2, SHANK3, and NLGN4 (Abrahams & Geschwind, 2008), which highlights the varied impacts on the development of the brain given the wide role on synaptic adhesion, chromatin modification, ion channel development, and the neurotransmitter receptors in which these genes are involved.

Our understanding of the genetics of ASD has advanced considerably since early twin studies, and these advances indicate ASD does not follow a simple pattern of inheritance and instead is the result of multiple genetic variants and mutations impacting a multitude of genes. Given the increased availability of high throughput sequencing and reduced cost for sequencing, a shift in the approach to studying the genetics of ASD has been proposed which entails the leveraging of technology to genetically classify individuals with ASD and then recontact and follow up for comprehensive evaluation to identify relevant behavioral subtypes and targets for treatment and intervention (Stessman, Bernier, & Eichler, 2014).

Environmental Risk Factors

Prenatal Risk Factors

A wide range of pre and perinatal complications has been associated with increased risk for ASD. Although no single prenatal factor has been associated with the etiology of ASD (Gardener, Spiegelman, & Buka, 2009), a large, population based study of environmental contributions of ASD suggested that fever during pregnancy increased the risk for ASD (Zerbo, Iosif, Delwiche, Walker, & Hertz-Picciotto, 2011). The proposed mechanism for this increased risk following maternal infections is that the immune response and maturational processes at critical developmental periods are disrupted (Hertz-Picciotto et al., 2008). It has also been reported that mothers with certain medical conditions, including diabetes (type 2 or gestational), chronic hypertension, or pre-pregnancy obesity was associated with increased risk for autism (Krakowiak et al., 2012). The authors hypothesize that metabolic disruption results in increased ASD risk. Rodent and non-human primate models mirror these findings of increased ASD susceptibility following maternal immune activation (M. D. Bauman et al., 2013; Malkova, Yu, Hsiao, Moore, & Patterson, 2012).

Other prenatal factors associated with ASD risk include exposures in utero to a variety of agents including thalidomide (Rodier, 2002; Stromland, Nordin, Miller, Akerstrom, & Gillberg, 1994), misoprostol (Bandim, Ventura, Miller, Almeida, & Costa, 2003), and valproic acid (Moore et al., 2000; Rasalam et al., 2005; Stromland et al., 1994). Across all of these exposures, the mechanism is based on reported observations of the teratogenic effects of these substances on neurodevelopment (Landrigan, 2010). More

recently, air pollution (Volk, Hertz-Picciotto, Delwiche, Lurmann, & McConnell, 2011; Volk, Lurmann, Penfold, Hertz-Picciotto, & McConnell, 2013) and agricultural pesticides (Eskenazi et al., 2007; Roberts et al., 2007; Shelton et al., 2014) have been associated with increased risk. The hypothesized mechanisms for these environmental pollutants are that thyroid hormones, which have been implicated in neurodevelopmental problems (Porterfield, 1994), are disrupted (Roberts et al., 2007) and that sex steroids are impacted, which have been proposed to account for the observed male to female ratio bias in ASD (Baron-Cohen, Knickmeyer, & Belmonte, 2005; Knickmeyer et al., 2006).

Use of prenatal folic acid supplements around the time of conception has been associated with decreased risk for autism (Suren et al., 2013). Research also suggests that the MTHFR C677T polymorphism is associated with increased ASD risk, and periconceptional folic acid may reduce ASD risk in those with MTHFR 677C>T polymorphism (Pu, Shen, & Wu, 2013).

Perinatal Risk Factors

A broad range of perinatal complications have been proposed to increase ASD risk, including breech presentation, umbilical cord complications, fetal distress, birth injury or trauma, multiple birth, maternal hemorrhage, summer birth, low birth weight, small for gestational age, congenital malformation, low Apgar scores, feeding difficulties, meconium aspiration, neonatal anemia, ABO or Rh incompatibility, and hyperbilirubinemia (Gardener, Spiegelman, & Buka, 2011). The relationship between the complication and ASD may be a function of the hypoxia associated with the event, which can impact central nervous system and later development. Elevated risk has also been found with non-elective C-sections, but it is likely a pre-existing condition necessitating the surgery as opposed to the surgery itself that increases ASD risk (Krakowiak et al., 2012). Additionally, a number of perinatal complications have not been found to associate with ASD, including use of anesthesia, post-term birth, and physical characteristics such as high birth weight and head circumference. Increased risk for autism has been associated with induced or augmented childbirth (Gregory, Anthopolos, Osgood, Grotegut, & Miranda, 2013). Further research is needed to explain this association which could be related to underlying pregnancy conditions required need to induce/augment as opposed an independent contributor of ASD risk.

In general, challenges to clarifying the extent and effects of these perinatal complications concern the interaction between birth complications and prenatal problems, making it difficult to determine the independent contribution of any of these factors to conferring ASD risk. For example, C-sections are more common in pregnancies with abnormal fetal presentation, fetal distress, and multiple births, preventing a clear understanding of the independent effect of any birth complication. Further research in this arena is needed.

Gene–Environment Interactions

An important area of investigation exists at the intersection between genetics and the environment, as it is likely that the etiology of many individuals with ASD is a function of both genetic and environmental factors (Newschaffer et al., 2007). This perspective is supported by the observation of abnormal neuroinflammation following infection in individuals with ASD and the potential role of gene disruptions related to DNA repair and immune and inflammatory response (Herbert et al., 2006) as well as the finding that individuals with a promoter variant to the MET gene who are prenatally exposed to environmental toxins are at increased risk above prenatal exposure and having the genetic variant alone (Volk et al., 2014). Another gene environment interaction is reflected in the finding that increased paternal age confers ASD risk potentially by the alteration in the germ cells as a result of accumulated exposure to environmental toxins over the lifetime (Hultman, Sandin, Levine, Lichtenstein, & Reichenberg, 2011). Given the recent advances in genetics of ASD and the scrutiny of the environment contributions to the disorder, the examination of the intersection of the two factors will be at the forefront of the research agenda in the coming years.

BRAIN STRUCTURE AND FUNCTION

Studies employing brain autopsies, structural and functioning imaging, and electroencephalography all converge to indicate atypical brain structure and function in ASD. Neuroanatomical findings, in general, conclude that ASD is marked by structural enlargement in some brain regions and reduction in other areas (see Koenig, Tsatsanis, & Volkmar, 2001, for a review). Although seemingly contradictory, these finding suggest that across the many etiologies of ASD, abnormal cell growth during the early

stages of prenatal and postnatal brain development may be the common underlying etiological mechanism. That is, in contrast to typical brain development in which neurons proliferate and become interconnected and then are pruned through experience and development, in ASD, the process of neural growth and pruning may be disrupted resulting in size differences across neuroanatomical structures (Minshew, 1996). Imaging studies show increased overall brain volume (Courchesne et al., 2001; Hazlett et al., 2011; Piven, Arndt, Bailey, & Andreasen, 1996; Piven et al., 1995; Schumann et al., 2010; Sparks et al., 2002) and autopsy studies report increased brain weight (Bailey et al., 1998; Bauman & Kemper, 1994). These findings are supported by studies of head circumference that demonstrates rapid, early growth in ASD (Chawarska et al., 2011; Courchesne, Campbell, & Solso, 2011; Courchesne & Pierce, 2005a; Dawson et al., 2007; Elder, Dawson, Toth, Fein, & Munson, 2008). Enlargement of both white and gray matter appears to account for this rapid growth (Hazlett et al., 2011; Schumann et al., 2010), but a large study of brain growth in teens and young adults suggests that atypical decline may occur at these ages as well (Courchesne et al., 2011). In addition to the observation of atypical brain growth in ASD, several specific brain regions have been implicated, including the cerebellum, the limbic system, several systems in the cerebral cortex, and corpus callosum. The specific regions and structures are outlined in Table 3.3.

Cerebellum

Studies employing different experimental methods have identified atypical structure and function of the cerebellum in ASD. Structural MRI studies report enlarged cerebellar volume (Carper & Courchesne, 2000; Courchesne, Redcay, Morgan, & Kennedy, 2005), magnetic resonance spectroscopy (MRS) studies indicate decreased concentrations of neural substrates indicating diminished cerebellar functioning (Chugani, Sundram, Behen, Lee, & Moore, 1999; DeVito et al., 2007), and functional MRI studies demonstrate atypical activity in the cerebellum during attention and motor tasks (Allen, Müller, & Courchesne, 2004). Similarly, postmortem studies in ASD have found a loss of Purkinje and granule cells in the region of the cerebellum that receives auditory and visual information (Bailey et al., 1998; Bauman & Kemper, 1985; ML Bauman & Kemper, 1988; Carper & Courchesne, 2000; Palmen, van Engeland, Hof, & Schmitz, 2004; Whitney, Kemper, Bauman, Rosene, & Blatt, 2008). Two proteins implicated in cell migration and pruning, Reelin and Bcl-2, are reportedly decreased in cerebellar tissue (Fatemi, Stary, Halt, & Realmuto, 2001).

TABLE 3.3 Brain Regions and Structures Implicated in in ASD and Their Purported Function

Brain area	ASD-related domain	Proposed function	Citation
Ventromedial prefrontal cortex	Social communication	Social decision making	Carper and Courchesne (2005)
Orbitofrontal cortex	Social communication	Adaptive learning through stimulus–reinforcement association	Girgis et al. (2007)
Anterior cingulate cortex	Social communication	Social orienting, initiation, motivation, goal-directed behaviors	Mundy (2003)
Inferior frontal gyrus	Social communication	Imitation, language production	Dapretto et al. (2006)
Posterior parietal cortex	Social communication	Imitation, understanding goals and intentions	Williams et al. (2006)
Fusiform gyrus	Social communication	Face perception and processing	Schultz et al. (2000)
Superior temporal sulcus	Social communication	Biological motion perception, understanding goals and intentions	Pelphrey and Carter (2008)
Amygdala	Social communication	Assignment of emotional valence, emotional learning	Baron-Cohen et al. (2000)
Basal ganglia	Repetitive and restricted behaviors	Compulsive behaviors, repetitive motor behaviors, routines	Langen, Durston, Staal, Palmen, and van Engeland (2007)
Substantia nigra	Social communication/Repetitive & restricted behaviors	Reward, reinforcement, and motivation	Lewis, Tanimura, Lee, and Bodfish (2007)
Thalamus	Social communication/Repetitive and restricted behaviors	Sensory-motor integration	Tsatsanis et al. (2003)
Cerebellum	Social communication/Repetitive and restricted behaviors	Engagement and disengagement of attention	Courchesne (1997)
Hippocampus	Social communication	Learning and memory	Bauman and Kemper (2005)

The findings of atypical cerebellar functioning mirror some of the atypical behaviors and skills observed in ASD that have been associated with the cerebellum. For example, many individuals with ASD have difficulties with sequencing language, motor movements, and shifting attention. These abilities are partially mediated by the cerebellum. Importantly, the ability to shift attention is critical for joint attention, theory of mind, and the ability to transition from one activity to another, all symptoms associated with ASD (Carper & Courchesne, 2000; DiCicco-Bloom et al., 2006; Gillberg, 1999).

The Amygdala

Evidence for disruptions in the amygdala and hippocampus in ASD follows from early findings of decreased neuronal cell size in these structures (Bauman & Kemper, 1988, 2005; Schumann & Amaral, 2006). Studies have found increased amygdala size (relative to total brain volume) in ASD with more severe symptoms (Schumann, Barnes, Lord, & Courchesne, 2009; Schumann et al., 2004; Sparks et al., 2002) although findings reveal a relationship with age and the amygdala (Stanfield et al., 2008). Size differences are not found in older children and adults (Aylward et al., 1999; Haznedar et al., 2000; Nacewicz et al., 2006) suggesting the growth observed in middle childhood in typical development does not occur in ASD (Amaral, Schumann, & Nordahl, 2008). Interestingly, enlargement of the amygdala in toddlerhood is predictive of more significant impairment trajectory in ASD between 3 and 6 years of age (Munson et al., 2006). Two competing hypothetical mechanisms have been proposed to account for the amygdala findings in ASD: either fewer neurons are generated in early development or an excessive number are but there is subsequent elimination of those neurons (Amaral et al., 2008).

Corpus Callosum

The wide band of nerve fibers linking the left and right hemispheres of the brain appears to be reduced in size in children and adults with ASD (Alexander et al., 2007; Boger-Megiddo et al., 2006; Egaas, Courchesne, & Saitoh, 1995; Hardan, Minshew, & Keshavan, 2000; Manes et al., 1999; Piven, Bailey, Ranson, & Arndt, 1997; Vidal et al., 2006). This observed size difference in these white matter tracts in ASD supports the theory that disruptions to cortical connectivity may play a role in ASD. Increased white matter has been observed throughout the brain with the frontal lobe white matter showing the greatest increase (Courchesne et al., 2001; Hazlett et al., 2005; Herbert et al., 2004) implicating a deficit in regional or hemispheric brain communication (Belmonte et al., 2004; Courchesne & Pierce, 2005b; Just, Cherkassky, Keller, & Minshew, 2004; Penn, 2006; Rippon, Brock, Brown, & Boucher, 2007).

Cortical Regions

Imaging and neurophysiological studies indicate abnormal development and functioning of a number of cortical regions. Consistent atypicality has been reported in the prefrontal cortex (Carper & Courchesne, 2000; Courchesne et al., 2005; DeVito et al., 2007). Dysfunction and thinning in the frontal lobes has been associated with theory of mind (F. Happe et al., 1996), imitation impairments (Dapretto et al., 2006), and executive functioning (Gilbert, Bird, Brindley, Frith, & Burgess, 2008). Other cortical regions have been proposed to be involved in ASD including the fusiform gyrus, implicated in functional imaging and neurophysiological studies of face processing (Dawson et al., 2002; Dawson, Webb, et al., 2004; Kleinhans, Muller, Cohen, & Courchesne, 2008; Schultz, 2005; Webb et al., 2006), and the superior temporal sulcus, implicated in perception of biological motion and intention understanding (Pelphrey, Morris, & McCarthy, 2005; Pelphrey, Adolphs, & Morris, 2004). The parietal lobe has been implicated as well through imaging and neurophysiological studies, consistent with the proposal of mirror neuron dysfunction in ASD (Bernier et al., 2007; Oberman & Ramachandran, 2007; Williams et al., 2006).

INTERVENTIONS AND TREATMENT

Pioneering work in the ’60s and ’70s adopted behavioral principles in the treatment of ASD (Berkowitz & Graziano, 1972; Hingtgen, Coulter, & Churchill, 1967; Leff, 1968; Lovaas, Schreibman, & Koegel, 1974; Mazuryk, Barker, & Harasym, 1978) and following the publication of Lovaas’s (1987) controlled intervention trial based on the principles of applied behavioral analysis (ABA), the notion that ASD could be treated was ushered into the professional and parent community. In the years since this early work, major advances in ASD intervention have been made, by building upon behavioral principles, incorporating naturalistic approaches, and embracing a developmental framework. Additionally, myriad psychopharmacological as well as complementary and alternative approaches have been developed and are currently in use in the treatment of ASD. However, large scale RCTs evaluating the efficacy

of autism interventions are still lacking (Warren et al., 2011). Despite this, with the advent of intervention there have been significant improvements in the outcomes for children with ASD with a minority of children actually losing symptoms altogether and achieving functioning within the normal range (Fein et al., 2013).

Behaviorally Based Intervention Models

Interventions based on ABA principles have garnered the most empirical support in the treatment and management of ASD (National Research Council, 2001). Multiple studies have replicated Lovaas's (1987) findings of efficacy (Cohen, Amerine-Dickens, & Smith, 2006; Howard, Sparkman, Cohen, Green, & Stanislaw, 2005; Sallows & Graupner, 2005) and long-standing gains have been observed (McEachin, Smith, & Lovaas, 1993). Indeed, one review of outcomes of 373 children in 13 studies indicated significant gains in cognitive ability following ABA based treatment (Reichow & Wolery, 2009). ABA based treatments have been shown to improve abilities across ASD domains including social communication and challenging behavior (Cohen et al., 2006; Horner, Carr, Strain, Todd, & Reed, 2002; McConnell, 2002; Sallows & Graupner, 2005).

Improved understanding of child development and the importance of generalizability of skills have led to the establishment of several naturalistic developmental models. Pivotal Response Training (PRT) is a naturalistic model that focuses on "pivotal" behaviors, such as motivation. Studies of PRT indicate improvement in social communication and play following intervention (Boettcher, 2004; Koegel, Carter, & Koegel, 2003; Koegel, Koegel, Shoshan, & McNerney, 1999; Koegel, Camarata, Koegel, Ben-Tall, & Smith, 1998; Schreibman, Stahmer, & Pierce, 1996). The Social Communication, Emotional Regulation, and Transactional Support model (SCERTS model) focuses on the specific learning styles to address the core deficits of children with ASD (Prizant, Wetherby, Rubin, & Laurent, 2003; Prizant, Wetherby, Rubin, Laurent, & Rydell, 2005). Kasari and colleagues (2006) have developed joint attention training to improve language and overall outcomes in ASD by addressing this precursor skill to so many core deficits in ASD. A randomized controlled trial of the 6-week intervention suggests improvements following treatment that persist 5 years later (Kasari, Gulsrud, Freeman, Paparella, & Hellemann, 2012) and that can be observed when administered in community preschool programs (Lawton & Kasari, 2012).

The Early Start Denver Model (ESDM), a downward extension of the Denver Model (Rogers et al., 2006; Rogers & Lewis, 1989), is a comprehensive developmental model based on ABA principles. A randomized, controlled trial of 48 toddlers demonstrated significantly greater improvement across cognitive, language, social, and adaptive domains for the ESDM group relative to the children receiving treatments in the community (Dawson et al., 2010). Further, following the 2 years of intensive intervention the children receiving the ESDM intervention showed normalization of brain activity in response to viewing faces and houses using EEG (Dawson et al., 2012), suggesting that this model significantly impacted not only behavior but also neurological functioning.

Pharmacological Intervention

Between 30 and 70% of children with ASD are prescribed medication in the course of their treatment (Aman, Lam, & Collier-Crespin, 2003; Aman, Lam, & Van Bourgondien, 2005; Esbensen, Greenberg, Seltzer, & Aman, 2009) although there are currently no medications that have demonstrated efficacy for addressing the core symptoms in ASD. The two FDA approved medications showing efficacy in ASD, risperidone and aripiprazole, target challenging behaviors and hyperactivity but not ASD itself (Marcus et al., 2009; Owen et al., 2009; Scahill et al., 2012). A comprehensive review of medical treatments in ASD indicates that most pharmacological interventions have limited evidence for their efficacy and those that do have been supported by private pharmaceutical companies. Further, no studies compare medical interventions to behavioral interventions or include combinations of both, even though most children with ASD receive both types of treatment (McPheeters et al., 2011).

Despite the limited extant literature, there are novel biomedical treatments under evaluation, such as arbaclofen, to address the core social deficits in ASD (Gurkan & Hagerman, 2012). Recent studies of oxytocin suggest promise (Domes et al., 2013) and indicate that even a single intranasal injection of oxytocin appears to normalize brain functioning and may therefore be an appropriate tool to bootstrap or enhance the effectiveness of behaviorally based interventions (Gordon et al., 2013).

Complementary and Alternative Approaches

Complementary and alternative treatments (CAT), defined as "medical and health care systems, practices, and products that are not generally considered to be part of

conventional medicine" (National Center for Complementary and Alternative Medicine, 2012), are commonly used in ASD with reports of between 32 and 80% of families reporting using or having used CAT to address ASD symptoms (Harrington, Rosen, Garnecho, & Patrick, 2006; Levy & Hyman, 2003; Levy, Mandell, Merhar, Ittenbach, & Pinto-Martin, 2003; Wong & Smith, 2006). This diverse group of treatments includes biomedical approaches, such as vitamins, supplements, diets, and procedures such as neurofeedback; mind–body interventions, such as meditation; body-based methods, such as massage; energy based treatments, including reiki; or alternative care systems (e.g., homeopathy) and the primary reported rationale for applying these approaches relate to safety concerns or adverse medication side effects (Hanson et al., 2007). Despite the widespread availability and application of CATs, there is limited scientific evidence supporting the efficacy of these approaches due to a lack of controlled trials, rigorous protocols, adequate sample sizes, clear inclusion criteria, and double blind designs (Lofthouse, Hendren, Hurt, Arnold, & Butter, 2012).

Many CATs have few or no studies examining their efficacy providing insufficient evidence in which to evaluate them; however, some have been studied using more rigorous designs. Melatonin is among the best-studied CAT for ASD and despite limitations to study designs, sample sizes, and variability in approaches, the existing literature suggests the use of melatonin holds promise for addressing sleep problems in ASD (Rossignol & Frye, 2011). Another well-studied CAT is Secretin. It has consistently been shown to have no utility in the management of ASD (Krishnaswami, McPheeters, & Veenstra-Vanderweele, 2011). Following media reports of its efficacy in a small group of children with ASD and diarrhea, excitement over Secretin as a treatment preceded the research, and only after dozens of studies failing to show efficacy was Secretin removed from favor (Schreibman, 2005). Other treatments that have failed to demonstrate positive effects through randomized controlled trials include auditory integration therapy (Sinha, Silove, Wheeler, & Williams, 2004), facilitated communication (Mostert, 2001), hyperbaric oxygen therapy (Jepson et al., 2011), and gluten/casein-free diet (Millward, Ferriter, Calver, & Connell-Jones, 2008). Countless other approaches still have insufficient evidence with which to evaluate their effectiveness, including many specific vitamin supplements, immune therapies, and movement therapies (Lofthouse et al., 2012). In total, although few specific CATs have sufficient evidence for effectiveness, it has been suggested that families work with their primary medical provider together to consider and perhaps utilize CATs that show potential promise, sensible rationale for effectiveness, fit with family's values, and show evidence for safety (Hendren, 2013).

FUTURE DIRECTIONS

Major advances in our understanding of ASD have been made in the intervening years since Leo Kanner first defined the disorder in 1943. It is clear now that ASD can be conceptualized as a group of disorders with significant heterogeneity in terms of etiology, course, response to treatment, and outcome. Developmental research has illuminated the core social impairments in ASD and provided insight into the downstream effects of these deficits on clinical presentation. Studies have also demonstrated the viability and importance of detecting ASD very early in development and identified several genetic and environmental contributors and risk factors. Investigations in neuroanatomy and function indicate atypical growth and disruption to a range of structures and regions and the focus on intervention has shown that although all children with ASD benefit from intervention, some clear show rapid gains while others show slower response. Future directions in ASD research will expand on these gains. The identification of biomarkers to be used in early detection of ASD is a key focus of research and will allow for earlier application of intervention focused on the core deficits in ASD. By addressing these core deficits earlier, developmental trajectories can be normalized and outcomes optimized. Studies focused on etiology will address the heterogeneity of ASD by continuing to clarify the contributions of specific ASD associated genes and environmental risk factors. Future treatment research will likely entail more rigorous analysis of complementary and alternative approaches, the discovery of novel pharmacological agents or novel application of existing medications, careful identification of the mediators and moderators of treatment response for all treatment types, and the matching of treatments for specific, etiologically linked ASD subtypes. Ultimately the future holds the potential for bridging our understanding of early detection, etiology, and treatment such that biomarkers can be used to identify children at risk for ASD, so that relevant, targeted treatments based on etiological subgroups can be applied to improve outcomes for individuals with ASD.

OVERVIEW

This chapter describes one way translational research has changed how we think about, diagnose, and treat the social impairments of autism spectrum disorder (ASD). It also relates the story of how the application of developmental science to the study of ASD has encouraged new ways of thinking about the typical development of human social cognition. In particular, human social cognition may be viewed as the outgrowth of a special form of human information processing that we call joint attention (Mundy & Newell, 2007). This chapter will describe how joint attention is more than a milestone in the development of social cognition in infancy. Rather, it is an executive form of information processing that contributes to social learning, stimulus encoding, and the facilitation of human social communication and connectedness across the life span. This executive joint attention function integrates information about oneself, other people, and shared attention to objects, events, or ideas. It does so through the integrated activation and functions of a distributed system of frontal and posterior cortical networks in the brain. Recognizing and understanding the parallel and distributed nature of executive joint attention functions contributes to new perspectives about the nature and development of social cognition and about the nature of the social brain in all people, including those affected by ASD (Mundy, 2003). This new framework has emerged from the

Work on this chapter was supported by the National Center for Advancing Translational Sciences, NIH grant number 8KL2TR000056 to the first author. The research and theory development reported in this paper were supported by NIH Grants HD 38052, MH 071273, IES Grant IES 324C2012–1, the support of Marc Friedman and Marjorie Solomon for the Lisa Capps Endowment to the UC Davis Department of Psychiatry and MIND Institute. The data and ideas have been fostered by collaborations at UCLA, the University of Miami, Marquette University, and UC Davis.

interplay between cognitive neuroscience, developmental science, and the science of autism. It integrates the idea that a "developmental analysis" (Cicchetti & Toth, 2009, p. 16), which underscores the importance of developmental timing, multiple determinants of behavior, and multiple pathways to positive or negative outcomes, is necessary to fully understand the impact of joint attention disturbance on development. As such, it provides a seminal illustration of a school of translational research that began three decades ago when a farsighted group outlined the new discipline of *developmental psychopathology* (Cicchetti, 1984; Sroufe & Rutter, 1984).

The chapter begins with a brief historical review of the conceptualization of ASD. One key message is that a lack of precise understanding of the typical developmental trajectory of social behavior impeded the accurate diagnosis of ASD until the early 1990s, which was 50 years after it was initially described by Asperger (1944) and Kanner (1943). Then we provide a review of the typical development of joint attention, the underlying neural systems supporting its development, and the utility of adopting a dynamic systems approach in understanding the neurocognitive development of joint attention. Following that review, we discuss the relation between social impairment and joint attention in ASD. This review also illustrates how social developmental research continues to be a vital source of information about the nature of ASD, and how research on ASD has led to insights about the precise nature of the typical development of joint attention in infants that have contributed to the framework for a new model of human social cognition development. As previously noted, this chapter adopts a parallel and distributed information processing perspective on joint attention and social cognition. An advantage of this model is that it explicitly attempts to link developmental behavioral research on social pathology to a range of recent observations, from research on neural connectivity and genetics, ocular motor control, and intervention in autism, discussed in the final section of the chapter.

A HISTORICAL PERSPECTIVE ON AUTISM SPECTRUM DISORDER

ASD is a biologically based condition that is characterized by impaired social development, impaired language, or pragmatic communication skill acquisition, and the presence of repetitive behaviors and thoughts (Asperger, 1944; Bailey, Philips, & Rutter, 1996; Dawson, Osterling, Rinaldi, Carver, & McPartland, 2001; Kanner, 1943). The symptoms of ASD in many affected children are observable by 24 months of age or earlier (Stone, Coonrod, & Ousley, 1997; Zwaigenbaum et al., 2005), with children expressing different courses of symptom onset. Some children may display clear symptoms by the end of the first year or early part of the second year of life. Other children may display more typical development through the first year but then not display the typical rate of advances in social communication behaviors in the second year, while others may display a second year course more indicative of the interruption or loss of elements of social communication development (Ozonoff, Heung, Byrd, Hansen, & Hertz-Picciotto, 2008).

Leo Kanner (1943) displayed impressive clinical acumen when he was able to discern three common characteristics that distinguished children with ASD from those in a larger clinical sample of children with varied exceptionalities. He noted that children with ASD appeared to have (1) a common impairment of affective relatedness to others, which (2) resulted in a disorder that primarily involved impairments of the capacity for typical social interactions and (3) was most likely caused by biologically based processes. The recognition of the biological, affective, and social-behavioral syndrome triumvirate of autism was a remarkable achievement and is as valid today as it was in 1944. Unfortunately, Kanner's initial perspective did not fit well with the psychodynamic zeitgeist of the time. The psychodynamic perspective of the time emphasized the primacy of environmental over biological factors in the etiology of all psychopathology. Sufficient challenges were brought to bear in this regard that Kanner (1949) recanted in his initial biological view of ASD.

In the ensuing thirty years, the science of autism drifted from one perspective to another. ASD was described as a disorder caused by an aloof parenting style that caused children to grow up to be severely emotional disengaged from all people (Bettleheim, 1959). By the early 1960s, compelling indirect evidence for the biological nature of ASD had been presented to counter this parenting style hypothesis (e.g., Rimland, 1964). However, the singular prototype of people with ASD as emotionless and aloof remained for a long time. Few data were available to critically appraise prototype because the social and emotional development of children with ASD was rarely a focus of empirical inquiry through the 1970s. For example, Pat Howlin (1978) required only seven pages and 39 citations to review the literature on the social behavior of children affected by ASD at the time. Moreover, only a handful of the citations referred to peer-reviewed empirical research publications on the social behavior of ASD. Alternatively,

research and theory at that time was taken with the notion that sensory, perceptual, or language impairments must be primary to the phenotype and etiology of ASD (Mundy & Sigman, 1989). Although this was a scientifically valid assumption given the dearth of any appreciable empirical research on autism, it had the untoward consequence of relegating social-emotional impairments to the status of epiphenomenon in models of ASD. The secondary status of social-emotional symptoms constrained the theory and methods used to establish the initial diagnostic criteria for ASD.

DIAGNOSTIC DESCRIPTION OF ASD

The first attempts in the USA to establish a systematic diagnostic definition of ASD were in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III;* American Psychiatric Association, 1980). *DSM-III* described only six symptom criteria for the diagnosis of autism: (1) onset before 30 months of age; (2) a pervasive lack of responsiveness to other people; (3) gross deficits in language development; (4) if speech is present, peculiar speech patterns such as immediate and delayed echolalia, metaphorical language, pronominal reversal; (5) bizarre responses to various aspects of the environment, (e.g., resistance to change, peculiar interest in or attachments to animate or inanimate objects); and (6) absence of delusions, hallucinations, loosening of associations, and incoherence as in schizophrenia.

The item in this initial set of symptoms that was specific to the social deficits of autism was the rather broad and vague descriptor of a pervasive lack of responsiveness to other people. There had been so little research on defining the nature of the social deficits of autism through 1980 that we simply had no idea how to precisely describe this symptom domain of ASD, even though Kanner had argued that it was the central symptom domain of the syndrome. Fortunately, in the subsequent decade there was a virtual explosion of research on the social-deficits of ASD. Indeed, when Pat Howlin published a second review of research on the social development of ASD, eight years after her first effort in 1978, she required 24 pages and 116 citations to adequately cover the field (Howlin, 1986).

This welcome increase in information on the social nature of ASD occurred because of translational research. Several groups in the United States, the United Kingdom, and throughout the world began to recognize that theory and methods used in the study of human infancy and primate social development could be used as powerful tools to examine and define the social deficits of ASD (e.g., Baron-Cohen, Leslie, & Frith, 1985; Cicchetti, 1984; Dawson & McKissick, 1984; Rogers & Pennington, 1991; Sigman & Ungerer, 1984; Wimmer & Perner, 1983); more recently, there has been acknowledgement that the social deficits of ASD may provide important insights on typical development, as well (Cicchetti & Toth, 2009). This new wave involved the translation of the basic developmental science studies of infant imitation, social learning, social cognition, preverbal communication, and attachment, as well as social cognitive development in young children. One fairly immediate and vital impact of this surge of translational research was the dawning awareness that the description of the social impairments of ASD singularly as a *pervasive lack of responsiveness to others* was at best limited and, at worst, misguided. That description established an ASD prototype of a completely socially unresponsive child, but empirical research indicated that this prototype did not effectively characterize the spectrum of children that were affected by the syndrome (Mundy & Sigman, 1989; Wing & Gould, 1979).

One of the most fundamental observations in the science of autism is that the expression of the social phenotype of ASD varies across children (Wing & Gould, 1979). Wing and Gould (1979) found that some children with ASD appeared to be socially aloof, much as the description of "a pervasive lack of responsiveness" suggests. These aloof children often performed in the severe or moderate range of intellectual disabilities on measures of IQ or developmental status. However, many other children with mild intellectual disabilities or IQs in the typical range were not pervasively underresponsive. Instead, some were passive but socially responsive in structured situations. Other children were even proactive in initiating interactions. However, while socially more active, these children displayed social behavior that was odd, atypical, and frequently maladaptive in engaging or maintaining interactions with other people (Fein et al., 1999; Volkmar, Cohen, Bregman, Hooks, & Stevenson, 1989; Wing & Gould, 1979).

In addition to the recognition of the Wing and Gould tripartite social typology of ASD, by the end of the 1980s, studies had reported the observation that many children with ASD displayed patterns of social strengths, as well as weaknesses, rather than only a pattern of a *pervasive lack of responsiveness to other*s. For example, children with ASD responded when others imitated them, and some children appeared to learn from observing social modeling. Many children reportedly increased their social behaviors in structured situations, and children with ASD varied greatly in their use of gestures and eye contact

to communicate (Curcio, 1978; Lewy & Dawson, 1992; Mundy & Sigman, 1989). Perhaps most remarkably, children with ASD often displayed levels of attachment behaviors that were commensurate with their mental development and *not atypical* relative to other groups of children with comparable developmental delays (Mundy & Sigman, 1989; Shapiro, Sherman, Calamari, & Koch, 1987; Sigman & Ungerer, 1984). In these studies, measures of attachment were used that assessed children's responses to separations, and, especially, reunions with their caregivers. Many children with ASD displayed behaviors that suggested they had developed emotional bonds that were specific to their caregivers and that supported the children's self-regulation in a strange laboratory environment. Such displays of social bonding to caregivers were wholly inconsistent with many of the then current models of ASD, including the notion that all affected children displayed a universal lack of responsiveness to others.

Consequently, by the early 1990s translational developmental research indicated that key elements of the nosology of ASD were incorrect. Children with ASD, as a group, did not display a *pervasive* lack of responsiveness to others. Not only was this inaccurate, it promoted a constricted view of ASD that excluded many children with the syndrome who frequently made eye contact, or displayed caregiver attachment, or any of a number of other social abilities. The persistence of this inaccurate taxonomic prototype likely contributed to a historic underestimation of the prevalence of ASD (Wing & Potter, 2002). Indeed, only with the publication of the fourth edition of the *DSM*, in 1994, did we begin to have sufficiently well-defined guidelines that both accurately captured something of the essence of the core social impairments of ASD, and acknowledged the range of phenotypic variability expressed across individuals with this syndrome. Prior to this, in the 1970s, 1980s, and early 1990s, we simply could not identify all the children with ASD in the population because we limited ourselves to those that just met a very limited and restrictive social criterion.

Research-based revisions of social diagnostic criteria of ASD by both the American Psychiatric Association (APA, 1994, 2000, 2013) and the International Classification of Disease (ICD), established by the World Health Organization (1991), have led to more effective and informed ASD identification and diagnosis. In the most recent revision (*DSM-5*; APA, 2013), the persistent impairment in social communication and interaction in ASD became defined in terms of the expression of the following symptoms: (1) deficits in social-emotional reciprocity, ranging from abnormal social approach and failure of normal back-and-forth conversation to reduced sharing of interests, emotions, or affect, to failure to initiate or respond to social interactions; (2) deficits in nonverbal communicative behaviors used for social interaction, ranging from poorly integrated verbal and nonverbal communication to abnormalities in eye contact and body language or deficits in understanding and use of gestures, to a total lack of facial expressions and nonverbal communication; (3) deficits in developing, maintaining, and understanding relationships, ranging from difficulties adjusting behavior to suit various social contexts to difficulties in sharing imaginative play or in making friends to absence of interest in peers.

"Deficits in relationships, or lack of sharing imaginative play or in making friends" as a symptom item is extremely useful, but not until children reach 3 or 4 years of age. As a result, the early identification and diagnosis of the social deficits of ASD relies on observation of the other social symptoms, which heavily draw from the concept of joint attention. Thus, this chapter attempts to provide a detailed consideration of why joint attention, operationalized as sharing interests, emotion, or affect, or initiating or responding to other people, via eye contact and nonverbal communication, is central to the description of the social pathology of ASD, and the very nature of this syndrome.

JOINT ATTENTION IN TYPICAL DEVELOPMENT

Well before infants learn to use symbols and language, they begin to spontaneously share information with other people. They do so by coordinating their attention with another person and by using eye contact and gestures to show objects to others, as well as to request objects or events (Bates, Benigni, Bretherton, Camaioni, & Volterrra, 1979). In a seminal paper in *Nature,* in 1975, Scaife and Bruner reported that between 6 to 18 months of age infants increasingly displayed the ability to follow the direction of gaze of a social partner. When a tester turned her head to the left or right many infants tracked and followed the visual attention of the tester with their own line of regard. This observation was groundbreaking. It was inconsistent with the prevailing notion of egocentrism or the idea that infants could not adopt dual perspectives, such as the perspective of self and another person, until late in the second year (Piaget, 1952). Scaife & Bruner's (1975) observations suggested that infants begin to differentiate information about their own visual perspective and that of another person, and then align their perspective with another person's much earlier in life than that.

Bruner (1975) adopted the general term *joint attention* for this domain of infant development. He recognized that this ability allowed infants and caregivers to adopt co-reference to the same object or event, and that this ability was a milestone in human social learning. One of Bruner's goals was to understand how young children learn, in order to improve early educational curriculums. Instead of studying only how knowledge was acquired (learning), he studied how the ability to share knowledge in social learning develops because this is essential to all forms of pedagogy. His work suggested that the development of the ability to participate in joint attention marked a critical turning point in some unknown set of early cognitive processes that enabled young children to more effectively benefit from caregiver scaffolding. Indeed, the emergence of joint attention ability in infants may even elicit or promote scaffolding in caregivers, suggesting that a multiple-level, bidirectional analysis of joint attention behavior in dyads would be necessary to fully understand the process (Cicchetti & Toth, 2009). Bruner, along with others before him (e.g., Werner & Kaplan, 1963), understood that the development of the capacity to adopt a common point of view (shared reference) was elementary to our human ability to perceive shared meanings and necessary for the development of symbolic thinking and language development.

Measurement of Subtypes of Joint Attention

In the early days of research, it became apparent that infants did not just develop one type of joint attention behavior. Rather, the development of joint attention was expressed in different functional forms in infancy (Bates et al., 1979). Infants may *respond* to others' joint attention bids or *initiate* joint attention bids (Seibert, Hogan, & Mundy, 1982). They do so to share declarative or imperative information about an object or event (Bates et al., 1979). In the declarative function, infants use their line of regard and gestures to share their experience of an object or event (e.g., interest) with another person, or they respond to others' attempts to indicate their experience of an object or event. These two types of behaviors came to be known as initiating joint attention (IJA) and responding to joint attention (RJA), respectively (Seibert et al., 1982). Current data supports the observations of Scaife and Bruner (1975) and indicates that infants begin to reliably turn their head or eyes to follow the visual line of regard of another person by 6 months of age (Gredebäck et al., 2010; Figure 4.1a). Less is known about the development of IJA, but data suggest that the ability to alternate eye contact between an object or event and another person, to spontaneously share interest or experience with a social partner, is well developed in many 8–9-month-olds (Bates et al., 1979; Mundy et al., 2007; Figure 4.1b, Figure 4.1c).

The declarative, social sharing functions of IJA and RJA can be juxtaposed with other behavior that involve establishing a common point of reference with other people for instrumental and imperative purposes (Bates et al., 1979). By 9 months of age, infants direct the attention of other people to express their desires (e.g. request) for an object or event using initiating behavioral requests (IBR; Figure 4.1d). In addition, they learn to respond to the attention directing bids that adults use to request objects or actions from infants. This is referred to as responding to behavioral requests (RBR; Figure 4.1e).

The theory and measurement concerning infant joint attention in the 1970s and 1980s interacted with the contemporary concern with identifying valid infant markers of individual differences in cognitive development. The types of sensory motor measures then used to assess infant intelligence and cognitive risk at the time were not sufficiently reliable or valid (Lewis & McGurk, 1972). Without valid measures, it was challenging to identify many infants who were at risk for developmental disorders. It was also difficult to know what constituted valid targets for early cognitive intervention. This impasse began to clear as applications of basic research indicated that measures of infant visual attention could be used as valid indicators of current and future cognitive development in infancy (Bornstein & Sigman, 1986). Although not fully appreciated at the time, this assertion could be expanded to include measures of infant *joint attention* development (Sigman & Mundy, 1993).

One laboratory for research on infant attention was created by Jeff Seibert and Anne Hogan at the Debbie School of the University of Miami. The Debbie School served preschoolers who had moderate to severe motor and developmental impairments. Their motor impairments made the use of sensorimotor cognitive assessments and interventions extremely impractical. So Seibert, Hogan, and their graduate student began to develop an early assessment and intervention curriculum that focused on joint attention and preverbal communication skill development. This resulted in the Early Social Communication Scales (ESCS), which organized precise observations of joint attention and social attention coordination into a measurement instrument that could also be used to guide early intervention (Seibert, Hogan, & Mundy, 1982). A lasting contribution of the ESCS, along with related measures (Stone, Coonrod, & Ousley, 1997; Wetherby, Allen,

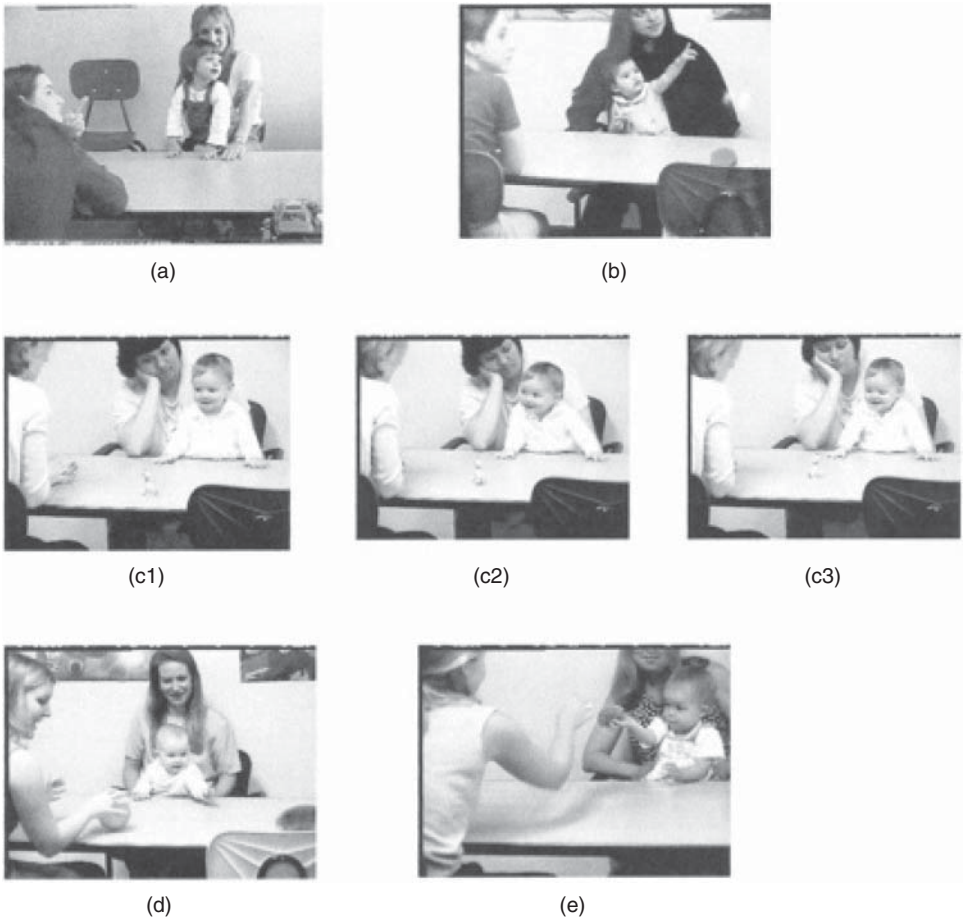

Figure 4.1 Illustrations of different types of infant social attention coordination behaviors: (a) responding to joint attention (RJA): following another person's gaze and pointing gesture; (b) initiating joint attention (IJA): using a conventional gesture (such as pointing) to share attention regarding a room poster; (c1,2,3) IJA: using an alternation of eye contact to share attention with respect to a toy; (d) initiating behavior requests: pointing to elicit aid in obtaining an out of reach object; (e) responding to behavior requests: following an adult's open-palm give-it-to-me gesture.

Cleary, Kublin, & Goldstein, 2002) was that joint attention assessment turned out to be a powerful instrument for the study of ASD and individual differences in social learning capabilities.

Learning and the Importance of Joint Attention

Early language learning often takes place in unstructured, incidental situations where parents spontaneously refer to a new object (Figure 4.2). How do infants know how to map their parents' vocal labels to the correct parts of the environment amid myriad potential referents? Baldwin (1995) suggested that they use RJA and use the direction of their parent's gaze to guide them to the correct area of the environment, thereby reducing referential mapping errors. Infants' use of IJA also reduces the chance of referential mapping errors. IJA serves to denote something of immediate interest to the child. This allows parents to follow their child's attention to provide new information in a context when the child's interest and attention is optimal for learning (Tomasello & Farrar, 1986). Hence, joint attention may be conceived of as a self-organizing system that facilitates information processing in support of social learning (Mundy, 2003). This learning function is fundamental to the nature of joint attention as a milestone of early development (Bruner, 1975). Moreover, joint attention continues to operate throughout our lives in many ways, such as affecting our emotional responses to stimuli (Bayliss et al., 2006), facilitating math learning (Nathan, Eilam, & Kim, 2007), improving mental spatial rotation in adults (Böckler, Knoblich, & Sebanz, 2011), affecting recognition memory in adults (Kim & Mundy, 2012), and facilitating or changing stimulus processing (Frischen et al., 2007). Indeed, it is safe to say that without the

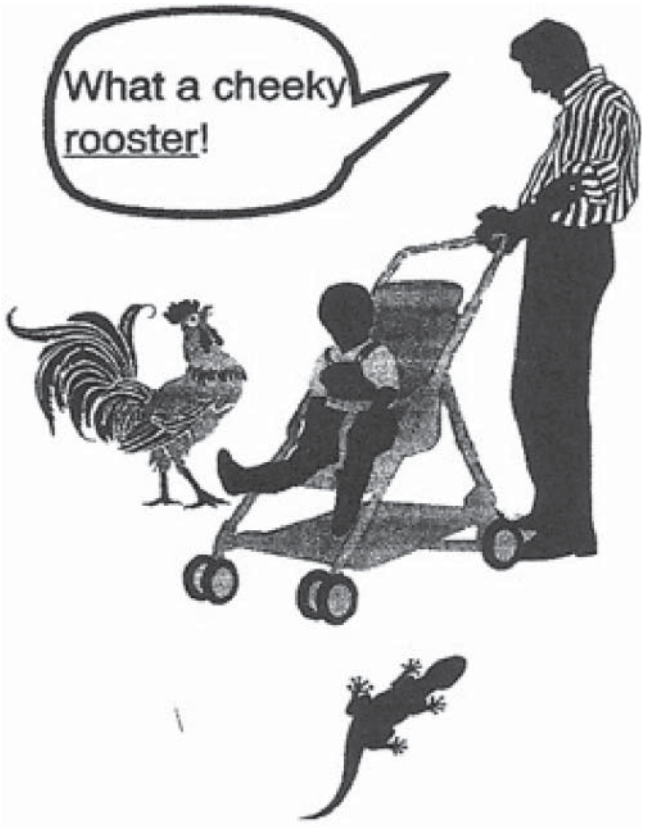

Figure 4.2 Illustration depicting the referential mapping problem encountered by infants in incidental social word learning situations. *Source:* D. Baldwin, Understanding the link between joint attention and language, in C. Moore & P. Dunham (Eds.), *Joint attention: Its origins and role in development* (pp. 131–158), Hillsdale, NJ: Erlbaum, 1995.

capacity for joint attention, success in many pedagogical contexts would be difficult. Imagine the school readiness problems of a 5-year-old who enters kindergarten, but is not facile with coordinating attention with the teacher. Similarly, children, adolescents, and adults who cannot follow, initiate, or join with the rapid-fire exchanges of shared attention in social interactions may be impaired in any social-learning context, as well as in their very capacity for relatedness and relationships (Mundy & Sigman, 2006).

To the degree that joint attention helps self-organize social learning in infancy, the more that children engage in joint attention, the more optimal social-learning opportunities they will help create for themselves. This may help to explain why the frequency with which infants engage in joint attention is positively related to their language acquisition and childhood IQ status (e.g., Mundy et al., 2007; Smith & Ulvund, 2003). More direct evidence of the links between joint attention and early learning is provided by the observation that coordinated social attention to pictures elicits electrophysiological evidence of enhanced neural activity and recognition memory associated with greater depth of processing in 9-month-olds (Kopp & Lindenberger, 2011; Striano, Chen, Cleveland, & Bradshaw, 2006a; Striano, Reid, & Hoel, 2006b).

Joint Attention and the Social-Cognitive Hypothesis

During the time that joint attention was first being conceptualized, another relevant kind of translational cognitive research was beginning to emerge. Premack and Woodruff (1978) described observational methods that enabled them to evaluate whether primates were aware of the thoughts or intention of conspecifics. That is, they began to study if apes had a theory of mind (ToM). Wimmer and Perner (1983), in the United Kingdom, further operationalized the construct of theory of mind with the development of the false belief task. With this paradigm they began to study the course of development of ToM and social cognition in preschool- and elementary school-age children.

Theory had previously linked the development of joint attention to the emergence of social cognition (Bretherton, 1991). This was further extended to its logical conclusion; namely, that young children would only consistently respond to or initiate joint attention bids if they understood that other people exerted intentional (goal-directed) control over their attention (Tomasello & Call, 1997). There was a cardinal problem with this model. Specifically, developmental studies indicated that infants displayed a wide range of individual differences in the frequency of their joint attention bids. For example, a large sample study indicated that 9-month-old infants displayed between four and forty IJA bids in a 20-minute interaction with an unfamiliar tester (Mundy et al., 2007). This variance was meaningful, in that the individual differences in IJA were reliable from 9 to 18 months of age (Figure 4.3). The social cognitive model was not developed to account for individual differences. Rather, it was an attempt to explain an all or none phenomenon, such as why older but not younger children display joint attention, or why typical children but not children with developmental disabilities display joint attention. However, joint attention does not simply develop in an all or none fashion. Some infants and children, with and without ASD, engage in more joint attention than others (e.g., Mundy, Sigman, & Kasari, 1990). It is very difficult to explain individual differences in joint attention on the order of those displayed in Figure 4.3 in terms of some scheme of incremental differences in understanding intentionality in others, at least as far as the social cognitive model has been articulated to date.

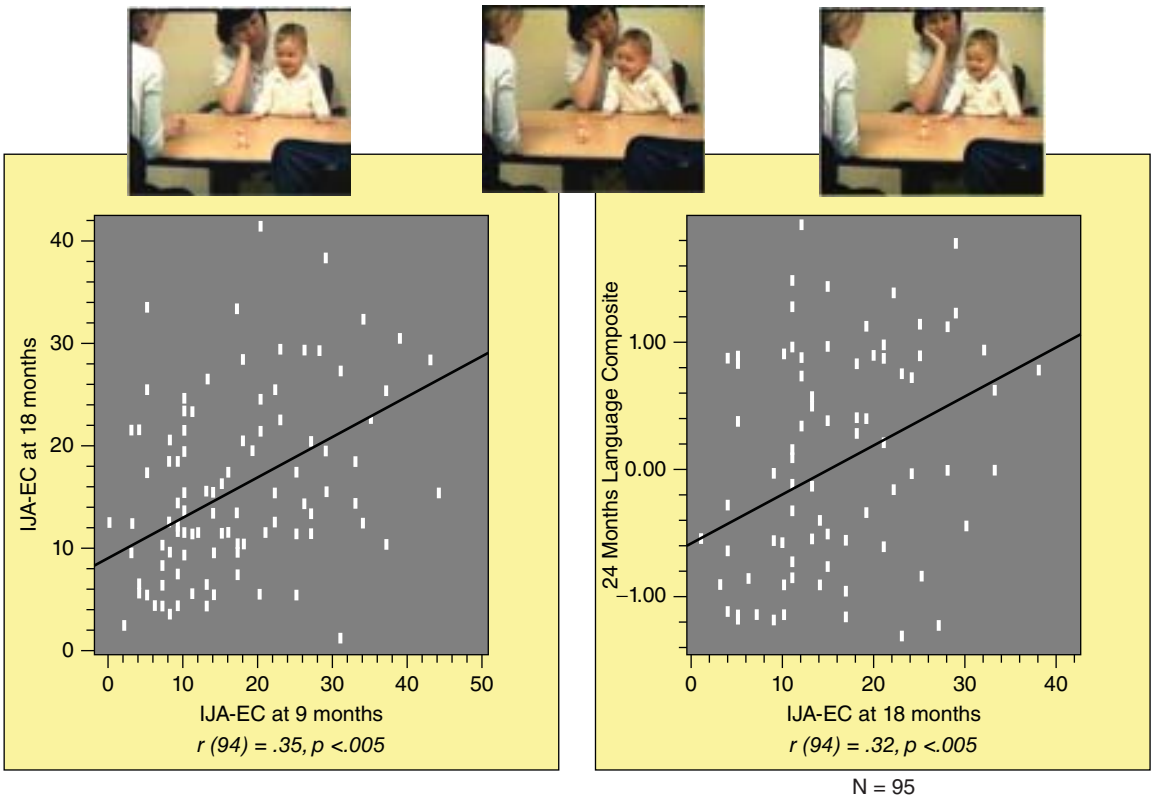

Figure 4.3 Illustration of the range and stability of individual differences in IJA alternating eye contact in 95 infants between 9 and 18 months of age (left panel), and the meaningful nature of individual differences in IJA alternating eye contact for a combined measure of receptive and expressive vocabulary development at 24 months. See footnote 1. *Source:* Data illustrations from P. Mundy, J. Block, A. Vaughan Van Hecke, C. Delgado, M. Venezia Parlade, & Y. Pomares, Individual differences and the development of infant joint attention, *Child Development, 78,* 938–954, 2007.

In summary, infant translational research provided a foundation for understanding the importance of joint attention for human development. Joint attention, by reflecting the capacity to share experiences and connect with others, likely provides a foundation for relational experiences with other people across the lifespan. Joint attention also provides a foundation for co-occurring and subsequent developments in language, thinking about others' minds, social learning, and social-emotional competence. It is not surprising, then, that the next major area of inquiry to develop would address better understanding the *neural foundations* of joint attention and its associated social-emotional outcomes.

THE NEURAL SYSTEMS OF JOINT ATTENTION

The neural systems associated with IJA and RJA development may be best understood within the context provided by two primary hypotheses within the contemporary research on functional brain architecture. The first hypothesis is that human cognition is best characterized as an emergent property of interactions among distributed, functionally specialized brain networks (McIntosh, 2000; Ramnani, Behrens, Penny, & Matthews, 2004). The second hypothesis is that there are at least *three superordinate brain networks* that interact in the development of cognition. These include the default network, which supports internal or self-referenced cognition, the dorsal attention system that serves external and other-referenced cognition, and the frontoparietal control or executive network, which regulates the expression or integration of the default and dorsal attention networks in cognition (Spreng, Sepulcre, Turner, Stevens, & Schacter, 2013; Figure 4.4). The default and dorsal attention systems show little evidence of positive (interactive) connectivity and may conflict or inhibit functions of the opposing network. Alternatively, the frontoparietal network has positive connectivity with both the default and dorsal attention networks. Moreover, Spreng et al. (2013) identified three different types of

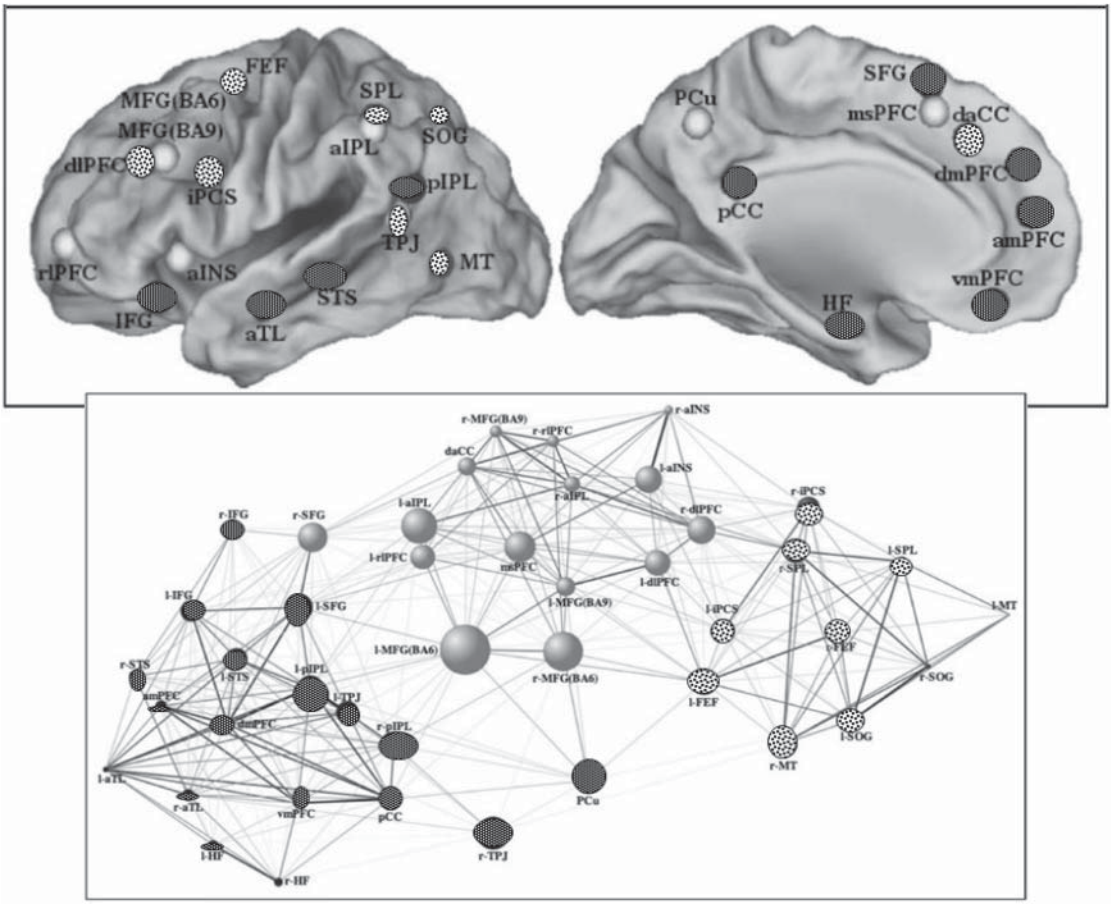

Figure 4.4 Illustration of the default network (circles with black background and white dots), frontoparietal network (circles in grayscale), and the dorsal attention network (circles with white background and black dots) in the top panel, and connectivity within and across networks in the bottom panel. *Source:* From R. N. Spreng, J. Sepulcre, G. R. Turner, W. D. Stevens, & D. L. Schacter, Intrinsic architecture underlying the relations among the default, dorsal attention, and frontoparietal control networks of the human brain, *Journal of Cognitive Neuroscience, 25*(1), 77, 80, 2013.

nodes within the frontoparietal network: default network aligned nodes, dorsal network aligned nodes, and dual aligned nodes. These nodes are thought to play a dynamic gatekeeping role in goal-directed cognition, mediating the adaptive balance between internal and external cognition, from moment to moment, across tasks and contexts. Regarding the development of these networks, Spreng et al. (2013, p. 82) noted, "Evidence suggests that patterns of intrinsic connectivity are sculpted by a history of repeated task-driven co-activation of brain regions, which in turn facilitates efficient coupling within task-relevant networks during future task performance." In other words, experience-based co-activity sculpts connectivity over time, which in turn affects later capacities (Cicchetti & Toth, 2009; Greenough, Black, & Wallace, 1987).

Early research on the similar and different processes that contribute to IJA and RJA emphasized the role of the dorsal attention network (Mundy, 2003). The dorsal attention network involves an anterior (frontal) and a posterior (temporal/parietal) component (Posner & Rothbart, 2007). Early studies suggested that IJA was more associated with the anterior attention network (Caplan et al., 1993; Henderson, Yoder, Yale, & McDuffie, 2002; Mundy et al., 2000; Torkildsen, Thormodsen, Syvensen, Smith, & Lingren, 2008), while RJA and related gaze-following behaviors were more closely associated with the posterior attention network (e.g., Emery, 2000; Frischen, Bayliss, & Tipper, 2007; Materna, Dicke, & Thern, 2008; Mundy et al., 2000). Interestingly, this observation provided one explanation of why higher primates (apes) were capable of RJA but not IJA (Tomasello, 2008). Several research groups have reported observations that suggest that the functions of the posterior network that support RJA are common to many primates, but the anterior network that

supports IJA is not well represented in primates other than humans (Astafiev, Shulman, Stanley, Snyder, Essen, & Corbetta, 2003; Emery, 2000; Gilbert & Burgess, 2008; Jellema, Baker, Wicker, & Perrett, 2000).

The posterior dorsal attention network regulates relatively involuntary attention, begins to develop in the first 3 months of life, and prioritizes orienting to biologically meaningful stimuli. It is supported by neural networks of the parietal/precuneus and superior temporal cortices (Figure 4.5). These neural networks are active in the perception of the eye and head orientations of others, as well as the perception of spatial relations between self, other, and the environment. The posterior system is especially involved in control of orienting on a trial-by-trial basis and the development of cognitive representations about the world built from information acquired through external senses (Cavanna & Trimble, 2006; Dosenbach et al., 2007; Fuster, 2006). This characterization of the posterior attention system comports with the notion that RJA is a relatively involuntary or reflexive response to human gaze shifts (Frischen et al., 2007).

In contrast, initiating joint attention was thought to be supported by later developments of the anterior dorsal attention network which were involved in cognitive processing addressing volitional, self-initiated, goal-directed action (Mundy, 2003). This network includes the anterior cingulate, rostral medial superior frontal cortex (including the frontal eye fields), anterior prefrontal cortex, and orbital frontal cortex (e.g., Dosenbach et al., 2007; Fuster, 2006). The development of the intentional control of visual attention is thought to begin at about 3 to 4 months of age. At that time, a pathway from the frontal eye fields (BA 8/9) begins to release the superior colliculus from inhibition, which enables the development of active prospective control of saccades and visual attention (Canfield & Kirkham, 2001; Johnson, 1990). The function of this pathway may underlie 4-month-old infants' ability to suppress automatic visual saccades to respond to a second, more attractive stimulus (Johnson, 1995), and 6-month-olds' ability to respond to a peripheral target when central, competing stimuli are present (Atkinson, Hood, Wattam-Bell, & Braddick, 1992). Hypothetically, the functions of this pathway also enable intentional gaze alternation between interesting events and social partners (Mundy, 2003).

More recent research suggests that it may not be accurate to allocate IJA exclusively to anterior systems functions and RJA to posterior system functions. Indeed, reliance only on the dorsal attention network is likely insufficient to characterize the complete system of neural networks that are involved in the maturation of human joint attention. For example, Schilbach et al. (2010) used imaging (fMRI) to examine whether the cortical correlates of RJA and IJA were common or distinct in adults. This research group reported that joint attention elicited activation in a specific frontal-temporal-parietal distributed network, that likely contains elements of the default and

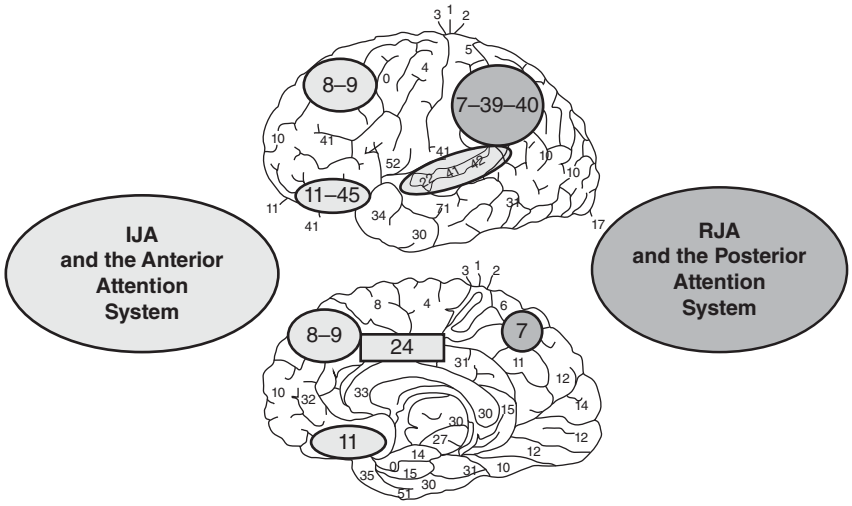

Figure 4.5 Illustration depicting the lateral (top) and medial (bottom) illustrations of Brodmann's cytoarchitectonic areas of the cerebral cortex associated with initiating joint attention and the anterior attention system, as well as RJA and the posterior attention systems. The former include areas 8 (frontal eye fields), 9 (prefrontal association cortex), 24 (anterior cingulate), 11, and 47 (orbital prefrontal association cortex). The latter include areas 7 (precuneus, posterior parietal association area), 22, 41, and 42 (superior temporal cortex), and 39 and 40 (parietal, temporal, occipital association cortex). *Source:* Illustration from P. Mundy & L. Newell, Attention, joint attention and social cognition, *Current Directions in Psychological Science*, *16*, p. 271, 2007.

frontoparietal network, as well as the dorsal attention network. Moreover, Schilbach et al. (2010) observed that RJA, but not IJA, was uniquely associated with medial frontal gyrus activation, a region that is part of the frontoparietal control network in the Spreng et al. (2013) model. Consistent with this observation, recent behavioral development studies also suggest that executive cognitive control functions are associated with RJA in infancy (Vaughan Van Hecke et al., 2012). In contrast, Schilbach et al. (2010) observed that IJA was more exclusively associated with striatal cortex activation than was RJA. Striatal cortex is associated with reward processing that is instrumental to motivating self-initiated goal directed behavior. This observation is consistent with the notion that prosocial motivation likely plays a role in IJA development (Vaughan Van Hecke et al., 2007). The ventral striatum is not represented in the Spreng et al. (2013) model, however; it is part of a reward-processing network that involves elements of the Default Network described by Spreng and colleagues, such as the dorsal medial prefrontal cortex (mPFC) (Carlson, Foti, Mujica-Parodi, Harmon-Jones, & Hajcak, 2011).

Subsequently, Redcay et al. (2012) reported a seminal sequence of fMRI observations on joint attention with adults. In this study, both IJA and RJA were associated with the activation of the posterior superior temporal sulcus and the mPFC, which are components of the default network (Spreng et al., 2013) often associated with social cognition. IJA displayed relatively stronger association with activation in the middle frontal gyrus and parietal cortex, areas associated with the dorsal attention and frontoparietal control networks described by Spreng et al. (2013). Alternatively, RJA was uniquely associated with ventral medial frontal and occipital cortical activation in this study. Only the former is included in the Spreng model and is aligned with the default network. Perhaps most interesting of all, Redcay et al. (2012) provided the only connectivity analysis to date and found evidence that joint attention is associated with functional connectivity among nodes that are part of all three networks described by Spreng et al. (2013).

Of course, the neurofunctional organization observed in adults may not necessarily inform our understanding of the developmental systems that give rise to the early development of joint attention. However, studies indicate that many elements of a distributed joint attention network that are evident in research with adults are also evident in early developmental research with infants. Grossman and Johnson (2009) reported that a pattern of anterior (medial frontal, left ventral frontal) and posterior (right temporal/parietal) cortical activation is associated with response to joint attention in 5-month-olds. Elison et al. (2013) also reported that the relative functioning of anterior frontal white matter fiber tracts (uncinate fasciculi) and posterior temporal white matter fiber tracts (inferior longitudinal fasciculi) at 6 months of age predicts RJA development at 9 months of age. It is also the case that a pattern of EEG activation across a distributed anterior and posterior cortical system predicts IJA development in infants from 14 to 16 months of age (Henderson et al., 2002).

Thus, the current research literature has given rise to the parallel and distributed processing model (PDPM) of joint attention development and its impairment in ASD (Mundy et al., 2009). According to this model, initial executive and behavioral motivation biases promote the tendency of infants to engage in the practice of processing of internal information about the direction and focus of their own visual attention, while also processing external information about the visual attention of other people. This dynamic system of early self-other information processing about attention leads to the concretization of connections between an anterior and posterior neurocognitive network that supports fast and efficient human joint attention (Figure 4.6; Mundy & Newell, 2007). This model incorporates the notion that patterns of what may appear to be intrinsic connectivity in adults have been sculpted by a history of repeated (practiced) task-driven co-activation of brain regions during development (Cicchetti & Toth, 2009; Spreng et al., 2013). The model is also consistent with neurocognitive theory that claims that an emergent function of the human rostral-medial frontal cortex is the capacity to switch attention between self-generated information and perceptual (external) information in support of social cognition (Gilbert & Burgess, 2008). The PDPM suggests that this function is allocated to the rostral medial frontal cortex, in large part, as a function of the adequate bio-behavioral exercise of joint attention behaviors early in development. Moreover, if behavioral practice does not facilitate efficient couplings within task-relevant networks, then the joint attention system may display quantitative reductions in its rapid and efficient execution. This in turn results in increased cognitive load associated with joint attention engagement and consequent reduced effectiveness of cognitive processing within social interactions, such as social learning situation or social conversational discourse (Mundy & Jarrold, 2010; Mundy et al., 2009, 2010).

Recently, two studies have provided evidence that part of the development of joint attention early in life may be characterized by an increase in the speed or efficiency with

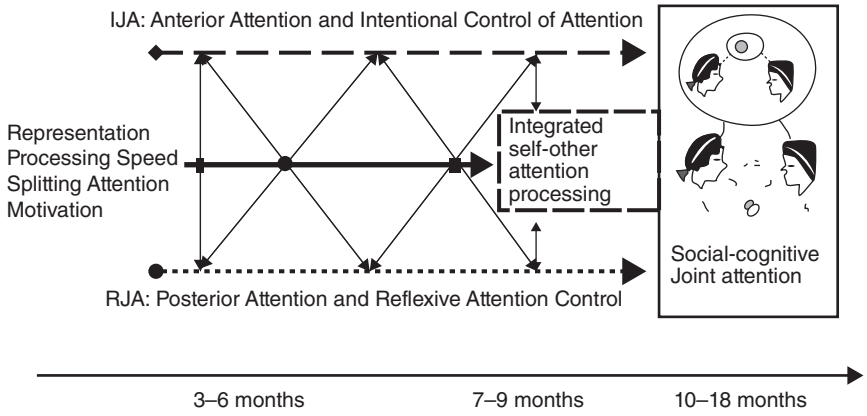

Figure 4.6 An illustration of the parallel distributed information processing system model of joint attention and social cognition. In this model, different types of lines depict the multiple paths of joint attention development. The posterior attention system path associated with RJA development is illustrated with a dotted line ····▶ and the anterior attention system path associated with IJA development is illustrated with a dashed line – – –▶. The central solid line in the figure depicts the developments of other processes during infancy that influence joint attention development, such as representational ability, speed of processing, motivation, and executive attention control, as well as each other, during infancy. The diagonal arrows connect all paths throughout early development. This reflects the dynamic and coactive nature of joint attention development, whereby the maturation of attention, cognitive, and affective systems interact in reciprocal cause and effect relations with experience, including the experiences children create for themselves through their own actions. Finally, the development of integrated self and other attention processing is considered to be a social attention executive function of the anterior system that emerges in the 4- to 9-month period. This is represented by the box. The capacity to integrate and share overt aspects of attention provides a foundation for the ability to share covert aspects of attention, such as representations, and social cognition. *Source:* From P. Mundy & L. Newell, Attention, joint attention and social cognition, *Current Directions in Psychological Science*, *16*, p. 272, 2007.

which young children execute joint attention behaviors. Gredebäck, Fikke, and Melinder (2010) reported longitudinal data across assessments at 2, 4, 6, and 8 months of age, whereupon infants displayed a significant linear increase from age to age in the tendency to shift gaze in response to the line of regard of a tester. More pertinent, though, was the observation that infants displayed a significant linear decrease in their latency to follow gaze, from about 3.5 seconds at 2 months to 1.5 seconds at 8 months. We have observed a similar longitudinal decrease in RJA latency, from approximately 2 seconds at 9 months to 0.8 seconds at 18 months (Vaughan Van Hecke et al., 2012). Moreover, 9-month-olds displayed a reduction in latency with practice across four RJA trials (Figure 4.7).

A definitive interpretation of the causes of the decrease in latency in RJA in these studies is not yet possible. Nevertheless, these patterns of results are consistent with the notion that execution of joint attention behaviors becomes more rapid, efficient and, perhaps, automated, across the first two years of life in typical development. One possibility is that this is due to practice effects interacting with interconnectivity within the frontal and posterior joint attention network that has been observed to develop in the first years of life (Elison et al., 2013).

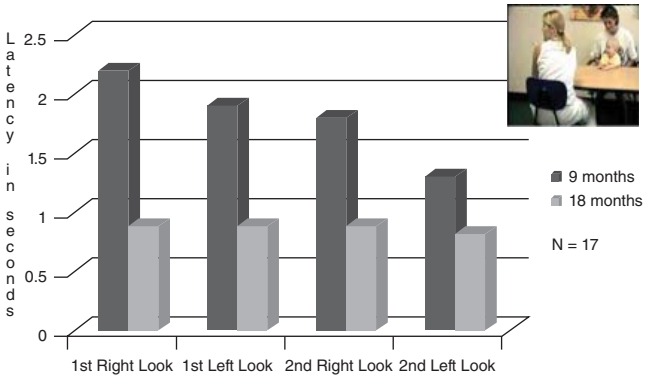

Figure 4.7 An illustration of the decrease in response latency to left and right RJA trials on the Early Social-Communication Scales (Mundy, Hogan, & Doehring, 1996) between 9 and 18 months of age. Also illustrated is the decrease in response latency across a sequence of RJA trials exhibited by infants at 9 months of age. See footnote 1.

In summary, the PDPM model of joint attention holds that integrated and, at times, collaborative processing of information about one's own focus of attention and the attention of other people is a necessary faculty for competent human social engagement, social learning, and social communication. In addition, joint attention is a

form of parallel processing that occurs across a distributed cortical network. Practice with joint attention in infancy contributes to the development of an efficient distributed neural network that plays a crucial role in human social cognition. The potential role of parallel and distributed processing in synthesis in human social cognition has previously been recognized (Decety & Sommerville, 2003; Keysers & Perrett, 2004). However, the developmentally primary role of joint attention in this synthesis is less well recognized.

Social Cognition and the PDPM of Joint Attention

Social-cognitive models often describe joint attention in terms of incremental stages of knowledge about the intentionality of other people. Baron-Cohen (1995) described a sequence of cognitive modules that included the *intentionality detector* (ID; i.e., a dedicated cognitive facility that attributes goal directed behavior to objects or people) and the *eye direction detector* (EDD; i.e., senses and processes information about eyes). These combine to form the *shared attention mechanism* (SAM), a cognitive module that represents self and other as attending to the same referent and attributes volitional states (intentionality) to direction of gaze of other people. As infancy ebbs the *theory of mind mechanism* replaces SAM and enables representation of the full range of mental states of others and enables us to make sense of others' behaviors.

Tomasello et al. (2005) more explicitly described joint attention development in terms of three stages of what infants know about other people. In the *understanding animate action stage*, 3- to 8-month-old infants can perceive contingencies between their own animate actions and emotions relative to the animate actions and affect of others. However, they cannot represent the internal mental goals of others that are associated with these actions. Next, in the *understanding of pursuit of goals* stage, 9-month-olds become capable of shared action and attention on objects (e.g., building a block tower with parents).

Tomasello et al. (2005) suggested that the *understanding of pursuit of goals* stage involves joint perception, rather than joint attention, because the social-cognitive capacity to represent others' internal mental representations necessary for true joint attention is not yet available. However, this ability emerges between 12 and 15 months in the *understanding choice of plans* stage. This stage is heralded when infants become truly active in initiating episodes of joint engagement by alternating their eye contact between interesting sights and caregivers (Tomasello et al., 2005). This shift to active alternating gaze indicates infants' appreciation that others make mental choices about alternative actions that affect their attention. Infants also now know themselves as agents that initiate collaborative activity based on their own goals. Hence, the development of true joint attention at this stage is revealed in the capacity to adopt two perspectives analogous to speaker–listener.

The capacity to adopt two perspectives is also assumed to be an intrinsic characteristic of symbolic representations. In this regard, Tomasello et al. (2005) raised a truly seminal hypothesis, that symbolic thought is a developmental transformation of joint attention. They argue that symbols themselves serve to socially coordinate attention so that the intentions of the listener align with those of the speaker. In other words, linguistic symbols both lead to and are dependent upon the efficient social coordination of covert mental attention to common abstract representations among people. This hypothesis fits well with the parallel and distributed processing model of joint attention, but the PDPM places it in a substantially different developmental framework.

The PDPM does not emphasize functional segregation of cognitive systems implicit to modular perspectives, but instead emphasizes the cortically multi-determined nature of human cognition because of the "massively parallel nature of human brain networks and the fact that function also emerges from the flow of information between brain areas" (Ramnani et al., 2004, p. 613). Furthermore, cognitive development need not be construed only in terms of changes in discontinuous stage knowledge. It can also be modeled as a continuous change in the speed, efficiency, and combinations of information processing that give rise to knowledge (Hunt, 1999). Specifically, the PDPM envisions joint attention development in terms of increased speed, efficiency, and complexity of processing of (1) internal information about self–referenced visual attention, (2) external information about the visual attention of other people, and (3) the neural networks that integrate processing of self-generated visual attention information with processing of information about the visual attention behavior of other people (Mundy & Newell, 2007).

Consequently, the notion that *true* joint attention does not emerge until requisite social-cognitive knowledge emerges at 12–15 months (Tomasello et al., 2005) is not germane to the PDPM. Rather, consistent with a growing empirical literature, the PDPM holds that the true joint processing of attention information begins to be practiced by infants by 3 to 4 months of age (D'Entremont, Hains, & Muir, 1997; Farroni, Massuccessi, & Francesca, 2002; Hood, Willen, & Driver, 1998, Morales et al., 1998; Striano, Reid, & Hoel, 2006b; Striano & Stahl, 2005). Indeed,

even the types of active alternating gaze behaviors thought to mark the onset of true joint at 12–15 months (Tomasello et al., 2005) develop no later than at 8–9 months of life, and quite possibly earlier (Mundy et al., 2007; Venezia et al., 2004).

Equally important, the PDPM assumes that joint attention is not replaced by the subsequent development of social-cognitive processes. Instead, joint attention is thought to remain an active system of information processing that supports cognition through adulthood (Mundy & Newell, 2007). As an example, recall the hypothesis that linguistic symbols enable the social coordination of covert attention to common mental representations across people (Tomasello et al., 2005). According to the PDPM, symbolic thinking involves joint attention but does not replace joint attention. Just as 12-month-olds can shift eye contact or use pointing to establish a common visual point of reference with other people, 4-year-olds can use symbols to establish a common reference to covert mental representations with other people. Symbolic representations are often, if not always, initially encoded during the joint processing of information about the overt attention of self and of others directed toward some third object or event (Adamson, Bakeman, & Dekner, 2004; Baldwin, 1995; Werner & Kaplan, 1963). The PDPM combines that hypothesis with the connectionist notion that "representations can take the form of patterns of activity distributed across processing units" that occurred during encoding (Munakata & McClelland, 2003, p. 415). Together these two ideas lead to the assumption of the PDPM that symbol acquisition incorporates the distributed activation of the joint self-attention and other-attention neural processing units, which were engaged during encoding, as part of their functional neural representational mappings. Hence, the distributed joint attention processing system may always be activated as a network encoding that contributes to the intersubjectivity (i.e., shared attention and meaning) of symbolic thought.

In infancy, the distributed joint attention processing system is initially effortful. However, thousands of episodes of practice allow the joint information processing of self–other attention to become efficient, less effortful, and even automatically activated in social engagement. As this occurs, joint attention becomes a social-executive subroutine that runs in support of symbolic thought, as well as that capacity to maintain a shared focus in social interactions and in social cognition (Mundy, 2003). The distributed neural activation patterns associated with joint attention are part of infants' sense of developing sense of relatedness to others (Mundy & Hogan, 1994; Mundy, Kasari & Sigman, 1992). Moreover, the distributed neural activation associated with joint attention can be thought of as an enduring stratum of a more continuous spiral of human social-neurocognitive development that supports, if not enables, later emerging human symbolic, linguistic, and social cognitive facilities (Figure 4.8).

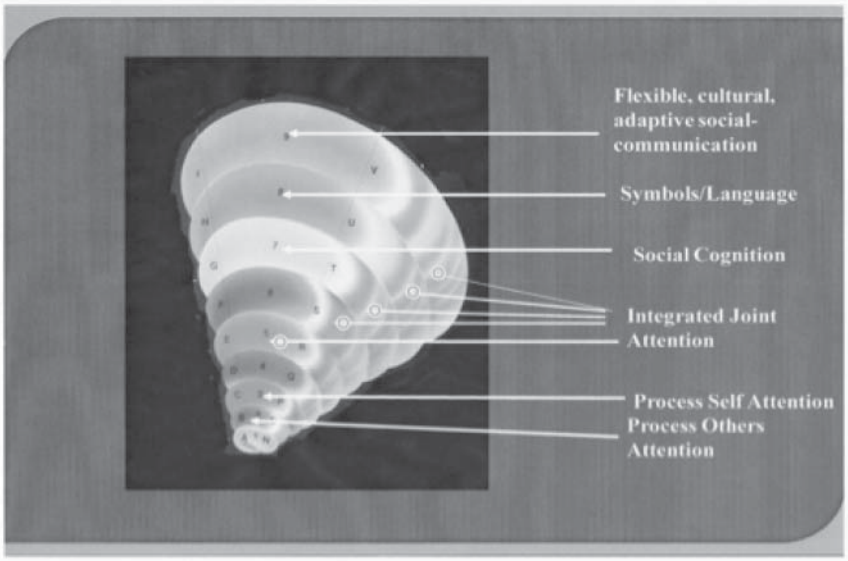

Figure 4.8 An illustration of the continuous information processing model of social attention, joint attention, and social-cognition. Here development is modeled as a spiral, in which the initial acquisition of the capacity for integrated processing of information about self- and other- attention (joint attention) remains an active but deeper layer of cognitive activity throughout life that supports symbolic thought, language, and cultural social exchange.

Inside-Out Processing and the Joint Attention PDPM

In addition to parallel and distributed processing, the PDPM may be distinguished from other models by its constructivist perspective on development. Rather than focusing on the development of knowledge about others, the PDPM gives equal footing to the significance of infants' development of their own intentional visual behavior in joint attention and social cognitive development (Mundy et al., 1993). The assumption here is that neonates and young infants receive greater quantities and fidelity of information about self-intended actions (e.g. active looking) through proprioception than they receive about other's intended actions through exteroceptive information processing. Thus, infants have the opportunity to learn as much or more about intentionality from their own actions as from observing the actions of others. A corollary of this assumption of the PDPM is that joint attention is an embodied form of cognition (Feldman & Narayanan, 2004). Its development is a constructivist process that involves self-perception as a foundation for the attribution of meaning to the perception of others' behaviors. We have referred to this as the inside-out processing assumption of the PDPM (Mundy & Vaughan Van Hecke, 2008).

The general tenor of this constructivist assumption is nothing new. Bates et al. (1979) suggested that a sense of self-agency was basic to joint attention. More generally, Piaget (1952) argued that infants do not learn through the passive perception of objects (or others) in the world. Rather, infants take action on objects and learn from their (causal) actions. They then modify their actions, observe changes in causal relations, and learn new things about the physical world. Thus, Piaget viewed the processing of self-initiated actions on objects as a singularly important fuel for the engines of cognitive development. The constructivist viewpoint is not only central to the PDPM, but it is also a mainstay of contemporary connectionist biological principles of typical and atypical neurocognitive development (e.g., Blakemore & Frith, 2003; Elman, 2005; Mareschal et al., 2007; Meltzoff, 2007; Quartz, 1999).

The vast number of functional neural connections that are made in early postnatal brain development are thought to be too numerous to be specified by genes alone. Instead, genes specify relatively wide channels of potential neurodevelopmental architecture (e.g., Quartz, 1999). Within these prescribed channels, the specifics of important functional connections in the developing nervous systems are sculpted by our experience. Since most of us experience relatively similar environments and experiences in early developmental life, brain organization displays significant similarities across most people (Mareschal et al., 2007). Greenough et al. (1987) referred to this gene–environment interaction in the ontogeny of neural connections as experience–expectant neurodevelopment. They also explicitly noted that infants' generation of actions, and observations of social reactions, likely play a role in experience-expectant processes specific to the neurodevelopmental basis of human social behavior (Cicchetti & Toth, 2009). So, just as Piaget envisioned that infants learn about the physical world from their self-generated actions on objects, it is reasonable to think that a significant portion of what infants learn about the social world comes from their self-generated actions with people. One type of self-generated action that may be developmentally key in this regard is active vision.

Active Vision and the Joint Attention PDPM

One of the first and most vitally informative types of actions infants take involves the self-control of their looking behaviors, or active vision. The science of vision has moved away from the study of seeing or passive visual perception to the study of looking or intentional, active vision and attention deployment (Findlay & Gilchrist, 2003). Active vision in infancy begins to develop at 3–4 months of age (e.g., Canfield & Kirkham, 2001; Johnson, 1990, 1995). It involves the goal-directed selection of information to process and can elicit contingent social behavior responses from other people, such as parental smiles, vocalizations, or gaze shifts. It also is one of the first types of volitional actions that infants use to control stimulation to self-regulate arousal and affect (Posner & Rothbart, 2007).

Vision and looking behavior have unique properties. Vision provides information regarding the relative spatial location of oneself and other people. Moreover, direction of gaze conveys the distal and proximal spatial direction of our attention to others, and vice versa. Comparable information on the spatial direction of attention is not as clearly available from the other senses. This is especially true in the first 9 months of life and for distal information. The importance of spatial visual information for the development of joint attention was emphasized by Butterworth and Jarrett (1991) in their influential article "What Minds Have in Common Is Space."

In some sense, primate eyes are specialized for *social* spatial attention processing (e.g., Tomasello, Hare, Lehman, & Call, 2006). Frontal binocular eye positions allow for

enhanced spatial processing and depth of perception through parallax perception. Intricate musculatures allow for rapid visual focus on objects that are far or near. Equally important, precise information about the spatial direction of attention is available from human eyes because of the highlighted contrast between the dark coloration of the pupil and iris, versus the light to white coloration of the sclera. These observations have led to the suggestion that the ease of processing the direction of attention of other people's eyes contributed to the human phylogenetic and ontogenetic development of social cognition (e.g., Tomasello et al., 2006).

It is also the case, though, that these characteristics of the human eye allow the saccades of infants to be readily observed by other people. Consequently, infant saccades can effectively act as elicitors of contingent social feedback. When infants shift attention to an object, their parents may pick-up and show them the object. When infants shift attention to their parents' eyes, they may also receive a vocal, affective, or physical parental response. Thus, just as the characteristics of eyes make it easier for infants to perceive the attention of others, the signal value of eyes makes the active control of vision a likely nexus of infants' developing sense of agency. A corollary here is that a sense of visual self-agency may play a role in joint attention and social-cognitive development.

The notion that active vision has primacy in social development relates back to the time-honored observation that visual behavior is at least as important to human social development as physical contact (Rheingold, 1966; Robson, 1967). However, the contemporary literature on social-cognitive development emphasizes only the importance of the information infants gather from processing the visual attention of others (e.g., Johnson et al., 2005). It neglects the potential importance of the information infants process about their own active vision, and socially contingent responses.

Alternatively, the active vision assumption of the PDPM offers one plausible explanation for why activation of the frontal eye-fields (a cortical area involved in volitional saccadic control) is a consistent significant correlate of social-cognition in imaging studies (Mundy, 2003). This is because the volitional control of active vision, via the frontal eye fields, may be central to developing an integrated sense of the relations between self-attention and other-attention, which is fundamental to joint attention and subsequent social cognition. This hypothesis leads to the testable prediction that the frontal eye fields should be less active in social-cognitive processing in older congenitally blind individuals than in sighted individuals (Mundy & Newell, 2007). If true, this hypothesis may also help to explain some of the developmental commonalities observed for children with autism and blind infants (Bigelow, 2003; Hobson, Lee, & Brown, 1999).

DYNAMIC SYSTEMS AND THE JOINT ATTENTION PDPM

The PDPM emphasizes inside-out processing, constructivism, and the role of active vision in the development of joint attention. However, it does not maintain that the inside-out processing of self-attention is more important for social-cognitive development than outside-in processing of others' attention. This is because the PDPM holds that social meaning, and even conscious self-awareness, cannot be derived from processing either self-attention or others' attention in isolation (cf. Decety & Sommerville, 2003; Keysers & Perret, 2004; Vygotsky, 1962). Ontogeny may be best viewed as a dynamic system that, through interactions of multiple factors over time and experience, coalesce into higher order integrations, structures, and skills (e.g., Smith & Thelen, 2003). The development of joint attention, or the joint processing of the attention of self and other, is such a dynamic system. Indeed, the pertinence of joint attention for human development derives in no small part from the unique synthesis that arises from the rapid, parallel processing of self-attention and other-attention across distributed neural networks. Consequently, it is not possible to account for the role of joint attention in typical or atypical development with research or theory that focuses on only one of its elements in isolation.

The dynamic system of joint attention begins to synergize as frontal executive functions increasingly enable attending to multiple sources of information during infancy. According to one definition, executive functions involve the transmission of bias signals throughout neural networks to selectively inhibit comparatively automatic behavioral responses, in favor of more volitional, planned, and goal-directed ideation and action, in problem-solving contexts (Miller & Cohen, 2001). These bias signals act as regulators for the brain, affecting visual processes and attention, as well as other sensory modalities and systems responsible for task-relevant response execution, memory retrieval, emotional evaluation, and so forth. The aggregate effect of these bias signals is to guide the flow of neural activity along pathways that establish the proper mappings between inputs, internal

states, and outputs needed to perform a given task more efficiently (Miller & Cohen, 2001). According to this definition, joint attention development may be thought of as reflecting the emergence of frontal bias signals that establish the proper mappings across (1) outside-in posterior cortical (temporal-precuneus) processing of inputs about the attention behaviors of other people; and (2) rostral-medial-frontal (BA 8–9, anterior cingulate) inside-out processing of internal states and outputs related to active vision. This mapping results in the integrated development of a distributed anterior and posterior cortical joint attention system.

It is conceivable that the early establishment of this mapping of the joint processing of attention is formative with respect to the shared neural network of representations of self and other, which Decety and Grezes (2006) suggested is essential to social cognition. It also may play a role in what Keysers and Perrett (2004) described as a Hebbian learning model of social cognition. Neural networks that are repeatedly active at the same time become associated, such that activity (e.g., representations) in one network triggers activity in the other (Hebb, 1949). Keysers and Perrett suggested that *common* activation of neural networks for processing self-generated information and information about conspecifics is fundamental to understanding the actions of others. This Hebbian learning process is fundamental to the hypothesized functions of simulation (Gordon, 1986) and mirror neurons (Decety & Sommerville, 2003; Williams, 2008) that are commonly invoked in current models of social-cognitive development.

The PDPM is consistent with these interrelated ideas and suggests that Hebbian mapping in social cognition begins with integrated rostral medial frontal processing of information about self-produced visual attention and posterior processing of the attention of others. Moreover, the PDPM specifically operationalizes the study of development of this dynamic mapping system, in terms of psychometrically sound measures of early joint attention development (Mundy et al., 2007). Indeed, IJA assessments may be relatively powerful in research on social cognitive development and developmental disorders because they measure variance in the whole dynamic system, rather than any one of its parts alone.

Once well practiced, the joint processing of attention information requires less mental effort. As the basic joint attention process is mastered and its effort to engage goes down, it can become integrated as an executive function that contributes to the initial development and increasing efficiency of social-cognitive problem solving. Thus, joint attention development may be envisioned as shifting from learning to do joint attention in the 6 to 9 months to learning from joint attention in the second year of life (Mundy & Vaughan Van Hecke, 2008; Figure 4.9). In the learning from phase, the capacity to attend to multiple sources of information in triadic attention deployment becomes more common (Scaife & Bruner, 1975). Triadic attention contexts provide infants with rich opportunities to compare information gleaned through processing internal states associated with volitional visual attention deployment and the processing of the visual attention of others in reference to a common third object or event. Through simulation (Gordon, 1986) infants may begin to impute that others have intentional control over their looking behavior that is similar to their own.

The role of simulation in the *learning-from phase* of joint attention development is well illustrated by a recent sequence of elegant experimental studies (Brooks & Meltzoff, 2002). Often, 12-month-olds follow the gaze direction of testers even if their eyes are closed. After 12 months, though, infants discriminate and follow the gaze of testers whose eyes are open but not closed. This suggests that infants' understanding of the meaning of the eye gaze of others may improve in this period, leading older infants to inhibit looking in the eyes-closed condition.

To examine this interpretation, Meltzoff and Brooks (2008) conducted an experimental intervention. They provided 12-month-olds with the experience of blindfolds that occluded their own looking behavior. After gaining that experience, 12-month-olds did not follow the head turn of blindfolded testers, but did follow the head turn and gaze of nonblindfolded testers. Meltzoff and Brooks also provided 18-month-olds with experience with blindfolds that looked opaque but were transparent when worn. After this condition, the 18-month-olds reverted to following the gaze of blindfolded social partners. These data strongly suggest that the infants demonstrated inside-out learning and constructed social-cognitive awareness about others' gaze based on the experience of effects of blindfolds on their own active vision.

In sum, infant translational research proposed that a foundational system of integrated attention to self and other, supported by a dynamic, distributed neural network, provides for enhancements in social communication, social learning, and social cognition in typical development. The ability to utilize this integrated, or joint, attention to share experiences with others develops in early infancy, and transitions from a phase of learning-to utilize joint attention to learning-from joint attention in toddlerhood, childhood, and even beyond. Individual differences in the capacity to utilize joint attention likely play a role in the range of

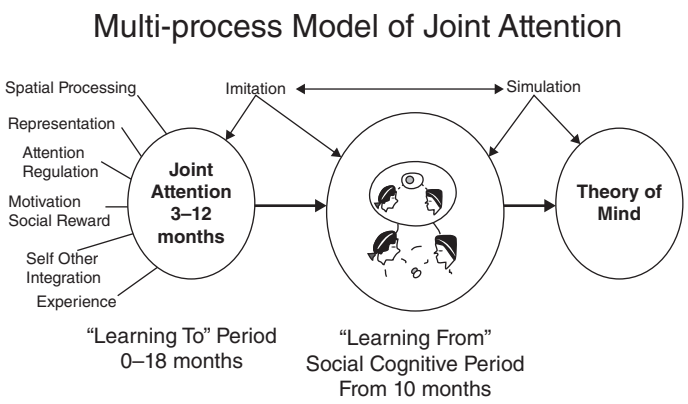

Figure 4.9 In the first year, the development of joint attention involves the "learning-to" phase. This period comprises the integration of executive, motivational, and imitative processes to support the routine, rapid, and efficient (error-free) execution of behavioral patterns, which enable infants' coordination of overt processing of aspects of visual self-attention, with processing of the social attention of other people. In the latter part of the first year and the second year, infants can better monitor their own experiences and integrate them with information about social partners during joint attention events. This provides a critical multimodal source of information to the infants about the convergence and divergence of self- and other-experience and behavior during sharing information in social interactions. Theoretically, this provides the stage for the "learning-from" phase of joint attention development. In this stage, infants can control their attention to self-organize and optimize information processing in social learning opportunities. The integration of anterior and posterior self–other attention processing (Figure 4.5) provides a neural network that enriches encoding in social learning. The internalization of the overt joint processing of attention to the covert joint processing of attention to representations is part of an executive system that facilitates symbolic development and the social cognition. Both symbolic thought and social cognition may be characterized by a transition from learning to socially coordinate overt attention to the capacity to socially coordinate covert mental representations of the attention of self and others.

social-emotional and social-cognitive skill present in the population. The next natural area of inquiry, then, involves how difficulties with joint attention play a cardinal role in a population in the extreme range of deficits in social abilities: individuals with ASD.

JOINT ATTENTION AND DEFINING THE SOCIAL DEFICITS OF ASD

The recognition of the centrality of joint attention impairment in the development of ASD followed from the growing understanding of how and when typical infants develop the ability to share experiences with other people (Bates et al., 1979; Bruner, 1975; Rheingold et al., 1976; Trevarthen, 1979; Werner & Kaplan, 1963). While other domains of social behavior, such as imitation, face processing, empathy, theory of mind, and pragmatic communication skills, are prominent in the literature (Travis & Sigman, 1998), none have had the impact on understanding the nature of ASD, its diagnosis, or its treatment that can be claimed for the study of joint attention (e.g., Bruinsma et al., 2004; Charman, 1997; Dawson et al., 2004; Kasari et al., 2006, 2008; Mundy & Crowson, 1997; Mundy et al., 2009; Sigman & Ruskin, 1999).

It was Frank Curcio (1978) who first documented joint attention disturbance in individuals with ASD. He noted that 50% of a sample of elementary school-age children with ASD observed in classrooms systematically used eye contact and conventional gestures to express their requests. However, few, if any, children with ASD displayed evidence of the use of eye contact or gestures to initiate joint attention bids or nonverbal declaratives. Curcio concluded that impairments in the capacity to initiate joint attention and declarative communicative functions could be central to the nature of the social impairments of ASD. Subsequent studies indicated that Curcio was correct (e.g., Charman, 2004; Dawson et al., 2004; Loveland & Landry, 1986; Mundy et al., 1986; Sigman & Ruskin, 1999; Wetherby & Prutting, 1984).

In work in the laboratory of Marian Sigman at UCLA, samples of children with ASD were compared with mental age, chronological age, and IQ-matched samples of 4- to 7-year-old children with intellectual disabilities and samples of mental age-matched children with typical development. These studies indicated that children with ASD displayed deficits in joint attention in interactions with unfamiliar testers (Mundy et al., 1986), as well as parents, compared with both control groups (Sigman et al., 1986). Moreover, just as Curcio observed, children with

ASD displayed quantities and qualities of communication bids to request objects and turn-taking opportunities with social partners that were comparable to those observed in the control sample with intellectual disabilities (ID). These case-controlled studies indicated that children with ASD did not display pervasive differences in eye contact or social-communication behaviors relative to children with ID, but rather a more nuanced pattern of syndrome-specific strengths and weaknesses in their social behaviors. They displayed comparable levels of eye contact in requesting and turn-taking social interactions. However, an eye contact disturbance specific to ASD was clearly manifested in their diminished use of alternating gaze to spontaneously initiate sharing of experience of a mechanical toy with the tester. This type of alternating gaze behavior is illustrated in Figure 4.1.

We cannot yet definitively describe why a child does or does not engage in IJA during a social interaction. Nevertheless, ESCS testers often arrived at the impression that IJA behaviors signal a child's desire (motivation) or goal (intent) to share the experience of an object or event, or spontaneously elicit attention to the child's own experience of an object or event (Figure 4.1). Hence, it was not too surprising to find that higher or lower frequencies of alternating eye contact in young children, with or without ASD, were significantly related to parents' independently assessed perceptions of their child's social relatedness (Mundy et al., 1994). These observations raised the possibility that diminished IJA was central to what Kanner perceived as the cardinal impairment in relatedness and positive affective contact with others in ASD (e.g., Mundy & Sigman, 1989).

The Social-Motivation Model and Joint Attention in ASD

The idea that IJA was related to a disturbance in positive social-affective contact in autism was more directly supported by research in the early 1990s that showed that about 60% of the IJA bids displayed by typical infants and children with intellectual disabilities involved the conveyance of positive affect (Kasari, Sigman, Mundy, & Yirmiya, 1990; Mundy, Kasari, & Sigman, 1992). However, positive affect was much less frequently part of the IJA behaviors of children with autism (Kasari et al., 1990). It was not the case, though, that children with ASD displayed significantly lower positive affect in requesting or turn–taking interactions. Hence, it was unlikely that the diminished positive affect in joint attention reflected a general aversion to social interactions. More recently, it has come to light that the onset of the systematic conveyance of positive affect as part of IJA bids begins to develop early in life, at about 8 to 10 months of age (Venezia, Messinger, Thorp, & Mundy, 2004) and that this type of anticipatory smiling in joint attention is associated with social outcomes in typical development (Parlade, Messinger, Delgado, Kaiser, Van Hecke, & Mundy, 2009). Thus, joint attention impairments reflect what are likely to be early arising deficits in the tendency of children with ASD to socially share positive affect. This in turn may involve a disturbance in their early appreciation of the positive social *value* of shared attention. That is to say, motivation factors or sensitivity to reward value of social gaze may play a role in joint attention disturbance in ASD (Dawson, Bernier, & Ring, 2012; Mundy, 1995).

Joint Attention and the Social-Cognitive Model of ASD

In a similar timeframe, other translational infant research groups in London began to translate Wimmer & Perner's basic false belief developmental paradigms to the study of ASD. This led to another sequence of seminal observations regarding the defining features of social impairments in ASD. Children with ASD appeared to have more difficulty with the development of social cognition than other aspects of cognitive development (e.g., Baron-Cohen, Leslie, & Frith, 1985; Frith, 1989; Leslie & Happé, 1989).

Thus, the parallel observations of deficits in joint attention development and theory of mind development in ASD during the mid-1980s provided the first empirical, albeit indirect, link between these two domains of development. Subsequently, the social cognitive view of ASD and typical social development became so compelling in the literature that joint attention disturbance began to be interpreted as a manifestation of social cognitive impairment in ASD (Baron-Cohen, 1989; Leslie & Happé, 1989). In developmental psychopathology, these ideas converged to form the social cognitive model of joint attention disturbance in ASD, which held that the social cognitive understanding that people intentionally share information, was a necessary precursor of joint attention (Tomasello, Carpenter, Call, Behne, & Moll, 2005), and that impairments in a social cognitive module explained the cause of joint attention impairment in ASD (Baron-Cohen, 1989).

The Disassociation of IJA and RJA in ASD

However, a potential problem for the social cognitive model is that both RJA and IJA development were assumed to

be equally dependent on social cognition. But IJA and RJA appeared to be dissociated in development. Thus one factor, such as social cognition, might not be adequate to explain all facets of joint attention development or its impairment in ASD. Both RJA and IJA are useful in the early identification and diagnosis of ASD (e.g., Lord et al., 2000; Stone, Coonrod, & Ousley, 1997). However, RJA impairments are less evident for children with more advanced levels of cognitive development (Mundy et al., 1994; Figure 4.10). Indeed, across studies of different age groups of children, there is at best inconsistent evidence of a robust syndrome specific impairment in the ability to process the direction of gaze or respond to joint attention in people with ASD (Nation & Penny, 2008). On the other hand, IJA deficits are observed in children with ASD from preschool through adolescence, *and* IJA is a better discriminator of children with ASD relative to children with other developmental disorders (e.g., Charman, 2004; Dawson et al., 2004; Hobson & Hobson, 2007; Mundy et al., 1986; Sigman & Ruskin, 1999). The correlates of IJA and RJA also diverge as much as they converge in studies of ASD. Both IJA and RJA are related to executive inhibition and language development in ASD (Bono, Daley, & Sigman, 2004; Dawson et al., 2002, 2004; Griffith et al., 1999; Sigman & McGovern, 2005). However, to our knowledge, only IJA is significantly associated with individual differences in social and affective symptom presentation (Charman, 2004; Kasari et al., 1990; Kasari et al., 2007; Lord et al., 2003; Mundy et al., 1994; Naber et al., 2008; Sigman & Ruskin, 1999).

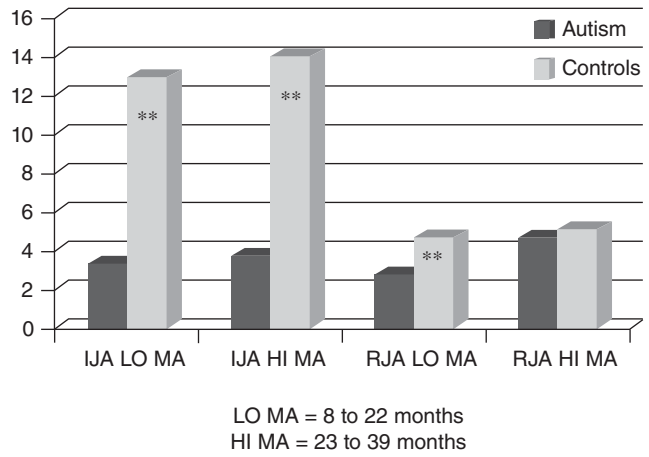

Figure 4.10 Illustration of the moderating effect of mental age on diagnostic group differences on RJA versus IJA. *Source:* Reported in P. Mundy, M. Sigman, & C. Kasari, Joint attention, developmental level, and symptom presentation in children with autism, *Development and Psychopathology, 6,* 389–401, 1994.

This literature emphasizes that joint attention deficits are neither absolute nor uniform in ASD, and the impairments of IJA and RJA likely constitute different developmental processes that are vital to symptom presentation in the syndrome. Moreover, of the two, deficits in initiating joint attention behavior appears be the more pathognomonic feature of ASD (Mundy, 1995). Observations from intervention research also emphasize that ASD is a disturbance of the spontaneous generation of social behaviors, as much as or more than a disturbance of perception and response to the social behaviors of others (Koegel et al., 2003). A similar interpretation is suggested by recent research with infant siblings of children with ASD (Zwaigenbaum et al., 2005). Indeed, the centrality of initiating deficits, especially IJA, was highlighted in the *DSM-IV*, where "a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people, (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people)" was described as one of the primary social symptoms of ASD (APA, 1994, p. 75). Unfortunately, the significance of the impairment of the spontaneous generation of behavior, and specifically initiating joint attention, is still not fully appreciated in the field. Consequently, the latter is not as clearly emphasized in *DSM-5* (APA, 2013) as it was in *DSM-IV* (APA, 1994). Nevertheless, the gold standard research-based diagnostic observation instrument, the Autism Diagnostic Observation Schedule-2nd Edition (ADOS-2: Lord et al., 2012), continues to recognize the primacy of IJA symptoms. Measures of both IJA and RJA are used in Module 1 diagnostic algorithms for the youngest children. However, Module 2, for older or more linguistically advanced children, only includes IJA measures in its diagnostic criteria (Lord et al., 2012).

Evidence of a developmental dissociation between IJA and RJA is also apparent in studies of typical infant development. Frequency measures of IJA and RJA are characterized by different growth patterns, and these domains display weak to non-significant correlations in infant development (e.g., Meltzoff & Brooks, 2008; Mundy et al., 2007; Sheinkopf et al., 2004; Slaughter & McDonald, 2003). They also have different patterns of correlations with childhood IQ (Ulvund & Smith, 1996), frontal brain activity (Caplan et al., 1993; Mundy et al., 2000), reward-based behavioral goal-inhibition and self-monitoring behaviors (Nichols et al., 2005), attention related self-regulation (Morales et al., 2005), and attachment (Claussen, Mundy, Malik, & Willoughby, 2002). These observations imply that the nature of the differences, as well as commonalities,

between IJA and RJA may be a key to conceptualizations of the joint attention impairments of ASD.

Specific Effects on Initiating Joint Attention in ASD

It is essential to be precise about the nature of the behavioral expression of IJA impairments in ASD, which are often equated with problems with pointing and showing gestures. However, diminished alternating gaze behavior (Figure 4.1) is a more powerful measure of IJA impairment in ASD. This type of measure was superior to pointing and showing, and correctly identified 94% of 54 preschool children with ASD, mental retardation, and typical development (Mundy et al., 1986). Others have observed that IJA measured with the Early Social-Communication Scales (ESCS; Seibert, Hogan, & Mundy, 1982) had a sensitivity of 83–97% and a specificity of 63–67% in discriminating 3- to 4-year-olds with ASD from controls (Dawson et al., 2004). Recent research indicates that most of the variance in ESCS-IJA scores is carried by alternating gaze behavior (Mundy et al., 2007). The IJA alternating gaze of 2-year-olds also predicts 4-year-old symptom outcomes in children with ASD (Charman, 2004) as well as social cognition in typically developing 4-year-old children (Charman et al., 2000).

These developmental and measurement details are important for models of joint attention disturbance in ASD. Often joint attention problems are viewed as growing out of developmental antecedent or successor processes that are considered to be more fundamental. A nonexhaustive list here includes affective processes, reward-sensitivity, executive attention control, social orienting, identification, imitation and mirror neurons, intersubjectivity, and most prominently social cognition (e.g., Baron-Cohen, 1989; Charman, 2004; Dawson et al., 2004; Mundy et al., 1986; Williams, 2008). This reductionism has lead to a paradox where joint attention deficits are viewed as pivotal to ASD but also as an outgrowth of more basic processes. Charman (2004) recognized this paradox in noting that we often think of joint attention not as "a starting point [for ASD], but merely a staging post in early social communicative development, and hence a 'postcursor' of earlier psychological and developmental processes . . . [which may] underlie the impaired development of joint attention skills in autism" (p. 321).

There are at least three problems with this perspective. First, as previously noted, stable individual differences in IJA alternating gaze are well established by 8 to 9 months in typical development (Mundy et al., 2007; Venezia et al., 2004), and the onset of cortical control of alternating gaze likely begins between 4 to 6 months of age (Mundy, 2003; Striano & Reid, 2006). Joint attention precursors would need to be present prior to this time. Second, there is little evidence that the association of joint attention with the etiology or outcomes of ASD is mediated by more basic antecedent or successor processes. Dawson et al. (2004) observed that neither social-orienting measures nor empathy measures could account for relations between IJA and language development in a large sample of children with ASD. Joint attention disturbance in ASD also cannot be explained in terms of affect regulation or social relatedness measured with attachment measures (Capps, Sigman, & Mundy, 1994; Naber et al., 2008). Moreover, joint attention accounts for significant portions of variance in the language, symbolic play, and symptom development of children with ASD above and beyond variance associated with executive functions, imitation, knowledge about others' intentions, or global measures of mental development (e.g., Charman, 2004; Kasari et al., 2007; Naber et al., 2008; Roeyers, Van Oost, & Bothutne, 1998; Rutherford, Young, Hepburn, & Rogers, 2007; Sigman & Ruskin, 1999; Smith, Mirenda, & Zaidman-Zait, 2007; Thurm, Lord, Lee, & Newschaffer, 2007; Toth, Munson, Meltzoff, & Dawson, 2006).

A third issue is that precursor and successor process hypotheses rarely account for the dissociation of IJA and RJA (Mundy et al., 2007). Social-cognitive hypotheses suggest that RJA and IJA should be highly related because they are precursors of a common mentalizing ability involved in perceiving the intentions of others (e.g., Baron-Cohen, 1995; Tomasello, 1995). Executive attention or social-orienting hypotheses don't explicitly account for why IJA deficits are more pervasive than RJA deficits even though both ostensibly involve comparable attention inhibition and attention reorienting processes (e.g., Dawson et al., 1998; Mundy & Burnette, 2005). Imitation and mirror neuron theory emphasizes the role of deficits in processing and responding to the behavior of other people in the development of ASD (e.g., Williams, 2008). Hypothetically, though, this should be more related to responsive joint attention than the spontaneous initiation of joint attention bids. Why, then, do IJA deficits appear to be the more robust form of joint attention disturbance in ASD than RJA deficits? An answer may be perceived from a constructivist vantage point on joint attention and human social learning (e.g., Bruner, 1975, 1995).

In light of the assumption that joint attention is basic to early learning, reconsider the observation that IJA and RJA dissociate in development. Theory and research suggest that this occurs because these forms of joint

attention involve functions of two distinct neural networks that support attention development (Mundy & Newell, 2007). In conjunction with this idea, note that parallel and distributed cognitive theory suggests that learning occurs best in the context of the simultaneous activation of multiple neural networks during encoding (e.g., Munakata & McClelland, 2003; Otten, Henson, & Rugg, 2001). Taken together, these ideas raise two hypotheses. First, joint attention may involve the early development of a form of social information processing across multiple distributed neural networks. Second, ASD may be characterized by a developmental impairment of distributed neural connectivity, and an early disturbance of the cortically distributed joint attention network is a characteristic of the developmental etiology of many, if not all, children with ASD. The next, and final, section of this chapter will explore this second hypothesis, and its implications, in more detail.

APPLYING THE JOINT ATTENTION PDPM TO ASD

Neural Connectivity and Activity-Dependent Genes in ASD

Assumptions of the PDPM bridge theory on the development of joint attention with phenomena are observed in other disciplines of research with ASD. Several of these will be briefly considered in this final section of the chapter. The first of these involves links with theory and research on neural connectivity impairments in ASD.

Over the last 10 years, several research groups have suggested that problems in functional connectivity between brain regions contribute to ASD (e.g., Courchesne & Pierce 2005; Geschwind & Levitt, 2007; Horwitz, Rumsey, Grady, & Rapoport, 1988; Just, Cherkassky, Keller, & Minshew, 2004; Lewis & Elman, 2008; Wickelgren, 2005). However, rather than specific to ASD, impaired connectivity may be central to many forms of intellectual disability and developmental disorders (Dierssen & Ramakers, 2006). So how do neurodevelopmental connectivity impairments lead to the specific social symptom impairments of ASD, and how are these different from the connectivity impairments that characterize other developmental disorders?

One possibility is that intellectual disability may be associated with connectivity impairments within proximal brain networks, but that ASD may be characterized by more distal connectivity problems (Courchesne & Pierce, 2005; Lewis & Elman, 2008). Indeed, several studies suggest that distal connectivity problems between frontal and temporal-parietal networks may be especially prominent in ASD (Cherkassky, Kana, Keller, & Just, 2006; Courchesne & Pierce, 2005; Murias,Webb, Greenson, & Dawson, 2007; Wicker et al., 2008). The PDPM offers a moderately explicit developmental account of how the impairment of distal frontal-parietal pathways may have an early and robust effect specific to a disturbance of joint attention and related social symptoms of ASD, such as a lack of spontaneously sharing experiences with other people. The PDPM's focus on the fundamental relations between the joint processing of attention information, learning, and symbolic development also provide a means for understanding why variations in the strength of the disturbance of anterior-posterior connectivity could contribute to phenotypic variability in ASD, such as the co-occurrence of intellectual disability or specific language impairments.

The connectivity assumptions of the PDPM also lead to the prediction that differences in the development of joint attention in typical and atypical children should be associated with measures of synchrony or coherence in cortical activity. There is some support for this, but currently available data are no more than suggestive in this regard (Mundy et al., 2000, 2003). Nevertheless, the PDPM offers a conceptual framework that emphasizes the benefits of a multidisciplinary approach to neurodevelopment, attention, and connectionist network models of development and ASD. This emphasis is in line with the recent call for the multidisciplinary examination of EEG or imaging connectivity/coherence in developmental and intervention studies of ASD (Cicchetti & Toth, 2009; Dawson, 2008).

It also may be that intellectual disability is associated with impairments of prenatal neural connectivity that are less activity dependent, but that ASD involves a greater degree of postnatal connectivity impairments that are more activity dependent (Morrow, Yoo, Flavell, Kim, & Lin, 2008). Morrow et al. recently observed several genome deletions in families of children with ASD. The expression of three genes associated with the two largest deletions (c3orf58, NHE9, and PCDH10) is regulated by neuronal activity. From this observation, Morrow et al. (2008) reasoned that defects in activity-dependent gene expression may be a cause of cognitive deficits in ASD. They noted that these genes likely have a defined temporal course of greater or lesser vulnerability to atypical expression, depending on the timing and quality of the young child's postnatal activity and experience dependent processes.

The PDPM proposes that problems with initiating joint attention activity may be especially key to understanding activity dependent alterations of gene expression associated with ASD. Some evidence consistent with this proposition stems from the observation that the behavior of children with ASD may affect and modify the attempts

of caregivers to scaffold the development of joint attention in their children (Adamson, McArthur, Markov, Dunbar, & Bakeman, 2001). If the PDPM is correct in this regard, it will be important to build a better understanding of genetic influences on the typical range of expression of individual differences in IJA in infant development. Little if any information currently exists on this topic. Fortunately, the recent observation of a surprising degree of longitudinal stability of individual differences, in a sample of 100 typical infants (Mundy et al., 2007), suggests that behavioral or metabolic genetic methods may be brought to bear in large-scale studies of the typical development of infant joint attention.

Visual Attention Control and Joint Attention in ASD

Complementary to genetic factors, the work of several research groups indicates that the basic mechanism of visual control may play a role in ASD (Brenner, Turner, & Muller, 2007; Johnson et al., 2005; Landry & Bryson, 2004). Brenner et al. (2007) noted that one of the essential issues for this line of research is to understand precisely, "how an ocular-motor system that is over-specialized for certain tasks and under-specialized for others early in life might affect later development in [social] domains such as joint attention" (p. 1302). The PDPM offers a guide in this regard. First, it encourages the research community to recognize the possibility that joint attention may not be a later development but one that begins as part of the development of volitional visual attention control by the fourth month of life. In addition, the PDPM provides a means for understanding how significantly altered early visual preferences could have a cascading effect on the development of intentional joint attention and ASD (Mundy, 1995). In this regard, consider two recent studies.

McCleery et al. (2007) observed that magnocellular visual processing may be atypically enhanced in a sample of 6-month-old infant siblings of children with autism. Similarly, Karmel et al. (2008) observed visual attention patterns that are consistent with a magnocellular bias in 6-month-olds in neonatal intensive care who later received the diagnosis of autism at 3 years of age. The magnocellular visual system contributes to orienting based on movement and contrast-sensitivity related to small achromatic differences in brightness. This system dominates early visual orienting. However, by 2 to 4 months of age, visual orienting is increasingly influenced by the parvocellular system, which contributes to orienting based on high-resolution information about shape or low-resolution information about color and shades of gray. Karmel et al. (2008) and McCleary et al. (2007) raised the possibility that a delay in the developmental shift from the magnocellular to parvocellular visual systems could alter what children with ASD choose to attend to early in life.

Hypothetically, the maintenance of a magnocellular bias may lead to a relatively long standing visual preference for stimuli or objects characterized by movement or achromatic contrasts, such as surface edges, power lines, spinning objects, the outlines of faces, or mouth movement. Reciprocally, the decreased influence of the parvocellular system could lead to developmental delays in the emergence of a visual attention bias to targets that are socially informative but involve differentiation based on high resolution of shape and color information, such as distal processing of eyes and facial expressions. Thus, the alteration of visual preferences during early critical periods of development could degrade the establishment of the dynamic system of internal information processing about active looking, relative to contingent social feedback, and information about the attention of other people (Mundy, 1995; Mundy & Burnette, 2005). Moreover, if magnocellular guidance bias and connectivity impairments are orthogonal processes, combinations of varying levels of their effects could present as phenotypic differences in joint attention processing and social symptom expression in ASD.

Joint Attention, Learning, and Interventions for ASD

The assumptions of the PDPM may also shed light on how joint attention serves as a pivotal skill in intervention, and as a foundation for the development of social cognition, symbolic thought, knowledge of intentionality, and social learning. First, the PDPM may help to explain why joint attention is a pivotal skill in early intervention for children with autism (Bruinsma, Koegel, & Koegel, 2004; Charman, 2004; Mundy & Crowson, 1997). Improvements in pivotal skills, by definition, lead to positive changes in a broad array of other problematic behaviors. According to the PDPM, joint attention is a pivotal skill in autism because its improvement has multiple effects on social learning. Recall that joint attention facilitates the self-organization of information processing to optimize incidental, as well as structured, social learning opportunities (Baldwin, 1995). Hence, impairment in joint attention may be viewed as part of a broader social-constructivist learning disturbance in autism. By the same token, effective intervention likely improves social constructivist learning in autism.

Small and large-scale trials have shown that joint attention can be improved with intervention for ASD (Table 4.1), and joint attention improvement has collateral

TABLE 4.1 Behavioral Intervention Studies With Effects on Joint Attention in Children With ASD[1]

Study	Intervention	Design	Participants in experimental treatment group (number/age)	JA outcomes
Small studies (fewer than 15 participants in experimental treatment group)				
Aldred, Green, and Adams (2004)	Developmental communication intervention (Aldred, Phillips, Pollard, & Adams, 2001)	RCT (vs. routine community care control)	14/2–5 yrs.	No change in CJA
Baker (2000)	Thematic ritualistic play intervention	MBL by participants	3/5–6 yrs.	Increase in CJA
Cheng and Huang (2012)	Joint Attention Skills Learning (JASL) virtual reality system/tool	MBL by participants	3/9–12 yrs.	Increase in IJA
Ezell et al. (2012)	Imitation	RCT (vs. Contingently Responsive Play control)	10/4–6 yrs.	Increase in IJA and RJA
Field et al. (1997)	Touch therapy	RCT (vs. non-therapeutic touch control)	11/mean 4 yrs., 6 mo.	Increase in RJA and IJA
Hwang and Hughes (2000)	Social interactive training: following child, imitation, natural reinforcement	MBL by participants	3/2–3 yrs.	Increase in IJA
Ingersoll and Schreibman (2006)	Reciprocal imitation training	MBL by participants	5/2–3 yrs.	Increase in RJA; Mixed results for IJA
Ingersoll (2012)	Reciprocal imitation training	RCT (vs. community treatment control)	14/2–4 yrs.	Increase in IJA
Isaksen and Holth (2009)	Reinforcement, prompting, modeling	MBL by participants	4/3–5 yrs.	Increase in IJA and RJA
Jones, Carr, and Feeley (2006)	Pivotal response training; discrete trial	MBL by behaviors and participants	5/2–3 yrs.	Increase in IJA and RJA
Jones and Feeley (2007)	Pivotal response training; discrete trial; parent training	MBL by behaviors and participants	3/3–4 yrs.	Increase in IJA and RJA
Jones (2009)	Pivotal response training: modeling, prompting	MBL by behavior	2/3–5 yrs.	Increase in IJA
Klein, MacDonald, Vaillancourt, Ahearn, and Dube (2009)	Reinforcement	MBL by participants	3/4–6 yrs.	Increase in RJA
Krstovska-Guerrero and Jones (2013)	Direct instruction of smiling and eye contact, prompting, reinforcement	MBL by participants and behaviors	3/2–4 yrs.	Increase in IJA and RJA
Lawton and Kasari (2012)	JASP/ER: Joint Attention symbolic play engagement and regulation intervention; teacher implemented	RCT (waitlist control)	9/3–5 yrs.	Increase in IJA
MacDuff et al. (2007)	Auditory scripts, reinforcement	MBL by participants	3/3–5 yrs.	Increase in IJA
Martins and Harris (2006)	Reinforcement	MBL by participants	3/3–4 yrs.	Increase in RJA; No change in IJA
Naoi et al. (2008)	JA reinforcement, modeling, preferred objects	MBL by participants	3/5–8 yrs.	Increase in IJA
Pierce and Schreibman (1995)	Pivotal response training; peer implemented	MBL by participants	2/10 yrs.	Increase in CJA
Rocha, Schreibman, and Stahmer (2007)	Parent training: discrete trial, pivotal response training	MBL by participants	3/2–4 yrs.	Mixed results for IJA and RJA
Rogers et al. (2006)	Early Start Denver Model (ESDM)	RCT (vs. prompts for restructuring oral muscular phonetic targets (PROMPT) control); MBL for participants and behaviors	5/2–5 yrs.	Mixed results for IJA and RJA for both interventions
Salt et al. (2002)	Scottish Center for Autism treatment program: Social developmental naturalistic intervention	Treatment (vs. waitlist control, not randomized)	14/3–4 yrs.	Increase in IJA and RJA (collapsed)
Schertz and Odom (2007)	Joint attention mediated learning (JAML) intervention (Schertz, 2005)	MBL by behaviors	3/1–2 yrs.	Mixed results for IJA and RJA
Schertz, Odom, Baggett, and Sideris (2013)	Joint attention mediated learning (JAML) intervention	RCT (vs. community treatment control group)	11/1–2 yrs.	Increase in RJA; No change in IJA

(*continued*)

TABLE 4.1 (*Continued*)

Study	Intervention	Design	Participants in experimental treatment group (number/age)	JA outcomes
Stickles Goods, Ishijima, Chang, and Kasari (2013)	JASP/ER: joint attention symbolic play engagement and regulation intervention	RCT (vs. community intensive Applied Behavior Analysis treatment control)	7/3–5 yrs.	No change in IJA
Taylor and Hoch (2008)	Behavioral: prompting, reinforcement	MBL by participants	3/3–8 yrs.	Increase in IJA and RJA
Tsao and Odom (2006)	Sibling mediated: stay, play, talk	MBL by participants	4/3–6 yrs.	Increase in CJA
Vismara and Lyons (2007)	Parent training, Pivotal response training; follow child's lead	Reversal; MBL by participants and behaviors	3/2–3 yrs.	Increase in IJA
Vismara and Rogers (2008)	Early Start Denver Model (ESDM: Rogers & Dawson, 2007)	Case study	1/1 yr.	Increase in IJA
Whalen and Schreibman (2003)	Pivotal response training; discrete trial	MBL by participants	5/4 yrs.	Increase in RJA; Mixed results for IJA
Zercher et al. (2001)	Peer-supported play, modeling	MBL by participants	2/6 yrs.	Increase in RJA; Mixed results for IJA
Large studies (15 or more participants in experimental treatment group)				
Green et al. (2010)	Preschool Autism Communication Trial (PACT)	RCT (vs. community treatment as usual)	77/2–4 yrs.	Increase in CJA
Gulsrud, Kasari, Freeman, and Paparella (2007)	Targeted joint attention intervention (based on Kasari et al., 2006)	RCT (vs. Symbolic Play Intervention control)	17/2–4 yrs.	Increase in CJA
Kaale, Smith, and Sponheim (2012)	Targeted joint attention intervention, based on Kasari et al. (2006)	RCT (vs. community preschool program control)	34/2–5 yrs.	Increase in IJA
Kasari, Freeman, and Paparella (2006)	Targeted joint attention intervention	RCT (vs. symbolic play intervention vs. control in existing early intervention program)	20/3–4 yrs.	Increase in IJA, CJA, and RJA
Kasari, Paparella, Freeman, and Jahromi (2008)	JASP/ER: joint attention symbolic play engagement and regulation intervention (6- and 12-month follow-up to sample in Kasari et al., 2006)	RCT (vs. symbolic play intervention vs. control in existing early intervention program)	20/3–4 yrs.	Increase in IJA and CJA
Kasari, Gulsrud, Wong, Kwon, and Locke (2010)	Focused joint attention intervention; parent training (based on Kasari et al., 2006)	RCT (vs. waitlist control)	19/2–3 yrs.	Increase in RJA; No change in IJA
Landa, Holman, O'Neill, and Stuart (2011)	Interpersonal synchrony intervention	RCT (vs. noninterpersonal synchrony intervention)	24/1–2 yrs.	No change in IJA in either intervention
Wong, Kasari, Freeman, and Paparella (2007)	Behavioral (prompting, social/natural reinforcement, imitation) joint attention intervention	RCT (vs. symbolic play intervention in existing early intervention program)	20/3–4 yrs.	Increase in IJA
Yoder and Stone (2006)	Responsive education and prelinguistic milieu teaching (RPMT)	RCT (vs. PECS: picture exchange communication system, Bondy & Frost, 1994, control)	16/1–3 yrs.	Increase in IJA in both treatments; children with >10 IJA acts at pretest had greater gains from RPMT; children showing < 2 IJA acts at pretest had greater gains from PECS

[1] IJA = initiating joint attention. RJA = responding to joint attention. CJA = coordinated joint attention. RCT = randomized controlled trial. MBL = multiple baseline design. Studies were included in this table if (1) a behavioral treatment, with or without a specific focus on joint attention, was employed with children with autism, autism spectrum disorder, or pervasive developmental disorder–not otherwise specified, and (2) either RJA, IJA, or CJA was assessed before and after the employed treatment. Typical measurement for RJA and IJA included various paradigms, such as gaze-following tasks, individual IJA, or RJA scores from the Autism Diagnostic Observation Schedule (Lord, Rutter, Dilavore, & Risi, 1999), or the Early Social Communication Scales (ESCS: Mundy, Hogan, & Doehring, 1996), among others. CJA was typically measured as a proportion of time children were engaged in focused, cooperative, free play with an adult or peer, wherein gaze alternating and eye contact occurred.

benefits on language as well as cognitive and social development (Jones, Carr, & Feely, 2006; Kasari et al., 2007; Rudd, Cain, & Saxon, 2008; Whalen, Schreibman, & Ingersoll, 2006). At this point, the bulk of large-scale trial evidence (see Table 4.1) for the malleability of joint attention in young children with ASD originates from the JASP/ER (Kasari et al., 2006) intervention at UCLA which focuses on joint attention as a primary intervention target and outcome. One other large-scale intervention (Green et al., 2010) focusing on communication, more generally, reported increases in bouts of coordinated joint attention between children with ASD and caregivers. Thus, it will be important for future ASD intervention studies to also report specific pre-test and post-test measurements of joint attention. This type of data will enable researchers to determine whether joint attention improvements must be specifically targeted by intervention, or whether joint attention can improve as a function of general positive treatment response to nonspecific interventions. Further, understanding the effects of intervention on joint attention will likely elucidate the mechanisms of healthy social development (Cicchetti & Toth, 2009). Joint attention also appears to mediate responsiveness to early intervention among children with autism (Bono et al., 2004; Yoder & Stone, 2006).

Second, the PDPM proposes that joint attention serves as a foundation for social-cognitive development. Social-cognitive development is defined in terms of advances in the processing of information about self and other, rather than singularly in terms of changes in knowledge about intentionality. Following connectionist cognitive theory (McClelland & Rogers, 2003; Otten, Henson, & Rugg, 2001), the PDPM assumes that information encoded during learning is stored as a distributed neural network activation pattern that involves parallel activation of networks of related semantic information. Additionally, whenever information is acquired during social learning and joint attention, it is also encoded in parallel with the activation of a frontal-temporal-parietal neural network that maps relations between representations of information about self-directed attention and information about the attention of other people. Thus, every time we process information in social learning, we encode it as an activation pattern in a distributed semantic network *in conjunction with* an activation pattern of the anterior-posterior cortical joint attention network (Figure 4.4, Figure 4.5). Recall that deeper information processing and learning occurs best in the context of the simultaneous activation of multiple neural networks during encoding (Otten et al., 2001). If so, joint attention may lead to deeper processing because it adds activation of the distributed social attention network (a form of episodic encoding) to the network activation associated more directly with semantic information. This conjecture provides one interpretation of the observation that joint attention facilitates depth of processing in 9-month-olds (Striano, Chen, Cleveland, & Bradshaw, 2006; Striano, Reid, & Hoel, 2006). It also suggests that part of the learning disability of ASD occurs because children with this disorder do not reap the full benefits of encoding semantic information in conjunction with episodic memory encoded within the integrated processing of self- and other-attention (Mundy et al., 2010).

Some evidence has recently been provided by a sequence of studies of the effects of joint attention on the recognition memory of adults and older children. A recent study has used a virtual reality paradigm to study the effects of picture recognition in college students (Kim & Mundy, 2012). In this study, participants studied pictures of faces, houses, or abstract designs under one of two conditions: (1) the avatar followed the gaze of participants to target pictures on study trials (IJA condition); or (2) participants followed the gaze of an avatar to target pictures on study trials (RJA condition; Figure 4.11). The results of the study indicated that adults correctly recognized significantly more pictures in the IJA than the RJA condition. There are several possible reasons for IJA-related information processing superiority. One is that self-initiated target choice is coupled with better or easier processing than directed target choice. Another possibility is that having another person or avatar follow one's gaze to an object, and the experience of directing or controlling another person's gaze, changes the perception and processing of the common focus of attention (Bayliss, Paul, Cannon, & Tipper, 2006; Mundy & Jarrold, 2010). More interesting, for the topic at hand, the paradigm used by Kim and Mundy (2012) was recently presented to 30 higher functioning children with ASD and 50 age-, gender-, and IQ-matched typically developing children (Kim et al., in preparation). The results indicated that the typically developing children displayed an advantage of picture recognition memory in the IJA condition versus the RJA condition, which was comparable to the pattern of data Kim & Mundy (2012) reported for adults. Moreover, the typically developing sample displayed significantly better performance in the IJA condition than the RJA condition, but the ASD sample did not display any differences in recognition memory across the IJA and RJA conditions. These data are consistent with the notion that, in childhood, joint attention does not affect information processing in children with ASD in a manner that is comparable to effects observed for children without ASD.

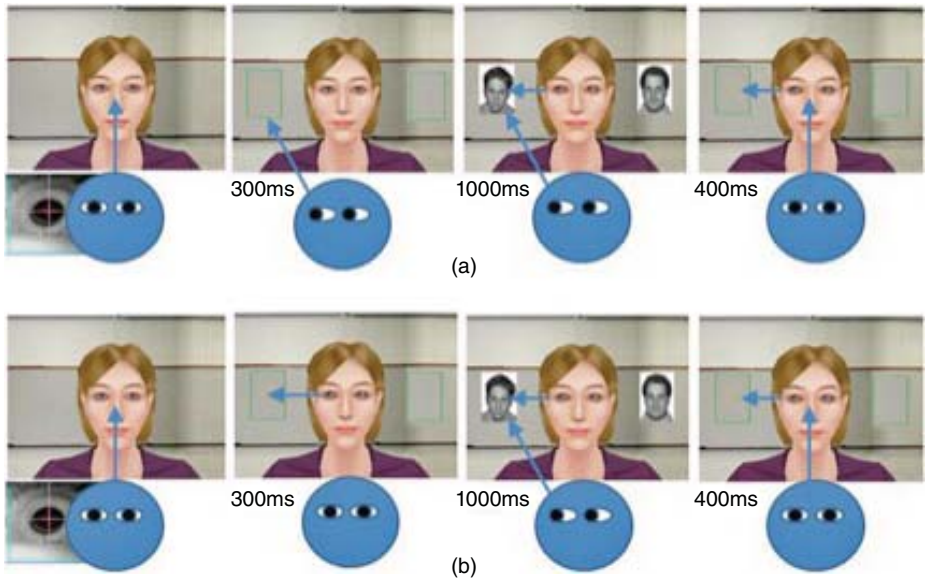

Figure 4.11 Illustration of the IJA and RJA conditions in the Kim & Mundy (2012) joint attention and memory paradigm. In the IJA condition (panel A), the participant first views the avatar, then chooses to shift attention to a stimulus window to the left or right of the avatar. Eye-tracking data then flows to a WorldViz© software program to trigger gaze following in the Avatar and onset of the study picture. The final illustration in panel A indicates that, after a study trial ended, the participant returned to midline, but the Avatar remained fixated on the target area to insure that the participant recognized that the avatar had followed his or her gaze. In the RJA condition, the participant fixated the Avatar and followed the direction of gaze of the avatar to choose a picture to study. Eye tracking control of stimulus onset ensured the picture did not appear until the participant followed the Avatar's gaze. This equated the study time that was available on each trial across IJA and RJA conditions. The Avatar again returned to midline gaze after the participant returned to midline. See footnote 1. *Source:* Reprinted with permission from Kim and Mundy (2012).

A third argument of the PDPM is that overt joint attention becomes increasingly internalized as a social-executive function that supports the social coordination of covert mental attention to cognitive representations. The spontaneous coordination of mental attention and cognitive representations is an essential element of symbolic thought (Tomasello et al., 2005). The PDPM assumes that months of practice of the social coordination of overt attention (i.e., joint attention) in the first years of life is required before this function can be internalized and transformed to an executive facility for socially coordinated covert mental attention and symbolic thought. Thus, symbolic thought processes incorporate, but do not replace, activation of the self-other joint attention system. Joint attention, on the other hand, does not necessarily involve symbolic processes (Mundy et al., 1987). These assumptions of the PDPM are consistent with two recent observations. Joint attention is a unique predictor of pretend play development in children with ASD relative to measures of imitation or executive functions (Rutherford et al., 2007). Moreover, successful symbolic play intervention, which according to the PDPM must involve effects on joint attention, *is* associated with parallel collateral improvements in joint attention in autism. However, intervention with joint attention has less immediate impact on symbolic play behavior (Kasari et al., 2006).

Fourth, the joint processing of attention information also plays a fundamental role in social cognition, defined in terms of the development of knowledge about intentions in self and other (Mundy & Newell, 2007). The assumption here is that when infants or primates practice monitoring others' attention (RJA), statistical learning ultimately leads to the associative rule: *where others' eyes go, their behavior follows* (Jellema, Baker, Wicker, & Perrett, 2000). Similarly, anterior monitoring, or self-awareness of control of visual attention, likely leads to awareness of the self-referenced associative rule: *where my eyes go, my intended behavior follows* (Mundy & Newell, 2007). An integration of the development of these concepts leads to the logical cognitive output: *where others eyes go → their intended behavior follows*, which is a building block of social-cognitive development (Mundy & Newell, 2007). Social cognition of this kind is thought to enable new and more efficient levels of social or cultural learning, and is atypical in ASD.

Finally, the constructivist assumptions of the PDPM stress that motivation factors are part of a crucial fifth path

of association between joint attention and social learning. Initiating joint attention requires "choosing" between behavior goals, such as fixated looking at an event, or alternating looking to the event and another person. Choosing among behavior goals is thought to involve frontal and medial cortical processing of the relative reward associated with different goals (Frank & Claus, 2006; Holroyd & Coles, 2002). Therefore, IJA impairment in ASD may be expected to be related to deficits in biobehavioral processes associated with reward sensitivity and motivation (Dawson, 2008; Kasari et al., 1990; Mundy, 1995). Such a deficit, however, could take several forms.

Social stimuli could be aversive in some way for children with ASD. However, the aversion hypothesis is complicated by observations of behaviors indicative of relatively intact caregiver-attachment in many children with ASD and a willingness to engage in playful physical interactions with strangers (e.g., Mundy et al., 1986; Sigman & Ungerer, 1984). On the other hand, social stimuli may not be aversive. Rather, social stimuli may simply not be sufficiently positive to compel social-orienting and joint attention early in the life of children with ASD (Dawson et al., 1998, 2012; Mundy, 1995). Finally, social stimuli could have a positive valence for children with ASD, but be overshadowed by an atypically strong visual preference that make objects, rather than social elements of the world, more interesting (Karmel, Gardner, Swensen, Lennon, & London, 2008; McCleary, Allman, Carver, & Dobkins, 2007; Mundy & Crowson, 1997).

The construction of effective empirical approaches to address these alternatives is one of the outstanding challenges in the science of ASD (Dawson, 2008; Koegel et al., 2003). Research on joint attention, in relation to motivation and the perceived valence of objects in adults (Bayliss et al., 2006), offers one potential route for developmental and functional neurocognitive studies on this topic. For now, though, the literature on intervention in ASD may be the best source of information in this regard. Early intervention studies offer some of the most systematic investigations to date of how to structure social engagements with young children with ASD to modify and increase their motivation to initiate episodes of shared attention and shared experience with others (e.g., Kasari et al., 2006, 2007). The impact of these interventions on the social development of children, their relationships to other people and the world, and transactional effects on their brain development and pathways to resilience (Cicchetti & Toth, 2009), cannot be underestimated.

SUMMARY

Only in its most expansive or grandiose interpretation can the PDPM be viewed as an explanatory model of joint attention, or ASD. Nevertheless, the PDPM does serve a purpose. It presents a new perspective on joint attention that suggests its impairment in ASD is more than an epiphenomenon associated with other fundamental precursor or successor processes. Rather, an impairment in joint attention constitutes a cardinal disruption in the process of healthy social development (Cicchetti & Toth, 2009), that then goes on to further affect social-behavioral development and neural development. This alternative perspective can be summed up in terms of several general principles.

First, ASD is as much about impairments in self-generated activity as it is about problems in perceiving or responding to the behavior of others. Hence, we need to consider the neurodevelopmental processes and networks involved in initiating behavior and attention control, as well as those involved in perceiving and responding to the behaviors of others, to understand this disorder (Mundy, 2003). Second, joint attention and social cognition are forms of information processing that give rise to knowledge, but their development may not be wholly defined in terms of stages of knowledge acquisition. Third, joint attention is a form of parallel processing because it involves the conjoint perception and analysis of information about self-attention and the attention of other people. This conjoint analysis of information also involves distributed processing across an anterior cortical system for guidance and self-monitoring of internal information about goal-directed attention, and a posterior cortical system for processing external information about the attention-related behavior of other people.

The third principle of the PDPM encourages a multidisciplinary approach to better link constructivist, connectionist neuroscience with parallel and distributed processing impairments in future research on ASD. Exemplary multidisciplinary efforts of this kind have already been published (e.g. Cohen, 2007; Lewis & Elman, 2008). However, the PDPM suggests that such efforts may be better informed with the appreciation of the following hypotheses. A disturbance of a distributed cortical system specifically involved in self-other representational mapping may be at the heart of human social cognition (Decety & Sommerville, 2003), and joint attention may be at the heart of the development of this quintessential form of human cognition, as well as its impairments in ASD.

This leads to the fourth principle of the PDPM. Joint attention is a social executive process that supports all forms of cognition that involve coordinating attention and knowledge about self and others, such as symbolic thought. Thus, neural network activation associated with joint attention is an enduring substrate that plays a role in the unique characteristics of human cognition throughout the life span (Mundy & Newell, 2007). Indeed, it may be one example of the type of hot executive function that Zelazo, Qu, and Muller (2005) theorized are central to social cognition. Hot executive functions are those that entail motivation processes and affect regulation specific to the support of successful goal-directed behavior in social engagement. Following from this notion, the fifth and final principle of the PDPM is that individual differences in the operation of the social executive function of joint attention may be an expression of variance in motivation processes.

FUTURE DIRECTIONS

One of the strengths of the PDPM in application to ASD research is that of hypothesis generation. The model proposes that joint attention is a fundamental, early-developing skill that supports the development of language, social connectedness, social cognition and learning, and social-emotional regulation. This skill is supported by a distributed neural network that integrates information about self (anterior) and other (posterior), and progresses from a learning phase into a routine phase via experience–expectant processes. The first question that follows from this model involves neural plasticity and the development of joint attention. Specifically, studies are needed that assess the development of joint attention and the concurrent development of the PDPM neural network, in typically developing samples, and in ASD samples undergoing interventions. A disruption in joint attention development may have a cardinal role in the endurance of social challenges across the lifespan in ASD, even as other challenges remit. This endurance may be due to the disturbance in the cycle of healthy social development, wherein shared attention and connectedness with others serves as crucial experience that propels brain development, activity, and structure, which then further constrains social abilities and stimulation over time. In light of this idea, prevention trials (Cicchetti & Toth, 2009), which assess whether neurophysiological domains are affected by treatments, are urgently needed. It will also be important to assess multiple levels of effect, such as neurophysiology, genetics, social behavior, and relationships with others, as all of these feed into the stimulation available to a developing organism. Recent work (e.g., Bolte et al., 2006; Faja et al., 2012; Vaughan Van Hecke et al., 2013) established that neural plasticity in response to intervention is possible in ASD and that white matter integrity is linked to early onset and duration of intervention (Pardini et al., 2012). One study reported increases in parietal-temporal EEG activity, perhaps reflective of the posterior network of the PDPM, in toddlers with ASD undergoing early, intensive intervention (Dawson et al., 2012). Thus, it will be critical, for our understanding of the syndrome, that we establish whether the PDPM is responsive to intervention for ASD and whether there are critical periods that bind this possibility. Additionally, it will be the task of similar studies to determine whether epigenetic effects of amelioration of joint attention deficits occur in response to interventions for ASD. Lastly, studies are needed that describe and measure joint attention across the life span. Although joint attention is well characterized in infancy and early childhood, very little is known about the progression of this uniquely human capability across the latter half of the life span. Studies that assess joint attention and PDPM neural function in adulthood and aging will be informative in this regard. In sum, understanding the nature of these processes, such as the degree to which they are mediated by learning processes or endogenous neural mechanisms, is a vital goal for future multidisciplinary developmental research on social cognition and ASD.

CONCLUSIONS AND FUTURE DIRECTIONS 176
REFERENCES 177

Over the past few decades, considerable progress has been made in the field of preschool psychopathology. There is now broad consensus that impairing, stable psychological conditions can be identified in a reliable and valid manner in young children (Dougherty, Leppert, et al., 2015; Egger & Angold, 2006). These research endeavors, coupled with increasing understanding of etiological processes in the development of early-emerging psychopathology, are essential to inform prevention and early intervention efforts to minimize the extent to which emotional and behavioral problems and associated impairment accumulate over time and impact children's development. Although much has been done, the next frontier in developmental psychopathology research is developmental specification of syndromes in a manner that sensitively differentiates normative variation from early emergence of atypicality and links this process to mechanisms. Given behavioral and neural plasticity in early childhood, detecting and treating emergent psychopathology and associated vulnerabilities in a manner that differentiates them from transient variability will be more effective than treatment of frank disorder after it becomes entrenched.

This chapter will focus on common emotional and behavioral syndromes that arise during the preschool period, including attentional, disruptive (oppositional and conduct), anxiety, and mood (i.e., depression) problems. Current knowledge based on the *Diagnostic and Statistical Manual* (*DSM*) will be summarized briefly to examine the state-of-the-science within the context of prior work. In keeping with the developmental psychopathology approach (Cicchetti, 1984; Cicchetti & Toth, 2009; Sroufe, 1979; Sroufe & Rutter, 1984) and novel conceptualizations of the underpinnings of mental disorder such as the Research Domain Criteria (RDoC; Cuthbert & Insel, 2013; Franklin, Jamieson, Glenn, & Nock, 2015; Insel et al., 2010; Sanislow et al., 2010), the central focus of the chapter will be an examination of preschool psychopathology within a dimensional, developmental domain framework as we see this as the next crucial advance for developmental psychopathology research. We will first describe measurement advances in the dimensional operationalization of behavior in preschool-age children. Next, we delineate broad developmental domains and their expression in early childhood as an example of a developmental approach

for establishing the normal–abnormal spectrum, including essential developmental capacities, their normative variation, and clinically concerning deviation within each domain. To further explicate each domain, we highlight developmental processes relevant to an exemplar diagnostic category. We also delineate steps for translating dimensional, developmentally sensitive measurement from research to clinical application. We will conclude with suggestions for future directions for research that are geared toward advancing multilevel, developmentally oriented conceptualization of psychopathology.

PRESCHOOL PSYCHOPATHOLOGY: WHAT HAVE WE LEARNED FROM A TRADITIONAL CATEGORICAL DSM-BASED APPROACH?

Over the past decade, it has become increasingly clear that common pediatric emotional and behavioral disorders often onset in early childhood. Sizable proportions of preschool-age children meet criteria for a range of *DSM* disorders. Overall, approximately one in five preschool-age children meets criteria for at least one psychiatric disorder (Dougherty, Leppert, et al., 2015; & Angold, 2006). This rate is similar to rates identified in older children and adults, and lends additional support to the notion that mental health problems often emerge early and persist throughout the life span. More specifically, in community samples of preschool-age children utilizing interview-based methods to establish clinical significance, overall rates of *DSM-IV* disorders in community samples range from approximately 16 to 27% (Bufferd, Dougherty, Carlson, & Klein, 2011; Egger, Erkanli, Keeler, Potts, Walter, & Angold, 2006; Ezpeleta, de la Osa, & Domenech, 2014; Wichstrøm et al., 2012).

In this section, we will provide a brief review of the rates of common *DSM* disorders (ADHD, disruptive behavior [DB; i.e., oppositional and conduct], anxiety, and mood disorders). Although there is a large literature on symptom and syndrome scales that laid the foundation for the field (e.g., Achenbach, Edelbrock, & Howell, 1987; Moreland & Dumas, 2008), this section will focus primarily on recent large community-based studies that assessed *DSM-IV* diagnoses using structured diagnostic interviews (Bufferd et al., 2011; Egger, Erkanli, et al., 2006; Ezpeleta et al., 2014; Keenan et al., 2007; Lavigne, Lebailly, Hopkins, Gouze, & Binns, 2009; Wichstrøm et al., 2012). In addition, we will discuss comorbidity among diagnoses. Next, we will summarize the available reliability and validity data relevant to *DSM* diagnoses. Finally, we will review measurement advances in the diagnostic assessment of preschool psychopathology and conclude the section with a discussion of the limitations of the *DSM* approach for capturing psychopathology in young children within developmental context.

In community-based studies that assessed *DSM-IV* diagnoses using structured diagnostic interviews, the range of rates of ADHD is 1.9–11.4%, and of DBDs is 1.8–12.1% for oppositional defiant disorder (ODD) (Bufferd et al., 2011; Egger, Erkanli, et al., 2006; Ezpeleta et al., 2014; Lavigne et al., 2009; Wichstrøm et al., 2012) and 0.7–3.3% for conduct disorder (CD) (Egger, Erkanli, et al, 2006; Ezpeleta et al., 2014; Wichstrøm et al., 2012). As this section focuses on traditional *DSM* categorical diagnoses, we have reported on CD separately from ODD. However, the distinction between ODD and CD at preschool age is questionable. Few studies have examined CD in this age group due to the developmental impossibility and improbability of most CD symptoms for young children (Wakschlag, Leventhal, Thomas, & Pine, 2007). Of those studies that have examined CD as a separate disorder, virtually all children who meet criteria also meet criteria for ODD (Keenan et al., 2007). Psychometric analyses suggest a common disruptive behavior factor and separate ADHD factor best fit the data at this age (Sterba, Egger, & Angold, 2007; Strickland et al., 2011). Overall, rates of anxiety disorders range from 1.5–19.6% (Bufferd et al., 2011; Egger, Erkanli, et al., 2006; Ezpeleta et al., 2014; Wichstrøm et al., 2012), with rates of individual disorders as follows: separation anxiety disorder (0.3–5.4%), specific phobia (0.7–9.1%), generalized anxiety disorder (GAD; 0.1–3.9%), social phobia (0.5–4.4%), agoraphobia (3.5%) and selective mutism (0.6–1.5%). Compared with other diagnostic areas, rates of depression diagnoses in preschoolers have been less well-studied. In the few studies that have assessed depression, rates range from 0.3–3.4% (Bufferd et al., 2011; Egger, Erkanli, et al, 2006; Ezpeleta et al., 2014; Lavigne et al., 2009; Wichstrøm et al., 2012). Across disorders, fairly wide ranges of rates are found and due, in part, to different instruments used, different numbers of disorders assessed (e.g., different number of individual anxiety disorders assessed), different age ranges within the preschool period, and samples recruited from a variety of geographic regions (Bufferd et al., 2011; Wakschlag, Leventhal, et al., 2007).

Similar to older children, adolescents, and adults, comorbidity among diagnoses is common in preschool-age children (Egger & Angold, 2006; Lavigne et al., 2009): rates range from 5.1 to 9.2% of preschoolers meeting criteria for two or more diagnoses. Studies have identified associations

between depression and ODD, anxiety and depression, anxiety and DBDs, and DBDs and ADHD (Bufferd et al., 2011; Egger & Angold, 2006; Ezpeleta et al., 2014; Lavigne et al., 2009; von Klitzing et al., 2014; Wichstrøm et al., 2012). When examining patterns of comorbidity, ODD emerges as commonly co-occurring with disorders in each of the other main diagnostic categories; similar findings have been identified in older children (Angold, Costello, & Erkanli, 1999; Ford, Goodman, & Meltzer, 2003) and are consistent with research on the cross-cutting role of irritability in contributing to later psychopathology (Dougherty, Smith, et al., 2013; Dougherty, Smith et al., 2015; Dougherty et al., 2015; Stringaris, Cohen, Pine, & Leibenluft, 2009).

The Measurement of Preschool Psychopathology

This work in identifying *DSM* disorders in young children has rested on critical measurement advances that provided an early childhood framework for clinical assessment of preschool-age children. The area of preschool psychopathology was built initially on the use of checklist measures to assess both broad (e.g., Achenbach & Rescorla, 2000; McGuire & Richman, 1986) and specific (e.g., Campbell & Breaux, 1983) symptom domains in young children. These early checklist methods offered feasible approaches for assessing problem behavior patterns and determined clinical thresholds quantitatively. However, limitations of this approach include limited assessment of severity or pervasiveness, and reliance solely on respondents' knowledge to interpret the meaning of their children's behaviors and estimate the relative frequency despite the fact that differentiation of normal and abnormal behavior in this period is a challenge to reliable clinical identification (Campbell, 1995; DelCarmen-Wiggins & Carter, 2004; Wakschlag & Danis, 2009). Further, although these approaches specifically shied away from diagnostic methods due to their adevelopmental focus, this shift also led to an often disjunctive approach in which diagnostic methods were suddenly introduced at school age, making it difficult to map coherent clinical pathways across age periods.

Over the past decade, a plethora of diagnostic instruments for clinical assessment of young children has been developed and validated, including structured and semistructured parent report diagnostic interviews developed for use with young children or adapted from interviews with older children (see also Chapter 1 in volume 1). These measures include interviews such as the Diagnostic Infant and Preschool Assessment (Scheeringa & Haslett, 2010), the Diagnostic Interview of Children and Adolescents for Parents of Preschool and Young Children (Ezpeleta, de la Osa, Granero, Domenech, & Reich, 2011), the Diagnostic Interview Schedule for Children: Young Child (Lucas, Fisher, & Luby, 1998), the Kiddie Disruptive Behavior Disorders Schedule (KDBDS; Keenan & Wakschlag, 2004; Keenan et al., 2007), the Preschool Age Psychiatric Assessment (PAPA: Egger, Ascher, & Angold, 1999), and the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS-PL) for the assessment of preschool children (Birmaher et al., 2009). The increased use of structured diagnostic interviews reflects a meaningful shift toward in-depth assessment of the intensity, frequency, duration, and contexts of behaviors relevant to psychopathology. For example, using data from the PAPA, Egger and Angold (2006) showed that applying ODD symptom frequency thresholds from older children to preschoolers results in significant overidentification, with 20–57% of preschoolers exhibiting common symptoms. The development and validation of clinical interviews in this age period is particularly advantageous in improving efforts to characterize the nature of emotional and behavioral problems in a developmentally sensitive manner. Further, many of these instruments incorporate some developmentally relevant information to enhance the relevance and quality of the assessment of psychopathology in young children (e.g., KDBDS, PAPA).

Reliability and Validity of Preschool Psychopathology

There is ample evidence to support the reliability and validity of psychopathology in young children, including data that suggest good interrater and test-retest reliability of diagnostic assessments, that rates found in young children are similar to those identified in older children, symptoms are associated with parent- and teacher-rated impairment, family history, observed behavior, later psychopathology, and response to empirically supported treatments.

First, there is evidence of interrater (e.g., Bufferd et al., 2011; Keenan et al., 2007; Wakschlag, Hill, et al., 2008) and test–retest (Egger, Erkanli, et al, 2006; Ezpeleta et al., 2011; Keenan et al., 2007; Wakschlag, Hill, et al., 2008) reliability in the use of diagnostic interviews and observations to assess psychopathology in young children. Regarding validity, rates of disorders identified in preschool-age children (e.g., Bufferd et al., 2011; Bufferd, Dougherty, Carlson, Rose, & Klein, 2012; Egger, Erkanli, et al, 2006; Lavigne et al., 2009) are generally similar to those found in epidemiological studies with school-age children and adolescents (Angold et al., 2012; Burstein

et al., 2011; Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Froehlich et al., 2007; Merikangas et al., 2010). Second, a range of known correlates have been linked to psychopathology in young children including associations with (1) impairment in functioning across domains (e.g., with parents, siblings, peers, in preschool and day care) in a range of studies based on both parent and teacher report (Bufferd et al., 2011; Danzig et al., 2013; DuPaul, McGoey, Eckert, & VanBrakle, 2001; Egger, Erkanli, et al., 2006; Luby et al., 2002; Luby, Belden, Pautsch, Si, & Spitznagel, 2009; Wakschlag & Keenan, 2001); (2) family history of psychopathology (Bufferd et al., 2014; Dougherty, Smith, et al., 2013; Dougherty, Tolep, et al., 2013; Luby et al., 2002); and (3) standardized clinical observation (Bunte et al., 2013; Dougherty et al., 2011; Dougherty, Smith, et al., 2013; Wakschlag, Briggs-Gowan, et al., 2008). Third, psychopathology assessed in preschool-age samples persists in some children and predicts later psychopathology and impairment (Bufferd et al., 2012; Dougherty, Smith et al., 2015; Dougherty et al., 2015; Keenan et al., 2011; Kim-Cohen et al., 2009; Lavigne et al., 1998; Lavigne, Dahl, Gouze, Bryant, & Hopkins, 2014; Lee, Lahey, Owens, & Hinshaw, 2008; Luby, Gaffrey, Tillman, April & Belden, 2014; Riddle et al., 2013; Wakschlag, Briggs-Gowan, et al., 2008). Finally, although there are no known large-scale randomized controlled trials (RCTs) of psychological treatments for preschool psychopathology, several well-conducted studies (including some small-scale RCTs) suggest that empirically supported treatments can be applied effectively (Axelrad, Butler, Dempsey, & Chapman, 2013; Chronis-Tuscano et al., 2015; Hirshfeld-Becker et al., 2010; Lenze, Pautsch, & Luby, 2011; Rapee, 2013; Riddle et al., 2013; Sonuga-Barke, Thompson, Abikoff, Klein & Brotman, 2006).

Despite evidence for the validity of preschool psychopathology, questions remain about the developmental appropriateness of some *DSM* symptoms in young children (Egger & Angold, 2006; Keenan & Wakschlag, 2002). Although some diagnostic instruments attempt to include age-appropriate manifestations of psychopathology (e.g., KDBDS; PAPA) and some researchers apply modified criteria to the assessment of disorders in preschool children (e.g., relaxing the requirement for persistent mood difficulties and adding suicidal/death themes in play for a depression diagnosis (Luby et al., 2002); modifications to some DBD items (Wakschlag, Hill, et al., 2008)), some diagnostic categories include developmentally impossible or improbable symptoms. As mentioned above, many symptoms of CD are very unlikely to apply to young children (e.g., use of weapons, forced sexual activity, theft, truancy). Even if a few extreme children engage in these behaviors, these behaviors do not meaningfully characterize developmental differentiation of behaviors along the latent domain of concern for others and internalization of norms and standards that CD represents (that is, the symptoms reflect behaviors of adolescent boys; Carter, Gray, Baillargeon & Wakschlag, 2013; Wakschlag, Tolan, & Leventhal, 2010). This issue is relevant to other diagnostic categories as well; for example, Lahey and colleagues' (2005) work suggests that the inattentive type of ADHD is not particularly stable from preschool through elementary school age. This may be due, in part, to the developmental inappropriateness of ADHD inattention symptoms which focus largely on school-based skills and sustained mental effort, which do not capture the central features of developmental expression of normative regulation of attention in young children (Chacko, Wakschlag, Hill, Danis, & Espy, 2009). In addition, some cognitive symptoms of anxiety and depression are less developmentally probable in early childhood, such as excessive anxious apprehension about future events and rumination about past events. Finally, it is unclear whether the display of some behaviors (e.g., a preschool-age child assaulting a peer with a toy) reflects the same clinical meaning as an older child's behavior (e.g., an adolescent assaulting a peer with a weapon; Keenan & Wakschlag, 2000). Further, emphasis on these extreme and rare behaviors misses the boat in terms of capturing manifestations of aggression that qualitatively distinguish typical from atypical in this age period such as mild aggression in response to peer conflict versus hostile, intense aggression with intent to hurt (Wakschlag et al., 2010).

Measurement Gaps in the Traditional Categorical *DSM*-Based Approach: Where Do We Go From Here?

These measurement advances described above have had a profound impact on the nature of the discourse about preschool psychopathology, changing the focus of scientific inquiry from the earlier focus on whether psychopathology exists to the current emphasis on defining developmental phenotypes, sharpening early identification, and establishing links to specific mechanisms. Additional work is needed to further our understanding of the variation in behavior that pertains to the development of early-emerging psychopathology. First, in a diagnostic interview, the typical goal of each question is to establish whether a child meets a criterion for a particular disorder. However, in this process of rating whether a behavior crosses the criterion threshold, only more extreme forms of behavior are captured;

therefore, potentially clinically relevant information may be lost, particularly in the preschool period when many symptoms overlap substantially with normative misbehaviors and variation. That is, behaviors are only rated categorically as absent or present (or, in some cases, present in varying degrees of severity) whereas behaviors that fall short of the threshold, yet may still be pertinent, are considered absent. This issue is especially problematic for identifying prodromal signs of emerging psychopathology in young children as early identification and prevention can ameliorate chronic and persistent mental disorder trajectories more effectively than treatment once there is frank disorder (Insel, 2009). This limitation is consistent with criticisms of categorical classification in that it highlights the value of assessing the severity and frequency of the full spectrum of behavior from normative variation to clinical problems rather than relying on the presence or absence of a particular behavior (Arend, Lavigne, Rosenbaum, Binns & Kaufer Christoffel, 1996; Carter et al., 2013; Cole, Luby, & Sullivan, 2008; Wakschlag, Briggs-Gowan, et al., 2014). Although dimensional approaches are receiving increasing prominence across the life span, this issue is especially salient during early childhood when the critical clinical distinction is not *whether* the child engages in the behavior but *how*.

In addition, empirically based guidelines for determining when the intensity and frequency of young children's behavior are clinically significant are lacking. Cutoffs for symptom thresholds are not typically empirically derived, nor are there sufficient data to operationally define *DSM* terms included in diagnostic criteria such as recurrent, persistent, and excessive. Without such data, it is challenging to accurately determine whether a child exhibits clinically concerning levels of behavior compared to other children. Given that many defining features of common emotional and behavioral disorders are developmentally normative in this age period (e.g., moodiness, tantrums, short attention span; Gullone, 2000; Marks, 1987; Muris, Merckelbach, Mayer, & Meesters, 1998; Stringaris, 2011) and the high degree of noise in normative behavior, clear guidelines for identifying the actual signal of clinically salient behavior are needed.

Therefore, methods to detect developmental variation along the full spectrum relevant to psychopathology are essential as advances beyond the current method of symptom assessment that only captures severe behaviors. These methods can also identify developmental manifestations of psychopathology as they shift over time. Compared to more standard categorical approaches, a dimensional method of assessment can offer a more nuanced understanding of developmental course, better characterize heterogeneity of behavior, better incorporate information from various informants, and better delineate contextual factors that inform etiology. To do so, integration between developmental and clinical science is necessary such that specific developmental domains for characterizing the normal-abnormal spectrum are applied to the assessment of psychopathology in young children (Wakschlag, Briggs-Gowan, et al., 2014; Wakschlag et al., 2010).

MEASUREMENT ADVANCES: DIMENSIONAL OPERATIONALIZATION OF THE CONCEPTUALIZATION AND THEORY

There have been a number of advances in identifying the dimensions that constitute abnormal behavior, particularly in the area of DBDs. These advances include questionnaire, daily diary, and observational measures.

Questionnaire

We (Wakschlag, Briggs-Gowan, and colleagues) have developed a suite of novel assessment tools to sharpen differentiation of the normal–abnormal spectrum of behavior within the developmental context of early childhood, including both questionnaire and direct observation measures (Mian, Carter, Pine, Wakschlag & Briggs-Gowan, 2014; Petitclerc, Briggs-Gowan, Anderson, Burns & Wakschlag, 2014; Wakschlag, Hill, et al., 2008; Wakschlag, Briggs-Gowan, et al., 2008; Wakschlag, Briggs-Gowan, et al., 2014; see also Chapter 1 in volume 1). The unifying theme of these instruments is their goal of operationalizing features of behavior we have theorized as key to the normal–abnormal differentiation (i.e., quality, frequency and expectability in context; Wakschlag, Hill, et al., 2008; Wakschlag et al., 2010). The Multidimensional Assessment Profile of Disruptive Behavior[1] (MAP-DB) is a questionnaire measure that assesses four dimensions of behavior: temper loss, aggression, noncompliance, and low concern for others (with low concern composed of two subdimensions: disregard for others and punishment insensitivity) theorized to be defining features of disruptive behavior syndromes (Nichols et al., 2014; Wakschlag, Briggs-Gowan, et al., 2014). Reflecting a core principle of

[1]This instrument was originally called the Multidimensional Assessment of *Preschool* Disruptive Behavior but has since been renamed to reflect its use across broader age periods.

the developmental psychopathology approach (Cicchetti & Toth, 2009; Sroufe, 1997), each dimension is defined as a deviation from normative developmental processes of early childhood (for theoretical underpinnings see Wakschlag et al., 2010; Wakschlag, Henry, et al., 2012). For example, the temper loss dimension reflects problems in regulation of overt anger, including both temper tantrums and irritable mood. The regulation of negative emotion is a core developmental task of early childhood and reflects the capacity to modulate the intensity and temporal features of emotional arousal in a goal-oriented manner (Batum & Yagmurlu, 2007; Cole, Michel & Teti, 1994; Gilliom, Shaw, Beck, Schonberg & Lukon, 2002). Temper loss quality is assessed in terms of modulation of angry, irritable behavior from expectable (e.g., becomes frustrated easily) to highly dysregulated (e.g., tantrums until exhausted). Items assessing the developmental expectability of temper loss in context includes normative contexts (e.g., tantrums when tired, hungry, or sick) and tantrums that are not contextualized (i.e., out of the blue). An objective frequency scale is used to determine how often behaviors typically occur and when a behavior occurs at a frequency outside expectable levels, using a psychometric definition of atypicality (i.e., occurs in less than 5% of the population) (Wakschlag, Choi, et al., 2012). This had enabled us to establish that contrary to the terrible twos myth (i.e., that problem behaviors predominate in early childhood), normative misbehaviors are common but not frequent. This is consistent with the PAPA's approach to define abnormality as behaviors occurring at a frequency that is present in less than 10% of the sample (Egger, Kondo, & Angold, 2006). For example, data from the MAP-DB in two independent community samples of demographically diverse preschoolers (N = 3,373) showed that while 83% of preschoolers have tantrums regularly, less than 10% do so daily; a pattern robust to individual differences in child age, sex, ethnicity and poverty status (Wakschlag, Choi, et al., 2012; Wakschlag, Briggs-Gowan, et al., 2014). Similar frequency patterns were detected across the other behavioral dimensions, although the frequency at which a behavior becomes atypical varies by its severity (Wakschlag, Briggs-Gowan, et al., 2014). For example, being aggressive when frustrated is only atypical when it occurs most days of the week, whereas spitting and cursing are atypical even when they occur rarely.

While dimensional approaches have long been a hallmark of developmental psychopathology research (Achenbach, 1997), assessments have typically been counts of problem behaviors rather than characterization along an ordered spectrum. One novelty of the MAP-DB is the inclusion of both normative and problem behaviors to capture the full behavioral spectrum of expression. Using item response theory (IRT) methods, we have characterized the normal–abnormal spectrum for each dimension in a large community sample of preschoolers (Nichols et al., 2014; Wakschlag, Briggs-Gowan, et al., 2014). Behaviors are psychometrically ordered from normative, commonly occurring behaviors to severe, rarely occurring behaviors. Table 5.1 provides examples of behaviors across the severity spectrum for each of the MAP-DB Dimensions.

This psychometric, developmentally based approach is designed to provide an empirical foundation for clinical applications of dimensional approaches that conceptualize psychopathology as falling along a continuum rather than being defined by a single extreme threshold. Early individual differences along these dimensions are shaped through development into adaptive or maladaptive patterns, which at their extreme constitute mental disorders (Cicchetti & Richters, 1997). While there is increasing emphasis on integrating dimensional approaches that characterize the spectrum from normative variation to abnormal behavior into clinical classification (Helzer et al., 2008; Insel et al., 2010), empirically based approaches for their clinical application are underdeveloped. This is an especially important gap in early childhood, where capturing the full liability spectrum may increase sensitivity for capturing prodromal stages of risk.

To advance the clinical application of spectrum approaches to preschool psychopathology, we have recently

TABLE 5.1 Illustrative Behaviors Across Normal–Abnormal Dimensional Spectrum

Dimension	Mild	Moderate	Severe
Temper Loss	*Have a tantrum*	*Have difficulty calming down when angry*	*Hit/bite/kick during tantrum*
Aggression	*Aggressive to get something s/he wants*	*Pinch/scratch/pull hair*	*Hit/shove/kick nonparental adults*
Noncompliance	*Act stubborn*	*Disobey out of the blue*	*Automatically resist whatever you ask*
Low concern for others			
Disregard for others	*Not care about others' feelings when frustrated/angry/upset*	*Act like didn't care about pleasing others*	*Enjoy making others mad*
Punishment insensitivity	*Deny did something not allowed*	*Keep on misbehaving no matter what you do*	*Refuse to apologize*

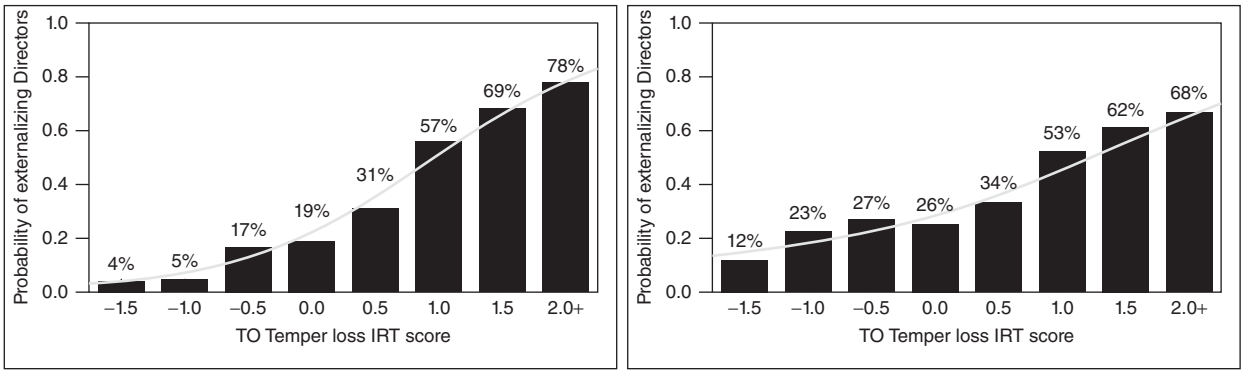

Figure 5.1 Relation of temper loss to externalizing disorders (left). Relation of temper loss to internalizing disorders (right). *Source:* Wakschlag, Estabrook, et al., 2014.

begun to examine the shape of the relation between the MAP-DB Temper Loss dimensions and clinical outcomes (Wakschlag, Estabrook, et al., 2014). In multivariate regression analyses, Temper Loss demonstrated a strong linear relation to probability of both externalizing and internalizing disorders (Figure 5.1), consistent with the cross-cutting nature of irritability in developmental psychopathology (Krieger, Leibenluft, Stringaris, & Polanczyk, 2013). For example, probability of externalizing disorder increases substantially as Temper Loss increases above the mean (Figure 5.1a). Importantly, this increased risk of disorder occurs at levels of Temper Loss typically considered to be normative. For example, children 1 standard deviation above the mean (typically considered at the upper bound of the normal range), had more than a 50% probability of an externalizing disorder. A similar, although less steep, linear trend was found for Temper Loss and internalizing disorders (Figure 5.1b). For continuous outcomes, a curvilinear pattern was found, such that a 1 standard deviation change at the lower end of the spectrum had little effect on level of clinical symptomatology, but this same level of change as children progressed along the dimensional continuum had a much larger impact (Wakschlag, Estabrook, et al., 2014). This dimensional approach to irritability assessment has also shown incremental utility in uncovering the neural substrates of irritability in young children (Perlman et al., 2014). For example, MAP-DB dimensional Temper Loss scores were associated with decreased activation of the anterior cingulate and striatum during a frustration task (Perlman et al., 2014).

Daily Diary

Compared with DBDs, relatively little attention has been devoted to characterizing the normal–abnormal spectrum of behavior relevant to internalizing problems such as anxiety, irritability, and sadness (Luby & Belden, 2006). Given that these problems can be identified in early childhood (Bufferd et al., 2011; Egger & Angold, 2006; Franz et al., 2013; Luby et al., 2002), persist over time (Bufferd et al., 2012; Luby et al., 2014) and that internalizing symptoms often reflect extreme displays of normative emotional processes in early childhood (e.g., separation anxiety, social fear; Gullone, 2000; Marks, 1987; Muris et al., 1998); irritability; Stringaris, 2011), it is essential to assess the severity and frequency of the full spectrum of behavior from normative variation to clinical problems, rather than assessing the presence or absence of behavior and identify the level of behavior that is associated with impaired functioning (Carter, Briggs-Gowan, & Davis, 2004; Eley et al., 2003). Improved developmental sensitivity of the assessment of children's emotions and behaviors can enhance the characterization of early-emerging psychopathology and refine intervention efforts to prevent or improve impairing developmental trajectories. To this end, we (Bufferd, Dougherty, & Olino, in preparation) have recently applied daily diary methodology in a novel manner to the assessment of behaviors relevant to anxiety and depression. In addition to beginning to document the typical range of behaviors displayed that may be clinically relevant, the daily diary methodology minimizes the biases introduced by retrospective recall required for parents to report about their children's behavior. Whereas most measures ask parents about their children's behavior in the previous month or so (up to three months or more), the daily diary requires parents to report about their child's behavior from that day. Ideally, a reduced recall period will diminish recall bias and enhance the accuracy of reports, which is essential in an endeavor that seeks to document the normative range of behavior and in which behaviors are frequently occurring. In addition, the daily diary provides a feasible method for obtaining objective

frequency of behavior rather than subjective frequency (e.g., asking parents to note whether children's behaviors occur sometimes, often, etc.), which, in some measures, relies on comparison to other children.

In a sample of 292 3–5-year-old children from two geographic regions (San Diego, CA and Washington, DC metro area) we asked primary caregivers to report about their children's daily behavior for 14 consecutive days, including the frequency, duration, and context of the behaviors. Items were derived from common anxiety problems in early childhood, including social anxiety and separation anxiety, as well as symptoms of depression. Items included behaviors such as distress when separating from a parent, somatic complaints, and social fear with other adults, children, and in new situations, and irritability, sadness, low interest or pleasure in activities, and sleep difficulties. In addition, each day, parents rated the extent to which each behavior was impairing (e.g., whether the behavior impacted the parent–child relationship that day) as well as provided overall ratings of impairment (extent of distress for the parent, the child, and the quality of the parent–child relationship from that day.

In a preliminary exploration of the anxiety and depressive behaviors, confirmatory factor analyses (CFA) tested dimensionality of the underlying separation anxiety, social anxiety, and depression dimensions. Both social anxiety and depression and, to a lesser extent, separation anxiety items assessed on a daily basis reflected coherent underlying dimensions. Using IRT analyses, we examined item characteristics with graded response models (GRM). Difficulty parameters reflected differential functioning across items such that some behaviors occurred less frequently than others to be severe (>95th percentile); for example, worry that a caregiver would get hurt or not return after being apart, worry about being left with another caregiver, shyness with familiar adults, avoidance of or withdrawal from social situations, low interest or pleasure, fatigue, and difficulty concentrating each had to occur at least three to four times over 14 days for the behavior to be considered severe; however, items such as distress when separation was anticipated from caregiver, fear about sleeping separately from the caregiver, shyness around new adults, sadness, and tearfulness were not severe at any frequency, suggesting that these behaviors are normative during this period of development.

The data from this study will provide preliminary evidence for the feasibility of a daily diary method to assess emotions and behaviors relevant to internalizing psychopathology in young children. In addition, the data begin to characterize the frequency of the spectrum of behavior from normative variation to clinical problems and will identify the level of daily behavior that is associated with impaired functioning. It is necessary to build on this study in future work with larger samples to more precisely document the parameters of the range of normative intensity, frequency, duration, and context of behaviors relevant to clinical risk in young children (Cole et al., 2008; Luby & Belden, 2006).

Observations

Drawing on robust findings that diagnostic observation, as exemplified in the Autism Diagnostic Observation Schedule (ADOS), adds precision for accurate early identification of autism (Lord, Leventhal, & Cook, 2001), we (Waskchlag, Briggs-Gowan, and colleagues) developed similar direct observation tools to aid in the differentiation of normative versus abnormal manifestations of disruptive behavior and anxiety in early childhood (Mian et al., 2014; Petitclerc et al., 2014; Wakschlag, Hill, et al., 2008). The Disruptive Behavior Diagnostic Observation Schedule (DB-DOS) uses presses designed to elicit differentiation of normative variation from clinically concerning behavior. Fundamentally, the goal of the DB-DOS is to tax the child's capacity for emotional and behavioral regulation during ecologically valid mild challenges (e.g., ease of elicitation and difficulty recovering from anger/irritability, intransigence of defiance); its conceptual developmental/clinical framework was the foundation for the MAP-DB. Behavior is rated along two domains: problems in anger modulation (akin to the MAP-DB temper loss scale) and problems in behavioral regulation (largely parallel to the MAP-DB noncompliance scale). Behavior is coded during interactions with parent and examiner along a clinical continuum ranging from normative variation to clinically concerning. Parameters of clinical concern include modulation, intensity, responsiveness to environmental support, and occurrence in developmentally unexpectable contexts. Observed behavior on the DB-DOS, particularly problems in behavioral regulation with the examiner, has demonstrated incremental utility for clinical differentiation and prediction of DBDs above and beyond parental report of DBD symptoms, and has also been used to predict ADHD (Bunte et al., 2013; Petitclerc et al., 2014; Wakschlag, Briggs-Gowan, et al., 2008). We also found sex differences in patterns such that disruptive boys' behavior is relatively stable across interactional contexts but disruptive girls show dramatic contextual differences—with high levels exhibited during interaction with their mothers but well-modulated

behavior during interactions with the examiner (Gray et al., 2012).

The Anxiety Dimensional Observation Scale (ANX-DOS) was developed along similar lines, although only a parent context has been validated to date (Briggs-Gowan et al., 2014; Mian et al., 2014). Here, presses are designed to elicit the full range of expression of fearfulness and anxiety (e.g., fear, arousal, startle, separation anxiety). The ANX-DOS builds on foundational work of behavioral inhibition paradigms (e.g., Kagan, Snidman, & Arcus, 1998; Rubin, 1989) but diverges from this approach by moving away from event-based coding (e.g., latency to touch) to capturing qualitative features of behavior that define the phenotype of anxious behavior in young children in a clinically and developmentally salient manner (see Chapter 1 in volume 1). In its early stages of validation, the ANX-DOS has demonstrated specificity in relation to neural substrates of anxiety (e.g., relation to attention bias to threat) not detectable based on parental report of anxiety, as well as incremental utility for clinical differentiation (Briggs-Gowan et al., 2014; Mian et al., 2014).

Thus, standardized clinical observations show promise for enhancing accurate identification of common emotional and behavioral problems of early childhood. This area is only beginning to be mined. One important next step is elucidation of where parent report and standardized observation converge and diverge in identification of clinically salient patterns and the correlates and prognostic differences between these groups (Shernoff, Hill, Danis, Leventhal, & Wakschlag, 2014). That is, which children are identified by both parent report and observation, which identified by only one source, and what does this mean for clinical progression? For example, one potential utility of the DB-DOS is its capacity to efficiently provide information about the cross-contextual pervasiveness of the child's disruptive behavior. Our findings suggest that behaviors displayed in the examiner context of the DB-DOS may serve as a proxy for patterns of behavior in real-world settings with nonparental adults (De Los Reyes, Henry, Tolan, & Wakschlag, 2009). Clinical observation may also be a particularly important informant when parental biases obscure accurate reporting if, for example, parental history of psychopathology colors their judgment of whether their children's behavior is problematic. Finally, with the recent advent of developmentally sensitive methods of all types, the field is now positioned to more rigorously test specific ways observation may be most useful. For example, we theorize that direct observation may be of greatest utility for children around the midpoint of the normal–abnormal dimensional spectrum. That is, it may be more straightforward to rely solely on informant reports for children at the extremes (i.e., with very well-regulated or highly dysregulated behavior). In contrast, milder, more intermittent or less pervasive types of problems are challenging for clinical decision making during this age period, when biases tend toward "watch and wait" with the assumption that these are transient normative misbehaviors. This conservative approach may constrain early identification in prodromal phases of psychopathology. For example, observed dysregulation on the DB-DOS differentiates preschoolers with a family history of bipolar disorder from those without, perhaps capturing children in the prodromal phase of risk (Tseng et al., 2015). As the field moves increasingly toward clinical applications of developmentally sensitive dimensional approaches (Wakschlag, Estabrook et al., 2014), a more robust knowledge base will importantly advance the science of early identification.

CROSS-CUTTING DEVELOPMENTAL DOMAIN-BASED APPROACH TO PRESCHOOL PSYCHOPATHOLOGY

Despite these important advances in developmentally based assessment of common emotional and behavioral problems, a framework for conceptualizing psychopathology in young children is still needed. In general, the current taxonomy does not include developmental terminology, age, and setting specifications, details about developmental variations in symptom manifestation, or information about how to consider deviations from normative developmental patterns. For example, we do not have guidelines for determining when normative variation and misbehaviors achieve clinical significance for behaviors such as tantrums and aggression for disruptive behavior, short attention span for ADHD, inhibited behavior toward others or fearfulness for anxiety syndromes, or irritable mood, feelings of guilt, or reduced interest or pleasure for depression. To better distinguish normative from problematic behaviors and identify when behaviors interfere with functioning and mastery of essential developmental tasks, we next delineate a developmental domain framework designed to advance clinical operationalization of the normal–abnormal spectrum of behavior in early childhood. This framework is consistent with both long-standing conceptualization of developmental psychopathology (Cicchetti, 1984; Cicchetti & Toth, 2009; Sroufe, 1979; Sroufe & Rutter 1984) as well as more recent neurodevelopmental approaches designed to promote a

brain-based clinical classification system (e.g., RDoC; Cuthbert & Insel, 2013; Franklin et al., 2015; Insel et al., 2010; Sanislow et al., 2010; Wakschlag et al., 2010) that consider psychopathology from a dimensional and transdiagnostic perspective of the full range of behaviors relevant to typical and atypical development.

We propose a set of domains to delineate psychopathology as deviations from normative developmental processes. These core developmental domains were selected with the following criteria in mind: (1) each domain reflects an area in which developmental acquisition of a particular capacity is a central task of the preschool period; (2) both high and low ends of the domain reflect possibly atypical or problematic levels of behavior; and (3) domains are broad, include multiple related facets (e.g., social, emotional, cognitive), and cross-cutting. Importantly, domains reflect dynamic, interrelated processes that are impacted by a range of factors, such as temperament, context, parental behavior, and culture. Further, although these domains reflect developmental tasks that are essential to acquire during the preschool period, these capacities are also necessary for subsequent development. Therefore, difficulty in these domains may reflect the presence of psychopathology during the preschool age or predict future psychopathology in subsequent developmental periods. Although we view the use of these domains as an important step toward enhancing the developmental sensitivity of preschool psychopathology research, this framework is intended as a heuristic rather than an exhaustive characterization. Specifically, the domains and related content (i.e., normative mis/behavior, clinical indicators, and impairment) proposed will require expansion and pruning over time as researchers further characterize the spectrum of behavior relevant to psychopathology. Although here articulated specifically for early childhood, this approach could be meaningfully applied across developmental periods (Carter et al., 2013; Gray & Wakschlag, in press).

Table 5.2 includes each domain, the key developmental tasks associated with the domain during the preschool period, normative variation in mis/behavior, and examples of atypical behavior at the extreme ends of the domain (i.e., clinical indicators). In addition, we propose examples of impairment associated with deficits across the domains. The four domains include: emotion regulation, self-control, social engagement, and internalization of rules and standards. These domains are proposed as a framework for capturing the full variation in behavior in a developmentally sensitive, comprehensive manner and contributing to the conceptual delineation of normal–abnormal boundaries. Of course empirical data are needed to verify or refine these boundaries via improved precision of identification and prediction, as well as targeted interventions at the early phase of the clinical pathway.

In this section, we explicate the salience of the normal–abnormal spectrum within each cross-cutting domain by linking it to a particular form of psychopathology (or syndromes or set of syndromes) as an exemplar. To illustrate each domain, we matched forms of psychopathology to a key corresponding developmental domain in which disruptions in acquisition of the developmental tasks in that domain is particularly relevant for phenotypic expression: (1) emotion regulation and depression; (2) self-control and ADHD; (3) social engagement and anxiety; and (4) internalization of rules and standards and DBDs. For each domain, we also highlight how extremes at both ends of expression may be atypical (e.g., under- and overinternalization of rules and standards for disruptive and depressive syndromes, respectively) and briefly mention the ways each domain applies to syndromes other than the exemplar in each category. Although for heuristic purposes we discuss these as distinct domains, they are clearly overlapping (e.g., emotion regulation has a significant self-control component).

Emotion Regulation: Typical and Atypical Patterns Exemplified in Depression

Emotion regulation reflects one of the essential developmental tasks of the preschool period that is relevant to the development of depression (Luby & Belden, 2006) and, as we describe in this chapter, other manifestations of psychopathology (Cicchetti, Ackerman & Izard, 1995; Cole & Deater-Deckard, 2009; Keenan, 2000). The development of basic emotions such as sadness, joy, and frustration in infancy and early childhood (Izard, Hembree, & Huebner, 1987; Lewis, Alessandri, & Sullivan, 1990; Tronick, 1989), as well as more complex emotions such as guilt and shame in the preschool period (Barrett, Zahn-Waxler & Cole, 1993; Eisenberg, 2000; Kochanska, Gross, Lin & Nichols, 2002; Parisette-Sparks, Bufferd, & Klein, in press; Thompson, Goodvin, & Meyer, 2006) contributes to the need for young children to express and regulate these emotional experiences. In particular, during this time period, preschool-age children build on regulation skills (ideally) acquired since birth that enable them to implement a range of strategies to evaluate and modulate (i.e., reduce, maintain, enhance) emotional arousal to pursue goals, coordinate and maintain social connection, adapt to stressful experiences, and preserve well-being (Campos,

TABLE 5.2 Illustrating the Normal–Abnormal Spectrum: Cross-Cutting Developmental Domains and Variation in Behavior in Preschool Psychopathology

Domain[1]	Key developmental task during preschool period	Normative variation in behavior	Atypical behavior at the extreme ends of the domain (examples)	Evidence of Impairment Across Domains
Emotion regulation	• Distress tolerance • Regulated emotional expression • Achieving emotional equilibrium • Use of emotion language • Flexibility: use of varied, increasingly complex strategies	• Mild temper tantrums when frustrated • Brief clinging to a caregiver when confronted with novelty • Use of temporary distraction when distressed • Some resistance to caregiver soothing • Mild sadness in response to an upsetting event • Intermittent boredom • Concern about parents' and own, well-being, safety, etc.	• Unpredictable, prolonged, or dysregulated temper tantrums • Frequent irritable mood • Persistent difficulty managing transitions • Persistently difficult to soothe • Separation distress does not abate with familiarity • Intrusive, unpleasant worry • Frequent withdrawal from distressing situations • Difficulty showing joy and deriving pleasure from activities	
Self-control	• Inhibitory control • Delay of gratification • Use of language/problem solving to negotiate • Goal-oriented, planful behavior • Executive functioning	• Reactive aggression to peer conflict • Some difficulty persisting on challenging tasks • Mild difficulty waiting • Impulsive in high motivation contexts	• Aggression as a predominant response to frustration • Disorganized, poorly modulated activity • Poor persistence • Limited ability to wait for desired object/event	• Child experiences distress • Disrupts family routines • Limits family activities • Limits peer activities (e.g., play dates, birthday parties) • Disrupts relationship between parents, parents and children, and siblings • Difficulty attending school/daycare • Poor school performance
Social engagement	• Reciprocal peer relationships • Social communication • Empathy	• Refusal to share • Mild selfishness when goals conflict with peers' • Intermittent solitary play • Difficulty approaching new children	• Provokes others/nasty • Disregards others feelings • Difficulty developing and maintaining friendships • Difficulty with social reciprocity/exchange • Persistent social reticence • Overly focused on internal experience	
Internalization of rules and standards	• Conscience development • Achieving autonomy: compliance balance	• Situational concern with fairness • Limit testing (e.g., breaks rules to push the limits) • Assertive noncompliance • Follows most authority figures' rules	• Blatant disregard • Proactive aggression • Intransigent defiance • Reflexive no • Overly compliant and unassertive • Rigid rule following	

[1] All domains reflect dynamic, interrelated processes that are impacted by temperament, context, parental behavior, culture, and other factors.

Mumme, Kermoian & Campos, 1994; Cole et al., 1994; Cole, Martin & Dennis, 2004; Kopp, 1982; Thompson, 1994). These strategies are impacted by cognitive, language, and social development, and include both individual (e.g., self-soothing, distraction) as well as socially mediated (e.g., parental soothing; peer request to play) attempts to manage internal and external affective experiences. In addition, emotion expressions and poor regulation may impact others' behavior to improve regulation (e.g., child sadness can elicit caregiver warmth; child guilt can elicit peer reassurance) (Cole et al., 2004). Further, emotion regulation is also moderated by social skills. For example, Rubin and colleagues (1995) found that preschool-age children who showed both poor regulation and worse social interaction skills were rated higher on internalizing problems than children with better regulation and interaction skills; poor emotion regulation also predicts later social incompetence (Denham et al., 2003).

In typical development, adaptive emotion regulation includes features such as distress tolerance, regulated emotional expression, achieving emotional equilibrium, use of emotion language, and flexible use of varied, increasingly

complex strategies. Although we know that poor regulation is associated with psychopathology in children (Cicchetti et al., 1995; Cole, Zahn-Waxler, Fox, Usher & Welsh, 1996; Lengua, 2002), less attention has been devoted to understanding problematic emotion regulation and depression (and other conditions) in young children.

In young children prone to increased sadness, irritability, shame, and guilt, and decreased joy and pleasure, deficits in the regulation of these experiences can increase risk for or accompany depression. These processes are consistent with temperament models of risk for depression that suggest that high levels of negative affect and low levels of positive affect and difficulty regulating these emotional states confer risk for depression (e.g., Clark & Watson, 1991; Lonigan, Phillips & Hooe, 2003). First, these children may be prone to displaying insufficient (e.g., low pleasure, proneness to boredom) or excessive (e.g., sadness, irritability) levels of these emotions. For example, preschool-age children identified as inexpressive during a negative mood induction were rated as having more depressed (and anxious) symptoms in 1st grade compared to the modulated and highly expressive groups of children (Cole et al., 1996). In laboratory observations, children with a depression diagnosis showed more dysphoria compared to children who did not meet criteria for a depression diagnosis (Dougherty et al., 2011); these children also displayed significantly lower levels of exuberance (e.g., pleasure, joy). These associations have been found to persist: children who displayed low laboratory-observed positive emotionality during the preschool period also displayed more helplessness and less positive information processing at age 7 (Hayden, Klein, Durbin, & Olino, 2006). Further, children with parental history of depression have been found to show more shame and guilt in a laboratory task than other children (Parisette-Sparks et al., in press), and in a study using children's narratives and parental report, shame and guilt were associated with depression (Luby, Belden, Sullivan, Hayen, McCadney, & Spitznagel, 2009). Finally, children who demonstrate excessive irritability are also at risk for depression (Dougherty, Smith, et al., 2013; Wiggins, Mitchell, Stringaris, & Leibenluft, 2014).

In addition, preschool aged children are tasked with the need to use increasingly flexible, complex strategies to regulate their emotional experience. For example, a typically developing child may initially require caregiver support to ameliorate sadness, but over time, develop increasing abilities to self-soothe, distract themselves, identify and express emotional states to solicit support appropriately, and engage in constructive problem-focused coping. When considering risk for depression, these strategies can serve to reduce the intensity and duration of negative emotional states (e.g., sadness, irritability, guilt, boredom) as well as increase and sustain positive emotional states (e.g., pleasure, enthusiasm, interest in activities) (Luby et al., 2004; 2006).

Luby and Belden (2006) propose a model of emotion reactivity curves to parse each feature of the process: emotion stimulus baseline, emotion arousal onset, emotion peak, emotional arousal offset, and return to baseline. They describe the various points in the curves where depressive responses may deviate from the optimal curve in which a youth can respond to an emotionally salient event in a reasonable amount of time, experience the peak of the emotion at an appropriate level of intensity, and return to a euthymic emotional baseline. This model has not been tested to our knowledge, but is consistent with empirical evidence that school-age children who reported difficulty regulating feelings of sadness were more likely to report depressive symptoms compared to other children with less difficulty (Zeman, Shipman, & Suveg, 2002), as well as related evidence that problematic regulation in preschool age reflects frequent (at least daily) and prolonged episodes of temper loss (Wakschlag, Choi, et al., 2012). Over time, children's difficulty flexibly applying a range of regulatory strategies can increase risk for depression. If, for example, a child primarily withdraws from distressing situations (e.g., sadness after exclusion from a game with peers; guilt after breaking a sibling's toy) rather than self-soothing and solving the problems associated with the situations, then this behavior will likely recur via negative reinforcement (i.e., withdrawal from the aversive situation relieves distress) and he or she may have difficulty learning effective coping strategies, gaining social skills, deriving pleasure from activities, and improving mood to reduce risk for depression. However, as discussed previously, there is a pressing need to define the parameters of the frequency, intensity, severity, and context of normative emotional experiences and regulatory strategies employed to more precisely understand the level at which young children's emotional expressions are clinically concerning (Cole et al., 2008; Luby & Belden, 2006). This work would chart the range of normative to problematic emotional development to improve the assessment of individual children's difficulties and risk for depression.

Difficulties with emotion regulation also apply to ADHD, anxiety, and DBDs.

ADHD

The interface of cognitive and emotional control have been suggested as contributing to ADHD phenotypes,

particularly in young children with high negative emotionality amplifying poor cognitive control (Martel, 2009). In fact, joint cognitive and emotion regulation deficits have been theorized to define the phenotype of chronic, preschool onset ADHD (Sonuga-Barke, Auerbach, Campbell, Daley, & Thompson, 2005).

Anxiety

Young children with anxiety have difficulty with emotion regulation. They tend to react negatively to stressful situations (e.g., excessive crying, anger, and distress when separated from caregiver; inhibition, avoidance, and withdrawal in distressing situations; frequent somatic complaints like stomach aches and headaches; difficulty being soothed) (e.g., Carthy, Horesh, Apter & Gross, 2010; Suveg & Zeman, 2004). Indeed, research suggests difficulties in emotion regulation represent a core feature of anxiety in early childhood (e.g., Henderson, 2010; Suveg & Zeman, 2004; Suveg, Morelen, Brewer & Thomassin, 2010). Moreover, high levels of temperamental reactivity in young children, such as behavioral inhibition, have been found to be associated with emotion dysregulation, particularly emotional hyper-reactivity and maladaptive regulatory behaviors (e.g., Carthy et al., 2010; Henderson, 2010; Suveg et al., 2010). More specifically, high temperamental reactivity may interfere with a child's ability to distinguish different emotions contributing to a poor understanding of one's own emotional experience, which is considered a critical component of adaptive emotional functioning (Baker, Holloway, Thomas, Thomas, & Owens, 2004). Additionally, high temperamental reactivity may negatively impact a child's ability to generate and engage in adaptive regulation strategies (e.g., reappraisal) to modulate his or her emotional experience (Carthy et al., 2010; Suveg et al., 2010). Quite plausibly, these difficulties in regulating emotion may also negatively impact peer interactions and contribute to reticence to engage with peers, as described above. Thus, in addition to the social engagement processes described below, emotion regulation may also mediate the association between high temperamental reactivity (e.g., behavioral inhibition) and anxiety in early childhood.

DBDs

Problems in emotion regulation are a defining feature of ODD including both tantrums and irritable mood (Wakschlag, Estabrook, et al., 2014). These include problems in modulation of angry mood, rapid escalation, ease of elicitation and difficulty recovering (Wakschlag, Choi, et al., 2012). In a very intriguing analysis of the features of tantrums that differentiate disruptive, depressed and typical children, Belden and colleagues (Belden, Thompson, & Luby, 2008) found that DBDs are more likely to have dysregulated tantrums that included violence and occurred with nonparental adults relative to children whereas the tantrums of depressed children were more likely to include self-harm. It has also been shown that chronic irritability at preschool age predicts ODD (as well as depression) at early school age after controlling for baseline disorders (Dougherty, Smith, et al., 2013). In fact, the overlapping feature of irritability across depression and disruptive behavior led to the proposal for *DSM* 5 of a disruptive mood dysregulation disorder (DMDD), which combines elements of both. We and others have recently demonstrated its validity at preschool age (Copeland, Angold, Costello, & Egger, 2013; Dougherty et al., 2014).

Self-control: Typical and Atypical Patterns Exemplified in ADHD

Self-control reflects the capacity to self-modulate and monitor behavior in response to shifting environmental cues and conditions even in the absence of external monitors (Vaughn, Kopp, & Krakow, 1984). We focus here particularly on a central aspect of self-control, i.e., cognitive control, including the capacity for planfulness, control of impulses, and delay of gratification (Calkins, 2007), a developmental domain of particular salience to ADHD. Alternately characterized by developmental and cognitive neuroscience literatures as effortful control and executive function respectively, these parallel cognitive control constructs refer to the capacity for control and regulation of automatic or prepotent responses including inhibitory control and working memory (Zhou, Chen, & Main, 2012). Cognitive control processes enable effective goal-directed behavior by directing attention toward contextually relevant, and away from contextually irrelevant, information, as well as the ability to modify behavior in response to situational contingencies. Infants can engage in sustained and selective attention by the age of 9 months (Ruff & Rothbart, 1996). Maturation of neural systems that subserve attention across early childhood, particularly the prefrontal cortex, enables the increased voluntary control of attention (e.g., orienting, redirecting and maintaining attention, which comes online toward the end of the first to second year of life (Calkins, 2007). This executive higher level control enables the young child to engage in goal-oriented behavior including prioritizing, resolving conflicting goals, and planning and generating behavioral sequences to achieve them (Ruff & Rothbart,

1996). More sophisticated capacity to regulate attention in high motivation contexts begins to emerge at the age of 2, develops rapidly, and is present at stable form by the end of the preschool years (Derryberry & Rothbart, 1997; Kochanska, Coy, & Murray, 2001). Developmental chains have been identified: for example, greater focused attention at 9 months predicts greater effortful control at 22 months, which in turn predicts better self-control at 33 months (Kochanska, Murray, & Harlan, 2000). When impulsive, in the moment behaviors are reigned in, the capacity of the child to attain future- and socially (rather than solely self-) oriented goals is expanded, including capacity for long-term gain with short term delay, and social rewards of conforming to expectations and deferring to others (Leerkes, Paradise, O'Brien, Calkins & Lange, 2008). The development and consolidation of inhibitory control across early childhood and delays in its acquisition is of particular salience to emergent ADHD during this period as inhibitory control involves the capacity to deliberately and effortfully inhibit prepotent behavioral responses and flexibly shift and focus attention (Ruff & Rothbart, 1996). When such responses cannot be inhibited despite threat of punishment or loss of reward, this is considered a deficit in inhibitory control (von Stauffenberg & Campbell, 2007).

From a developmental perspective, the key features of ADHD are all defined by deficits in self-control: inattentiveness characterized by problems organizing and persisting, overactivity as poorly modulated movement, and impulsiveness as acting without reflecting (Taylor & Sonuga-Barke, 2008). At preschool age, self-control deficits manifest as problems in inhibitory control are associated linearly with ADHD symptoms (Sonuga-Barke, Dalen, Daley, & Remington, 2002).

Important early work by Campbell demonstrated that early problems in self-control indicative of ADHD are evident as early as the toddler period (Campbell, 2002). Direct observation of hard-to-manage 2–3-year-old boys across a range of contexts revealed that they had frequent activity changes (often <2 minutes), distractibility, and impulsive responding (Campbell, Pierce, March, Ewing & Szumowski, 1994). Interestingly, the hard-to-manage children did not differ in absolute level of activity—rather it was the *quality* of this activity that differed (i.e., they were more often out of their seats and off-task); 30% of these children met criteria for ADHD at age 6, and this group had a high risk of showing persistent ADHD through adolescence (Pierce, Ewing, & Campbell, 1999). In addition, observed toddler attentional disengagement during free play, a behavioral indicator of unoccupied wandering during unstructured activities, predicted impulsivity at age 8 (Olson, Bates, Sandy, & Schilling, 2002). Deficits in self-control as defined by impaired inhibitory control have been demonstrated in multiple studies of preschool ADHD, and such deficits at preschool age also predict ADHD persistence (von Stauffenberg & Campbell, 2007). There is also some evidence that taking preschool-age inhibitory capacity and symptoms jointly into account enhances prediction of school age ADHD (von Stauffenberg & Campbell, 2007). Low levels of self-control at preschool-age also have long-lasting impact on functioning and mental health through adulthood (Moffitt et al., 2011). Early findings from interventions designed to promote self-control by facilitating brain growth and self-regulatory capacities during early childhood via cognitive enrichment games and training in metacognitive strategies have shown promising results, including sustained improvements in executive function and reduction in hyperactive/impulsive symptoms over a 1-year period (Halperin, Bedard, & Curchack-Lichtin, 2012).

The validity of preschool ADHD in broad terms is well established (Egger, Kondo et al., 2006). One of the primary challenges to differentiation of preschool onset ADHD from transient neurodevelopmental lags or normative variation is that *DSM* symptoms do a poor job of capturing developmental expression of self-control within this age period (Campbell, Halperin, & Sonuga-Barke, 2014). This issue may contribute to high rates of false positives reported for ADHD (Healey, Miller, Castelli, Marks & Halperin, 2008). Although preschool ADHD shows modest stability (Lahey, Pelham, Loney, Lee & Willcutt, 2005; Willoughby, Pek & Greenberg, 2012), preschoolers identified with ADHD are approximately as likely to remit as to persist (Sonuga-Barke et al., 2005; Willoughby et al., 2012). High rates of intraindividual variability are also evident early in development: e.g., 60.4% of boys who often fidgeted at 29 months were not often doing so at 17 months, and similar intraindividual variation is seen in reverse (from 17 to 29 months) (Baillargeon et al., 2007). Although many factors shape individual differences in course (Campbell et al., 2014), one possible explanatory factor for the high level of remittance is that the current ADHD nosology fails to distinguish normative variation and transient delays in the acquisition of self-control from the onset of atypical patterns that mark the onset of a clinical pathway. Intriguingly, for differentiation of normative variation and clinical indicators, in the Campbell et al. study mentioned above, a subgroup of the early hard-to-manage children were identified that showed catch-up in these areas over time so that their behavioral profiles more resembled those of the healthy controls

by age 6–9. This neurodevelopmental lag is consistent with more recent findings from neuroimaging studies at older ages, indicating that children with ADHD exhibit delayed trajectories of cortical development particularly in prefrontal regions important for control processes, and that remittance is linked to alignment with typical cortical growth trajectories (Shaw et al., 2007). Improved cognitive control across the preschool period is associated with diminution of problems over time for children who were hyperactive/impulsive at age 3, whereas poorer cognitive control is associated with increased severity of problems over time (Rajendran et al., 2013). Normative variation is substantial in the timing of skill acquisition; thus, defining the features of poor self-control that demarcate atypicality versus transient delays is important for sharpening precision of identification (Sonuga-Barke & Halperin, 2010). Enhancing accuracy of identification of early ADHD is of particular importance given concerns about escalating rates of prescribing psychotherapeutic medication in preschoolers (Zito et al., 2000).

This is supported by developmental analysis of *DSM* ADHD symptoms. Many of the hyperactive-impulsive symptoms are plagued by developmental *imprecision* because they do not specify the developmentally expectable levels of self-control and how deviations from these are defined; in addition, many of the inattentive symptoms are developmentally *inappropriate* because they focus on aspects of self-control that are not developmentally relevant at preschool age (Chacko et al., 2009). Developmental imprecision may explain the fact that preschool hyperactivity symptoms are common and occur in ~50% of preschool children (Egger, Kondo, et al., 2006; Egger & Angold, 2006; Smidts & Osterlann 2007), along the lines of the normative misbehaviors we have psychometrically identified for DBDs. For example, symptoms such as difficulty waiting turn, often fidgeting, often runs and climbs are all defining features of early childhood behavior reflecting the emergent self-control skills of this age period. In fact, several studies have shown that as many as 47% of preschoolers often interrupt and up to 72% are on the go (Egger, Kondo, et al., 2006; Pavuluri, Luk, & McGee, 1999; Smidts & Osterlann, 2007). In contrast, the emphasis of the inattention symptoms on sophisticated capacity for self-control expectable at older ages with particular emphasis on the demands of a school setting (e.g., often has trouble organizing tasks and activities, fails to finish schoolwork, chores or work, makes careless mistakes, avoids tasks requiring sustained mental effort) is out of step with the developmental capacities of preschool-age children (Chacko et al., 2009; Egger, Kondo, et al., 2006). Thus, it is not surprising that inattentive symptoms are less common at this age (Smidts & Osterlann, 2007).

Egger and colleagues have suggested that the use of psychometrically derived frequency cut-points specific to this age group may reduce over-pathologizing of variation in self-control as ADHD. They have also noted that while over-identification is likely at the symptom level in this age group (i.e., 1–2 symptoms are developmentally normative in 36.7% of preschoolers in the PAPA sample), having multiple ADHD symptoms is not normative (i.e., occurs <6% of preschoolers). While this addresses over-identification concerns to some extent, we postulate that developmental specification of ADHD symptoms will increase accuracy of identification, particularly as dimensional approaches gain more traction and identifying a spectrum of risk (rather than distinguishing extreme cases) becomes key. When behavioral indicators are defined in terms of age appropriate manifestations, more closely tied to developmental capacities for self-control, and empirically derived frequency parameters are available, this will bring much needed clarity to pediatric clinical decision making. This would mean characterizing ADHD symptoms at this age as problems of dyscontrol in reference to developmentally expectable tasks and capabilities in early childhood, e.g., difficulty controlling attention to relevant rules in 1:1 play activities, cannot control talking in situations where remaining quiet is expected (e.g., when being read to), and continues to interrupt during structured, developmentally engaging activities (Chacko et al., 2009).

Lack of attention to developmental considerations of pervasiveness and impairment in ADHD also makes it difficult to know when levels of self-control are consistent with clinical problems. For example, defining pervasiveness as occurring in two or more settings (with particular emphasis on the school setting) may constrain accurate identification of ADHD in early childhood because the social ecologies of young children differ from that of older children (Willoughby et al., 2012). In particular, not all young children attend a structured school setting, and may not have a second regular context in which the nature of the context would make these behaviors evident except in extreme cases. This may, at least partially, explain why many hyperactive/inattentive preschoolers do not demonstrate cross-situational impairment (Healey et al., 2008). Evidence from developmental studies indicates that preschoolers' attentional control varies widely depending on the demand characteristics of activities (Ruff, Capozzoli, & Weissberg, 1998), suggesting that cross-contextual

variation is important to take into account for determining clinical salience (Chacko et al., 2009). Further, early cross-contextual problems of hyperactivity and impulsiveness have been shown to mark a more persistent ADHD pattern (Campbell et al., 2014). On the PAPA, this issue is addressed by requiring that problems be present in at least two activities and that the child be unable to control the behaviors and not modulate them by admonition (Egger et al., 2006).

Halperin and colleagues suggested greater consideration of impairment as a method of differentiating normative variation in self-control from clinically salient problems reflective of preschool ADHD (Healey et al., 2008). They found that consideration of developmentally specified ADHD impairment criteria reduced the number of preschoolers identified as having ADHD by 46–77%. These findings are intriguing not only for ADHD but also for preschool psychopathology research more broadly, as impairment has received inadequate attention as a component of developmental specification.

Difficulties with self-control also apply to depression, anxiety, and DBDs.

Depression

Self-control involves tasks such as the use of goal-oriented behavior, attending to the full range of emotional experiences, and persistence in activities. Children with difficulty mastering these areas of development may display attention deficits in that they are overly attentive to the negative aspects of experiences (e.g., sadness, irritability, guilt) and ignore or minimize the positive aspects (e.g., low pleasure, low interest). In addition, children with poor self-control may easily withdraw from challenging situations. These self-control difficulties increase the likelihood of the development of depressive symptoms by reducing reinforcing opportunities for sustained, enjoyable activities that enhance self-worth and self-efficacy.

Anxiety

Preschool anxiety may also be associated with difficulties in self-control, which may manifest in anxious young children as deficits in attention shifting, overcontrol, and rigidity/inflexibility (Carver, 2005). Growing evidence indicates that children with a shy, inhibited temperament exhibit heightened attention biases to threat. As such, these children may display difficulties with flexibly shifting their attention from emotionally distressing stimuli, increasing risk for anxious symptoms (Briggs-Gowan et al., 2014; Pérez-Edgar et al., 2010, 2011). Similarly, high levels of inhibitory control (i.e., a child's ability to override a dominant response for a more appropriate response) have been shown to contribute to a shy, inhibited child's risk for anxiety, despite being an adaptive or protective factor for other young children at risk for conduct problems (Volbrecht & Goldsmith, 2010; White, McDermott, Degnan, Henderson & Fox, 2011). For instance, White and colleagues (2011) found that high levels of inhibitory control assessed at 48 months moderated the relationship between BI assessed at 24 months and anxiety during preschool age. Therefore, in conjunction with a heighted fear circuitry system, high inhibitory control may lead to overcontrolled, inflexible behaviors (e.g., excessive concern about making mistakes; poor persistence when faced with challenging tasks; avoidance of social situations; difficulty with transitions) in shy, inhibited children, thus elevating risk for anxiety (Volbrecht & Goldsmith, 2010; White et al., 2011).

DBDs

Preschoolers with DBDs have decrements in inhibitory control independent of ADHD (Shoemaker, Bunte, Wiebe, Espy & Dekovic, 2012). This is particularly true in motivational contexts (Shoemaker et al., 2012). Kochanska and colleagues have shown an interesting interaction effect of children's guilt (see internalization section below) and effortful control in predicting DBD trajectories (Kochanska, Barry, Jimenez, Hollatz & Woodard, 2009). For children observed to be guilt-prone across the toddler and preschool period (such as those with anxious or depressive tendencies), effortful control was unrelated to later DBDs. In contrast, toddlers observed to be low on guilt following transgression were protected from later DBDs if they had high effortful control (Kochanska et al., 2009). This interface across developmental domains highlights the complexity and multidetermined nature of early psychopathology trajectories (Cicchetti, 1984). They suggest that guilt may inhibit disruptive, rule-incompatible behavior via triggering of negative arousal for some children and promotes affective control to reduce this discomfort. Children who do not experience an aversive response to others' displeasure may be protected against later disruptive behavior via cognitive control that promotes restraint (Kochanska et al., 2009).

Social Engagement: Typical and Atypical Patterns Exemplified in Anxiety

Many development theorists argue that a key etiological factor contributing to the development of anxiety

in children is a shy or inhibited temperament style, which has been variously referred to as behavioral inhibition (BI), shyness, social reticence, and dysregulated fear (e.g., Kagan, 1997; Rapee & Spence, 2004; Rapee, Schniering, & Hudson, 2009). This temperamental style is characterized by long latencies to approach or communicate with unfamiliar people, onlooking or hovering behavior, the tendency to stay within close proximity of caregivers, and exhibiting signs of distress and withdrawal in reaction to novel contexts or challenging situations (Kagan, Reznick, Clarke, Snidman & Garcia-Coll, 1984; Rubin, Burgess, Coplan, 2002; Rubin, Burgess, Kennedy & Steward, 2003). Thus, differentiating a shy, inhibited temperament from anxiety disorders/symptoms is often challenging, as few studies have tested explanatory models of the nature of the relation between temperament and anxiety (Pagura, Cox & Enns, 2009) and these constructs share a number of similarities (Degnan, Almas, & Fox, 2010). For instance, several of the core features of BI (e.g., fearful affect, vigilance, social withdrawal) are also characteristic of several types of anxiety disorders (Degnan et al., 2010; Rapee & Coplan, 2010); however, only a subset of shy, inhibited children go on to develop an anxiety disorder (Fox, Henderson, Marshall, Nichols & Ghera, 2005). Nonetheless, research has consistently found that preschoolers' shy, inhibited, and withdrawn behaviors in response to social situations can indeed manifest as impairing anxious behaviors in early childhood (Biederman et al., 1990; Bosquet & Egeland, 2006; Coplan, Wilson, Frohlick & Zelenski, 2006; Henderson, Marshall, Fox & Rubin, 2004; Hirshfeld et al., 1992) and adolescence (Chronis-Tuscano et al., 2009; Schwartz, Snidman & Kagan, 1999).

The preschool years represent a period of dramatic advances in social engagement (i.e., child's involvement with peers), which is associated with age-related increases in social communication skills and empathy. During this stage, children are expected to transition from engaging in solitary or parallel play to more complex, interactive group play (Rubin, Coplan, Chen, Buskirk & Wojslawowicz, 2005). As such, the preschool years are often considered a sensitive period for the development of social communication skills required to initiate and sustain interactive and reciprocal peer relationships (Martin, Fabes, Hanish & Hollenstein, 2005). Examples of typical social communication skills during the preschool period include using verbal (e.g., using words to send a clear, direct message) and nonverbal (e.g., eye gaze, bodily gestures, facial expressions) behaviors to share ideas, problem-solve, and express one's needs; engaging in prosocial behavior (e.g., sharing, giving, helping); and demonstrating agreeableness (e.g., acquiescing to other's requests) and turn-taking (e.g., reciprocal role playing in fantasy play) (Rubin, Bukowski, & Parker, 2006). Additionally, in typical development, preschool children continue to expand their theory of mind and comprehension of others' emotions, desires, intentions, and beliefs that impact behavior (e.g., preschool-age children can comfort a peer who fell and hurt himself on the playground and can consider fairness in peer relationships) (Rubin et al., 2006). The accomplishment of these typical developmental tasks has implications for mental health, as the ability to flexibly navigate these social-emotional tasks can set the stage for healthy development, whereas deficits in these skills may place these children at risk for psychopathology. Below we describe how a shy, inhibited temperament or vulnerability to anxiety in early childhood might be associated with particular patterns of social engagement.

Although there is significant variation in expectable levels of social engagement in early childhood (e.g., behaviors such as occasional solitary play, initial hesitancy in approaching new peers, and refusal to share toys are to be expected), when these asocial activities predominate, they may reflect clinically significant anxiety that impairs expectable development of social engagement in this age period. As such, an inhibited, shy, and socially wary temperament style may become problematic and interfere with the development of adequate social communication skills and empathy necessary to initiate and maintain peer relationships, which in turn may contribute to clinically significant anxious symptoms (Rubin et al., 2005). For instance, children who display reticent behavior (e.g., watching other children from afar, remaining unoccupied during free play), rarely initiate contact, or retreat from social overtures from peers (e.g., demonstrate limited social reciprocity and exchanges) have fewer opportunities to practice and develop adaptive social communication skills and empathy. As such, these children may increasingly avoid age appropriate activities (e.g., play dates, birthday parties, playing with new peers at the playground) that they find anxiety-provoking and may be less appealing as a playmate to his or her peers (Ollendick & Hirshfeld-Becker, 2002). In fact, several studies have linked inhibited, shy temperament in preschoolers to greater social reticence and withdrawal in social settings and poorer social competence with peers (e.g., Bohlin, Hagekull, & Anderson, 2005; Coplan & Prakash, 2003; Henderson et al., 2004; LeMare & Rubin, 1987; Rubin et al., 2002). However, there is still much work to be done in the study of the relationship between social engagement and anxiety in

preschoolers to better identify those behaviors that are indicative of clinical concern, as well as those behaviors or factors that might facilitate new opportunities for social mastery (e.g., parents who use supportive strategies, such as encouragement, warmth, and support, to help their child explore and participate in social activities; having a best friend).

Difficulties with social engagement also apply to depression, ADHD, and DBDs.

Depression

Building on social development in infancy and toddlerhood that enables children to develop social skills, generate social expectations of others (typically based on interactions with caregivers), and use cues to interpret emotions related to the self and others (Baldwin & Moses, 1996; Tronick, 1989), preschoolers develop reciprocal peer relationships, improve social communication, and experience empathy for others. There are several ways these normative social processes may become problematic during the preschool period and confer risk for depression. Related to difficulties attending to the full range of emotions, when children are overly focused on their internal experiences and distress, their ability to meet others' needs, empathize, and engage in social reciprocity is compromised. Such children may, for example, be overly focused on feelings of sadness, loneliness, worthlessness, helplessness, or guilt. Children with these limitations are less appealing as playmates, which can reduce opportunities to develop social skills. In addition, such experiences may increase social withdrawal, further limiting social opportunities and worsening children's self-esteem (Hymel, Rubin, Rowden & Lemare, 1990; Rubin & Mills, 1988). Similar problematic social processes can occur in children prone to displaying excessive irritability and having difficulty maintaining friendships (Coplan & Armer, 2007; Rubin & Mills, 1988; Rubin et al., 2006).

ADHD

Social engagement of children with ADHD is also impaired, due in part to their difficulties with inattention and inhibiting responses in interactional contexts. Children with ADHD-related behavior have been found to be intrusive, over controlling and bossy, easily frustrated, transition frequently in play, have difficulty focusing one-on-one and in groups of peers, and understand social norms but cannot always modulate their behavior to conform to appropriate social standards (Alessandri, 1992; Barkley, 1997; Carpenter, Loo, Yang, Dang & Smalley, 2009; DuPaul et al., 2001; Guevremont & Dumas, 1994). More specifically, difficulties in attention may preclude a child from learning how to attend to social cues that are necessary for successful social interactions, whereas hyperactivity or impulsivity lead to inappropriate, annoying, disruptive behaviors in interactions. Thus, these behaviors are likely to dissuade peers from spending time with children with these difficulties, further reducing opportunities for the children to practice more appropriate behavior and enhance their social skills (Carpenter et al., 2009; Wheeler Maedgen & Carlson, 2000).

DBDs

Social inflexibility is a hallmark of preschool ODD including having a reflexive no, and stubborn resistance (Wakschlag & Danis, 2009). Young children with DBDs also have social information processing problems that bias them toward hostility in interpretations of social interactions (Coy, Speltz, DeKlyen & Jones, 2001). In addition, young children with callous traits have impaired eye contact during affectionate interactions with their mothers (Dadds et al., 2014).

Internalization of Rules and Standards: Typical and Atypical Patterns Exemplified in DBDs

The ability to act in accord with social standards and internally direct behavior accordingly is a hallmark of the acquisition of self-regulation in early childhood and is fundamental to adaptive socialization across the life span (Kochanska et al., 2001; Moffitt et al., 2011). From the infant-preschool period, the developmental progression of these behaviors shifts from externally regulated (in the presence of parent/caregiver) to internally motivated. Central to this domain is the early development of conscience articulated in seminal work by Kochanska as an internalized guidance system, with its two main components of self-regulated conduct (acting in accord with rules/standards) and moral emotions (feeling remorse or shame for violating rules/standards and concern about impact of behavior on others) (Kochanska & Aksan, 2006; Kochanska, Koenig, Barry, Kim & Yoon, 2010). Many intrinsic and extrinsic features influence the developmental acquisition of conscience (e.g., child cognitive and language capacity; the extent to which rules and standards are consistently conveyed and upheld by parents) but we here focus on the core intrinsic elements of conscience that undergird internalization of rules/standards of salience to psychopathologic patterns. In particular, we highlight atypicalities in compliance with rules and standards in

relation to ODD, and the development of moral emotions in relation to emergent conduct problems.

Compliance with Rules and Standards

Internalization of rules and standards necessitates child comprehension, mental representation of prohibitions, attentiveness to parental/environmental input, monitoring behavior, ability to shift behavior in response to environmental demands, inhibit behavior in response to both internal and external controls, generalize these principles across varying contexts, cognitively represent their consequences and enact the sequence of behavior associated with these rules/standards, and be motivated to uphold them (Forman, 2007). Early compliance with rules and standards occurs in the presence of an external regulator (Kochanska et al., 2001). Rudimentary capacities emerge very early in life, including the awareness of basic rules, modulation of behavior, and the ability to comply with demands by 12–18 months; the capacity to inhibit in the absence of external controls by 24 months, and the capacity to flexibly shift behavior and generalize rules and standards across varied situations and contexts by 36 months (Forman, 2007; Kochanska et al., 2001; Reznick, Morrow, Goldman, & Snyder, 2004).

Internalization reflects the autonomous owning of these standards by the child such that rule-compatible conduct occurs even in the absence of the caregiver, integrates a range of experiences, and is generalized (Forman, 2007; Kochanska et al., 2001). These internalized standards develop in tandem with the child's emerging sense of autonomy, such that noncompliance can be normative as it is neither desirable nor adaptive for children to rigidly adhere to rules and standards regardless of context or individual goals (Dix, Stewart, Gershoff, & Day, 2007). Thus, noncompliance is a normative misbehavior and commonly occurs in most children (Wakschlag et al., 2010). As compliance begins with directives or goals that are contrary to the child's goals, noncompliance actually increases from the toddler to the preschool period as part of burgeoning independence (Forman, 2007). Simple refusals, saying no without strong affect, and active negotiation and persuasion increase and are associated with positive developmental outcomes and contexts (Dix et al., 2007).

This presents a conundrum for the application of *DSM* ODD criteria at this age in a developmentally meaningful way. Noncompliance is a core feature of *DSM* ODD with symptoms such as often defiant, and often argues with adults (APA, 1994), which are often conceptualized as the beginning phase of antisocial behavior pathways (Loeber, Burke, Lahey, Winters, & Zera, 2000). The substantial evidence of the reliability and validity of *DSM-IV* ODD in preschoolers has importantly demonstrated that clinical levels of disruptive behavior can be differentiated even at this young age (Egger & Angold, 2006; Gadow & Nolan, 2002; Keenan & Wakschlag, 2004; Lavigne, Gouze, Bryant & Hopkins, 2014). Most recently parsed as a headstrong dimension derived from ODD symptoms (Stringaris & Goodman, 2009), noncompliance at preschool age has been shown to have distinct predictive utility and correlates relative to irritable ODD behaviors (Ezpeleta, Granero, de la Osa, Penelo, & Domenech, 2012; Stringaris & Goodman, 2009; Wakschlag, Choi, et al., 2012). However, such top down approaches (i.e., how do patterns in older children fit for early childhood) are limited for addressing the central problem of the developmental imprecision of ODD symptoms (Wakschlag, Leventhal, et al., 2007). For example, ODD headstrong symptoms, such as often defiant, argumentative are highly overlapping with normative misbehaviors. Further, *DSM* ODD is a conglomeration of heterogeneous behaviors that are not tied coherently to developmental domains, making it difficult to tie problematic behavior to specific atypicalities in developmental capacity (Wakschlag, Henry, et al., 2012). In addition, symptoms are determined by presence or absence rather than qualitative distinctions, which is problematic when the occurrence of a behavior is normative. Further, while preschool ODD substantially increases risk for later disorder, predictive accuracy is not strong (Bennett, Lipman, Racine, & Offord, 1998). While there is substantial stability in *inter*-individual differences over time, *intra*-individual stability is poor; for example, the majority of toddlers who exhibit frequent oppositional behaviors at age 17 months are not still doing so at 29 months (Baillargeon et al., 2007).

An emergent body of recent work that synthesizes developmental and clinical science has importantly advanced a developmentally informed understanding of noncompliance and features that demarcate the normal–abnormal spectrum based on the quality of compliance and noncompliance, the contexts in which it is elicited, and its frequency (Drabick, Strassberg, & Kees, 2001; Wakschlag, Briggs-Gowan, et al., 2007; Wakschlag, Henry, et al., 2012; Willoughby, Kupersmidt, & Bryant, 2001). Normative manifestations of noncompliance are goal directed, flexible, contextually expectable, and tempered by a desire to please others. In contrast, clinical manifestations are characterized by recalcitrant and dysregulated defiance and deliberate rule breaking. For example, differentiation of skillful (e.g., reasonable, calm) versus unskilled (e.g., dysregulated and confrontational) noncompliance in the

Response Style Questionnaire (RSQ) demonstrates that the same behavior (e.g., defiance) at preschool age may be adaptive or maladaptive depending on its quality (Drabick et al., 2001). When noncompliance is skillfully expressed, it is positively associated with social competence, whereas its unskillful expression is associated with disruptive behavior (Drabick et al., 2001). Adaptive noncompliance is assertive (i.e., goal directed, skillful, and socially engaged; Crockenberg & Litman, 1990; Drabick et al., 2001; Kuczynski & Kochanska, 1990). Observed quality of noncompliance (e.g., stubborn, pervasive and inflexible) during interactions with an examiner on the DB-DOS adds incremental utility to prediction of persistent disruptive behavior and impairment beyond *DSM* symptoms (Adjusted Odds Ratio = 4.53) (Wakschlag, Briggs-Gowan, et al., 2008). Observed rule-compatible conduct (with and without external regulation) across the toddler and preschool period is also associated with reduced risk of school age conduct problems (Kochanska et al., 2010).

To operationalize the full normal–abnormal spectrum of noncompliance, the MAP-DB includes a range of noncompliant behaviors that vary in terms of their developmental expectability (e.g., disobey when tired or frustrated vs. not do what you ask no matter what), provocativeness (e.g., show off or laugh while misbehaving), inflexibility (e.g., automatically resist whatever you ask) and context (e.g., with parent vs. other adults). Figure 5.2 shows the normal–abnormal spectrum of noncompliance, which was derived via IRT, a method that orders behavior along a severity continuum of a latent trait (Wakschlag, Briggs-Gowan, et al., 2014). As Figure 5.2 shows, theorized normative misbehaviors that occur in most children (e.g., acts stubborn) fall at the normal end of the spectrum, whereas behaviors theorized as pathognomonic (i.e., their occurrence per se is pathognomonic) fall at the severe end of the spectrum (e.g., do risky things he or she knew were not allowed).

We have theorized that high frequency is particularly important for determining developmental atypicality for normative misbehaviors, i.e., those in which most preschoolers engage, and less important for behaviors that are qualitatively pathognomonic (Wakschlag et al., 2010).

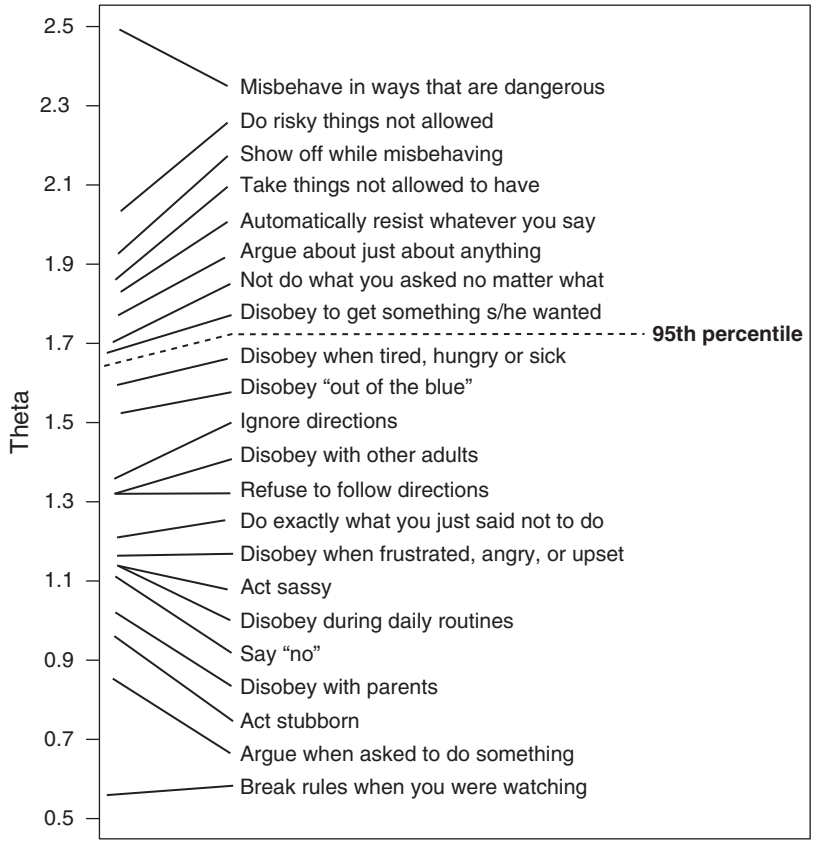

Figure 5.2 Normal–abnormal spectrum of MAP-DB noncompliance. *Source:* L. S. Wakschlag, M. J. Briggs-Gowan, S. W. Choi, S. R. Nichols, J. Kestler, J. L. Burns, . . . D. Henry, Advancing a multidimensional, developmental spectrum approach to preschool disruptive behavior, *Journal of the American Academy of Child and Adolescent Psychiatry, 53*, 82–89, 2014.

Questionnaires typically rely on subjective frequency ratings (never, sometimes, often) and *DSM* ODD symptoms also rest on occurrence of behavior such as defiance as often. The use of this approach has established that frequent occurrence of noncompliance is not normative. For example, population based studies indicate that <15% of toddlers often exhibit disregard for rules (recalcitrant noncompliance uncurbed by internal or external controls) and that doing so often across the early childhood period is atypical (Baillargeon, Sward, Keenan & Coa, 2011; Petitclerc, Boivin, Dionne, Zoccolillo & Tremblay, 2009). However, the absence of empirical parameters for determining how often is too often for normative misbehaviors leaves substantial room for error in clinical judgment and introduces a high level of informant bias (e.g., a lower tolerance for misbehavior would lead to lower threshold for what is considered often). The generation of empirically derived frequency thresholds is likely to be particularly informative for clinical decision making for those young children at the boundaries between normal and abnormal—where there is ambiguity about whether intervention is warranted. To generate empirically derived thresholds, we employed an objective frequency scale (ranging from never in the past month to many times per day) on the MAP-DB. This highlighted the variability in frequency patterns depending on the quality of the behavior. For example, normative expressions of noncompliance within developmentally expectable contexts (e.g., disobey during daily routines such as bedtime) occur regularly in 80% of preschoolers. In contrast, the exact opposite pattern is true for provocative forms of noncompliance (e.g., misbehave in ways that are dangerous or unsafe), which 80% of preschoolers are reported never to have exhibited over the past month. As a result, the frequency at which noncompliant behaviors becomes severe (i.e., occurs in <5% of the population) varies depending on their quality (Wakschlag, Briggs-Gowan, et al., 2014). This is consistent with prior work showing that frequency of noncompliance adds incremental utility for prediction of disruptive behavior for normative, but not qualitatively atypical, forms of noncompliance (Drabick et al., 2001).

Moral Emotions. Fundamental to internalization, is the experience of self-conscious emotions and aversive arousal following transgressions or distress caused to another, such as shame, guilt, discomfort, embarrassment, reparations in response to rule transgression, and empathic concern (Kim, Kochanska, Boldt, Nordling, & O'Bleness, 2014). It has been theorized that a key aspect of acquiring these complex emotions is the desire to please the caregiver that occurs within the context of a mutually responsive relationship (Grusec, Goodnow, & Kuczynski, 2000; Kochanska, Forman, Asksan & Dunbar, 2005). The expression of distress or discomfort following transgressions normatively emerges by the age of 2, building on emergent empathic capacities (Barrett et al., 1993; Chase-Lansdale, Wakschlag, & Brooks-Gunn, 1995; Kim et al., 2014).

Callousness, or the failure to experience such concern or remorse, is a core aspect of severe antisocial behavior as in CD, which in its most extreme form manifests as psychopathy (Blair, Mitchell, & Blair, 2005; Frick et al., 2003). We have suggested that the marked deficits in empathy, internalization and socio-moral function that mark this pathway can best be understood as *reduced responsiveness to socialization* with components of *low concern for others* and *punishment insensitivity* (Nichols et al., 2014). There is emergent evidence that low concern and callousness are evident at preschool age and have predictive utility for conduct problems (Ezpeleta, de la Osa, Granero, Penelo & Domenech, 2013; Hyde et al., 2013; Kimonis et al., 2006; Willoughby, Waschbusch, Moore & Propper, 2011; Wakschlag, Henry, et al., 2012). However, to our knowledge, no studies have yet linked low concern at preschool age to later severe antisocial behaviors or psychopathy.

On the MAP-DB, we have operationalized low concern for others and punishment insensitivity within a developmental framework. Developmental manifestations of low concern include not seeming to care about others' feelings and enjoy making others mad, and of punishment insensitivity include keep on misbehaving no matter what you do and refuse to apologize. Using IRT, both have demonstrated a severity spectrum for both domains (Nichols et al., 2014; Wakschlag, Briggs-Gowan, et al., 2014). While low concern varied along a severity dimension, all behaviors were pathognomonic, i.e., occurred rarely and exceeded a 95th percentile severity threshold. In contrast, punishment insensitivity included both common manifestations (act like s/he didn't hear you) and atypical manifestations (e.g., not care when punished and act like s/he did not know right from wrong), suggesting that punishment insensitivity is atypical when it predominates. Punishment insensitivity also demonstrated incremental utility for prediction of impairment over and above traditional disruptive behavior symptoms (Nichols et al., 2014). We have also demonstrated that preschool age punishment insensitivity is associated with concomitant impairments in reward learning that have been demonstrated in psychopathic adolescents and adults, suggesting that it might be an early indicator of this risk pathway (Briggs-Gowan et al., 2013; Dadds & Salmon, 2003). These findings suggest

that the defining features of CD are identifiable even at preschool age when they are defined in a developmentally meaningful way. However, as this type of developmental specification is relatively new, there is not yet a strong empirical knowledge base about its predictive utility for later CD and callous behaviors (Hyde et al., 2013). Using developmentally based paradigms, Kochanska and colleagues have shown that deficits in moral self observed during the toddler and preschool period predict later callous traits. For example, toddlers who did not exhibit tense discomfort and empathic concern during contrived mishaps, were more likely to exhibit school-age conduct problems (in interaction with parent–child relationship quality; Kim et al., 2014; Kochanska et al., 2010).

Difficulties with internalization of rules and standards also apply to depression, ADHD, and anxiety:

Depression

Preschoolers' increasing ability to engage in internalization of rules and standards reflects typical development during this period (Cole et al., 2008). For example, during the preschool period, children can evaluate their sense of self, empathize with others, and understand social and moral standards (Denham, 2007; Eisenberg, Spinrad, & Sadovsky, 2006; Muris & Meesters, 2014). Further, when children engage in misbehavior that disrupts others' well-being, they may show normative guilt and shame responses and can build on skills typically learned in toddlerhood such as repairing transgressions, confessing their role in the problem, and feeling temporarily badly about oneself (Barrett et al., 1993; Cole, Barrett & Zahn-Waxler, 1992; Kochanska, DeVet, Goldman, Murray, & Putnam, 1994). These skills enable empathy of others' distress and contribute to prosocial behaviors that repair transgressions.

However, some children show excessive and dysfunctional guilt and shame reactions to transgressions (Luby, Belden, Sullivan, et al., 2009). These reactions may include responses such as inaccurately blaming oneself for others' transgressions, feeling guilty/ashamed about a behavior long after the behavior occurred, and engaging in excessive apologizing or reassurance seeking in an attempt to relieve distress associated with the behavior. Consistent with themes described above, these behaviors likely increase negative self-focus, which can limit empathy toward others and interfere with reparative problem solving behavior (Eisenberg, McCreath, & Ahn, 1988; Eisenberg & Fabes, 1990), further worsening self-image and risk for depression. Girls may be more likely to display these behaviors compared to boys as suggested by recent findings (Luby, Belden, Pautsch, et al., 2009) and related to evidence that such internalizing emotions are likely to be differentially socialized by parents and teachers for girls compared to boys (Crick & Zahn–Waxler, 2003). Luby and colleagues (Luby, Belden, Sullivan, et al., 2009) suggested that such behavior may reflect that children are stewing in their negative emotion, particularly feelings of guilt and shame, and that this difficulty regulating emotional processes should be a target of intervention.

In addition, although children at risk for DBDs have difficulty following rules and social/moral standards, children at risk for depression may be apt to *overly* internalize rules and standards. For example, preschoolers of depressed mothers do not show age expectable increases in noncompliance (Dix et al., 2007). These children may show behaviors such as excessive compliance or following all rules without question or protest. Although these behaviors are normative in some cultures, Western cultures typically value children's assertion of their needs and shift toward increasing independence. Children who comply with rules and standards regardless of personal needs or preferences may be viewed as well-behaved and easy to manage by parents and teachers, further reinforcing the behavior. However, it is possible that these children are learning that their needs are not worthy of expression or attention, thus increasing their risk for depression.

ADHD

Internalization of rules and standards may also be deficient due to a range of cognitive control problems that interfere with holding rules in mind (working memory) and difficulty inhibiting without external surveillance. Impulsivity may interfere with children's abiding by rules even if they know them and want to keep them (Callender, Olson, Kerr & Sameroff, 2010). During laboratory observations of preschoolers' cheating behavior designed to differentiate normative from atypical cheating patterns, children observed to cheat without restraint and to display inappropriate positive affect while doing so were more impulsive and more likely to demonstrate later externalizing problems (Callender et al., 2010). Preschoolers with poor attention regulation have also been shown to display less empathic responding to peer distress (Eisenberg & Fabes, 1995).

Anxiety

In conjunction with high levels of inhibitory control, anxious preschoolers may be prone to over-internalizing rules and standards. Kochanska (1991, 1993) purports that a fearful temperament or vulnerability to anxiety in

early childhood may facilitate to the development of moral conscience and the internalization of rules and standards. More specifically, temperamentally fearful children may be less likely to engage in rule-breaking behavior because they are more likely to experience affective discomfort, such as shame, guilt, or worry, when they are criticized or commit a transgression (Kochanska, 1991, 1993; Kochanska, et al., 1994). Although this proneness to guilt may serve as a protective factor for some children, in its dysfunctional form, young children with a vulnerability to fearfulness or anxiety may be especially likely to develop excessive guilt and self-blame, which negatively impacts their self-efficacy and self-worth, and may contribute to their being overly compliant and unassertive in relationships. Likewise, an overinternalization of rules and standards may also lead to inflexibility and poor problem solving when faced with challenging situations, further exacerbating a child's anxiety symptoms.

TRANSLATIONAL APPLICATION OF DEVELOPMENTALLY SENSITIVE ASSESSMENT

Unquestionably, the momentum toward dimensional, developmentally specified approaches will enhance precision of clinical characterization. This is particularly true in the area of preschool psychopathology because the overlap of normative misbehavior and high levels of normative variation make reliance on categorical approaches that define atypicality based on frequency of extreme behaviors especially problematic. The many recent strides we have described above have substantially advanced developmentally sensitive methods in the dimensional characterization of early emerging psychopathology within a research context. However, their clinical application as a means of enhancing early identification is in its infancy (Wakschlag, Estabrook et al., 2014).

In particular, three steps are critical to moving dimensional, developmentally sensitive measurement from research use to clinical application for preschool psychopathology:

1. **Conduct empirical studies to systematically test whether developmentally sensitive approaches enhance accuracy of early identification.** We and others have theorized that developmentally sensitive measurement will reduce over- and underidentification by more accurately differentiating normative variation from clinical problems (Wakschlag & Danis, 2009). However, this theory has not been put to the test! Although measures such as the PAPA (Egger, Erkanli, et al., 2006; Egger et al., 1999) and the DB-DOS (Petitclerc et al., 2014; Wakschlag, Hill, et al., 2008; Wakschlag, Briggs-Gowan, et al., 2008) have demonstrated reliability and validity, the incremental improvement provided by their use for clinical differentiation has not been tested. An empirical knowledge base in this area is crucial for justifying the likely changes in nosology and one-size-fits-all approach that would ensue. For example, a number of studies using *DSM* diagnoses have shown that ~50% of children remit over a 6-month to 3-year period (Bufferd et al., 2012; Keenan et al., 2011; Kim-Cohen et al., 2005; Wakschlag, Briggs-Gowan et al., 2008). Does the use of developmentally sensitive measurement identify a group of children with more stable difficulties? Further, does the measurement identify young children with milder or variable difficulties or developmentally specific expressions who would not have been captured using traditional, adevelopmental approaches? These questions require longitudinal assessment and a thoughtful approach to assessing impairment given that the use of later diagnosis as outcome would be circular and would not necessarily offer more information than the current standard approach. For example, in keeping with recent modeling of the structure of preschool psychopathology (Olino, Dougherty, Bufferd, Carlson, & Klein, 2014), *a dimensional latent clinical risk factor* could be generated that would be composed of a higher order severity factor and two lower order latent factors: (1) a clinical symptoms factor, derived from symptom interviews and dimensional assessments on broad clinical domains (e.g., mood regulation, behavioral regulation); and (2) an impairment factor, across three impairment domains: family, social, and functional. This approach could be used to capture overall clinical severity as well as domain-specific patterns. Frequent and intensive longitudinal assessments that include retrospective and real time measures would be important to characterize the ebb and flow of these patterns over time. This is because typical annual assessments often miss a great deal of variation that occurs in between the end points, which may importantly inform understanding of who persists.
2. **Develop algorithms for integrating multimethod approaches into clinical decision making.** We now have a range of methods that have been specifically developed for preschool age assessment including clinical interviews, clinical observation, and dimensional questionnaires. Each of these measures provides a unique

source of information and error. Researchers and clinicians need to identify how various instruments can be best used in clinical practice. For example, there is evidence that the MAP-DB (Nichols et al., 2014; Wakschlag, Briggs-Gowan et al., 2014), DB-DOS (Petitclerc et al., 2014; Wakschlag, Hill et al., 2008; Wakschlag, Briggs-Gowan et al., 2008), and PAPA (Egger et al., 1999) identify early emerging disruptive behavior problems in a developmentally sensitive manner via parental report along multiple dimensions of children's behavior (MAP-DB), observation of behavior (DB-DOS), and interviewer-rated behaviors relevant to clinical diagnoses (PAPA). This multimethod, multiinformant approach would capture various dimensions relevant to psychopathology, offer specific details about the nature of the full range of behaviors, and generate traditional *DSM* diagnoses often required for reimbursement in clinical practice. However, the extent to which these developmentally sensitive measures provide convergent and divergent information remains unclear. Given the challenges of normative:atypical differentiation in early childhood, developing methods for combining these sources of information will undoubtedly enhance early identification. A first step toward this direction would be determining overlap and divergence across these methods and clinical profiles of children who are captured by one but not another method (see for example Kraemer et al., 2003; Risi et al., 2006).

3. **An algorithm that guides mental health clinicians in their use of a developmentally sensitive suite of assessment methods.** To do so, this approach must (1) be feasible for use in practice such that clinicians can access the measures, receive training in the administration and scoring, and incorporate the approach into real-world assessment and treatment planning; (2) provide added value over existing methods (e.g., symptom checklists, clinical interviews) by yielding information that is sufficiently sensitive, specific, and predictive of qualities such as treatment response and future behavior; and (3) capture varying developmental manifestations of latent qualities over time as challenges, competencies, and associated risk shift with age and experiences (Carter et al., 2013; Rutter & Sroufe, 2000; Rutter et al., 2006; Wakschlag, Leventhal, et al., 2007). Given that current assessment methods likely identify children displaying extreme behaviors quite well, this approach would be particularly beneficial for identifying children whose current behaviors are not extreme but are red flags for later clinical risk. Capturing such children in the gray area of behavior is essential for improving efforts to identify prodromal risk, and is particularly well-suited to the use of low-risk interventions (e.g., those that enhance developmental capacities described above such as emotion regulation and self-control versus more intensive pharmaceutical interventions).
4. **Develop a dimensional continuum for treatment decision making and test its effectiveness for improving outcomes.** The strength of these approaches (i.e., that they capture behaviors along a more natural spectrum and do not falsely dichotomize them as present or absent) is also their challenge. That is, because dimensional approaches do not provide clear thresholds for determining clinical significance, it is difficult to know how to incorporate them into clinical decision making. We would suggest a dimensional continuum of clinical decision that incorporates longitudinal assessment. Taking longitudinal change into account is at the heart of characterizing psychopathology within a developmental context and is particularly crucial for effective clinical use of dimensional approaches. Young children can vary within the normative range, within the abnormal range, and jump between these ranges over relatively short periods of time, and this variation predicts outcomes. Approximately one-third of children vary on dimensional scores by one standard deviation (SD) or more when longitudinal dimensional assessments are employed (Wakschlag, Estabrook et al., 2014). By accounting for the noise of transient events and the change reflecting developmental growth, longitudinal, dimensional assessment will provide key information for sharpening the distinction between normative variation and abnormal patterns. This would include empirically establishing the optimal number of time-points and intervals between them that will provide an adequate level of certainty and is also clinically feasible. Ideally, longitudinal assessment of all young children would precede clinical decision making except in the most extreme of cases where behavior is dangerous or severely impairing. In light of the high rates of stimulant medication to treat ADHD in preschoolers and concerns about overmedication, this might be an ideal domain with which to test such an approach.

   Below is an example of this type of approach:

Level 1: Well-regulated emotions and behavior

Level 2: Watch (longitudinally) and wait: clinically at risk

This level would be targeted to children with mildly elevated scores along a single dimension (e.g., .5–1 SD from the mean) to assess whether patterns escalate, remain

stable, or diminish. Clinical parameters could be empirically established; for example: preschoolers with scores within this range at three time points within a six month period are clinically at risk and warrant intervention.

Level 3: Low intensity intervention: clinically prodromal

For children with moderately elevated scores (>1 SD above the mean) in at least two domains.

Interventions that are low intensity or cost, and are developmentally promotive (e.g., improving self-regulation skills) may be warranted for young children at this level who have a 50% or greater chance of clinical disorder (e.g., 1 SD above the mean, Wakschlag, Briggs-Gowan, et al., 2014) as the benefits of preventing frank disorder are likely to far outweigh the costs of intervention.

Level 4: Treatment: clinically significant

Children with highly elevated scores (e.g., >2 SD above the mean) in at least two domains are clearly showing signs of atypicality that warrant treatment.

Despite the potential utility of the development of this type of approach for clinicians to employ to improve their assessment of early emerging psychopathology, many families more frequently encounter pediatricians or family physicians than specialty mental health providers, and parents may be more likely to express concerns about their young children's behavior in medical versus mental health settings. Therefore, an approach that capitalizes on these opportunities is essential. Often, parents' concerns reflect developmentally typical behaviors, and a pediatrician is tasked with the need to (often briefly) assess the behavior, its frequency, duration, and persistence, and the extent to which the behavior causes the child distress and interferes with family and peer relations. Wakschlag and colleagues (Wakschlag, Choi, et al., 2012; Wakschlag, Briggs-Gowan, et al., 2014) have mapped the dimensions of disruptive behaviors, and this work can be translated for use in pediatric practice to offer guidelines for the levels at which normative behaviors may connote risk. For example, they identified that although temper tantrums were normative in young children, tantrums that occurred unexpectedly or daily were rare; when persistent, such behaviors could warrant clinical attention. It is essential to generate similar information for behavior relevant to anxiety and depression; the research program described above that makes use of a daily diary approach will provide these data. Further, the use of computer adaptive test (CAT) approaches for incorporating preschool behavioral and socioemotional assessment into pediatric practice may be particularly useful because they are brief and efficient to administer (Choi, Reise, Pilkonis, Hays, & Cella, 2010; Wakschlag, Estabrook et al., 2014). Of course, guidelines for their interpretation and action steps would need to be well delineated. This type of concrete and concise information that can be feasibly conveyed to practitioners who frequently encounter young children and their families to guide decision making for services is essential in translating early psychopathology research into clinical practice.

In summary, foundational validation of preschool psychopathology has led to a proliferation of developmentally sensitive methods for its assessment. Our charge for the next decade is to ensure that empirical investigations focus on standardized methods for their clinical application and use. This work should importantly contribute to a more developmentally based, sensitive, and specific framework for the identification and treatment of preschool psychopathology.

CONCLUSIONS AND FUTURE DIRECTIONS

As described in this chapter, we have summarized clear evidence that symptoms and syndromes of psychopathology can be identified in a reliable and valid manner in early childhood. These difficulties have been found to be associated with impairment that impacts the child and family, and often persist into later development. Early identification and intervention are essential given that 1) earlier onset of psychological difficulties may contribute to greater long-term impairment and chronicity than later onset (Weissman et al., 1999), 2) early childhood offers a window for prevention or early intervention before school entry (Anticich, Barrett, Silverman, Lacherez & Gillies, 2013; Chronis-Tuscano et al., 2015; Kennedy, Rapee & Edwards, 2009; Lau & Rapee, 2011; Luby, Lenze & Tillman, 2012; Njoroge & Yang, 2012; Pincus, Eyberg & Choate, 2005; Rapee, Kennedy, Ingram, Edwards & Sweeney, 2005), and 3) earlier interventions may be more effective than later interventions, possibly due to greater behavioral and neurodevelopmental plasticity in early childhood (Barrett, Lock & Farrell, 2005; Hirshfeld-Becker & Biederman, 2002). Although this chapter focuses on the preschool period, behavior relevant to psychopathology may be identified as early in childhood as possible (Egger & Emde, 2011); for example, endogenous self-regulation typically begins in infancy. Therefore, improving children's emotional and behavioral functioning early in life is essential to enhance children's healthy development (Sroufe, 1979).

Although remarkable advances in preschool psychopathology have increased awareness of emotional and behavioral problems in young children, this work has also highlighted the need for developmentally specific approaches to elucidate the developmental phenotype of preschool psychopathology and promote discovery of mutable mechanisms that can be targeted in early phases of the clinical pathway. Future research should be geared toward advancing a multilevel, developmentally oriented conceptualization of psychopathology that (1) consistent with the RDoC approach, links domains of functioning to various units of analysis such as genetics, neural circuitry, physiologic responses, and observable behaviors (Cuthbert & Insel, 2013; Franklin et al., 2015; Insel et al., 2010; Sanislow et al., 2010); (2) improves empirically based distinctions between typical and atypical behavior across the life span; and (3) uses a multidimensional approach to identify individual profiles of behavior across contexts, informants, and development to shape prevention and treatment efforts. These efforts would be most productively pursued as prospective longitudinal studies with community samples of young children to follow the development, correlates, and outcomes of impairing behavioral profiles.

We argue that the domains proposed in this chapter provide a guiding framework for pursuing developmentally oriented research on early-emerging psychopathology to better characterize normative expression and variability of behavior and risk for psychopathology. Such an approach spans diagnostic categories and minimizes limitations associated with applying diagnostic criteria that impose cut points to phenomena that are dimensional in nature. Although the domains proposed will require revision as researchers further characterize the spectrum of behavior relevant to psychopathology, we view the use of this framework as an essential next step in improving the developmental sensitivity of preschool psychopathology research and its differentiation from normative variation in this age period.

Developmentally sensitive, dimensional, multilevel conceptualizations of psychopathology that are linked to behavior, physiology, and neural circuitry are essential for delineating the normal–abnormal spectrum both in early childhood and across the life span. Although current methods to detect psychopathology are sensitive to and likely appropriate for children demonstrating more severe forms of behavior, the majority of children's behavior is decidedly ambiguous or variable in severity (i.e., existing in a gray area). Therefore, better methods to identify endogenous and exogenous factors that influence children's transitions into and out of normal/typically developing and abnormal/impaired behavior are needed to better understand clinical risk. Further, such factors are complex and transactional in nature; for example, a child who has difficulty with emotion and behavior regulation may be less vulnerable if surrounded by particularly supportive, flexible caregivers and teachers compared to a child with similar difficulties in a more harsh, punitive environment. In addition, interactions among domains are likely to influence conceptualization of a child's behavior. For example, a child with poor self-control but high internalization of rules and standards would likely be less at risk than a child with difficulties across both domains.

Using the domain framework we propose, a profile of children's behavior across the domains would be created that, in conjunction with cross-informant and contextual information about their behavior, temperament, caregiving environment, and culture, would illustrate their clinical risk. The use of individual profiles can shape new intervention efforts to improve behavior and impairment associated with functioning in each domain; for example, treatment could increase flexibility, delay of gratification, and empathy in a child with difficulty in emotion regulation, self-control, and social engagement. Therefore, rather than focus on diagnostic criteria, such efforts would aim to restore typical developmental processes to reduce impairment in functioning and improve children's developmental trajectories across domains.

SETTING THE STAGE

In 1995, in the introduction to a special issue devoted to emotions in the journal *Development and Psychopathology*, Cicchetti and colleagues argued that the study of emotions in atypical populations required consideration of the construct emotion regulation (Cicchetti, Ackerman, & Izard, 1995), which refers broadly to processes that allow an individual to manage emotional arousal. Around that same time, volumes edited by Dodge and Garber (1991) and Fox (1994) addressed the significance of emotion regulation (ER) for both normative and problematic development. These germinal works noted that the ability to control one's emotions in an adaptive manner is critical to everyday functioning for both children and adults. These works also made clear that such skills begin to emerge early in postnatal life, and that their development is influenced by a host of biological, behavioral, and contextual factors. Moreover, they described the development of ER as relatively rapid so that by the time a child enters school, he or she should possess a varied repertoire of emotion regulatory skills that will support the successful transition to the school environment, with its social and academic challenges.

Since the publication of these early works on ER, there have been hundreds of empirical papers published examining the relation between ER and a range of developmental outcomes. This body of literature clearly suggests that the construct has become nearly ubiquitous in accounts of social and emotional development (Eisenberg, Eggum, Sallquist, & Edwards, 2010; Eisenberg & Sulik, 2012; Gross & Thompson, 2007) and in our current conceptualizations of the etiology of psychopathology (Werner & Gross, 2010). In addition, considerable research in the fields of both developmental and clinical psychology provides a blueprint for the emergence of ER skills, the factors that support or undermine their development, and the difficulties children face when they lack the ability to regulate emotional arousal. This work includes research that has examined the underlying biological processes (e.g., Brooker

& Buss, 2009; Dennis & Hajcak, 2009), behavioral correlates (e.g., Calkins, Gill, Johnson, & Smith, 1999; Supplee, Skuban, Shaw, & Prout, 2009), and environmental influences (e.g., Morris, Silk, Steinberg, Myers, & Robinson, 2007; Spinrad, Stifter, Donelan-McCall, & Turner, 2004) that affect the display and development of ER. And these works have guided empirical investigations of the various psychological (Hum, Manassis, & Lewis, 2013; Siener & Kerns, 2012); social (Blair et al., 2013; Chang, Shelleby. Cheong, & Shaw, 2012); and academic outcomes (Graziano, Reavis, Keane, & Calkins, 2007; Herndon, Bailey, Shewark, Denham, & Bassett, 2013) that may be a consequence of various developmental patterns of ER. In this chapter, we consider the development of ER and its role in child adaptation broadly construed, with the goals of (1) elucidating some of the complex mechanisms and pathways that are operating in development; (2) citing challenges and controversies that have emerged through the study of ER and adaptation; and (3) advocating for an integrated approach to the study of ER at all levels of child functioning in the next generation of theory and research in this area.

Although there have been a number of different conceptual and empirical approaches to the study of ER, such work is often conducted from within a developmental psychopathology framework (e.g., Cummings, Davies, & Campbell, 2000; Rutter and Sroufe, 2000). This perspective suggests that there are multiple contributors to maladaptive and adaptive outcomes, that these contributors may interact in various ways within different individuals, and that the consequences for development are multiple pathways to disordered behavior and/or multiple variants of an outcome from individual causative factors (Cicchetti, 1984, 1993; Cicchetti & Rogosch, 1996; Sroufe & Rutter, 1984). Conceptualizing the development of psychopathology in this way highlights the need for complex, process-oriented models of development and emphasizes the importance of conducting longitudinal investigations of the factors that may both influence and be influenced by early contextual, familial, or individual differences. Finally, a developmental psychopathology perspective advocates an organizational view of development; multiple factors, or levels of a given factor, are considered in the context of one another, rather than in isolation (Cicchetti & Dawson, 2002).

Implicit in a developmental psychopathology framework is the notion that biological functioning is an important level of analysis for theoretical and empirical work. This level of functioning incorporates genetic, neural, and physiological processes that, from our perspective, operate in a transactional way with behavioral and social processes. In our view, such a perspective is integral to understanding both normative and nonnormative developmental processes. Thus, in this chapter, we highlight work that utilizes multiple behavioral, biological and relational indicators of ER and the outcomes influenced by ER. We organize the chapter in five sections: (1) definitional and theoretical considerations; (2) developmental and contextual issues; (3) empirical approaches and challenges; (4) relations to child outcomes (including psychopathology, social competence, and academic achievement); and finally (5) implications and challenges for future research. Our overarching aim is to go beyond a summary of research findings to highlight the many conceptual and empirical issues that ought to be considered in studies examining the relation between ER and child outcomes related to developmental psychopathology.

DEFINITIONAL AND THEORETICAL CONSIDERATIONS

Defining the Construct of ER

Numerous definitions of the construct of ER have been offered from within both the child and adult emotion literatures (Gross & Thompson, 2007). However, there has not been clear agreement among these definitions on what the boundaries of the construct are and how these might translate into measurement. Indeed, a decade ago, in the midst of a burgeoning literature addressing the role of ER in psychological and social functioning, Cole and colleagues published a theoretical piece designed to stimulate discussion of these issues and thus the scientific utility of the construct of ER (Cole, Martin, & Dennis, 2004). They challenged researchers to thoughtfully address the complexities inherent in defining and measuring the construct in a way that would allow for meaningful interpretation of research findings. These challenges were potentially serious risks to the field in terms of its commitment to studying a construct that had such intuitive appeal, but clearly required much greater attention to definitional and empirical issues. It is important to note, though, that Cole and colleagues' challenge was in the spirit of recognizing that a scientifically rigorous approach to ER could yield findings that would elucidate processes that distinguished typical from atypical development (Cole et al., 2004).

In our view, this challenge to our field has been fruitful, resulting in more explicit definitions of ER and empirical approaches that map onto those definitions. Our definition reflects recent theoretical and empirical work in both

developmental (Cole et al., 2004; Fox & Calkins, 2003) and clinical psychology (Keenan, 2000) that highlights the fundamental role played by emotion processes in both child development and child functioning (Eisenberg et al., 2000), and, importantly, that is anchored in the measurement of such processes during emotionally evocative situations (Calkins & Hill, 2007). Consistent with many of our colleagues (Eisenberg, Hofer, & Vaughn, 2007; Gross & Thompson 2007), we view ER processes as those behaviors, skills, and strategies, whether conscious or unconscious, automatic or effortful, that serve to modulate, inhibit, and enhance emotional experiences and expressions (Calkins & Hill, 2007). These ER processes are composed of both a reactive and a control dimension (Fox & Calkins, 2003). And, we, like some of our colleagues (Gross & Thompson, 2007), see a value in examining emotional reactivity as distinct from the efforts to manage it. The ER process is clearly a dynamic one in which reactive and control dimensions alter one another across time and levels. Moreover, in our view, the reactive dimension, as opposed to the control dimension, is present and functional early in neonatal life, as it is strongly influenced by genetic and biological factors (Fox & Calkins, 2003). Finally, we note that the display of emotional reactivity and emotional control are implicated in a range of developmental achievements across the life span, including socioemotional functioning and academic performance, and that these indictors of child functioning are often critical factors in the development of behavior problems and various forms of psychopathology (Calkins & Dedmon, 2000; Eisenberg et al., 2007; Thompson & Meyer, 2007).

Two challenges have repeatedly emerged in the translation of definitions of ER to the interpretation of empirical investigations of the construct. First, there has been a tendency to characterize ER as *adaptive* versus *maladaptive* (often using the term dysregulation to capture this quality (Beauchaine, Gatzke-Kopp & Mead, 2007)). And, relatedly, there has been a tendency to view negative affect expression as maladaptive and positive affect expression as adaptive. However, it is important to acknowledge that, conceptually at least, different patterns of emotion expression and regulation may be differentially adaptive based on the goals of the individual and the circumstances in which they are trying to regulate affect (Cole et al., 2004; Thompson & Calkins, 1996). Thus, although it may be challenging to avoid characterizations of particular patterns of ER as more or less adaptive, in the absence of evidence that specific behaviors cause particular problematic outcomes, as opposed to characterize problematic outcomes, it may be prudent to do so.

A second challenge to conceptualizations of ER is how to characterize the integrated nature of seemingly discrete emotional processes. Thus, although many researchers agree that the process of reacting to an emotional stimulus is distinct from efforts to regulate that response, and most measurement strategies reflect this view (cf., Morris, Silk, Steinberg, Terranova, & Kithakye, 2010), the distinction becomes artificial unless one acknowledges that the two processes are often difficult to disentangle and that they interact dynamically across time. Static measurement of either is bound to obscure individual differences in such things as initial level of reactivity, success or failure of particular strategies over time, and whether reactivity constrains regulation or vice versa. In fact, few studies have attempted to either measure cross-time patterns of both processes (Buss & Goldsmith, 1998) or discern patterns of time-linked responding across children.

The dynamic nature of emotional responding leads to the possibility that there are several different dimensions of responding that may be relevant to specific psychological disorders and outcomes. So, it is possible that the relevant aspect of emotion regulation we should be interested in when trying to understand developmental psychopathology will vary depending on the particular features of the outcome of interest. Appraisal may be a process that is more relevant to anxiety disorders (Carthy, Horesh, Apter, & Gross, 2010), for example, so understanding the way appraisal leads to differential patterns of emotional responding, which subsequently leads to increases versus decreases in anxiety symptomatology, may result in a different assessment strategy other than that which is used to examine the relevant emotional processes inherent in externalizing disorders. Framing the issue in this way moves us away from focusing on broad conceptualizations of psychopathology that focus simply on the regulation of anger or fear for example, to a more process-oriented approach that asks questions about the specific dynamics of emotional responding and their relation to behavioral patterns that underlie functioning.

The definition we provide for ER, that it consists of both reactive and control dimensions, and that these dimensions influence behavioral and physiological responding in social and nonsocial contexts, suggests that there are likely to be different theoretical perspectives on how these processes influence the development of psychopathology. Next, we address the dominant perspectives, those that focus on the biological and behavioral characteristics individuals bring to the process of ER, the interpersonal nature of the process, and the implications of these processes for psychological functioning and mental health.

Theoretical Perspectives on ER

Current research and theory in the area of ER and developmental psychopathology has its roots in disparate literatures, including work that focuses on child temperament (e.g., Rothbart & Bates, 1998), parenting and attachment in early development (e.g., Sroufe, 1996), child behavior problems (e.g., Keenan & Shaw, 2003), and biological processes in emotion and cognition (e.g., Lewis et al., 2008; Lewis, Todd, & Honsberger, 2007). Here, we discuss the dominant conceptual approaches within these literatures that have informed current conceptualizations and empirical investigations of ER.

Temperament literature was among the first to specify regulation as a core aspect of the developmental process. The construct of temperament is commonly viewed as the basic organization of personality that is observable as early as infancy and that becomes elaborated over the course of development as the individual's skills, abilities, cognitions, and motivations become more sophisticated (Rothbart & Bates, 1998; Shiner & Caspi, 2003). Temperament thus refers primarily to relatively stable early differences in emotional and behavioral characteristics that have genetic and biological components (DiLalla & Jones, 2000; Goldsmith, Lemery, Aksan, & Buss, 2000). Rothbart and colleagues (Derryberry & Rothbart, 1997; Rothbart, 1981, 2011; Rothbart & Bates, 1998; Rothbart & Derryberry, 1981) have articulated one of the most influential theories of early temperament and one that has generated a great deal of research on infant development over the last twenty years (Buss & Goldsmith, 1998; Calkins, Dedmon, Gill, Lomax & Johnson, 2002: Calkins & Fox, 1992; Stifter & Braungart, 1995). The theory defines temperament along two broad dimensions of *reactivity* and *self-regulation*, which then subsume six subscales that place an emphasis on basic emotion, attention, and motor processes.

With respect to the reactive dimension of temperament, Rothbart notes that the initial responses of an infant may be characterized by their physiological and behavioral reactions to sensory stimuli of different qualities and intensities. This reactivity is believed to be present and observable at birth and reflects a relatively stable characteristic of the infant (Rothbart, Derryberry & Hershey, 2000). Moreover, infants will differ initially in their threshold to respond to visual or auditory stimuli, as well as in their level of reactivity to stimuli designed to elicit negative affect (e.g. Calkins, Fox & Marshall, 1996). The second dimension proposed by Rothbart, that of self-regulation, has been described largely in terms of attentional and motoric control mechanisms that emerge across early development. For example, the development of attention and its use in the control of emotional reactivity begins to emerge in the first year of life and continues throughout the preschool and school years (Posner & Rothbart, 2000; Rothbart, 1989; Rothbart & Bates, 1998). Individual differences in the ability to voluntarily sustain focus or shift attention are paramount to the self-control of attention. Attentional orienting skills, in particular, have been identified as a critical component of the regulatory process, as orienting has the direct effect of amplifying, at a neural level, the stimuli toward which attention is directed, thus changing the affective experience of the individual (Rothbart, Ahadi & Hershey, 1994). Thus, orienting skills assist in the management of both negative and positive emotions, and consequently to the development of adaptive control of emotion and behavior.

Qualitative shifts in attention skills across the first twelve months of life may be integral to the qualitative shifts in ER that are subsequently observed during childhood (Calkins, 2009). However, there are clear individual differences in the ability to utilize attention to successfully control emotion. Those individual differences are likely a function of early differences in neural processing (Thompson, Lewis, & Calkins, 2008), but the development of these foundational regulatory mechanisms clearly takes place in the context of early interactions with caregivers and others, making it important to consider the role of these interactions on emerging skills. An important theoretical perspective that emerged as a function of this observation is that ER may be inherently a social phenomenon (Campos, Walle, Dahl, & Main, 2011; Sroufe, 1996).

In one of the earliest articulations of this point of view, Sroufe (1996) argued that emotional development is inextricably linked with social development, with the course of emotional development described as the transition from dyadic regulation of affect to self-regulation of affect. He argues that the ability to self-regulate arousal levels is embedded in affective interactions between the infant and caregiver. Positive interactions with caregivers, and caregiver intervention that is effective in reducing distress reactions, provides infants with the experience of arousal escalation and reduction (Sroufe, 1996). Such experiences contribute to the working model of affect-related expectations that will transfer from the immediate caregiving environment to the larger social world of peers and others (Cassidy, 1994). Campos (Campos et al., 2011) has also articulated a theory of ER that emphasizes the relational (versus intrapersonal) aspect of ER. The significance of this perspective lies in the fact that human beings are

embedded in social relationships, thus, the person and the environment are intertwined.

Another way of conceptualizing ER and its role in adaptation has come from the child clinical literature. This work places a particular emphasis on emotion regulation and the way specific manifestations of very early problem behaviors are characterized by poor or maladaptive regulatory skills (Cole, Hall, & Radzioch, 2009; Keenan & Shaw, 2003). From a developmental perspective, success or failure at important developmental tasks, like the acquisition of emotion regulation skills during toddlerhood and preschool, likely plays some role in the trajectory of more serious problem behavior as children enter the peer and school contexts (Hill, Degnan, Calkins, & Keane, 2006; Keane & Calkins, 2004). Moreover, from this standpoint, early childhood behavior problems are considered a risk factor for later antisocial behavior and suggest that the mechanisms responsible for ongoing behavioral difficulties are to be found in the interactions between very early child functioning, particularly with respect to the regulation of arousal, and the contexts in which the development of regulation is occurring: namely family and peer relationships.

Although there are large literatures that offer conceptualizations of ER from differing perspectives examining the separate roles of child characteristics, family processes, and psychological functioning, there is a growing interest in the biological processes implicated in emerging ER abilities, child competencies, and maladjustment in particular. For example, Perlman and Pelphrey (2011) document the changes that occur in frontal brain regions implicated in the control of affect across early and middle childhood. Thompson and colleagues (2008) also describe the integration of the neural and physiological mechanisms that serve as the basis of cognitive and affective processes involved in ER. And, behavior genetics research has clearly stimulated growing appreciation for the role of genetic processes in emerging child psychopathology (cf. Horwitz & Neiderhiser, 2011).

Biological processes involved in the regulation of attachment and emotion processes during infancy and early childhood have also been investigated. For example, Hofer (1994; Polan & Hofer, 1999) addressed the multiple psychobiological roles that the caregiver plays in regulating infant behavior and physiology early in life. Based on his research with infant rat pups, he describes these hidden regulators as operating at multiple sensory levels (olfactory, tactile, and oral, for example) and influencing multiple levels of behavioral and physiological functioning in the infant. Moreover, removal of these regulators, during separation, for example, disrupts the infant's functioning at multiple levels. Clearly, then, opportunities for individual differences in the development of emotional self-regulation may emerge from differential rearing conditions providing more or less psychobiological regulation. Thus, perspectives that emphasize the inherently social nature of ER often address both biological and behavioral processes that are both influenced by and influence caregiver–child interactions.

This appreciation of biological processes in child functioning has already led many developmental scientists to reconfigure their models of development to incorporate both genetic and other biological processes as factors in the emergence of complex behavior (Sameroff, 2010; Shonkoff, 2010). And, it is this perspective that has had a major influence on subsequent empirical investigations of ER processes that have adopted the tenets of developmental psychopathology (Beauchaine, Hinshaw, & Gatze-Kopp, 2008; Propper et al., 2008). The conceptual integration of genetics and biology into developmental theories has led to greater appreciation of the complex role of biological processes in transactional models of development that seek to account for the emergence of patterns of adjustment and maladjustment across multiple levels of child functioning. A biopsychosocial perspective motivates *multilevel* research that incorporates biological and behavioral indicators of the factors that may be implicated in complex developmental pathways to outcomes such as child psychopathology. From our view, a broader conceptual framework that incorporates biological, behavioral, and social levels of analyses is essential to better understand the role of ER in the emergence of complex behavioral patterns leading to adjustment and maladjustment. A biopsychosocial perspective is therefore emphasized throughout our review of ER research.

As our review of theoretical perspectives implies, important developmental changes occur in ER processes over the course of development and in the context of important relationships. This developmental process, when viewed from a developmental psychopathology perspective, provides multiple opportunities for continuity and change in the pathways from ER to child outcomes. Next, we provide a brief overview of these developments and address the contexts in which they occur.

DEVELOPMENTAL AND CONTEXTUAL ISSUES

Although some children appear to be quite proficient in the use of basic ER skills at a relatively early age, it is clear

that dramatic growth occurs in the acquisition and display of ER skills and abilities across early childhood (Blandon, Calkins, Keane & O'Brien, 2008). The process may be described broadly as one in which the relatively passive and reactive neonate becomes a child capable of self-initiated behaviors that serve an emotion regulatory function. The infant moves from near complete reliance on caregivers for regulation (e.g., via physical soothing provided when the infant is held) to independent ER (e.g., choosing to find another toy to play with, rather than throwing a tantrum, when the desired toy is taken by a companion), although the variability in such regulation across children, in terms of both style and the efficacy, is considerable (Buss & Goldsmith, 1998; Calkins, in press). As the infant makes this transition to greater independence, the caregiver's use of specific strategies and behaviors within dyadic interactions become integrated into the infant's repertoire of ER skills, across, we presume, both biological and behavioral levels of functioning (Calkins & Dedmon, 2000; Calkins & Hill, 2007). The child may then draw upon this repertoire in a variety of contexts, in both conscious, effortful ways (e.g., walking away from a confrontation with a peer), and in nonconscious, automatic ways (e.g., reducing vagal regulation of the heart to facilitate behavior coping) (Calkins, 2009). Here we address the specific kinds of changes we observe from infancy to adolescence, as well as the dominant contextual influences (parents and peers) that may affect the emergence and use of ER strategies in social and nonsocial contexts.

The Development of ER

Kopp's (1982) seminal treatise on regulation in infancy provided an excellent overview of the early developments in emotional self-regulation. This description has been verified by studies of both normative development (Buss & Goldsmith, 1998; Rothbart, Ziaie, & O'Boyle, 1992) and studies of individual differences (Stifter & Braungart, 1995). These descriptions provide an explanation of how infants develop and utilize a rich behavioral repertoire of strategies in the service of reducing, inhibiting, amplifying, and balancing different affective responses. It is also clear from these descriptions that functioning in a variety of nonemotional domains, including motor, language, cognition, and social development, is implicated in these changes (Kopp, 1989, 1992).

Early efforts at ER, those occurring prior to about three months of age, are controlled largely by physiological mechanisms that are innate (Kopp, 1982). By three months of age, primitive mechanisms of self-soothing, such as sucking, simple motor movements such as turning away, and reflexive signaling in response to discomfort, often in the form of crying, are the primary processes operating, independent of caregiver intervention (Kopp, 1982; Rothbart et al., 1992). The period between 3 and 6 months of age marks a major transition in infant development. First, sleep–wake cycles and eating and elimination processes have become more predictable, signaling an important biological transition. Second, the ability of the infant to voluntarily control arousal levels begins to emerge. This control depends largely on attentional control mechanisms and simple motor skills (Rothbart, Ellis & Posner, this volume; Rothbart et al., 1992; Ruff & Rothbart, 1996), and leads to coordinated use of attention engagement and disengagement, particularly in contexts that evoke negative affect.

By the end of first year of life, infants become much more active and purposeful in their attempts to control affective arousal (Kopp, 1982). First, they begin to employ organized sequences of motor behavior that enable them to reach, retreat, redirect, and self-sooth in a flexible manner that suggests they are responsive to environmental cues. Second, their signaling and redirection become explicitly social as they recognize that caregivers and others may behave in a way that will assist them in the regulation of affective states (Rothbart et al., 1992). During the second year of life, the transition from passive to active methods of emotional self-regulation is complete (Rothbart et al.). Although infants are not entirely capable of controlling their own affect by this age, they are capable of using specific strategies to attempt to manage different affective states, albeit sometimes unsuccessfully (Calkins & Dedmon, 2000; Calkins et al., 1999). Moreover, during this period, infants begin to respond to caregiver directives and, as a consequence of this responsivity, compliance and behavioral self-control begin to emerge (Kopp, 1989). This shift is supported by developments in the motor domain, as well as changes in representational ability and the development of language skills. Brain maturation contributes as well, and by the end of toddlerhood, children have executive control abilities that allow control of arousal, regulation of affective expression, and inhibition and activation of behavior (Bronson, 2000).

Verbal abilities begin to develop in mid to late infancy and as the child moves into the preschool period they contribute to children's ability to regulate and deal with emotional content. As such, the development of language is considered a major milestone in the development of ER (Campos, Frankel, & Camras, 2004). Greater internal state language that develops through parent–child

disclosure of emotion is thought to scaffold children's ability to reflect on their own emotional experience and foster self-awareness, thus resulting in enhanced emotion regulation (Saarni, 1999; Shields et al., 2001). In contrast, language delays that make the use and production of verbal information more difficult may hinder children's ability to successfully utilize effective verbal regulation strategies common during this developmental time period. Children's self-verbalizations of their thoughts and actions have also been suggested as a means through which children may regulate their behavior (Cole, Armstrong, & Pemberton, 2010; Vygotsky, 1962). Taken together, this work suggests that the development of expressive language during preschool allows children to better communicate their needs in socially appropriate ways and enhances their ability understand their own and other's emotional states, therefore facilitating the development of additional tools that aid in the regulation of emotional arousal (Cole et al., 2010).

Across preschool, regulation strategies become more flexible over time to meet contextual demands, allowing children to inhibit or activate behavior accordingly through context-appropriate arousal, planning, and accurate processing of social information in the environment (Eisenberg et al., 2007; Thompson et al., 2008). In an assessment of the trajectories of ER and negativity from ages 4 to 7, ER increased over time (Blandon et al, 2008). There was, however, significant variability in these trajectories indicating that changes in ER over time are susceptible to both individual child factors and also external, environmental factors. As children continue to develop regulatory abilities via modeling, language acquisition, and social interactions, regulation increases while reactivity decreases, though these trajectories are affected, at least to some degree, by early levels of physiological regulation (Blandon et al., 2008).

The practice of these newly emerging skills during the preschool period leads to greater automaticity so that by the time the child is ready to enter the arena of formal schooling, greater effort may be directed toward more demanding academic and social challenges. Importantly, these expanding interactional contexts will place demands that call on the child to integrate emotional and cognitive skills in the service of achieving diverse academic and social goals. Rapid changes have been documented in children's ER and reactivity across early and middle childhood as the capacity for self-regulation increases (Calkins et al., 1999; Calkins & Johnson, 1998; Kochanska, 1994; Kopp, 1989). School-age children are capable of more active and planful regulation strategies including increasing abilities to distract themselves and to reevaluate frustrating and disappointing situations in a more positive manner (Kalpidou, Power, Cherry, & Gottfried, 2004; Stansbury & Sigman, 2000).

Although ER is considered relatively stable from early childhood on (e.g. Raffaelli, Crocket, & Shen, 2005), biological and behavioral aspects of ER continue to be refined into late childhood and early adolescence and are subject to the influence of the environment. Recent evidence from developmental neuroscience suggests that the regions of the brain associated with the ER process include the prefrontal cortex, anterior cingulate cortex, and the amygdala (Beauregard, Levesque, & Paquette, 2004). Brain growth, interconnections in nerve cells, and pruning of connections within these regions occur throughout late childhood and adolescence and are implicated in several domains of functioning including executive functioning, goal directed behaviors, and the regulation of arousal (Giedd, 2008; Spear, 2000).

Late childhood into adolescence is noted as a time of transition, both biologically and environmentally. These transitions are influenced by, and also impact, individuals' experience and expression of emotion. As children enter late childhood, there is a shift in children's developmental contexts, with an increasing emphasis on the peer group and peer influences (Steinberg, 2008). These environmental systems adapt to, and organize themselves around, emerging biological changes within the brain, in hormone levels, and in physical growth. The reciprocal relations that evolve from the interplay between adolescents' social environments and biological changes are believed to have long term impacts on developmental outcomes (Granic, Hollenstein, Dishion & Patterson, 2003).

There is also an emerging literature on the behavioral nature of ER into later childhood and adolescence (e.g. Morris et al., 2007, Raffaelli et al., 2005). With age, children are able to distinguish between both long- and short-term strategies to regulate as they are better able to identify long-term consequences and outcomes of their behavior (Moilanen, 2007). Similarly, children can identify more goals, specifically social goals, for regulating their behaviors. For example, older children expect that displays of negative emotionality are damaging to peer relationships, particularly when the goal is to take care of another's feelings (Shipman, Zeman, & Stegall, 2001; Zeman & Shipman, 1998). Thus, children engage in more sophisticated regulation strategies to mask these negative emotions in front of peers including verbal and facial strategies (Shipman et al., 2001; Zeman & Shipman, 1998). Emotional arousal is heightened during adolescence, likely

due to the fact that neither regulation nor the systems of risk and reward are fully mature. This offset provides links to observed sensation seeking, reckless behaviors, and increased risk for emotional problems (Steinberg, 2004). Further, the increase and instability in hormone levels during adolescence may be implicated in the more labile and negative emotional experiences during this time (Rosenblum & Lewis, 2003).

Research aimed at better understanding the development of emotion regulation again supports the notion that regulatory processes, although grounded in early biological influences like reactivity, are subject to environmental influences and the impact of maturation, and are the means through which these early processes impact later development. Relationships have been described as the inputs and outputs of ER (Bell & Calkins, 2000), therefore highlighting that ER is not only influenced by social partners, but plays a pivotal role in the initiation and maintenance of successful social relationships. As children's social interactions become increasingly more complex, new and unique demands are placed on regulatory processes. Next, we turn to the relationships that likely have the most influence on the development of ER: caregivers and peers.

The Context of ER: Caregiving Practices

One important assumption of much of the research on the acquisition of ER is that parental caregiving practices may support or undermine development and thus contribute to observed individual differences among young children's emotional skills (Morris et al., 2007; Thompson, 1994). As children shift from the more dyadic regulation of infancy to more independent self-regulatory abilities, interactions with parents in emotion-laden contexts teach children that the use of particular strategies may be more useful for the reduction of emotional arousal than other strategies (Sroufe, 1996). Importantly, such interactions both contribute to normative developments and individual variability in ER (Cassidy, 1994).

Although multiple dimensions of caregiving may contribute to the development of self-regulation (Eisenberg, Cumberland, & Spinrad, 1998; Morris et al, 2007), the attachment relationship that develops between caregivers and infants over the first year of life is of particular importance. Current theorizing about childhood attachment and its role in emotional functioning and behavioral adjustment has its roots in the work of John Bowlby (1969/1982), whose evolutionary theory of attachment emphasized the biological adaptiveness of specific attachment behaviors displayed during the infancy period. Such behaviors permit the infant to initiate and maintain contact with the primary caregiver, which serve a survival purpose (Bowlby, 1988). In typical development, infants exhibit a repertoire of behaviors, including looking, crying, and clinging that allow them to signal, and elicit support from, the primary caregiver in times of external threat. Bowlby argued that, by the end of the first year of life, the interactive history between the infant and caregiver, including during times of stress or external threat, would produce an attachment relationship that would provide a sense of security for the infant and significantly influence the child's subsequent adaptation to a variety of challenges (Bowlby, 1988). Emotion regulation theories, specifically, posit that secure attachment relationships, developed through sensitive and supportive caregiver responses, increase children's expectations regarding their own ability to respond to environmental challenge, in addition to increasing the expectations that caregiver intervention will be both available and successful at reducing arousal should children require assistance (Sroufe, 1996). As a result of increased exploration and confidence in one's own abilities to engage in and navigate through emotionally charged situations, a shift from dyadic to self-regulation occurs, resulting in increased self-regulatory capabilities (Sroufe, 1996; Thompson, 1994).

The pattern of findings linking attachment and specific ER behaviors provides support for the important role of caregivers in this process. For example, Diener and colleagues (Diener, Manglesdorf, McHale & Frosch, 2002) observed that attachment classification predicted infants' regulatory strategies during a mildly stressful task in which infants were left with nothing to do while their parent completed a questionnaire. Infants in secure attachment relationships with both parents used strategies emphasizing social orientation. Likewise, in a challenging problem solving task during which the mother was present, toddlers who were classified as secure a year earlier engaged in more maternal help seeking than did avoidant and disorganized toddlers (Schieche & Spangler, 2005). In contrast, mother-reported attachment security was unrelated to the use of mother oriented regulation strategies during laboratory tasks designed to elicit fear and frustration, but was linked with more positive and less negative affect suggesting more adaptive ER among secure children (Smith, Calkins & Keane, 2006). Similarly, infants who were classified as secure at 15 months of age were less likely than avoidant infants to be classified as dysregulated on the basis of high negative affect and defiance during a compliance task at 24 months (NICHD ECCRN, 2004).

Importantly, this effect was significant independent of a variety of demographic characteristics, infant temperament, and maternal sensitivity indicating that the link was robust and not merely an artifact of maternal sensitivity.

Few scholars have examined links between attachment security and emotional regulation processes beyond the infancy period. In a study of preschoolers' use of specific anger control strategies during a waiting paradigm, a secure attachment in infancy predicted greater use of attentional distraction that was linked to successful waiting (Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002). Likewise, 7-year-olds who had been classified as securely attached in infancy reported greater expectations that others would help them emotionally and instrumentally during peer provocations (Ziv, Oppenheim, & Sagi-Schwartz, 2004). This supports the view that children with a secure attachment history have positive expectations of others that may contribute to the use of other-oriented regulation strategies beyond infancy.

Studies examining the relations between specific aspects of parenting thought to be linked to attachment and emotional self-regulation are also of interest when examining the context of ER development. These studies are worth noting because they are mostly conducted with toddlers, children for whom there are clear expectations of emerging autonomous emotional control. In one study of mothers and toddlers, for example, we examined the relations between maternal behavior across a variety of different situations and child emotional self-control in frustrating situations (Calkins, Smith, Gill, & Johnson, 1998). Our analyses indicated that maternal negative and controlling behavior (thought to be reflective of intrusive behavior characteristic of insecure attachment relationships) was related to the use of orienting to or manipulating the object of frustration (a barrier box containing an attractive toy) and negatively related to the use of distraction techniques. Likewise, maternal nonresponsiveness and disengagement following toddler distress cues were linked with children's use of ineffective attentional control strategies during a delay of gratification task (Rodriguez et al., 2005). These data are important in light of findings that the ability to control attention and engage in distraction has been related to the experience of less emotional arousal and reactivity (Calkins, 1997; Crockenberg & Leerkes, 2004; Grolnick, Bridges, & Connell, 1996) and to the display of early externalizing (Calkins & Dedmon, 2000; Crockenberg, Leerkes, & Jó, 2008) and internalizing (Crockenberg & Leerkes, 2006) behavior problems. Finally, maternal sensitivity to infant distress cues, but not nondistress cues, at 6 months was linked with less affect dysregulation at age 2 among temperamentally reactive infants (Leerkes, Blankson, & O'Brien, 2009). That sensitivity to distress was a particularly salient predictor of attachment security in the same sample (McElwain & Booth La Force, 2006), suggests that attachment-related processes may account for this effect.

Although caregiving practices are often attributed a role in the development of ER, the specific processes by which these practices affect children's development are often discussed at a global level (Fox & Calkins, 2003). Greater specificity in *how* caregiving affects children requires a consideration of the multiple levels of functioning that are emerging during early development. As previously discussed, research with infant rat pups demonstrates the importance of caregivers in regulating infant behavior and physiology early in life (Hofer, 1994; Polan & Hofer, 1999). Through hidden regulators operating across multiple sensory levels (e.g., olfactory, tactile, and oral), caregivers play a psychobiological role in the development of infants' behavioral and physiological functioning. So, for example, maternal tactile stimulation may have the effect of lowering the infant's heart rate during a stressful situation, which may in turn, support a more adaptive behavioral response. Moreover, removal of these regulators, during separation or distress, for example, is thought to disrupt infants' functioning. Consistent with this view, maternal holding and rocking are particularly effective at reducing infant distress (Jahromi, Putnam, & Stifter, 2004) and mother–infant skin-to-skin contact has been linked with greater physiological and emotional regulation among premature infants (Feldman, Weller, Sirota, & Eidelman, 2002). Findings have also consistently demonstrated that maternal sensitivity is associated with effective autonomic regulation in response to challenge, and, conversely, that negative, controlling behaviors are related to poor autonomic nervous system (ANS) regulation (e.g., Calkins, Graziano, Berdan, Keane, & Degnan, 2008; Calkins et al., 1998; Conradt & Ablow, 2010; Ham & Tronick, 2006; Moore et al., 2009; Propper & Moore, 2006).

Importantly, evidence from animal models also suggests that caregiving affects infants' biological and behavioral systems of regulation through the environment the caregiver provides rather than through shared inherited traits. For example, Meaney and colleagues have shown that high levels of maternal licking/grooming and arched backed nursing in rats affects the neurological systems associated with the stress response, a process that has a long-term influence on stress-related illness, certain cognitive functions, and physiological functions (Caldji et al., 1998; Champagne & Meaney, 2001; Francis, Caldji, Champagne,

Plotsky, & Meany, 1999). Furthermore, cross-fostering studies demonstrate convincingly that these maternal behaviors are transmitted behaviorally through the nursing mother and not through the biological mother, indicating that early caregiving is a crucial factor in early development and may affect the organism's level of emotional reactivity even when they reach adulthood (Calatayud, Coubard, & Belzung, 2004; Champagne & Meaney, 2001).

Longitudinal studies have been more informative about the relations over time between caregiving and physiological regulation in infants. One recent study (Propper et al., 2008), identified children who might be at genetic risk for problems with regulation because they carried the risk allele of the dopamine transmitter gene DRD2. The findings revealed that infants without the risk allele displayed appropriate cardiac vagal regulation in a laboratory paradigm that was challenging to the infants, and this pattern held across the first year. Infants with the risk allele, however, displayed a different pattern of results, depending on the level of caregiver sensitivity to which they were exposed. For infants with the risk allele and mothers who were not sensitive, poor physiological regulation was observed across the first year. Infants with the risk allele and mothers who were sensitive displayed poor physiological regulation during assessments at 3 and 6 months of age, but by the end of the first year, their pattern of physiological responding to challenge was no different than the infants without the risk allele. This G×E interaction demonstrates convincingly that infants and caregivers each bring something to the developmental process of acquiring regulatory skills very early in development.

The Context of ER: Peer Relationships

Peer interactions offer a socialization experience that places different demands on children's regulatory abilities than those of parent–child interactions. Typically, research examines the influence of emotion regulation on interactions with peers. For example, children's anger reactions that are less constructive, such as venting and physical retaliation, have been shown to be related to greater emotional intensity and less socially adaptive behavior, but children who employ more constructive methods are rated as having better social skills and social status as well as lower aggression and emotional intensity (Eisenberg, Fabes, Nyman, Bernzweig, & Pinuelas, 1994). Similarly, maladaptive behaviors with peers have been found to be associated with lower social status, peer-reported social behaviors such as engaging in fighting and bossiness in boys, and ratings of aggressiveness and sneakiness for girls (Keane & Calkins, 2004). Given these findings, it is of no surprise that children who lack the regulatory abilities necessary for successful social interaction also have fewer mutual friendships (Dishion, Piehler, & Myers, 2008). Thus, a body of research indicates that children who are well regulated develop the social skills necessary to form successful peer relationships, and children who display deficits in ER abilities have difficulties engaging in positive social interactions and developing positive relationships with peers.

Although ER has been consistently shown to influence children's social skills and peer interactions, the development of ER abilities are also developed in and facilitated by peer relationships (Howes, 2009). Children who are highly reactive and have difficulty regulating their emotions are viewed by peers as socially unskilled or aggressive and, as a result, they are less likely to engage in positive peer interactions and develop friendships that provide beneficial socialization experiences. Increased participation in social contexts with multiple social partners affords children greater opportunities for the development of more sophisticated ER abilities. Time spent in friendships, for example, allows children to practice interpersonal skills that would not be provided by other kinds of relationships such as the parent–child relationship (Laursen, Finkelstein, & Betts, 2001). Maintenance of friendships offers opportunities to develop conflict resolution skills and note the outcomes of these strategies (Fonzi, Schneider, Tani, & Tomada, 1997). Finally, lasting friendships provide children evidence for the continued reward of adaptive social skills (Laursen et al., 2000).

Although friendships may serve as a developmental resource in the socialization of adaptive regulatory behaviors when the identity and qualities of a friend are positive, friendships with children who engage in maladaptive behaviors may impede the development of ER. Continued participation in deviant behaviors limits the development of social and emotional competencies including ER. In turn, children are more susceptible to peer influence as they lack the planning and impulse control necessary to decline participation in the negative behaviors endorsed by their friends (Dishion et al., 2008). By engaging in these maladaptive behaviors with similarly deviant peers, children are unlikely to develop the competencies necessary to enhance their ER and resist negative influences. Individual differences in self-regulation may serve as a protective factor from deviant peer influence, as a well-regulated adolescent is less susceptible to the immediate rewards posed by engaging in deviant talk or behavior among their peers (Gardner, Dishion, & Connell, 2008). This may be

supported by the finding that deviant youth experience greater susceptibility to peer influence (Brown, Clasen, & Eicher, 1986; Steinberg & Monahan, 2007). Similarly, self-control has been found to moderate the link between deviant peers and delinquent behavior given that a lack of self-control leads to maladaptive behaviors (McGloin & Shermer, 2009). This work suggests that ER is necessary for youth to avoid succumbing to negative peer influence and poor regulation is associated with a vulnerability to engage with deviant peers (Dishion et al., 2008).

Our review of the development of ER and the contextual influences that may be observed during development suggests that caregivers and peers can serve to facilitate the acquisition of ER skills or disrupt the process of developing those skills. Importantly, though, this development is somewhat dynamic and the nature and degree of contextual influence may vary as a function of both where the child is developmentally and in terms of their general level of psychological functioning. The challenge of modeling these pathways over time is significant. Moreover, as we see in the next section, measuring and quantifying the ER processes themselves poses significant challenges that are also in part a function of studying development in context.

EMPIRICAL APPROACHES AND CHALLENGES

Early emotion regulation research focused on single method measurement approaches and on assessments of constructs thought to reflect ER or ER deficits (such as behavior problems) rather than on the measurement of the construct itself. A conceptualization of ER that acknowledges the biological, psychological, and social components of the construct implies a multimethod approach to studying ER and its relation to child functioning. Thus, in the following section we first discuss methodological considerations related to measuring ER and then highlight approaches in which behavioral, biological, and social processes integral to the regulation of emotion are assessed. In addition, because ER develops through transactional associations at multiple levels in a variety of contexts across development, the consideration of the environmental context and children's developmental status are also considered.

Developmental and Contextual Implications for Measurement

One of the most significant challenges to the study of the development of ER and its relation to adaptive versus maladaptive behavior is that the manifestation of ER abilities changes significantly over time. Because of its dependence on the maturation of prefrontal-limbic connections, the development of emotion regulatory skills is relatively protracted (Beauregard et al., 2004), and extends from the emergence of basic and automatic regulation of biological processes in infancy to the more self-conscious and intentional regulation of behavior and cognition in middle childhood and adolescence (Ochsner & Gross, 2004). Further, development from infancy through adolescence is marked by continuous changes and restructurings within and across many relevant psychological and biological domains, including emotional, social, cognitive, and neural development. To be empirically valid, measures need to be sensitive enough to capture developmental changes associated with these reorganizations and to assess the construct in a developmentally appropriate manner (Zeman, Klimes-Dougan, Cassano, & Adrian, 2007).

For example, infants and young children are not often developmentally capable of articulating their specific emotional experience; thus, observational indicators of emotional expression and regulation may be more informative and age appropriate during infancy and early childhood than during middle childhood or adolescence when regulation abilities become more internalized and display rules influence the behavioral indicators of ER. Further, depending on the age of the child, certain behavioral and physiological responses may be considered more or less adaptive. For example, physical self-soothing behaviors are thought to be an adaptive ER strategy in infancy and toddlerhood (Rothbart, 1989). However, once children move beyond infancy and develop more advanced attentional, verbal, and social skills, self-soothing behaviors are considered to be an immature way to regulate emotion and more sophisticated strategies are expected. Similarly, a strong physiological response to a stranger may be adaptive and developmentally appropriate at 9 months, but the same physiological response in middle childhood may be an indicator of maladjustment. Thus, consideration of the developmental time period during which ER is being assessed is important for the selection, utility, and validity of ER measures.

In addition to considering the developmental time period, the measurement of ER cannot be considered outside of the environmental context in which the emotion is embedded (Campos et al., 2011). ER is often defined as the ability to modulate emotional expressions and experiences in a way that allows for the accomplishment of one's goals (Calkins, 2004b; Thompson, 1994), and goals vary based on specific social situations. Therefore,

the adaptive nature of the physiological and behavioral processes underlying emotional control is often dependent on the context in which the emotion is experienced or expressed. For example, physiological responses that are thought to underlie the generation of coping behaviors may be adaptive within a threatening environmental context. However, the same physiological response may be considered maladaptive within a context of social engagement or cognitive challenge. And indeed, although many studies have found greater vagal withdrawal to be associated with adaptive developmental outcomes, empirical work assessing the functional role of cardiac vagal functioning in the development of psychosocial adjustment has shown moderate vagal withdrawal or augmented vagal reactivity to be related to optimal functioning in some cognitive and social contexts (Hastings et al., 2008; Marcovitch et al., 2010). Relatedly, if we consider a child engaged in a frustration task, employing caregiver oriented strategies may only be adaptive if the caregiver is readily available to intervene or serve as a distraction, and problem focused strategies may only be useful at reducing arousal if the frustrating situation has the potential to be manipulated by the child. Therefore, although there is a variety of measures utilized in the assessment of ER, the assumptions made about the adaptive nature of behavioral and physiological emotional responses should be considered in conjunction with the environmental context in which the emotion is elicited.

Approaches to Assessing ER

Behaviors and Strategies

Emotions are thought to initiate and guide behavior such that the experience of negative arousal, such as intense anger or fear, prompts individuals to engage in behaviors that will lessen the intensity of the negative emotion experienced (Youngstrom & Izard, 2008). Researchers studying the regulation of emotion have defined behaviors that are enacted to modulate or maintain emotional arousal as ER strategies (Thompson, 1994). Although it is necessary to regulate both positive and negative emotion, individual differences in children's abilities to control negative arousal have been found to be particularly salient to the understanding of developmental psychopathology. Thus, the majority of ER research has focused on children's abilities to manage emotional distress through the measurement of behavioral strategies used to regulate negative emotion. The development and use of ER strategies can vary across development as the result of increased attentional abilities, memory, and cognitive function. Thus, in addition to discussing commonly measured behavioral strategies, we highlight the salience of each strategy for different developmental time periods.

Observed Strategies of Early Childhood. Because young children have relatively limited physiological, attentional, and cognitive abilities, emotion regulation strategies tend to be more behaviorally based and are therefore more easily observed during the infancy, toddler, and preschool periods than later in development. To observe children's ER strategies, researchers often devise experimental paradigms to elicit a variety of negative emotions by simulating situations children experience on a daily basis (Goldsmith, Reilly, Lemery, Longley, & Prescott, 1999; Goldsmith & Rothbart, 1993). Examples of such simulations include frustration paradigms, in which children are blocked from a desired goal (e.g., Dollar & Stifter, 2012), fear paradigms, in which children engage with an unpredictable or frightening object (e.g., Hane, Fox, Henderson, & Marshall, 2008), disappointment paradigms (e.g., Durbin, 2010), in which children receive an undesirable gift when they were expecting a more exciting one, and delay of gratification paradigms (e.g., Kochanska & Knaack, 2003) in which children are asked to withhold their engagement with a desirable object. In addition to variation in the type of emotion-eliciting task, paradigms differ with regard to who is present. Some tasks are designed to observe mother–child interactions during common negatively charged situations, such as the discussion of conflict (e.g., Allen, Hauser, Bell, O'Connor, 1994), or the clean up of toys (e.g., Kochanska, Coy, & Murray, 2001). Other tasks require children to comply with an experimenter (Goldsmith & Reilly, 1993), or engage with a peer or a social setting (e.g., Lam, Dickerson, Zoccola, & Zaldivar, 2009), and some tasks are performed completely independently (Goldsmith & Rothbart, 1993). Strategies to regulate emotions may vary, or be more or less adaptive, depending on the type of task, who is involved and available, and the age of the child (Grolnick, McMenamy, Kurowski, 2006; Zeman et al., 2007). For this reason, when examining the associations between ER strategies and child adjustment, consideration should be given to the type of emotional challenge and the available social partners.

ER strategies observed within these paradigms have been organized within behavioral ER categories including self-soothing or self-comforting, orientation toward a caregiver, disengagement of attention, avoidance, and approach (Gross, 1998; Rothbart & Derryberry, 1981; Rothbart et al., 1992). These observed regulatory strategies are most commonly measured in terms of presence, frequency, or duration. For example, researchers can

observe and record whether or not a child engaged in specific regulatory behaviors, the number of times a child employs a particular regulatory strategy, or they may document the length of time the child engages in different strategies (Dollar & Stifter, 2012; Graziano, Calkins, & Keane, 2010; Mirabile, Scaramella, Sohr-Preson, & Robinson, 2009; Perry, Calkins, Nelson, Leerkes, & Marcovitch, 2012; Trentacosta & Shaw, 2009). Below, we highlight commonly observed regulatory strategies measured during experimental contexts designed to elicit negative emotional arousal.

Self-Soothing Physical self-soothing behaviors include sucking on the fingers or gums, engaging in repetitive or gentle rubbing, hair twirling, or hand clasping (Diener & Mangelsdorf, 1999; Rothbart, 1989). Although physical self-soothing is a primary regulatory strategy observed in early infancy, children's increased attentional control and locomotive capabilities often forecast a normative decrease in physical self-soothing and an increase in more sophisticated behaviors by age 2 (Grolnick et al., 1996; Mangelsdorf, Shapiro, & Marzof, 1995; Rothbart, 1989). As children's language and representational capabilities develop, use of symbolic self-soothing often emerges. Specifically, children may regulate and comfort themselves by mentally transforming a distressing emotional situation into a manageable one by developing game-like activities around the source of distress (Grolnick et al., 2006).

Orientation Toward a Caregiver Although there is a shift toward more autonomous self-regulation of emotion, ER is not always independent from others or accomplished alone; children can utilize caregivers in a way that assists in the regulation of emotion without being dependent (Grolnick et al., 2006). For example, a child who initiates a conversation with a caregiver during a stressful situation is quite different from a child relying on a mother to intervene and take responsibility for reducing his or her arousal. Thus, caregiver-oriented behaviors that children employ such as social referencing, proximity seeking, help seeking, and bids for attention are often used as indictors of child-initiated attempts to reduce arousal by facilitating coregulation between themselves and their caregiver (Diener et al., 2002; Perry et al., 2012; Supplee et al., 2009).

Disengagement of Attention Infants are able to voluntarily shift their attention between 3 and 6 months of age (Rothbart, Posner, & Boylan, 1990), and a number of empirical studies have shown that infants who are able to disengage and avert their gaze from emotional arousing stimuli show decreased negative affect (e.g., Buss & Goldsmith, 1998; Crockenberg & Leerkes, 2004; Stifter & Braungart, 1995). As attentional networks mature and children develop increased autonomy, they begin to more actively re-direct attention through the use of distraction strategies. Thus, attentional distraction behaviors characterized by shifting attention to less emotionally relevant aspects of a situation, or away from the situation entirely, are commonly observed in early childhood and can serve to reduce emotional arousal (Grolnick et al., 2006; Gross, 1999).

Avoidance Avoidant regulatory behaviors include moving or turning away from the negative stimuli or leaving the emotionally charged context (Gross, 1999). Increased autonomy in movement allows children to decrease negative arousal by physically and mentally disengaging from the source of arousal. For example, avoidant strategies observed in early childhood may include movement away from negative stimuli or attempting to leave a negative situation.

Approach Approach strategies involve maintaining or increasing attentional focus and engagement with the source of arousal and are utilized as a means of regulation throughout childhood (e.g., Compas, Connor-Smith, Saltzman, Thomsen & Wadsworth, 2001; Grolnick et al., 1996). Observed problem solving responses such as brainstorming solutions to a problem, or planning a course of action, are specific and conscious attempts to modulate arousal by changing a distressing situation and attempting to control the consequences that may arise as a result of a negative event (Aldao & Nolen-Hoeksema, 2010; Aldao, Nolen-Hoeksema, & Schweizer, 2010). It is important to note that although attention and problem-focused engagement with the source of negative arousal may be effective at reducing distress in some instances, attempting to alter an environment that cannot be changed (i.e., continued searching for the mother during separation) may in contrast heighten negative arousal (Grolnick et al., 1996).

Cognitively Based Strategies of Middle Childhood and Adolescence. As children develop increased attentional abilities, memory, and cognitive function, strategies used to regulate emotion are thought to become more internal and cognitively based (Kopp, 1982). Therefore, researchers are often unable to observe regulatory strategies beyond early childhood and begin to rely more heavily on alternative measurement strategies. Although a number of studies ask children and adolescents to report on the frequency or likelihood of employing specific regulatory strategies (Aldao, Mennin, McLaughlin, 2013; Gullone et al., 2010; Hsieh & Stright, 2012; Martini & Busseri, 2012; Romens & Pollak, 2012), many researchers design experimental paradigms in

which they teach or instruct children to use different strategies to modulate negative arousal (Carthy, Horesh, Apter, Edge, & Gross, 2010; Davis & Levine, 2013; DeCicco, Solomon, & Dennis, 2012; Dennis & Hajcak, 2009; McRae et al. 2012); by controlling which type of strategies children employ and comparing strategy use to the experience of negative emotion, researchers are able to better understand the regulatory function and developmental implications of each regulatory behavior. Below we highlight three commonly measured ER strategies throughout middle and late childhood: cognitive reappraisal, rumination, and suppression.

Cognitive Reappraisal Cognitive reappraisal refers to altering the way an individual thinks about a situation to change its emotional impact (Werner & Gross, 2009). In an effort to reduce arousal, individuals may attempt to change the situation's emotional significance by generating neutral or positive interpretations of emotionally charged contexts, or change their belief in the extent to which they can control the situation (Aldo et al., 2010; Gross, 1998, 1999). For example, if a child was anxious over an exam, they may remind themselves that it is only a test and acknowledge their ability to manage the demands of the exam through studying and preparation.

Rumination Rumination involves repetitive attentional focus on thoughts and feelings surrounding negative emotional contexts. Although individuals often engage in rumination as a way of decreasing negative arousal around a specific emotion-eliciting situation (Papageorgiou & Wells, 2003), rumination increases attention to the source of negative arousal and thus may produce more intense and longer lasting experiences of negative emotion (Gross, 1999).

Suppression Another avoidant strategy used in late childhood and adolescence is expressive suppression of negative emotion. An example of this may be a child maintaining a neutral face while children on the playground are teasing her. Although suppression of negative emotion may reduce negative arousal and the subjective experience of negative emotion temporarily, it may be less effective at reducing arousal over an extended period of time (Gross, 1998).

Reported Measures of ER

To gain additional insight into children's ability to emotionally regulate with different social partners within and across different environmental contexts, parent report, teacher report, and self-report measures are often utilized. Although it is important for researchers to consider the challenges associated with reported measures of ER, such as whether children are developmentally capable to accurately reflect and report on their own emotional competence, whether parents and teachers are objective, and whether there is concordance across reporters (Zeman et al., 2007), reported measures of children's ER have several advantages. First, social contexts in which emotions take place can have a large impact on the emotion experienced, the extent to which the emotion is expressed, and the specific strategies or skills used to modulate that emotion. Therefore, both other and self-report measures provide an index of children's regulatory capabilities across a wide variety of settings outside the laboratory that might not have otherwise been obtained. Second, observed measures don't reveal insight into the reasoning and motivation behind emotional behavior that children's self-reported measures may uncover (Zeman, et al., 2007). Finally, reported measures of ER are easier to obtain than observed or physiological indices, and the Likert scales often associated with them can allow for greater variability in the report of ER capabilities.

Self-report. Although there has been an increased interest in the construct of ER and its association with the development of psychopathology across the last 20 years, there are a surprisingly small number of validated questionnaire measures within this area, and measures of children's self-reported ER are particularly scarce. Most self-report measures designed to assess ER specifically, including the ER Questionnaire (ERQ; Gross & John, 2002), the Difficulties in ER Scale (DERS; Gratz & Roemer, 2004), and the Cognitive ER Questionnaire (CERQ; Garnefski, Kraaij, & Spinhoven, 2001), have primarily been developed and used with adults. However, a few studies have used these measures in developmental populations (e.g., Garnefski, Boon, & Kraaji, 2003; Gullone, Hughes, King, & Tonge, 2010; Neumann, van Lier, Gratz, & Koot, 2010). Moreover, self-report measures utilized with children often focus on a specific regulatory strategy, emotion, or general emotionality from a temperament perspective. Examples include the Pediatric Anger Expression Scale-III (PAES-III; Jacobs, Phelps, & Rohrs, 1989), which measures anger turned inward, anger expressed outwardly, and anger controlled cognitively or behaviorally, the Early Adolescent Temperament Questionnaire (EATQ-R; Capaldi & Rothbart,1992), which measures self-regulation, reactivity, and emotionality (Cox, Stabb, and Hulgus, 2000; Hewitt et al., 2002), the How I Feel (HIF; Walden, Harris & Catron, 2003), which measures the intensity and control of emotion, and the Children's Worry Management Scale (CWMS;

Zeman, Cassano, Suveg, & Shipman 2010), which assesses children's self-reported methods of regulating worry (i.e., suppression of worry, exaggerated displays of worry, and constructive ways of managing worry). More recently, however, Phillips and Power (2007) have developed the Regulation of Emotions Questionnaire (REQ) to assess the frequency with which adolescents use both functional and dysfunctional ER strategies to regulate emotions.

Other-report. Because infants and young children are often not capable of self-reporting their own ability to manage and control emotional arousal, the majority of other-reported questionnaires are designed for and used with parents of young children. However, many have been successfully implemented with teachers and day care providers (e.g., Fujiki, Spackman, Brinton & Hall, 2004; Goldsmith, Rieser-Danner, & Briggs, 1991; Ramsden & Hubbard, 2002). Similar to self-reported measures of ER, other-report measures specifically assessing children's ability to modulate emotional arousal are limited. Often, scales of the Infant Behavior Questionnaire (Rothbart, 1981), the Toddler Behavior Questionnaire (TBQ; Hagekull, 1985), Child Behavior Questionnaire (CBQ, Rothbart 1981; CBQ-VSF, Putnam & Rothbart, 2006) and the Child Behavior Checklist (CBCL; Achenbach, 1991), which assess negative affectivity, emotional reactivity, and self-regulation, have been utilized within the ER literature (e.g., Batum & Yagmurlu, 2007; Carter, Little, Briggs-Gowan, Kogan, 1999; Goldsmith, Buss, & Lemery, 1997). However, the most frequently used measure given to parents and teachers designed to specifically assess children's ability to modulate emotional arousal is the ER Checklist (ERC; Shields & Cicchetti, 1997), which addresses parents' perceptions of their children's ER and emotionality. Although useful, the ERC provides a more general account of children's ER and does not provide information on regulation of specific types of emotions or strategies used to regulate emotion. Thus, additional parent-reported measures of children's ER strategies are needed.

Biological Measures of ER

In addition to assessing the regulation of emotion through observations and reports, there has been an increase in the use of measures of underlying physiological responses in the expression and experience of emotion. The use of physiological measures is advantageous in that it allows for assessment at a level of child functioning that is often thought of as foundational to the development of subsequent skills (Lewis & Todd, 2007), and identifies underlying mechanisms integral to the regulation of emotion that cannot be observed or communicated through observation alone. Moreover, assessing physiological biomarkers of specific patterns of emotional responding allows for greater insight into the bidirectional associations between behavior and physiology, allowing developmental researchers to identify important aspects of the physiology-behavior connection for developmental trajectories (Fox, Hane, & Pérez-Edgar, 2006). Over the last decade, researchers attempting to better understand the physiological underpinnings of ER have primarily focused on autonomic arousal, activation of the hypothalamus-pituitary-adrenal (HPA) system, frontal electroencephalographic asymmetry underlying the experience and control of emotion, and event-related potentials in response to emotional stimuli. Thus, in the section below we discuss the measurement of activation within each physiological system and its relation to ER and developmental psychopathology.

Autonomic Arousal. ER theories that focus on the underlying physiological components highlight the maturation of the autonomic nervous system (ANS) as playing a fundamental role in the regulation of emotion and behavior (Santucci et al., 2008). The ANS is composed of two branches: the excitatory sympathetic nervous system (SNS) and the inhibitory parasympathetic nervous system (PNS). The primary job of the ANS is to maintain the body's homeostasis; therefore, the two subsystems work in conjunction to increase or decrease physiological arousal in an organ or system. The SNS is primarily dominant during threatening or stressful situations and produces increased physiological arousal (i.e., increased heart rate, dilated pupils) to meet environmental demands, while the PNS is primarily dominant during calm and restful periods to maintain homeostasis. Given the complexity of ANS functioning, ER researchers often investigate PNS and SNS responses and their association to behavior during environmental contexts that are perceived as challenging or threatening. Thus, we discuss the measurement of both sympathetic (i.e., rejection period and electrodermal activity) and parasympathetic (i.e., heart rate variability, or vagal tone) activation, and their relation to emotional behavior and adjustment.

Preejection Period Preejection period (PEP) is defined as the sympathetically mediated time interval between the onset of ventricular depolarization and the onset of left ventricular ejection (i.e., ejection of blood into the aorta; Brenner & Beauchaine, 2011; Brenner, Beauchaine, & Sylvers, 2005; Fox et al., 2006) and is measured by simultaneously collecting both electrocardiogram and

impedance cardiography. PEP can serve as an estimate of sympathetic influences on the heart because it usually reflects changes in how forceful the heart contracts (Stern, Ray, & Quigley, 2001). PEP is negatively correlated with sympathetic activation such that lower values represent increases in sympathetic activity while higher values indicate decreased sympathetic activity. Sympathetic reactivity, as measured by PEP, has been found to be related to toddlers' freezing behaviors during mildly threatening stranger interactions (Buss, Davidson, Kalin, & Goldsmith, 2004), children's memory of stressful events (Quas, Carrick, Alkon, Goldstein, & Boyce, 2006), externalizing behaviors in middle childhood (Boyce et al., 2001), the presence of conduct disorders in adolescence (Beauchaine, Katkin, Strassberg, & Snarr, 2001), and ER (Stifter, Dollar, Cipriano, 2011).

Electrodermal Activity Another way of assessing sympathetic nervous system activation is through the measurement of electrodermal activity (EDA), or skin conductance. EDA results from activity of eccrine sweat glands, a special type of sweat gland concentrated on the palms of the hands and the soles of the feet. Specifically, when environmental stimuli activate the sympathetic nervous system, sweat rises toward the skin's surface and eccrine sweat glands act as resistors. The hydration of the skin associated with the increase in sweat creates greater skin conductance and lower skin resistance. To measure skin resistance, researchers pass a small current between two electrodes on the skin. Thus, the measurement of skin conductance is the extent to which electrical conduction is increased and skin resistance is decreased (Dawson, Schell, & Filion, 2000; Stern et al., 2001). Empirical work has found measures of electrodermal responsivity to be associated with preschoolers' emotional expression (Cole, Zahn-Waxler, Fox, Usher, Welsh, 1996), delinquency symptoms in middle childhood (El-Sheikh, Hinnant, & Erath, 2011), and adolescents' behavioral warmth (Diamond & Cribbet, 2013).

Respiratory Sinus Arrhythmia Pathways of the parasympathetic nervous system serve to modulate changes in sympathetic activity and are therefore thought to play a critical role in the regulation of emotion (Porges, 2003). Specifically, the myelinated vagus nerve, originating in the brainstem nucleus ambiguous, provides input into the sinoatrial node of the heart, producing dynamic changes in cardiac activity that allow the body to transition between sustaining metabolic processes and generating responses to the environment (Porges, 2007). Parasympathetic influences on heart rate can be quantified by measuring heart rate variability that occurs at the frequency of breathing (i.e., respiratory sinus arrhythmia, RSA). Two common ways of measuring RSA include the peak-to-valley method (Fouad, Tarazi, Ferrario, Fighaly, & Alicandri, 1984) and spectral analysis (Porges, 1986). The peak-to-valley method quantifies RSA by a breath-by-breath measure of heart rate that represents the difference between the longest and shortest heart period within the respiratory cycle (Grossman & Svbeak, 1987). Using spectral analysis, Porges (1986) applied an algorithm to detrend periodicities in heart period (HP) slower than RSA. A band-pass filter then extracts the variance of HP within the frequency band of spontaneous respiration. A multitude of empirical studies have linked parasympathetic activity, as measured by RSA, with the regulation of emotion (e.g., Brooker & Buss, 2009; Gentzler, Santucci, Kovacs, & Fox, 2009; Moore, 2009; Vasilev, Crowell, Beauchaine, Mead, & Gatzke-Kopp, 2009) and behavioral outcomes such as internalizing and externalizing problems (e.g., Fortunato, Gatzke-Kopp, Ram, 2013; Graziano & Derefinko, 2013; Hastings et al., 2008; Hinnant & El-Sheikh, 2009).

The Hypothalamic-Pituitary-Adrenocortical System. The most common way of assessing activation of the hypothalamic-pituitary-adrenocortical (HPA) axis is through the measurement of the hormonal product of this system, cortisol. Although most developmental researchers obtain cortisol through noninvasive saliva samples, it can also be assessed in the blood or urine. As part of the body's normal functioning, the hypothalamus produces both a cortisol-releasing hormone (CRH) and vasopressin. In combination, CRH and vasopressin stimulate the anterior pituitary gland to produce adrenocorticotrophic hormone (ACTH). ACTH is then released into general circulation and stimulates cells in the adrenal glands to produce and release cortisol into the bloodstream (Chrousos & Gold, 1992). Although cortisol production varies rhythmically in the course of a 24-hour period, psychological stressors increase cortisol above basal levels at that time of day. Therefore, cortisol reactivity to emotional contexts and stimuli has been of particular interest to ER researchers and has not only been associated with children's regulation of emotion (e.g., de Veld, Riksen-Walraven, & de Weerth, 2012; Lam et al., 2009; Stansbury & Gunnar, 2004; Zimmerman & Stansbury, 2004), but internalizing and externalizing behaviors as well (e.g., Alink et al., 2008; Allwood, Handwerger, Kivlighan, Granger, & Stroud, 2011; Bagner, Sheinkopf, Vohr, & Lester, 2010).

Electroencephalographic Activity.

Frontal Electroencephalographic Asymmetry Researchers have suggested the possibility that the brain systems assessed by frontal e lectroencephalographic (EEG) asymmetries may moderate or mediate emotional experience

and responding (Fox, 1991, 1994; Fox & Davidson, 1987). EEG is collected via electrodes placed on the scalp and electrical activity is recorded and referenced to inactive electrode sites. The electrical signal collected via the electrodes is thought to be derived from the aggregate of postsynaptic potentials and EEG power is summed across frequency bins to form measures of band power (Fox et al., 2006). A number of studies have shown that the association between asymmetry and behavioral activation is specific to anterior brain regions (Sutton & Davidson, 1997). Therefore, the most common ways to measure EEG asymmetry is by subtracting the natural log of left hemisphere alpha power from the natural log of right hemisphere alpha power (ln[right alpha] − ln[left alpha]) at frontal electrode sites. This approach results in a one-dimensional scale representing the relative activity of the right and left hemispheres, with the middle point of the scale equaling zero or symmetrical activity (Coan & Allen, 2004). Because alpha power reflects the inverse of activation, higher scores indicate relatively greater left frontal activity whereas lower scores indicate relatively greater right frontal activity (i.e., a leftward and rightward asymmetry). Within the ER and psychopathology literature, EEG asymmetry has been frequently measured and related to behavioral adjustment and mental health (Curtis & Cicchetti, 2007; Gatze-Kopp, Jetha, & Segalowitz, 2012; He et al., 2010; Santesso, Reker, Schmidt, & Segalowitz, 2006).

Event-Related Potentials In addition to EEG asymmetry, recent work in developmental neuropsychology has begun to examine the relation between event-related potentials (ERPs) and emotion regulation. ERPs are electrical potentials generated by the brain and reflect the synchronous activity of neurons (Luck, 2005). Unlike spontaneous EEG, which is recorded continuously across time, ERPs are time-locked to specific events (i.e., the presentation of a stimulus or the execution of a response), resulting in positive or negative voltage changes over time (Hajcak, MacNamara, & Olvet, 2010). Because the ERP is smaller in voltage than spontaneous EEG, ERPs are commonly assessed by repeatedly presenting a stimulus and averaging the electrocortical signal to each of these stimuli (Stern et al., 2001). Although a relatively small amount of empirical work has assessed the associations between ER and ERPs, interest in this area has been rapidly growing and associations between multiple ERP components (e.g., the late positive potential (LLP), the N200, and the P300) and ER have been consistently found (Hajcak et al., 2010; Hajcak & Nieuwenhuis, 2006; Lamm & Lewis, 2010; Lewis, Lamm, Segalowitz, Stieben, & Zelazo, 2006; Lewis & Stieben, 2004; Moser, Hajcak, Bukey, & Simmons, 2006).

Measures of Coregulation

Because of the interpersonal nature of the development of ER, developmental scientists often utilize caregiver–child interactions as a means of assessing ER capabilities. Work in this area is founded on the belief that one partner's behaviors and emotions affects the other in reciprocal and dynamic ways, and these complex associations influence children's growing ability to self-regulate emotion (Cole et al., 2004).

To gauge reciprocal regulation of the dyad, infant studies have examined the synchrony and contingency between infants' and mothers' emotional communication and expressive behavior by examining the timing and sequencing of changes in each partner's expression, behavior, and physiology (e.g., Cohn & Tronick, 1989; Feldman, 2009; Field, 1994; Tronick & Cohn, 1989). Crockenberg and Leerkes (2004) demonstrated that adaptive regulation is contingently linked with prior sensitivity behaviors such that in dyads in which mothers responded contingently to their looking away, infants were less distressed than infants whose mothers did not respond contingently; thus identifying contingent maternal responsiveness as a key predictor of ER in infancy. These contingencies have also been examined in the still-face paradigm to assess infant regulation when there is a disruption in the expected course of social interaction (e.g., Braungart-Rieker, Garwood, Powers, & Notaro, 1998; Weinberg, Tronick, Cohn, & Olson, 1999).

In studies of older children, researchers have used previously described laboratory paradigms to assess the social interaction between the caregiver and the child in highly emotionally charged contexts. In a study assessing coregulation during a delay of gratification task, Putnam, Spritz, and Stifter (2002) found that attending away from the forbidden toy most frequently occurred in response to mothers' directives, and when children redirected their attention, mothers appeared to support this regulation strategy through continued distraction. These results emphasized the coregulatory process in which mothers were both affecting their toddlers' regulatory strategies and being affected by their children's behavior. Thus, methods employed to assess the contingent and synchronous interactions between infants' and caregivers' behavior and physiology are well-suited for the measurement of ER.

Multiple Methods and Measures Across Developmental Domains

Last and perhaps most importantly, it is imperative that researchers continue to conduct multilevel research that incorporates multiple methods and measures to assess development within and across levels of child functioning

to better understand the complex behavioral, biological, and social processes implicated in developmental pathways to ER and child adjustment. In their discussion of methodological challenges for future work in emotion regulation, Cole and colleagues (2004) posited that some of the most compelling evidence for the construct of emotion regulation has come from studies that have independently assessed activated emotion and emotion regulation strategies, have analyzed temporal relations among regulatory phenomena, have compared emotion regulation abilities in contrasting conditions, and have used multiple converging measures to demonstrate the organization of emotional regulatory processes. For example, research measuring developmental functioning at various levels might be able to better address how genes influence neural changes in response to emotional stimuli, and how neural changes impact cognition and the production of complex behavior during emotion-eliciting environmental contexts. Moreover, research employing multiple methods to examine within level associations may help clarify and integrate previous work examining behavioral or physiological regulation of emotion. For instance, when individuals encounter situations that require the modulation of emotional arousal, we know that multiple biological systems are enacted (Calkins & Hill, 2007, Thompson et al., 2008). Yet there is relatively little synthesis of theoretical or empirical work addressing the relations among various biological processes and regulatory functioning. Further, Weems and Pina (2010) have underscored the importance of understanding the interrelations of a variety of assessment strategies (i.e., attending to method variance—self-report vs. observation vs. physiological functioning) to improve the assessment of the construct of emotion regulation in psychopathology research. Therefore, measurement of ER at multiple levels of child functioning and the use of multiple assessment strategies may best elucidate the dynamic interplay among multiple developmental processes involved in the regulation of emotion.

CONTRIBUTIONS OF EMOTION REGULATION TO DEVELOPMENTAL OUTCOMES

Considerable research on ER demonstrates it is a powerful mediator of interpersonal relationships and socioemotional adjustment as early as the first few years of life and continuing throughout childhood and adolescence (Thompson & Meyer, 2007). From infancy onward, the practice of early and newly emerging emotion regulation skills leads to greater automaticity and flexibility so that by the time the child is ready to enter an academic setting, greater effort can be directed toward more demanding academic and social challenges, challenges that will change as the child moves through various developmental periods. Importantly, these expanding interactional contexts will place demands that call on the child to use these skills in the service of displaying appropriate social behavior and achieving diverse academic and social goals. Here we consider both normative (social competence, academic performance) and nonnormative outcomes in the form of various presentations of psychopathology.

ER and Developmental Psychopathology

The study of childhood psychopathology has focused largely on two broad sets of difficulties, those characterized by aggression and acting-out behaviors (externalizing problems) and those characterized by anxiety, withdrawal, and depression (internalizing problems; Achenbach, 1991, 1992; Achenbach & Edelbrock, 1983). Here we provide a selective, rather than exhaustive, review of this work, highlighting studies that have addressed specific ER processes and their relation to behavioral outcomes. We address these relations in studies of both normative and clinical samples. Our goal is to highlight the important findings as well as the numerous issues and challenges that illustrate the complexity inherent in the relations between ER and psychopathology.

Externalizing Problems

Much of the early work on ER and psychopathology focused on externalizing spectrum problems, like aggression. Externalizing spectrum problems have likely received more focus because they are more easily observed and may cause greater disruptions in the family, peer, and school contexts. Disruptive behaviors such as aggression, defiance, and temper tantrums are some of the most common externalizing-type behavioral problems seen in children (Beauchaine, Strassberg, Kees, & Drabick, 2002). Traditionally, it was thought that as young children acquire more cognitive, linguistic, and regulatory skills, they are better able to cope with developmental challenges and outgrow these types of problem behaviors (Kopp, 1982; Campbell, 2002). Indeed, much research has shown a normative developmental pathway of externalizing-spectrum behavior problems that peaks during the second year and shows a distinct decline with age (Hartup, 1974; Tremblay, 2000).

Although it may be the case that most children acquire adaptive skills that help them manage challenging

situations in appropriate and constructive ways (e.g., Coie & Dodge, 1998; Tremblay, 2000), for some children, early onset externalizing problems remain stable and lead to more serious maladaptive outcomes such as conduct disorder, attention-deficit/hyperactivity disorder, and juvenile delinquency (Campbell, 2002; Campbell, Shaw, & Gilliom, 2000 for reviews; Cummings, Iannotti, & Zahn-Waxler, 1989).

Such problems are of interest to clinicians and researchers alike because of their influence on concurrent psychological and social functioning (Campbell, 2002), their role in influencing later behavior across social and school contexts (Keane & Calkins, 2004), and their potential to constrain the development of a range of emotional, cognitive, and social skills (Calkins, et al., 2002; Nigg & Huang-Pollock, 2003). For example, in a study of children followed from infancy through late adolescence, Olson and colleagues (Olson, Bates, Sandy, & Lanthier, 2000) found that toddlers who were observed as highly resistant to maternal control received higher teacher ratings of over-activity and aggression across the school-age years. These effects extended into late adolescence such that toddlers who were reported by their mothers to be more difficult and demanding rated themselves as more inattentive at age 17 and were perceived by parents to be higher in aggression. Thus, for some children patterns of aggressive, defiant, destructive, and under-controlled behavior remain stable from preschool to middle childhood (Gilliom & Shaw, 2004),often resulting in more severe maladjustment in adolescence and young adulthood (Olweus, 1979).

The emphasis on ER as a predictor of behavior problems is logical because excessive emotional lability and reactivity, and a lack of behavioral and emotional control, are considered core symptoms for children with externalizing-type behaviors (Gilliom & Shaw, 2004; Keenan and Shaw, 2003). Here we begin by addressing early work examining the relation between ER and broad spectrum indicators of externalizing behaviors and then move to a discussion of more nuanced approaches and differential externalizing outcomes. We focus our review on early development as this is when such problems emerge and become stable, often because they are resistant to treatment.

Some of the earliest work on ER and externalizing spectrum problems focused primarily on the *expression* of emotions such as anger and frustration and used clinical or at-risk samples of children (Barron and Earls, 1984; Bates, Bayles, Bennett, Ridge & Brown, 1991; Campbell, 1990; Shaw, Keenan, & Vondra, 1994). The prevailing perspective on the relation between anger and behavior problems was that children who were quick to anger were more likely to be quick to engage in aggressive and destructive behavior. And, children who are highly reactive to frustration may act aggressively when provoked or aggravated because of their tendency to perceive these provocations as hostile (Vitaro, Brendgen, & Tremblay, 2002).

The view that negative emotion was a prime reason that children engaged in aggressive behavior was in part an outgrowth of temperament theory and research (Rothbart & Bates, 1998; Gilliom & Shaw, 2004). The relation between negative affect and aggressive behavior is not straightforward, however. First, the main effect of anger on aggression is often modest (e.g., Rubin, Burgess, Dwyer, & Hastings, 2003; Runions, & Keating, 2010; White, Jarrett, Ollendick, 2013). Moreover, there is a normative developmental trajectory of early behavior problems characterized by anger and aggression; some children go on to have behavioral difficulties while other children decline in such behaviors (Campbell, 1990; Tremblay et al., 1999). Differentiating these groups of children suggests a more complex pathway from negative emotionality to externalizing-type behaviors such as aggression and defiance.

From a temperament perspective, children's emotional reactivity in combination with their ability to control emotional arousal influences a variety of developmental outcomes (Rothbart & Bates, 2006). Thus, to address the challenge of modest main effects of negative affect or anger on children's adjustment, a number of laboratories began to address the moderating effects of the control or regulation of emotion and behavior. Eisenberg and colleagues (Eisenberg et al., 2001; Eisenberg, Fabes, Guthrie et al., 1996; Eisenberg, Fabes, Karbon, & Murphy, 1996; Eisenberg, Fabes, Murphy et al., 1996; Eisenberg, Fabes, Murphy, & Maszk, 1995; Eisenberg et al., 1994; Fabes, Bernzweig, & Karbon, 1993; Fabes & Eisenberg, 1992) began a series of investigations addressing the interaction of reactivity and regulation in the prediction of social behavior and maladjustment in school age children. Their work consistently demonstrated that children high in anger but lacking behavioral control skills were more likely to display anger and conflict with peers and behavior problems. Subsequent research examining the interaction of reactivity and regulation as predictors of behaviors that fall along the externalizing spectrum focused on younger children. Among preschoolers, caregiver-reported negative emotionality was only related to externalizing behaviors when children were also reported to have lower regulatory skills (Gartstein, Putnam, & Rothbart, 2012). Calkins and colleagues (Calkins et al., 1998) studied a community sample of toddlers and found that the level of frustration

interacted with specific ER strategies (physical venting and attention focused on the object of frustration) to predict conflict with peers. Importantly, all measures from this study were observational, thus providing convergent evidence with prior work relying on parent and teacher report of behavior.

The joint effects of emotional reactivity and emotional control on later externalizing spectrum problems have also been studied during infancy. Stifter and colleagues examined the influence of early ER on subsequent aggressive behavior and found that infants who were highly frustrated and highly regulated were less defiant as toddlers (Stifter, Spinrad & Braungart-Rieker, 1999). More recent work has examined specific dimensions of regulation in infancy as moderators of early emotional reactivity. Belsky and colleagues found that in 15-month-olds, poor attentional persistence moderated the effect of early negativity in predicting poor social competence (Belsky, Friedman, & Hsieh, 2001). Further, Crockenberg and colleagues (Crockenberg, Leerkes, & Jo, 2008) found that attention toward the object of frustration at 6 months moderated the effects of negative affect on later aggressive behavior. Work using observational measures with more diverse samples has validated these early findings (Morris et al., 2010), providing additional evidence to support the general conclusion that ineffective or poor regulation of negative emotional reactivity, particularly attention focused on the object of anger or frustration, is predictive of childhood maladjustment characterized by aggression, acting out, and the display of socially inappropriate behavior.

Although negative emotion has been the primary affect examined in relation to externalizing problems, more recent work has focused on the role of exuberance in the emergence of such problems (Berdan, Keane & Calkins, 2008; Degnan et al., 2011; Stifter, Putnam & Jahromi, 2008). Exuberant children are notable for their positive affect and approach behaviors. A greater tendency to display positive emotions has generally been regarded as adaptive (Eisenberg, Wentzel, & Harris, 1998) and has been associated with greater social competence and fewer behavior problems (Denham, McKinley, Couchoud, & Holt, 1990; Eisenberg, Fabes, Murphy, et al., 1996; Lengua, West, & Sandler, 1998). However, intense positive affect is often associated with greater approach behaviors and thus has been linked to impulsivity and externalizing problems (Cole, Michel, & Teti, 1994; Eisenberg, Fabes, Guthrie, et al., 1996; Underwood, 1997). Similar to work examining negative emotionality, work with exuberant children has found ER abilities to play a role in the association between positive emotionality and behavioral adjustment. Rydell, for example, found that children low in exuberance had fewer externalizing behaviors regardless of how well-regulated they were, whereas among exuberant children, poor regulators were reported to have greater externalizing problem behaviors than children with better regulatory capabilities (Rydell, Berlin, & Bohlin, 2003). Additional work has shown that children high in exuberance who were also observed to have poorer regulation, were also more likely to be rated by parents as aggressive (Dollar & Stifter, 2012). Moreover, exuberant children who displayed higher levels of negative emotion and poorer regulation were rated by their parents as having higher levels of externalizing problem behaviors than exuberant children who could regulate their emotional expression (Stifter et al., 2008) Thus, externalizing problems are perhaps best characterized by poor regulation of affect and behavior that increases children's likelihood of inappropriate social behavior, behavior that may include unregulated approach behaviors associated with peer conflict and aggression.

In addition to a very large literature examining the behavioral manifestations of ER and their relation to externalizing spectrum work, a growing body of work using multiple biological measures has examined neural and physiological ER processes (Dennis & Hajcak, 2009; Hare et al., 2008; Hessler & Fainsilber Katz, 2007; Santucci et al., 2008), and the way these biological mechanisms influence outcomes characterized by externalizing spectrum behavior problems (Granic, Meusel, Lamm, Woltering & Lewis, 2012). There is growing consensus that ineffective biological mechanisms, observed at various levels and involving different systems, are implicated in ER processes that underlie children's social functioning and adjustment (Beauchaine & Gatze-Kopp, 2012; Stifter et al., 2011). Early work with children in this area focused on the role of basal cardiac functioning in the display of emotions (Stifter & Fox, 1990), while more recent work has examined the response of various biological systems under conditions of emotional and cognitive challenge (Calkins, 1997; Calkins, Graziano & Keane, 2007; Granic et al., 2012). Work examining biological response to challenge assumes that underlying neural or physiological mechanisms supports the behavioral processes of ER.

Prior research indicates that there are concurrent relations between externalizing spectrum behavior problems and physiological regulation in response to challenge across childhood, with poor cardiac vagal regulation linked to higher levels of behavior problems (Calkins, 1997; Calkins et al., 2007; El-Sheikh, Harger, & Whitson, 2001). Longitudinal studies also confirm the significance of biological responding to challenge. For example, in

one study, trajectories of ER as indexed by cardiac vagal functioning predicted patterns of externalizing behavior over time, again with poorer regulation predictive of stable externalizing problems (Degnan, Calkins, Keane, & Hill, 2008). It should be noted, however, that within this body of literature there are inconsistencies with regard to optimal levels of cardiac vagal responding, and how vagal regulation during varying types of challenge may be differentially associated with children's adjustment (Beauchaine et al., 2013; Calkins et al., 2007; Hinnant & El-Sheikh, 2013).

Developmental neuroscience confirms the assumption of early work that biological processes may underlie more sophisticated behavioral processes.

Compelling evidence of such a connection has been provided by recent neural work with children. In one study, for example, children who participated in an intervention for externalizing problems displayed changes in neural activity in parts of the brain linked to inhibitory control (Beauchaine et al., 2013). An additional intervention study demonstrated that neural correlates of response inhibition and control differed between children with clinically significant externalizing behavior and an age-matched comparison group. After intervention, however, both neural and behavioral indices of regulation changed for clinical children suggesting more efficient response inhibition in the presence of challenging emotions (Woltering, Granic, Lamm, & Lewis, 2011) These findings suggest that the control processes linked to impulsive, acting-out behaviors originate in neural processes.

Though a substantial body of work established that emotion regulatory process, whether biological or behavioral, may be a critical factor in pathways to externalizing behaviors, consideration has been given to the role that contextual factors play in such pathways. Work that moved beyond main effects models of ER influence on externalizing behaviors initially focused on the caregiving context. Parents can either in the moment or over the longer term affect how children manage their emotions (Calkins, 1994; Morris, 2007; Thompson, 1994). Multiple models of these effects have been proposed: parenting may lead to patterns of ER, moderate existing ER processes, or do both. Much of this work has examined caregiver behavior as affecting ER development through its effect on children's affective reactivity. Thus, caregiving may enhance or undermine the development of important regulatory skills, which, for example, reactive children would have difficulty acquiring otherwise (Braungart & Stifter, 1991; Calkins, 2002; Calkins et al., 1998). Specifically, mothers who are sensitive and responsive may help children who are easily frustrated develop appropriate strategies for managing their affect and social behavior. In contrast, mothers who are intrusive or hostile may exacerbate their children's frustration reactivity, leading to poor regulatory skills, and, in turn, greater disruptive behavior problems (Bates, Pettit, Dodge & Ridge, 1998; Gilliom et al., 2002; Rubin et al., 2003). Thus, there is good evidence that caregiver behavior may support or undermine the development of regulatory skills that increase or decrease the likelihood a child will develop externalizing behavior problems.

Although the moderating effect of maternal sensitivity or intrusiveness may seem straightforward, not all studies find the same direction of effects. For example, one study found that maternal control had a positive impact on children's frustration reactivity (Bates et al., 1998), suggesting that the same level of maternal control may not operate the same way in all contexts or with all children. In some instances (e.g., when danger is present; Bates et al.), maternal control may help dampen children's frustration reactivity and limit the display of disruptive behavior. However, in other situations (e.g., free play; Calkins, 2002), maternal control may exacerbate a negative temperament and increase disruptive behavior. In addition, maternal control may lead to disruptive behavior when children are not prone to frustration, but have strong approach tendencies. Parents may attempt to inhibit the approach behavior, frustrate the child, and increase the likelihood of disruptive behavior (Derryberry & Reed, 1994). An additional challenge to interpreting the large empirical literature on the effects of caregiving on the relation between ER and externalizing is that these reports typically each focus on different aspects of caregiving. Research examining the joint effects of maternal behavior and temperament, for example, reveals that children's frustration reactivity typically predicts externalizing outcomes when mothers are high on control *or* low on positivity (Calkins, 2002; Paterson & Sanson, 1999; Rubin et al., 2003). This makes the explication of the mechanism through which caregiving influences subsequent child problem behavior challenging. Thus, caregiver behavior may have different implications for child externalizing outcomes depending on the child's individual level of frustration reactivity and regulatory capabilities, the context in which such behaviors are observed and the developmental level of the child.

Numerous mechanisms in addition to actual parenting behavior are also likely operating in the developmental processes linking ER and externalizing behavior, including family expressiveness and emotional climate (Morris et al., 2007). Cultural and racial differences in how maternal behavior relates to ER have also been found. For example, Supplee and colleagues (2009) found that

different patterns of ER strategy use were differentially related to externalizing behavior for European Americans and African Americans. These data support the idea that within different cultural groups the expression of emotion and management of emotion may be viewed differently.

In sum, data on caregiver effects for the development of ER and its relation to externalizing behavior suggest that these effects will vary by the age of the child, the specific caregiver behavior, and familial and cultural expectations for the display of emotion. However, caregiving is not the only contextual factor that may influence the relation between ER and externalizing behaviors. Rose-Krasnor and Denham (2009) propose transactional relations between peers and ER, with poor regulatory ability influencing the quality of peer relationships and these peer relationships influencing subsequent behavior. For example, Trentacosta and Shaw (2009) found that ER strategy use in childhood predicted peer rejection in middle childhood, which in turn predicted antisocial behavior in early adolescence. In particular, this study examined use of active distraction and task focus as two replicable strategies typically related to concurrent emotion expression and subsequent behavior. Boys who were unable to engage in distraction during a delay task were more likely to be rejected by peers and more likely to display antisocial behavior. This study helps to identify at least one possible mechanism through which patterns of ER influence adjustment outcomes within the peer context.

To this point, our review has largely considered externalizing behavior problems as broad spectrum and undifferentiated. However, the contribution of ER to different disorders like attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), and conduct disorder (CD) has also been examined. For example, although there has been a long-standing view of the cognitive or executive functioning deficits in ADHD (Barkley, 1997; Nigg, 2001; Nigg & Huang-Pollock, 2003), more recent work has focused on the role of ER in the disorder (Anastopoulos et al., 2011; Beauchaine et al., 2013; Martel, 2009; Musser, Galloway-Long, Frick, & Nigg, 2013). The pathway from ER to ADHD likely involves failure in the development of basic attention processes used to control impulses and behavior, which have been implicated in the normative decline of more general externalizing problems in early childhood. For example, toddlers with hyperactivity and related behavior problems were rated as high in inattentiveness by both of their parents (Campbell, Szumowski, Ewing, Gluck, & Breux, 1982). In older children, Melnick and Hinshaw (2000) demonstrated that a high-aggressive subgroup of ADHD boys showed significantly less constructive patterns of emotional coping during frustration than both a low-aggressive subgroup and a nondiagnosed comparison group. Recent work has also linked functioning of the ANS, a key biological factor in externalizing broadly construed, to ADHD (Beauchaine et al., 2013; Musser et al., 2011). Thus, the ER difficulties experienced by children with ADHD are likely a function of deficiencies in the attentional systems and neural processes that underlie the disorder.

Like ADHD, ODD is characterized by a distinct cluster of externalizing problems, notably emotional lability, resistance, aggression, and argumentativeness. Thus, problems with the regulation of emotion may be symptomatic of ODD, but may also contribute to it (Dunsmore, Booker & Ollendick, 2013). Conduct disorder (CD) is considered a more serious and persistent pattern of antisocial behavior that is characterized by aggression, destruction of property, more serious rule breaking and deceitfulness. Not only may children with CD display externalizing behaviors similar to children with ODD, but they may also seriously violate the rights of others and society's moral codes. Although theoretical work has implicated deficits in emotion regulation as contributing to ODD and CD, empirical work is relatively limited. In a study of mutual emotion regulation between preschoolers and their mothers, Cole, Teti, and Zahn-Waxler (2003), demonstrated that children who engaged in less mutual positive emotion, more mutual anger, and more emotional mismatches with their mothers had more stable conduct problems than children of other dyads. In a sample of 7- to 9-year-old children at risk for disruptive behavior problems, Duncombe and colleagues (2013) found that parent-reported emotion regulation was significantly related to children's disruptive behavior after controlling for IQ and symptoms of inattention/hyperactivity (Duncombe et al., 2013). Studies with older children and adolescents have shown that inattention, in particular problems with sustaining attention during work tasks, has been linked to conduct disorder (Bellanti, Bierman, & the Conduct Problems Prevention Research Group, 2000; Campbell, Pierce, March, Ewing, & Szumowski, 1994; Olson, Schilling, & Bates, 1999). Further, inadequate vagal modulation of cardiac output, suggesting deficiencies in the physiological regulation of emotion has also been found in children with ODD and CD during middle childhood and adolescence (Beauchaine et al., 2007).

In addition to examining the relations between particular presentations of externalizing problems, recent research has also examined the patterns of problem behaviors over

time. Consistent with a developmental psychopathology framework, theories of externalizing behavior suggest that there are individual differences in developmental patterns of disruptive behavior. Although typically defined a priori, these patterns can be empirically estimated using new statistical techniques, such as semi-parametric mixture modeling (Muthén, 2004; Nagin & Tremblay, 2005). Studies using these techniques reveal empirical support for several patterns of disruptive behavior across early childhood (Shaw, Gilliom, Ingoldsby, & Nagin, 2003; Shaw, Lacourse, & Nagin, 2005). Recent research on trajectories of problem behavior finds that there are multiple trajectories of antisocial behaviors that start early in life (Broidy et al., 2003; Hill et al., 2006; Nagin & Tremblay, 1999; NICHD ECCRN, 2004; Shaw et al., 2003). These trajectories include a normative decline pattern consistent with the findings of longitudinal studies of toddler and early childhood functioning (c.f. NICHD ECCRN, 2004), an early onset pattern, which accounts for the stability of problem behavior across early childhood (Broidy et al., 2003), and an adolescent-limited pattern, which appears to be more transient and less predictive of ongoing difficulties (Moffitt, 1993, 2003).

Although the existence of multiple patterns of disruptive behavior has been supported empirically, the array of factors that might distinguish among these trajectories is less clear. Prior research has focused on several child and environmental factors, including, but not limited to, genes, neural and physiological processes, temperament, family functioning and interaction, and peer relationships and social skills (c.f. Lahey, Moffitt, & Caspi, 2003; Olson & Sameroff, 2009). It is important to note, though, that much of the work on antecedents of early behavior problems has been framed largely in terms of risk factors for problematic behaviors and outcomes, with less emphasis on understanding the mechanisms and processes that link risk factors to outcomes (Rutter, 2003); frameworks that focus on developmental process rather than correlates will likely lead to further elucidation of how risk factors are implicated in the continuity or discontinuity of problem behavior.

Early work has focused on patterns of externalizing problems more broadly, but there is increasing evidence that different patterns of emotional responding and regulation may be involved in different subtypes of externalizing behaviors. Keenan and Shaw (2003), for example, proposed two pathways to reactive versus proactive antisocial behavior. They argued that highly emotional poorly regulated infants when parented in the context of caregiving that was over-responsive to emotions but not demanding would yield a preschooler with difficulties controlling anger and a tendency toward reactive aggression. In contrast, an under aroused infant in concert with overly lax or harsh discipline would yield a toddler unresponsive to punishment and a preschooler who engages in more proactive antisocial behavior like lying, stealing, and fighting.

Another perspective on differentiation of behavior problems has focused on the role that ER plays in altering pathways to subtypes of externalizing problems. In this perspective, ER skills are seen as moderating the early vulnerability to conduct problems that are indexed, for example, by early trait impulsivity (Beauchaine & Gatzke-Kopp, 2012). The assumption here is that ER is a socialized skill that can be a point of intervention for children who are biologically predisposed to impulsive behavior or that under conditions of family emotional lability or negativity may lessen the likelihood that children transition from ADHD symptoms to more severe conduct problems (Beauchaine et al., 2007). Other researchers have taken a different approach and examined the cluster of problems characterized broadly by the term externalizing. Olson and colleagues (Olson et al., 2013) discussed five subcomponents (over aggression, covert aggression, oppositional defiance, impulsivity/inattention, and emotion dysregulation) that they argue compromise-externalizing problems. This taxonomy suggests that ER isn't simply a precursor to disruptive behavior problems, but in fact, constitutes one subtype of behavior problems. Clearly, there is still ambiguity in the field as to whether ER assumes a central role in the etiology of various externalizing disorders, or whether particular deficiencies in ER functioning constitute particular disorders.

In sum, although patterns of emotional control are often seen as symptoms of externalizing behavior problems, developmental research suggests that they emerge earlier than such problems, and in the context of important early relationships, play a causal role in the emergence and maintenance of a range of externalizing type behaviors. Regulation of arousal through both neural and physiological means may be foundational to this process. Important variables that affect the timing, chronicity, and presentation of externalizing problems include the specific strategies that young children rely on in situations requiring the regulation of both negative and positive affect, and the particular strategies that caregivers and peers may rely on when interacting with children learning to manage emotional arousal. Important questions remain about the specific pathways that may be observed behaviorally and the role of neural and physiological processes as precursors or consequences of behavior and behavior problems.

Internalizing Problems

Internalizing-spectrum symptoms primarily include symptoms of depression and anxiety, as well as social withdrawal and somatic changes (Achenbach & Edelbrock, 1981). Historically, developmental research on internalizing symptoms has focused on the early adolescent period and onward (e.g., Angold, Erkanli, Silberg, Eaves, & Costello, 2002; Deković, Buist, & Reitz, 2004; Galambos, Barker, & Almeida, 2003; Kovacs & Paulauskas, 1984; Twenge & Nolen-Hoeksema, 2002), under the assumption that adolescence is a time of risk for such problems. Recent work has shown, however, that rates of internalizing problems during childhood are comparable to rates later in life, with 10 to 15% of US preschoolers meeting diagnostic criteria for a DSM anxiety or depressive disorder at any one assessment (Egger & Angold, 2006; Keenan, Shaw, Walsh, Delliquadri, & Giovannelli, 1997). Such early-onset internalizing problems predict more severe and persistent later mental health problems (e.g., Christie, Burke, Regier, & Rae, 1988; Kasch & Klein, 1996; Kovacs, 1996).

Few studies have examined developmental trajectories of internalizing symptoms before adolescence. To date, these studies typically report no or small increases in mother- and teacher-reported internalizing symptoms from ages 2 to approximately ages 8 to 10 (Colder, Mott, & Berman, 2002; Gazelle & Ladd, 2003; Sterba, Prinstein, & Cox, 2007). However, changes tend to be observed and/or more pronounced in subsets of participants, including children with individual-level (e.g., temperamental) and/or contextual-level (e.g., poor relationships) risks (Gazelle & Ladd, 2003). Given these observations, understanding the relations between ER and internalizing spectrum problems requires studying these associations in childhood as well as adolescence. Like externalizing problems, there has been work that has addressed general internalizing problems, as well as work addressing specific patterns of anxiety and depression. Here, we examine these links in much the same way as we did with externalizing, beginning with early work emphasizing links to temperament and emotion processes and moving to more complex biological and social models.

The early work on the role that emotion plays in internalizing spectrum problems focused on a pattern of behavioral and physiological responding referred to as behavioral inhibition (BI). Children high on BI display fear, withdrawal, and negative affect in response to novel stimuli, have high heart rate and salivary cortisol, and have low heart rate variability (Kagan, Reznick & Snidman, 1987; Kagan, Snidman, Zentner & Peterson, 1999). This pattern of behavior is moderately stable over time (Pérez-Edgar & Fox, 2005). More importantly, though, longitudinal studies indicate that for some children, BI may presage anxiety problems (Chronis-Tuscano et al., 2009; Lahat, Hong & Fox, 2011). Among the processes thought to be implicated in pathways to anxiety among children with BI are internal mechanisms having to do with the regulation of attention and emotion, with the assumption being that children with internalizing spectrum problems have difficulty regulating fear and negative affect (Calkins, 1994; Calkins & Fox, 2002; Degnan & Fox, 2007). Relatively few studies have examined these measures behaviorally with children identified as behaviorally inhibited. The research that has been done does suggest that attention to threat and difficulty controlling attention are characteristic of children with BI (Lahat et al., 2011; Pérez -Edgar & Fox, 2007), and that BI children with these problems are more likely to suppress emotions and display anxiety in adolescence (Pérez -Edgar et al., 2011).

Children with internalizing behavior problems have been sometimes labeled as overcontrolled, implying that they use attention and ER strategies in a hypervigilant way to suppress the expression of negative affect (Eisenberg, Spinrad, & Eggum, 2010). And indeed, among children and adolescents, attentional focus on the source of distress and the suppression of negative emotion have both been linked to higher internalizing behaviors. (e.g., Eastabrook, Flynn, Hollenstein, 2013; Hsieh, & Stright, 2012; Hughes, Gullone, & Watson, 2011; Silk, Steinberg & Morris, 2003). However, the association between ER and internalizing behavior is not that clear, and the processes through which hypervigilance occurs and relates to anxiety are often left unspecified.

Much of the work on ER and internalizing has addressed the role of specific strategies. Following from the adult literature (cf. Dennis, 2007), this work has addressed the role of emotion suppression and attention to threat, as these are strategies that can be observed in children. Recent research has shown that the flexible control of attention, which is critical in successfully regulating emotional arousal, may be challenging for some children. Children who perseverate on some features of the environment to the exclusion of others may be especially vulnerable to increases in experience negative affect and anxiety (White, Helfinstein, Reeb-Sutherland, Degnan, & Fox, 2009). In particular, some children may display an attention bias toward negative/threatening stimuli putting them at risk of developing anxiety due to the increase in fear and arousal that may occur as attention to threat is sustained (Derryberry & Rothbart, 1988; Lonigan, Vasey, Phillips, & Hazen, 2004; Roy et al., 2008). Thus,

it is not surprising that researchers have found rumination to be linked to depression, anxiety, and overall poor mental health in childhood and adolescence (e.g., Hatzenbuehler, McLaughlin, & Nolen-Hoeksema, 2008; Legerstee, Garnefski, Jellesma, Verhulst, & Utens, 2010; Silk et al., 2003).

Although much of the emphasis in the study of ER and internalizing problems has focused on fear and anxiety, other work has examined the relations of negative emotions like anger and sadness to internalizing in children and adolescents (Zahn-Waxler, Klimes-Dougan, & Slattery, 2000). For example, Eisenberg and colleagues (2005) found that elementary school children high on internalizing were prone to greater sadness, low attentional control, and low impulsivity. In another study of children in middle school, Zeman and colleagues (Zeman, Shipman, & Suveg, 2002) found that poor emotion awareness, inhibition of anger, and dysregulated anger and sadness were related to internalizing symptoms. Children who have difficulty recognizing their own negative emotions may have difficulty regulating them, leading to inhibition or dysregulation of negative affect. Although the suppression of negative emotion may help children regulate negative arousal in the moment, failure to express anger and sadness appropriately may exacerbate the experience of those emotions, which in turn leads to greater distress in the form of anxiety or depression (Zeman et al., 2002). In another study conducted by this group, children diagnosed with an anxiety disorder had difficulty managing anger, sadness, and worried emotions (Suveg & Zeman, 2004).

Work with older children and adolescents has addressed the idea that anxiety problems may be a consequence of increased negative affect and distress as well as difficulty coping with that distress (Suveg & Zeman, 2004). For example, some work has examined cognitive reappraisal, thought to be a strategy that helps individuals cope with distressing stimuli (Carthy, Horesh, Apter, Edge, et al., 2010). Children with a diagnosed anxiety disorder were more distressed and less likely to successfully use cognitive reappraisal, particularly when the stimuli they faced were potentially threatening (Carthy, Horesh, Apter, & Gross, 2010).

In addition to the work on internalizing broadly construed and anxiety specifically, recent work highlights the association between ER and the development of depressive symptoms. For example, Silk and colleagues (Silk, Shaw, Forbes, Lane, & Kovacs, 2006; Silk, Shaw, Skuban, Oland, & Kovacs, 2006) have found that for children at risk for developing depressive symptoms, specific types of ER strategies, such as using passive ER strategies, may increase their risk. Yap and colleagues (2007) proposed that the increases in adolescent depressive disorders are a function of increased negative affect that may be observed during this period of time. Specifically, their model proposes that temperament (positive emotionality and negative emotionality) influences the propensity to be negative during this time and that family processes, including family ER and socialization affect adolescent ER.

Although the emphasis in the work on ER and internalizing problems in children and adolescents has focused on negative affect, recent work suggests that positive affect may play a role as well. Recent work in the area of positive psychology suggests that ER strategies for increasing positive emotion are related to well-being and mental health in adults (Fredrickson & Joiner, 2002). In one study, children of depressed mothers who generated positive affect in the face of a delay of gratification task displayed lower internalizing scores (Silk et al., 2006). The ability to control positive affect and utilize it in situations that are challenging may be an alternate ER mechanism that places children at higher versus lower risk for internalizing problems.

To this point, our discussion of ER has largely focused on the use of specific strategies that are thought to lead to increases or decreases in certain emotions and thus contribute to symptomology characteristic of anxiety or depression. However, it is important to note that most studies examine a small number of specific strategies to test the association between ER and problem behavior. A different approach, though it is used in very few studies, is to test whether the use of multiple strategies may in fact be a better predictor of problem behavior. In one study of a community sample of adolescents, 5 different ER strategies were used to differentiate group profiles. The findings indicated that adolescents with a varied repertoire, meaning a high use of several different strategies, displayed lower levels of internalizing problems than those with a more restricted repertoire (Lougheed & Hollenstein, 2012). Flexibility in accessing strategies may be a characteristic that, when in challenging situations, reduces the likelihood of an increase in negative emotions generally.

Thus, the evidence suggests that specific strategies of managing emotion may be related to internalizing broadly and to symptoms specific to anxiety and depression. Similar to the work on externalizing behaviors, important questions regarding the role of ER in patterns of behavior and trajectories of symptomology over time have been addressed. Kim-Spoon and colleagues examined the role of negative emotionality/liability in predicting the trajectory of internalizing symptoms in a high risk sample. Among both maltreated and nonmaltreated children, ER

played a mediating role in the relation between negativity/liability and increases in internalizing symptoms over time (Kim-Spoon, Cicchetti, & Rogosch, 2013).

As with the emergence of externalizing behaviors, internalizing problems develop in the context of social relationships. A number of factors related to parenting and childrearing have been studied (Lahat et al., 2011). A well-known risk factor for internalizing problems is maternal depression (Hammen, 2000), though many children of depressed parents do not develop depression themselves. ER abilities may function as one mechanism that protects children from developing such problems themselves or put children at greater risk if they are vulnerable to such problems by virtue of their own compromised skill at regulating affect (Suveg, Shaffer, Morelen, & Thomassin, 2011).

Environments created by mothers with high levels of internalizing symptoms have been described as emotionally disengaged from the child, with high levels of negative and depressive affect, as well as depressive behaviors and cognitions (Goodman & Gotlib, 1999). Furthermore, anxious and depressed mothers have sometimes been described as over-intrusive and controlling (Lovejoy, Graczyk, O'Hare, & Neuman, 2000; Wood, McLeod, Sigman, Hwang, & Chu, 2003). When coupled with a child's own difficulties in engaging with environmental challenges, maternal depression and anxiety could become overwhelming to the child (Beauchaine, 2001; Crowell et al., 2005), and, thus, further enhance risks for child internalizing symptoms (e.g., Goodman & Gotlib, 1999; Sterba et al., 2007).

Negative and controlling parental behaviors have long been considered a factor in the maintenance of childhood internalizing spectrum problems (Wood et al., 2003). Rubin and colleagues (Rubin, Hymel, Mills, & Rose-Krasnor, 1991) speculated that overcontrolling parents may function to help reduce child distress, but may create overreliance on parental involvement and minimize the opportunity to develop skills to manage independently. Or parental control may be negative in affective tone and serve to increase a child's negative affect. Indeed, in one study, children high on BI who were exposed to high levels of maternal negative control were likely to display more internalizing symptoms in adolescence (Lewis-Morrarty et al., 2012). Feng and colleagues (Feng, Shaw & Moilanen, 2011) examined a moderated mediation pathway from early shyness to ER to internalizing problems in the presence of maternal negative control. In their sample of low income boys they observed that the strategies of active distraction and passive dependence mediated the relation between shyness and internalizing, with active distraction lowering the risk for internalizing and passive dependence exacerbating this same temperament-conferred risk. However, these effects were moderated by the degree of maternal negative behavior; thus mediation depended on the degree of maternal control. Among temperamentally shy children, active distraction only mediated shyness when maternal negative control was low.

Other dimensions of maternal behavior have also been examined as contextual factors that affect ER in children. In a study of 10–12 year old children, attachment to mothers affected indicators of ER including emotional awareness, coping strategies, and biased interpretations of emotion-laden events (Brumariu, Kerns, & Siebert, 2012). These strategies were in turn partial mediators of the relation between attachment and children's internalizing. The argument supports the basic tenets of attachment theory, that secure attachment will lead the child to view the world as nonthreatening, but the mechanism linking attachment to internalizing problems is the way children cope with emotionally charged situations.

In addition to contextual factors that may play a role in the relation between ER and internalizing, work has focused on the biological underpinnings of this relation. Like the work on externalizing behavior problems, much of the work on biological factors implicated in internalizing focused on cardiac indictors of ER. Findings with respect to internalizing-spectrum symptoms and disorders are less consistent than those with externalizing, however (Rotenberg, 2007). Some work suggests that low vagal withdrawal could restrict children's ability to successfully cope with stressors (Graziano & Derefinko, 2013). And indeed, some studies have reported evidence of lower withdrawal scores being associated with more internalizing symptoms (Gentzler, Santucci, Kovacs, & Fox, 2009; Schmidt, Fox, Schulkin, & Gold, 1999). Other work, however, suggests that it may be *high* levels of vagal withdrawal that are associated with dysregulated affect and internalizing-spectrum problems (Beauchaine, 2001; Fortunato et al., 2013; Friedman, 2007; Gazelle & Druhen, 2009; Hinnant & El-Sheikh, 2009). In fact, the highest levels of vagal withdrawal have been reported in young people with particularly severe (Crowell et al., 2005) and also comorbid forms of internalizing symptoms (Calkins et al., 2007). Additional work investigating neural mechanisms of emotion regulation and their relation to internalizing symptoms has shown event-related potentials (ERPs) associated with attention and cognitive control to be different among anxious children compared with typically developing children (Hum et al., 2013). Specifically, anxious children have been shown to have greater mean amplitudes

suggesting that children with internalizing symptoms may exert more cognitive control in anticipation of responding during an emotional eliciting task and their regulation efforts in response to error increase with anxiety induction (Lewis & Stieben, 2004). Thus, the pattern of emotion regulation may depend in part on the underlying biological support mechanisms and in part on the contextual factors that affect emerging ER abilities.

In sum, the work on early ER and internalizing suggests that, like externalizing, child characteristics, such as behavioral inhibition and negative temperament may be the start of a developmental pathway that is mediated by ER processes. How these processes operate in given contexts and as predictors of specific outcomes is still emerging, although the evidence suggests that particular ER mechanisms and potent environmental triggers, like parent psychopathology, are important. Clearly, ER, and in particular, mechanisms of attentional control, are significant factors in the emergence of both internalizing and externalizing disorders, particularly in young children, whose behavioral repertoires may be limited due to the developmental constraints imposed by cognitive and linguistic abilities. Next we address the role that such regulatory processes may play in two other important indicators of child functioning: Social and school functioning. We include these outcomes in our discussion of ER and child adjustment because they are broader indicators of child functioning that are often implicated in the more complex pathways to mental health outcomes.

ER and Social Functioning

Social competence is a multifaceted and dynamic construct that results in positive social experiences with others and the formation of close relationships (Hubbard & Coie, 1994). A large body of literature has identified complex and dynamic relations between social functioning and psychological adjustment and maladjustment both concurrently and longitudinally (e.g., Bornstein et al., 2010; Burt, Obradovic, Long, & Masten, 2008; Kouros, Cummings, & Davies, 2010). Empirical work suggests that social competence may play an underlying role in the emergence and development of internalizing and externalizing behaviors over time (Hinshaw, 1992). Specifically, social competencies may influence child functioning and achievement across multiple developmental domains, and the lack of adaptive social functioning across these domains can prove to be emotionally challenging; increased frustration, anxiety, or depression stemming from highly emotionally charged contexts may result in more aggressive, antisocial, or withdrawn behaviors (Bornstein, Hahn, Haynes, 2010). It is likely that children who do not possess the skills necessary to regulate their emotional arousal have difficulties interpreting and sending clear social messages and consequently experience fewer positive social interactions (Bornstein et al., 2010). Moreover, less social acceptance and increased rejection may also lead to various maladaptive emotional and behavioral responses (Burt et al., 2008). Thus, the degree to which children are able to regulate their emotions has important implications for the development of social competence. Three dimensions central to children's adaptive social functioning have been most commonly associated with ER and psychological well-being: social skills, peer group acceptance, and friendship quality.

Social Skills

Social skills are a foundational component of overall social competence and include the ability to engage in behaviors that benefit others and improve social interactions, such as sharing, cooperating, helping others, appropriately asserting oneself, and responding appropriately in conflict and nonconflict situations (Gresham & Elliot, 1990; Rose-Krasnor & Denham, 2009). These behaviors have been the target of a large body of empirical research across multiple developmental time periods and are found to be associated with children's overall mental health and adjustment in both normative and at-risk samples (e.g., Blandon, Calkins, Grimm, Keane, & O'Brien, 2010; Winsler & Wallace, 2002).

Of the multiple dimensions of social competence, the association between ER and social skills has been most commonly examined. In theory, children who are more competent at modulating emotional arousal are better able to utilize their social skills in a variety of situations (Eisenberg, Fabes, & Spinrad, 2006). Empirical work confirms that greater ER capabilities are associated with increased social skills concurrently and longitudinally, and among young children and adolescents (Carlo, Crockett, Wolff, & Beal, 2012; Eisenberg et al., 1997). Rydell and colleagues (2003, 2007), for example, found that regulation of exuberance, sadness, and anger was positively associated with preschool and elementary school children's ability to engage in positive behaviors such as sharing and conflict prevention at home and at school, and adolescents' ER has been shown to predict prosocial behaviors with strangers, friends, and family (Padilla-Walker & Christensen, 2011).

Friendship

Young children engage in interactions with their peers (Dondi, Simion, & Caltran, 1999), and preschoolers

can develop stable relationships defined by proximity and shared activity (Howes, 1996; Vandell & Mueller, 1980). These relationships can provide companionship and support (Dunn, 2004; Gunnar, Senior, & Hartup, 1984), and are thus an important component of early social functioning (Gottman, 1983). By the beginning of middle childhood, peer relationships take on the qualities of more adult-like friendships such as affective reciprocity, mutual influence, reciprocal recognition of the relationship, a shared history, and relational commitment (Hinde, 1979; Rubin, Bukowski, & Parker, 2006). Friendships high in positive qualities are sources of support (Way, Becker, & Greene, 2006), outlets for intimate disclosure (Newcomb & Bagwell, 1995), and provide companionship (Parker & Asher, 1993). With these relational needs met, high-quality friendships result in youths' positive psychosocial development (Hartup & Stevens, 1999; Savin-Williams & Berndt, 1990). However, friendships that are high in negative qualities, such as conflict and antagonism, are related to higher levels of children's externalizing and internalizing behavior problems (Burk & Laursen, 2005; Sentse & Laird, 2010).

Children's ability to regulate their emotions appropriately and effectively allows for better control of social behavior and facilitates greater communication with social partners. Thus, ER is critical to the development of friendships because ER skills are thought to be necessary for the understanding and interpretation of social interactions, as well as children's behavior in social contexts, thereby shaping the way others perceive and respond to them. Although relatively small in number, there are empirical studies linking ER and friendship. For example, ER has been found to be associated with reciprocal friendships nominations from preschool through young adulthood (Lopes, Salovey, Côté, Beers, & Petty, 2005; Walden, Lemerise, & Smith, 1999). And a recent longitudinal study assessing the relation between ER and friendship quality from ages 5 to age 10, found that increases in mother and teacher-reported ER from age 5 to age 7 was associated with increases in child-reported positive friendship quality and decreases in negative friendship quality from age 7 to age 10 (Blair et al., 2013).

Peer Group Acceptance/Rejection

Another commonly studied dimension of social competence is peer group acceptance and rejection. It has been theorized that peer-rejected children may interpret benign social cues as hostile, leading to a tendency to enact aggressive behaviors (Dodge et al., 2003). Alternatively, peer rejection may lead to behavior problems through truancy, dropout, or association with other deviant peers (Coie, 1990; Dishion, Capaldi, Spracklen, & Li, 1995). Indeed, a number of negative outcomes including early conduct problems, depression, school truancy, and suspension, have been associated with peer rejection in childhood (Coie, Lochman, Terry, & Hyman, 1992; Gazelle & Ladd, 2003; Miller-Johnson, Coie, Maumary-Geremaud, Bierman, & Conduct Problems Research Group, 2002; Woodward & Fergusson, 2000). Relatedly, social withdrawal and peer victimization have been associated with internalizing symptoms such as depression, loneliness, and anxiety (Hodges, Boivin, Vitaro, & Bukowksi, 1999; Hodges & Perry, 1999), as well as externalizing behavior (Blandon et al., 2010; Prinstein & La Greca, 2004).

Children with greater regulatory capacities are thought to be better able to control emotional arousal thus increasing their ability to navigate multiple social settings, cooperate, and positively contribute to peer groups (Eisenberg et al., 2006; Spinrad et al., 2006). Research spanning multiple developmental time periods has highlighted the importance of ER for peer acceptance. For example, 4- to 6-year-olds' emotionality and regulation were related to sociometric ratings of social status concurrently and over time (Maszk, Eisenberg, & Guthrie, 1999). In a study of middle childhood, Kim and Cicchetti (2010) demonstrated that greater reported ER was predictive of higher peer acceptance, and greater peer acceptance was subsequently associated with fewer internalizing symptoms, after controlling for initial levels. Similarly, preadolescents' use of adaptive regulatory strategies, during a laboratory task designed to elicit negative affect were found to be indirectly related to children's antisocial behavior through peer rejection (Trentacosta & Shaw, 2009), such that greater distraction behaviors were associated with less peer rejection, which was in turn related to fewer antisocial behaviors.

Physiological processes of arousal and regulation have also been linked to multiple aspects of social competence. In a sample of preschool children, higher resting vagal tone and greater vagal withdrawal during a negative affect task was related to greater parent-rated sociability (Doussard-Roosevelt, Montgomery, & Porges, 2003). In a similar study, Blair and Peters (2003) found higher resting vagal tone and vagal increase during a cognitive task to be associated with higher ratings of social competence in a preschool Head Start sample. Also, recent research from our longitudinal study indicated that kindergarten children who had better vagal regulation tended to display more adaptive social skills as reported by their teachers and their classmates (Graziano, Keane, & Calkins, 2007). Taken together, these findings provide evidence that

emotion regulation at both a behavioral and physiological level have important implications for children's social functioning and peer relationships.

In addition to the considerable amount of research underscoring the role of social competence in the development of subsequent adjustment and maladjustment, there is also evidence for the reverse association (Hinshaw, 1992; Patterson, Griesler, Vaden & Kupersmidt, 1992). Specifically, psychological maladjustment and deficits in regulatory functioning could undermine social competence such that difficulties processing social behavior, the display of inappropriate or aggressive behavior, or increased anxiety or depression, may disrupt the development of social skills, the formation of healthy peer relationships, and interactions with peers (Bornstein et al., 2010). For example, in early childhood data consistently implicate disruptive and aggressive behavior as a contributor to peer difficulties and rejection (Hinshaw & Lee, 2003), and boys' aggressive and withdrawn behavior during preschool has been linked to social competence in middle childhood (Mesman, Bongers, & Koot, 2001). However, social competence in middle childhood has also been associated with internalizing behaviors in early adolescence (Burt & Roisman, 2010), thus highlighting the inconsistencies in the direction of effects across development.

It is both possible and likely that there are reciprocal relations between social competence and children's maladjustment across time, and one way researchers have begun to disentangle the direction of effects is by utilizing developmental cascades models. The developmental cascades framework allows for modeling complex, dynamic, and longitudinal associations spanning multiple domains (Masten & Cicchetti, 2010), and tests multifaceted hypotheses of developmental theories that aim to represent the complexity of individual development across time and contexts (Cairns, 2000; Magnusson & Cairns, 1996; Masten, Burt, & Coatsworth, 2006). For example, in a 20-year longitudinal study initiating with children 8 to 12 years old, social competence in childhood, as measured by child and parent reported peer popularity and friendship, showed negative longitudinal links to internalizing symptoms in adolescence. Further, social competence in emerging adulthood was negatively associated with internalizing problems 10 years later (Burt et al., 2008; Obradovic, Burt, & Masten, 2010). A similar study investigating developmental cascades among social competence and behavior problems from age 4 to age 14, found lower social competence at age 4 to be associated with more externalizing and internalizing behaviors at age 10, and more externalizing and internalizing behaviors at age 14. Finally, in a preschool sample, Blandon and colleagues found early social skills to have an effect on subsequent levels of externalizing behaviors controlling for previous levels of externalizing behavior, ER, and sociometric nominations. Combined, these results suggest there may be a stronger association from social competence to children's behavioral adjustment across development (Blandon, Calkins, Keane & O'Brien, 2010).

Although researchers are just beginning to untangle the complicated and reciprocal associations between social competence and psychological well-being across development, evidence supporting a significant association is clear: children's ability to utilize adaptive social skills, form and maintain positive friendships, and function appropriately in peer group settings is intricately related to the regulation of emotion and positive behavioral adjustment. Future work addressing the direction, timing and processes involved in these cross-domain relations not only has implications for developmental theory but may elucidate the etiology and consequences of mental health, and identify specific behavioral, social, and emotional processes that can serve as targets of intervention.

ER and Academic Functioning

Successfully navigating the academic environment requires children to function more autonomously and learn important academic and interpersonal skills that contribute to continued academic competence throughout the school years. Meeting increasingly difficult academic demands can elicit frustration, anxiety, fear, and excitement, and the regulation of these emotions may result in a greater use of higher order cognitive processing (e.g., working memory, planning, and attention) (Blair, 2002). Consequently, increased higher order cognitive abilities put children at an advantage and allow for greater attention to classroom tasks, retention of information, efficient learning, and success in achieving academic goals (Graziano et al., 2007).

Poor ER abilities have been linked to deficits in behavioral control such as aggression and antisocial behavior (e.g., Davidson, Putnum, & Larson, 2000; Roberton, Daffern, & Bucks, 2012). Thus, children's ability to control their behavior may be one mechanism through which ER is related to academic success and achievement. The general hypothesis is that children who are emotionally aroused but unable to effectively modulate that arousal in appropriate ways are more likely to display externalizing type behaviors; these behaviors may then lead to decreased academic competence because children are unable to stay academically focused when acting out or

being disciplined for their misbehavior (Hinshaw, 1992; Mile & Stipek, 2006). In contrast, children who are able to modulate negative emotional arousal and demonstrate greater control over their behavior are more likely to stay on task, finish tasks, and focus attention on learning, all of which are needed for continued academic achievement (Breslau, Breslau, Miller, & Raykov, 2011; Moilanen, Shaw, & Maxwell, 2010; Neuenschwander, Rothlisberger, Cimeli, & Roebers, 2012).

Children's academic performance has been shown to be highly stable after the first grade (Entwisle & Hayduck, 1988), and early academic success has been found to be a predictor of later academic achievement (Breslau et al., 2009; Fergusson & Horwood, 1995). Because of this stability, the early childhood period and the transition to school is of particular interest to scientists investigating the associations between ER, externalizing behaviors, and academic outcomes. As children transition from the preschool and home environment to the more academically rigorous environment of elementary school, they are faced with novel academic demands and receive far less external support than they have previously been given (Graziano et al., 2007). Thus, the transition to school can be particularly challenging emotionally, and the ability to regulate emotions and gain increased behavioral control may make the school transition easier and less frightening, in turn setting the stage for greater academic achievement and more adaptive developmental trajectories. In contrast, poor ER abilities and deficits in behavioral control that are linked to aggressive or antisocial behaviors may impede children's ability to function within the classroom, attend to academic demands, and even hinder the student–teacher relationship.

Associations among ER, behavioral control, and academic success in early childhood have been found. For example, Howse, Calkins, Anastopoulous, Keane, and Shelton (2003) found that preschoolers' ER was related to both literacy achievement and math achievement in kindergarten through children's behavioral control (see also Trentacosta & Izard, 2007). Similarly, observed behavioral regulation in emotion eliciting tasks in kindergarten was found to be related to classroom behavior problems and academic performance in first grade (von Suchodoletz, Trommsdorff, Heikamp, Wieberm, & Gollwitzer, 2009), and kindergartners' ER was found to predict fewer parent reported externalizing behaviors, which were associated with decreased academic performance in the classroom and on standardized measures of math and literacy (Graziano, et al., 2007).

There is a small body of research examining the role of both physiological and emotional regulation in school success, broadly defined as social functioning and academic achievement. For example, research examining biological reactivity and regulation has found that these processes are linked to skills necessary for school success. For example, researchers using a different measure of biological reactivity (salivary cortisol) found that preschoolers who evidenced moderate arousal display greater executive functioning (cognitive self-regulation) and were reported by their teachers to have better attentional and behavioral control within the classroom (Blair, Granger, & Razza, 2005). These results support the notion that regulation at the biological level facilitates one's ability to engage and disengage with the environment (Porges, Doussard-Roosevelt, Portales, & Greenspan, 1996), whether that environment consists of social or cognitive challenges, both of which are critical to school success. The question of direction of effects is an important one, though. For example, Blair (2002) proposes that inefficient ER physiologically inhibits the use of higher order cognitive regulation.

There is also support for associations between ER and academic achievement beyond the early school years. A high percentage of school-age children exhibit both externalizing behaviors and low academic achievement (Hinshaw, 1992). However, there is a lack of consensus regarding the direction of effects. One hypothesis is that externalizing behaviors are predictive of later academic difficulties. More specifically, in addition to limiting learning opportunities, externalizing behaviors in middle childhood and adolescence may increase the probability of social rejection or acceptance by deviant peers; thus leading to decreased academic achievement via a disinterest in school or even expulsion (Moilanen et al., 2010; Schwartz, Gorman, Nakamoto, & McKay, 2006). Indeed, empirical studies examining these longitudinal relations suggest that poor ER abilities, and increases in behaviors commonly associated with these regulatory deficits (e.g., hostility, aggression, impulsivity), may undermine later academic achievement. For example, using data from the NICHD Study of Early Child Care and Youth Development, Campbell, Spieker, Burchinal, & Poe (2006) found that children displaying even low levels of physical aggression across childhood were lower in academic achievement at age 9 than children who were not at all aggressive, and ADHD symptoms in sixth grade, as measured by hyperactive and impulsive behaviors, were found to be negatively associated with grade-point average in eleventh grade (Scholten, Rydell, & Yang-Wallentin, 2013). Further,

studies have reported externalizing behaviors to impede children's ability to acquire skills. For example, problem behavior at ages 6 and 11 were uniquely predictive of math and reading abilities by age 17, even after controlling for child, mother, and family characteristics (Breslau et al., 2011). Finally, children's engagement in delinquent behaviors and substance abuse has been found to be associated with lower levels of academic success among adolescents (e.g., Ansary & Luthar, 2009).

ER abilities and behavioral control may also predict academic achievement through the student–teacher relationship. Close and positive relationships with teachers are important for continued academic success such that children with close teacher relationships are more likely to receive positive and helpful feedback, which may in turn increase children's self-efficacy and facilitate a positive view of the academic environment (Birch & Ladd, 1997; Denham, Bassett, & Zinsser, 2012; Pianta, 1999; Pianta & Stuhlman, 2004). And indeed, a number of researchers have found associations between teacher–child relationships and later academic achievement (e.g., McCormick, O'Connor, Cappella, McClowry, 2013; Williford, Maier, Downer, Pianta, Howes, 2013; Zee, Koomen, Van der Veen, 2013).

Because the nature of emotional interactions between students and their teachers are most strongly associated with teachers' perceptions of students (Stuhlman & Pianta, 2002), and there is evidence that teachers have a low tolerance for dysregulated children who are unable to behave in socially appropriate ways (Coie & Koppel, 1990; Roorda, Koomen, Spilt, Thijis, & Oort, 2013), children's ability to regulate their emotions and inhibit aggressive or antisocial behaviors that disrupt classroom activities may result in better student–teacher relationships and subsequently a more positive school experience and increased academic competence (Denham et al., 2003). In alignment with this hypothesis, studies have shown that children who are able to regulate their negative emotions and calm themselves when upset form closer relationships with their teachers and are rated as more well-adjusted in the classroom (Shields et al., 2001). Moreover, kindergartners whose relationships with teachers are characterized by low conflict receive fewer disciplinary actions and are less likely to be suspended through the eighth grade (Hamre & Pianta, 2001). An additional study examining the role of student–teacher conflict in the association between aggression and academic achievement from first to fifth grade, found that changes in aggression significantly predicted changes in the amount of teacher–child conflict, which in turn predicted changes in students' academic achievement. Interestingly, not only did changes in aggression predict changes in teacher–child conflict, but the reverse was also true such that changes in teacher–child conflict also predicted changes in children's aggression, suggesting a complex and reciprocal relation (Stipek & Miles, 2008).

The relation between ER, behavioral control, and academic achievement is more complex than the unidirectional association presented thus far; in addition to externalizing behaviors playing an influential role in children's academic success, academic achievement has also been hypothesized to be a predictor of subsequent externalizing problems. Children who find school more challenging and have a history of repeated failure may become frustrated or unhappy and act aggressively or engage in destructive behaviors, which may then lead to the development of externalizing symptomology (Miles & Stipek, 2006; Zimmerman, Schutte, Taskinen, & Koller, 2013). Academic failure may lead children to develop low self-esteem and a negative attitude toward school, thus prompting the display of negative behaviors (Rutter & Guller, 1983). Miles and Stipek (2006), for example, found that poor literacy achievement in first and third grades was associated with relatively higher aggressive behaviors in grades three and five. An additional study investigating the associations between reading performance and self-reported problem behavior from preschool to second grade found that lower levels of reading performance at the end of first grade were positively associated with more externalizing behaviors at the start of second grade, and lower reading performance at the beginning of second grade was associated with more externalizing behaviors by the end of second grade (Halonen, Aunola, Ahonen, & Nurmi, 2006).

Although the research findings are sparse and less consistent, internalizing symptoms have also been found to be associated with academic achievement. The majority of this literature suggests that objective and perceived academic failures are related to increases in internalizing symptoms such as depression and anxiety. Poor academic performance is often accompanied by low self-esteem and self-efficacy for school related tasks and children may receive negative feedback from parents, teachers, and peers regarding their academic achievements (Cole, 1991; Donnellan, Trzesniewski, Robins, Moffitt, & Caspi, 2005). The inability to regulate negative emotions associated with negative moods, failure, criticism, and negative feedback may in turn result in a negative self-perception and increased internalizing type symptoms. For instance, several studies have linked academic

achievement with subsequent depression (e.g., Huang, 2013; Undheim & Sund, 2005), and anxiety disorders have been consistently linked less decreased academic competence and educational attainment (e.g., Davidson, Hughes, George, & Blazer, 1993; Van Ameringen, Mancini, & Farvolden, 2003).

As with the study of externalizing behaviors, there is also a small body of work suggesting a bidirectional relation. Specifically, internalizing symptoms may underlie subsequent academic functioning. Symptoms of depression such as an impaired ability to concentrate, loss of interest, self-worthlessness, and social withdrawal may hinder cognitive performance and academic achievement if children focus on depressive thoughts or interpretations instead of academic tasks (Hartlage, Alloy, Vazquez, & Dykman, 1993; Kirkcaldy & Siefen, 1998). Jaycox and colleagues (2009), for example, found depression severity in adolescents ages 13 to 18 to predict self-report of academic efficacy and parent report of school functioning 6 months later, even after adjusting for coexisting baseline emotional and behavior problems. Similarly, Obradovic and colleagues (2010) demonstrated that childhood internalizing problems had an effect on adolescent academic achievement over and above the stability of both domains.

Given the evidence supporting bidirectional associations between behavior problems and academic competence, a growing number of researchers have begun to examine transactional and reciprocal relations to gain a more complex and nuanced view of the interplay between both externalizing and internalizing symptoms and academic competence over time. In a study assessing the longitudinal relations between depressive symptoms and academic performance from late childhood to adolescence, Verboom and colleagues (2014) found support for transactional relations such that that for girls, parent and child reported depressive problems were predictive of a decrease in academic performance a year later, and decreases in academic performance were subsequently associated with later increases in depressive problems. However, the reverse was also true. Specifically, greater academic performance was associated with decreases in depressive problems the following year, and decreases in depressive symptoms were associated with subsequent academic performance.

Reciprocal effects between externalizing problems and academic achievement have also been documented. For instance, externalizing problems at fifth grade have been found to be associated with children's math and language grades by the end of sixth grade, and children's math and language grades at the end of sixth grade predicted externalizing problems in seventh grade, which subsequently predicted math achievement and language grades by ninth grade (Zimmerman et al., 2013). Finally, some studies have examined transactional effects of both internalizing and externalizing behaviors and academic achievement in the same model. For example, in a 20-year investigation, externalizing behaviors in childhood were found to be associated with less academic competence by adolescence, which was subsequently associated with increased internalizing problems in young adulthood (Masten et al, 2005). These associations remained significant controlling for within-domain stability, IQ, parenting, and socioeconomic status. Moreover, a similar pattern of findings was found with a different sample, in an earlier developmental time period, and over a shorter period of time (Burt & Roismen, 2010). Additional work has shown externalizing problems at age 6 and age 8 to be associated with less academic competence at age 8 and age 10 respectively, controlling for prior academic competence. In turn, academic competence at age 10 was associated with fewer externalizing and internalizing behaviors at age 11 (Moilanen et al., 2010).

The findings reviewed here suggest that the deficits in regulatory functioning associated with internalizing and externalizing problems impact academic achievement in complex and reciprocal ways. Not only does academic competence predict developmental psychopathology, but there is evidence that maladaptive psychological functioning also plays a role in the development of academic competence. Future work aimed at further disentangling this association across multiple developmental time periods, and identifying important mechanisms, is likely to provide valuable insight for the identification and prevention of problem behavior associated with children's academic competence and achievement.

In sum, the large literature on the relations between child ER and functioning across several distinct but related domains suggests some general conclusions. The regulation of emotions is a multilevel process that integrates biological and behavioral mechanisms. Fundamental to early ER and many later developmental skills and abilities is the control of attention (Zhou et al., 2007). Emotion regulatory ability is both a moderator of affective expression and experience and is moderated by contextual factors like parenting and relationships outside the home with peers and teachers. And, although the regulation of negative affect has been the focus of much work, positive affect and differential strategy use and flexibility in strategy use are also of interest when examining relations between ER and outcomes. Importantly, though, there are clearly multiple

routes from ER to functioning in various domains, and the domains of functioning themselves interact in complex ways to produce constellations of functional challenges for children. The utility of identifying some common routes to specific patterns of dysfunction is critical to intervention and prevention efforts. Identifying critical points of entry and targets of intervention will depend on our field's ability to make sense of the data being generated by an emerging literature and future research. In the next section, we discuss some of the issues that will require attention for this kind of translational contribution to be realized.

INTEGRATION, IMPLICATIONS, AND FUTURE DIRECTIONS: MODELING COMPLEX PATHWAYS BETWEEN ER AND CHILD FUNCTIONING

Despite considerable progress in our understanding that ER is influential in the emergence and/or maintenance of psychopathology and adjustment more generally, many unanswered questions remain about *how* this occurs. This knowledge gap exists, in part, because of a number of conceptual, empirical, and analytical challenges to the study of ER. One solution to addressing these challenges is to apply the *integrative principles* of developmental psychopathology to the specific lingering questions and issues relevant to the study of ER and child outcomes. That is, developmental psychopathology is a framework that requires us to think in an interdisciplinary way about complex processes and outcomes that are predicated upon interactions across multiple levels of analysis. Here we apply this integrative approach to address several important conceptual, empirical, and analytical issues raised by our review.

Conceptual Integration of Developmental Perspectives

There are extensive literatures examining ER from varying theoretical perspectives and considering both intrinsic (Calkins & Johnson, 1998; Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Kopp, 2002; Rothbart & Bates, 1998; Stifter & Braungart, 1995) and extrinsic processes (Sroufe, 1996; Morris et al., 2007; Volling, 2001), including a recent burgeoning interest in the biological processes associated with ER (e.g., Blandon et al., 2008; Hessler & Fainsilber, & Katz, 2007; Vasilev, Crowell, Beauchaine, Mead, & Gatzke-Kopp, 2009); however, we, along with others, argue that a broader conceptual framework that incorporates each of these components is needed to better understand the emergence of complex behavior such as ER (Sameroff, 2010; Shonkoff, 2010).

The conceptual integration of biological, behavioral, and social levels of analysis (Gottlieb, 1997), sometimes referred to as a biopsychosocial perspective (Calkins, 2011; Sameroff, 2010), has led to greater appreciation of the complex role of biological processes in transactional models of development. This perspective aims to account for the emergence of patterns of adjustment and maladjustment in child functioning within the context of families and the broader social context, and with an appreciation of the contribution of underlying biological processes. Regardless of the focus of the research or the levels described or assessed, the underlying assumption in this work is the same: genes initiate developmental pathways to complex behavior that are receptive to influences that occur from the cellular level to the level of social context, and all of these pathways and behaviors are candidates for developmental interactions that may influence child outcomes (cf. Cicchetti, Rogosch, & Thibodeau, 2012). Coaction, transaction, and interaction across levels characterize development in a biologically informed model of child functioning (Sameroff, 2010). Thus, a biopsychosocial perspective motivates multilevel research that incorporates biological and behavioral indicators of the factors that may be implicated in developmental pathways to ER and child adjustment (Beauchaine & Gatzke-Kopp, 2012). We use this perspective to highlight additional challenges and future directions in ER research that we believe will clarify our understanding of developmental trajectories important to the origins of mental health or illness, and specifically, to the role that ER processes play in these trajectories.

Developing an Integrated Understanding of Biological Processes

Another direction for future research in ER is to develop a more nuanced and integrated understanding of biological processes that are associated with ER. Much of the work investigating the role of biological systems has focused on the separate physiological correlates of emotion and ER. And, although it is important to understand the implications of each biological system for the development of ER, we believe it is imperative that future work move beyond using traditional correlational approaches and investigating single physiological mechanisms in isolation, and instead incorporate the complexity of biological processes into empirical investigations.

From a biopsychosocial perspective, biological mechanisms underlie transactional associations across multiple levels of child functioning, and a core component of

psychobiological approaches to development is the assumption that genes play an initiating role in developmental pathways (Cicchetti et al., 2012). Although the investigation of genetic variants associated with complex behavioral phenotypes is quickly evolving (Brookes et al., 2006; Goldsmith, Pollak, & Davidson, 2008), studies of the role of genetics in the regulation of emotion remain limited. To explicate the various developmental processes integral to the regulation of emotion, greater attention should be devoted to identifying candidate genes thought to be associated with ER processes. Further, future work designed to disentangle the biological underpinnings of the interactions across behavioral, cognitive, and social levels would provide a richer understanding of the development of ER. For example, how do genes influence neural changes in response to emotional stimuli, and how do neural changes impact cognition and the production of complex behavior during emotion-eliciting environmental contexts?

In addition to investigating how biological processes are related to ER across levels of functioning, it is important that future work examine within level associations in an effort to clarify the integration of multiple biological systems. For instance, when individuals encounter situations that require the modulation of emotional arousal, we know that multiple biological systems are enacted (Calkins & Hill, 2007; Thompson et al., 2008). Yet there is relatively little synthesis of theoretical or empirical work addressing the relations among various biological processes and regulatory functioning. For example, associations have been made between HPA functioning and ANS functioning in the regulation of emotion (Cole, Zahn-Waxler et al., 1996; Stansbury & Gunnar, 1994), but more work is needed to better understand how HPA and cardiac systems work together in affecting children's ability to emotionally regulate.

Of the work considering multiple biological systems involved in the regulation of emotion in adults and children, interesting and important findings have emerged. For example, using functional magnetic resonance imaging (FMRI) and measures of adults' salivary cortisol, Urry and colleagues (2006) found that the ability to emotionally regulate, as indexed by high levels of ventromedial prefrontal cortex activation and low levels of amygdala activation, was related to the steepest diurnal cortisol slopes. These results suggest that the circuitry involved in prefrontal cortex and amygdala functioning enables effective regulation of negative emotion and is associated with the regulation of endocrine activity, which has been found to be important for health and adjustment. Moreover, several studies have explored the association between the sympathetic and parasympathetic branches of the autonomic nervous system as it relates to processes integral to children's ability to regulate emotion (e.g., Beauchaine et al., 2007; Boyce et al., 2001). For example, Stifter et al. (2011) showed that reciprocal sympathetic activation, or increases in sympathetic activity accompanied by decreases in parasympathetic activity, was associated with better ER in the preschool period. In sum, we believe that to broaden our understanding of physiological regulation of emotion, and ultimately move closer to a more unified approach to the understanding of biological processes and their relation to ER across various levels of child functioning, it is important to move beyond studying a single physiological mechanism and begin to measure transactions across two or more of these biological levels.

Integrating Development into Methodology

Clear from our review is that a range of methods is used to assess ER, which likely stems from the varying working definitions of this construct (Cole et al., 2004). However, a challenge to the field is to ensure that we are measuring ER appropriately during different developmental time periods. ER is, of necessity, developmentally defined. Although some children appear to be quite proficient in the use of basic ER skills at a relatively early age, it is clear that across development dramatic growth occurs in the acquisition and display of ER skills and abilities. Because of its dependence on the maturation of prefrontal-limbic connections, the development of emotion regulatory skills is relatively protracted (Beauregard et al., 2004), from the emergence of basic and automatic regulation of biological processes in early childhood to the more self-conscious and intentional regulation of behavior and cognition in middle childhood and adolescence that require and are supported by biological processes (Ochsner & Gross, 2004).

Development from infancy through adolescence is marked by continuous changes and restructurings within and across many domains, including emotional, social, cognitive, and biological development. For our measures of ER to be empirically valid, these reorganizations make it necessary for measures to be sensitive and informed enough to capture developmental changes (Zeman et al., 2007). Because of these developmental reorganizations, the methodology employed is likely to be different across development. It is important to acknowledge that because young children are not capable of accurately assessing and reporting their own emotions (Zeman et al., 2007), ER is often captured through observational and psychophysiological measures in infancy and early childhood.

Alternatively, it is not necessarily developmentally appropriate to be able to observe children's emotion regulatory abilities in middle childhood and adolescence, therefore making self-report measures more appropriate.

Finally, we note the importance of construct validity and comparison across development when designing studies of ER. Although it is imperative to ensure that measures of ER are developmentally appropriate, it is also important to consider if measures of ER can be compared across time. For example, we know that the same situations at age 2 and age 10 cannot be used to successfully elicit anger from children. Yet it is important for the field to consider whether these different measures used to elicit anger and its regulation capture the same process at different points in time. Careful selection of measures and comparisons of both behavior and biology might help ensure that the construct of interest matches the measure employed in a study.

Integrating Negative and Positive Emotions

Although it is widely accepted that ER includes maintaining, enhancing or upregulating, as well as blunting or downregulating, both positive and negative emotions (Cole et al., 1994; Thompson, 2011), the majority of past research has largely focused on the regulation of negative emotion, likely due to its prominence in psychopathology and negative outcomes. Very little is known about the importance of regulating positive emotion for adaptive social and psychological functioning, especially early in development.

In research with adults, there is evidence that upregulating positive emotion is adaptive (Davidson, 2000; Fredrickson, 1998, 2001) because positive emotions are a means of building enduring personal resources, such as physical and intellectual well-being, and social and psychological resources. As importantly, in Fredrickson's undoing hypothesis, which has been empirically supported in research with adults, positive emotions can reverse the effects of negative emotions (Fredrickson & Levenson, 1998; Fredrickson, Mancuso, Branigan, & Tugade, 2000) and therefore, serve as a valuable means of regulating negative emotions. Because there is little research investigating these hypotheses early in development, research is needed to examine if children prone to intense or frequent experiences of negative emotion may benefit from learning to upregulate positive emotion in an effort to downregulate negative emotion. Such findings could have important implications for children at risk for developing various forms of psychopathology in both the internalizing and externalizing realms.

In addition to the need for future investigation of *how* and *when* children's upregulation of positive emotions may promote adaptive social and psychological functioning, it is also important to consider the possibility that some children need to learn to successfully downregulate positive emotions. Although perhaps counterintuitive, recent discussions in the adult literature have acknowledged that more is not always better in terms of positive emotions (Gruber, 2011; Fredrickson, 2013). This may also be true for children. Intense excitement is not always contextually appropriate and may interfere with children's developing self-regulatory systems, increasing their risk for later behavioral and psychological difficulties (e.g., Rydell et al., 2003). Although there has been some discussion of this notion in the developmental literature, more empirical and theoretical work is needed. More research is needed investigating *when* and *how* positive emotion is expressed and regulated, in addition to if and how parents socialize positive emotion, including its regulation, in childhood.

Integrating the Social Context into Studies of ER

Another important area of future ER research is to better understand the intricacies of the transactional nature of the caregiver–child relationship in the development of ER. During the first years of life children make a dramatic transition from relying primarily on the caregiver for the regulation of emotion, to increasing levels of self-regulation. Thus, given young children's minimal self-regulating capacities, developmental theories of ER suggest that the mechanisms responsible for growth in the acquisition of adaptive ER skills are embedded within the interactions between early child characteristics and the relational contexts in which development is occurring. The implication for this perspective is that assessment tools that allow us to capture the dyadic nature of ER may be more informative than tasks that yield information about the individual in isolation.

One way to increase our understanding of the dyadic nature of ER is to assess transactional and bidirectional relations between children and their caregivers from a biopsychosocial framework. Much conceptual work and empirical research supports the view that caregiver behavior affects the development of behavioral regulation of emotion (e.g., Calkins, 2004a; Crockenberg & Leerkes, 2004). However, a challenge for future research is to determine whether caregivers contribute to the *development* of physiological regulation, what mechanisms underlie this association, and how parental influence on children's

physiological functioning affect subsequent dyadic interactions. Theories of self-regulation that focus on underlying biological components assume that maturation of different biological support systems lays the foundation for increasingly sophisticated emotional, cognitive, and behavioral regulation that is observed across childhood (Calkins & Fox, 2002). To the extent that caregivers can provide the support for such physiological control early in development, particularly through the use of physical comforting and support, children should be more successful at using attentional, cognitive, and behavioral strategies to control emotion. In turn, successful physiological, attentional, and behavioral strategies prepare children to engage in interactions with caregivers, facilitating the transactional relationship that reinforces sensitive and responsive caregiving over time. More empirical work is needed to gain a clearer understanding into the complex bi-directional associations between children and their caregivers and to show how these dyadic interactions influence the development of ER process.

In addition to bidirectional relations between caregiving and child ER, we also consider parenting behaviors as regulatory *and* regulated. That is, caregivers must regulate their own behaviors and biological processes even as they are attempting to regulate their children's behavior (Calkins, 2011). For example, an emotional tantrum in a grocery store aisle may elicit anxiety, embarrassment, frustration, or even anger from a parent. To respond sensitively, model appropriate behavior, and provide children with the feedback and support necessary for further facilitation of children's adaptive emotional functioning, parents need to regulate their own physiological arousal, emotions, cognitions, and behavior. We acknowledge that such a theoretical proposition may be difficult to test empirically since the direction of effects may be hard to untangle; however, future work should aim to identify *how* caregiving affects children's ER across multiple levels of child functioning. Further, future research should aim to elucidate the way traits and behaviors of both children *and* caregivers influence multiple developmental processes integral to the development of ER.

Finally, the parent–child relationship is not the only social context in which the development of ER takes place. Once children move into the school environment, teachers and peers take on the partner role in ER processes, by providing feedback and modeling in contexts that may place multiple demands on the child. Given that symptoms of many psychological disorders include aspects of social relationships and relationship functioning, some emphasis on these relations may yield information about the dimensions of ER that are deficient. Thus, assessing dyadic interactions between children and teachers, and within peer groups, is an important future direction.

Incorporating Multiple Indicators of Child Functioning

Our review of the relations between ER and child adjustment is expansive in addressing both psychopathology as well as indicators of social and academic functioning. Clear from this review is that the indicators themselves are related in quite complex ways. Moreover, within the developmental psychopathology literature, the high degree of co-occurrence and comorbidity of symptoms and disorders is also evident. There are at least three challenges here: the challenge of predicting co-occurring problems themselves (e.g., ADHD and anxiety), the challenge of identifying cascading pathways to poor functioning in different domains (e.g., aggression to peer rejection to depression to academic failure), and the challenge of understanding when, where, and how to intervene given these complex pathways.

Co-occurrence and comorbidity have long been an empirical and analytical challenge to the field. Nevertheless, there is good evidence that observations of cascades of problems and the appearance of clusters of symptoms falling into different diagnostic categories are real phenomena reflecting the actual functioning of the individual (Beyers & Loeber, 2003; Lillienfeld, 2003; Masten & Cicchetti, 2010) and have differential prediction to long-term outcomes (Fanti & Henrich, 2010). Acknowledging these likely observations and attempting to unpack them is critical to intervention and prevention efforts. Using ER processes as a window on the child's functioning that is impacting and impacted by experiences in the home, peer and school environments may provide useful signposts for where in the developmental process disruptions to competence are occurring (Blandon et al., 2010).

Integrating Theoretical and Empirical Complexity

Much of the early work on the relations between ER and child functioning relied on relatively simplistic correlations and regressions to examine longitudinal developmental associations. However, the data we have reviewed supporting the relation between ER and child functioning increasingly point to models that capture the complexity inherent in these developmental pathways. Cutting edge research driven by theoretical models designed to capture the multiple levels of functioning and how these change over time requires appropriately sophisticated analytical

techniques. The analytic landscape is rapidly evolving in an effort to meet this need and new advanced statistical techniques are being developed for both person-centered and variable-centered analyses. Within variable-centered approaches, techniques such as repeated measures analysis of variance and regression analyses have been overshadowed by growth curve modeling, path analyses, and time series analyses, with the goal of describing the trajectories of change in variables and identifying multiple predictors of deviation from those trajectories (Laursen & Hoff, 2006). Researchers have also begun to use more person-centered approaches including profile or class analyses to address questions regarding group or individual differences in patterns of development across time and associations among variables at multiple levels of child functioning (Bergman & Magnusson, 1997; Laursen, Furman, & Mooney, 2006; Sterba &Bauer, 2010). Measurement challenges are associated with these techniques, but nevertheless, they offer a means through which researchers can examine trajectories and complex associations among behavioral constructs of interest.

A key point here is that, often, developmental pathway models, which are clearly well suited to the study of ER and child outcomes, predated the statistical techniques to test them (Curran & Willoughby, 2003). This will likely continue to be the case with research on ER as models are modified with new data that, using a developmental psychopathology framework, incorporates multiple levels of analysis over time. Nevertheless, the ongoing development and refinement of statistical methods to test such models is key to further advances in this area.

Adopting an Integrative Model of Control Processes

Implicit, and sometimes explicit in the large body of work on ER is the acknowledgement that emotion regulation is never a purely emotional process (Barret, Fox, Morgan, Fidler & Daunhauer, 2013; Thompson et al., 2008). Emotion regulation draws on fundamental neurological, physiological, cognitive, and behavioral processes, all of which become elaborated and integrated over the course of development. We believe that emotion regulation, and other behavioral and cognitive control processes, are linked in fundamental ways to more basic biological and attentional processes, and have consequences for later-developing and more sophisticated social and cognitive skills. And we, like some of our colleagues (Barret et al., 2013; Blair & Razza, 2007; Eisenberg et al., 2007; Rothbart & Sheese, 2007), embed these processes within the larger construct of self-regulation.

In our conceptualization, we have considered ER as one component of the larger self-regulatory system, which we describe as a system of adaptive control that may be observed at the level of physiological, attentional, emotional, behavioral, cognitive, and interpersonal or social processes (Calkins & Fox, 2002; Calkins & Marcovitch, 2010). Control at these various levels emerges, at least in primitive form, across the prenatal, infancy, toddler, and early childhood periods of development. Fundamental to this developmental process is the maturation of different neural systems and processes that provide a functional mechanism for the behavioral integration we ultimately observe as children mature (Dennis, O'Toole, DiCicco, 2013; Lewis, Todd, & Xu, 2010). Importantly, though, the mastery of earlier regulatory tasks becomes an important component of later competencies, and by extension, the level of mastery of these early skills may constrain the development of later skills. Thus, understanding the development of specific control processes, such as emotional regulation or executive functions, becomes integral to understanding the emergence of other childhood skills and adaptive functioning across developmental domains (Calkins & Fox, 2002).

One task for those interested in the development of emotion regulation is to understand the way rudimentary control processes become integrated into more sophisticated functioning. For example, a putatively emotional task of early childhood, the management of frustration, may be parsed into many smaller challenges for the child, involving processes that are observable in different ways and across different levels of functioning. However, many of these same component processes might also be involved in the successful negotiation of other childhood challenges, which may not have an obvious emotion regulation demand, such as a math test, a soccer game, or a plea to a parent to attend a social event. Because of the challenge in distinguishing whether similar processes that are activated in such different contexts are components of the same or different biological and behavioral systems, in our view, it may be more useful to adopt an approach that considers multiple levels of analysis of self-regulation, rather than isolating emotion regulation and executive functioning from related, or even integrated, control processes (Calkins, 2009; Calkins & Fox, 2002; Posner & Rothbart, 2000). Such an approach has clear implications for empirical strategies for the study of emotion regulation, which are often too narrowly construed to reveal much about the more fundamental processes that may be at the heart of later emerging psychological dysfunction.

One hypothesis that we have been exploring (Howse et al., 2003; Leerkes et al., in press) is that *emotion control processes* moderate trajectories of development of the other more sophisticated control processes. Our rationale for this hypothesis is derived from recent work in the area of self-regulation more broadly construed (Baumeister & Vohs, 2004) and from research in the area of attention development (Posner & Rothbart, 2007). First, at both a neural level and a behavioral level, ER processes recruit and integrate multiple psychological functions (attention, appraisal, affective experience, and motor responding) (Lewis & Steiben, 2004). Thus, it is clear that emotions have the capacity to organize and facilitate, or disorganize and disrupt, other psychological processes (Cole et al., 2004; Gray, 2004), both in the moment, and at the level of the emergence of these skills over the course of early development (Bell & Wolfe, 2004). Second, emotion control processes appear to emerge earlier in development than do cognitive control processes (Blair, 2002). Recent work by Blair and Razza (2007) provides support for such a conceptualization of self-regulation and for the importance of self-regulation on children's early academic skills. Specifically, they found that attentional regulation (effortful control) and cognitive regulation (attention shifting and inhibitory control) were moderately correlated with one another. Even so, measures of both in preschool uniquely predicted academic achievement in kindergarten. To the extent that children understand and control emotions successfully, they have a greater opportunity to attend to, assimilate, and process events in the world around them, thus enhancing both social and academic competence. Therefore, from both a behavioral and a neuroscience perspective, there appears to be support for these relations. However, there may be multiple possible ways control processes influence one another over the course of development; studying the integration of these processes may help elucidate different paths to more sophisticated regulation.

TRANSLATIONAL IMPLICATIONS

Over the last 2 decades, ER research has made important advancements toward understanding the underlying regulatory mechanisms thought to influence childhood adjustment. More longitudinal work across multiple developmental time periods, however, is needed to appreciate the nuances of these associations. For example, currently, there is not a clear consensus whether ER difficulties are a risk factor for the development of psychopathology or whether the onset of psychopathological symptoms makes it more difficult for children to regulate their emotions. Moreover, whether the direction of effects remains consistent from early childhood through adolescence and adulthood is also unknown. Empirical work that can illuminate the direction of effects across development is critical for prevention and intervention work aimed at targeting ER. If poor ER is a risk factor for later psychological symptoms, the goal of intervention and prevention programs should be to increase children's ER abilities. In contrast, if difficulties in regulating emotion are a consequence of psychopathology, tactics used to target ER may be better utilized in treatment rather than prevention (McLaughlin, Hatzenbuehler, Mennin, & Nolen-Hoeksema, 2011).

In spite of the existing challenges to understanding the role of ER in developmental psychopathology, progress has been made integrating the research that has been conducted on ER and adaptive functioning in children and adolescents. For example, there have been a number of emotion-focused preventative interventions targeting children and adolescents' mental health problems. Promoting alternative thinking strategies (PATHS; Kusche & Greenberg, 1994) and the emotion-based prevention program (EBP; Izard et al., 2008), for example, are designed to improve children's ability to discuss, understand, and regulate emotions in an effort to increase social competence and decrease problem behavior.

Programs focused on ER specifically have also been developed and studied. Contextual Emotion Regulation Therapy (CERT), designed by Kovacs and colleagues (Kovacs et al., 2006), aims to identify dysfunctional ER strategies and contextual factors that may maintain maladaptive emotional responses. Although these programs have been shown to be successful in enhancing the development of children's emotional functioning and reducing problem behavior, additional programs derived from a broader self-regulation framework that target multiple regulatory processes (e.g., cognitive, social, emotional, attentional) might further increase the beneficial effects of prevention and intervention. These programs may not only aim to increase understanding of emotion, but also help children reduce physiological arousal, increase attentional abilities, cognitively recognize and reappraise emotional interactions, in addition to strengthening caregivers abilities to assist children during heightened emotional contexts.

Current empirical work has also not provided a clear answer as to how multiple components of ER develop in combination with one another, or what it means for children's adjustment to be competent in one regulatory

domain but deficient in another. For example, it may be that sensitive caregiving can offset biological predispositions to negative emotionality and poor regulation; children's biological predispositions, however, may also make them more or less susceptible to caregiving influences (Kovacs, Joormann, & Gotlib, 2008). Thus, research investigating the associations among regulatory mechanisms in multiple domains is essential for design and implementation of preventative intervention programs because it may highlight specific regulatory processes that, in combination with one another, are more or less impactful to children's adaptive functioning.

Empirical work focused on the specific types of strategies children use to effectively and appropriately manage their emotions also has important translational implications. By eliciting strong emotional responses and examining behavioral techniques that allow children to modulate arousal, research can identify which strategies are most effective during different developmental time periods and across various emotionally charged contexts. Finally, ER research can elucidate the way emotional functioning differs among psychopathological profiles and whether developmental processes that lead to adaptive or maladaptive ER function similarly across levels of severity (Cole & Deater-Deckard, 2009), thereby advancing our understanding of the way ER contributes to the development and maintenance of psychopathological disorders.

Throughout this chapter, we have underscored the way a biopsychosocial perspective may help elucidate developmental mechanisms within the biological, cognitive, social, emotional, and contextual domains that are important for understanding the etiology and development of psychopathology in childhood. We believe that ER research aimed at distinguishing among regulatory processes to acquire more insight into how these processes unfold, while also attempting to understand the way maturation of neurobiological and other physiological systems interact with one another, will be particularly useful in the design and implementation of comprehensive interventions for at-risk children.

CONCLUSIONS

In response to the challenge of Cole and colleagues (Cole et al., 2004) to demonstrate that the construct of ER is scientifically useful, the field of developmental psychopathology provides a clear answer. ER processes continue to be identified as fundamental to functioning across development and vulnerabilities in ER are core features of a range of mental health problems.

Although the study of ER has proven to be fruitful in identifying developmental processes important to social and psychological adjustment, or alternatively maladjustment, there are still fundamental questions about the mechanisms involved in this association, particularly as they relate to identifying pathways to specific deficits and disorders and co-occurring problems. We, along with others (e.g., DelCarmen-Wiggins, 2008), believe that there is still much to understand about the underlying developmental processes, as well as the developmental trajectories, of psychopathology from infancy through adolescence. Research using a biopsychosocial framework may contribute to this endeavor by detecting the mechanisms responsible for psychopathology in children. To this end, we have highlighted the utility of a biopsychosocial perspective for understanding and characterizing how ER confers risk in children and adolescents in several key functional domains. The use of this perspective will encourage researchers to investigate developmental mechanisms across and between multiple levels of child functioning that are fundamental to the regulation of emotion and that protect against or promote mental health risk. Importantly, identifying the etiology and developmental trajectories of mental illness not only will inform preventative interventions targeting ER but also will help in the treatment of mental health issues by determining when and how to best intervene (DelCarmen-Wiggins, 2008).

Moving from Theory to Practice 298
Conclusion 299
REFERENCES 299

Interpersonal relationships lay at the core of human adaptation, making life worthwhile and keeping individuals fulfilled, successful, and happy. Reflecting this truism, the significance of interpersonal relationships serves as a unifying theme across many disciplines involved in understanding human nature and optimizing adaptation across the life span, including developmental science, social and clinical psychology, social neuroscience, psychiatry, medicine, social work, and education. Across these disciplines, relationships are viewed as a crucial context for development. From early psychological writings to recent theories, a guiding assumption of these perspectives is that humans have a fundamental need for relatedness, as embodied in concepts such as a *need for affiliation* (McClelland, Atkinson, Clark, & Lowell, 1953), *need to belong* (Baumeister & Leary, 1995), and *need for approval* (Rudolph, Caldwell, & Conley, 2005). Thus, historical and contemporary frameworks converge on the theoretical consensus that strong, satisfying, and stable interpersonal relationships play an indispensible function in achieving and maintaining well-being. An unfortunate corollary of this assertion is that failure to fulfill these needs—or fulfilling these needs in unhealthy ways—threatens well-being and places individuals at risk for psychopathology. Indeed, when social conditions impede individuals' ability to meet these core needs, they experience social pain with biological, neural, and psychological sequelae akin to those of physical pain (Eisenberger, 2012).

This chapter explores how psychopathology both emerges from, and contributes to, a disruption in developmentally salient interpersonal processes that interferes with youths' need for relatedness. Whereas some interpersonal theories of developmental psychopathology delve into the early experience of children (e.g., theories of attachment and early deprivation), others emphasize more proximal interpersonal risk (e.g., stress-based and parenting theories). Yet others provide a developmental perspective that integrates across various life stages to explicate intertwined developmental trajectories of interpersonal vulnerability

[1]A color version of Figure 7.3 is available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

and psychopathology. Regardless of focus, these theories highlight the undeniable status of interpersonal relationships as defining contexts for healthy or unhealthy development.

In the first section, we discuss historical perspectives on the role of interpersonal relationships in development and psychopathology. Second, we apply principles of the developmental psychopathology paradigm to provide an overarching framework for considering the interface between interpersonal relationships and psychopathology. We integrate these principles throughout the chapter to illustrate how they can organize, interpret, and enrich interpersonal theories. The bulk of the chapter presents interpersonal theories of psychopathology. Admittedly, our foremost challenge was the inevitable requirement to carve theories at their joints. To be sure, there are some distinct interpersonal theories, many of which revolutionized the fields of developmental and clinical science. Yet, as a consequence of the field's successful push for multifaceted, multilevel, integrative models, we have reached a point where it is common, if not the norm, to contextualize vulnerability within complex conceptualizations that cut across theoretical perspectives and even disciplines. Given this success, we take diverse approaches to summarizing the theoretical state of the field. First, we present theories that focus on particular domains of interpersonal vulnerability, such as parents, families, and peers. Then we describe how interpersonal theories interface with other perspectives by considering factors that moderate or mediate the effects of interpersonal vulnerability on psychopathology. Finally, we present some representative examples of integrative models for particular disorders and we discuss future directions for elaborating these models. In this way, we hope to pay tribute to pioneering interpersonal theories, which have paved the way for continuous advances in theory and research, while also allowing the reader to appreciate the multifaceted complexity of contemporary interpersonal models of psychopathology.

Given the broad scope of this chapter and its theoretical focus, we devote most of our efforts to providing a thorough description of interpersonal theories, with less attention to reviewing supportive empirical evidence. Of course, when evaluating these theories, it is essential to understand their current status in the field. Thus, we provide a limited critical analysis of specific theories and models, but we rely heavily on qualitative, and where available quantitative, syntheses, to which readers can refer for more detailed summaries of empirical investigations. Because the primary aim of interpersonal theories of psychopathology is to account for the precursors and consequences of disorder, we emphasize prospective longitudinal research. Where applicable, we describe the range of methodological approaches used to test the theories.

HISTORICAL PERSPECTIVES ON INTERPERSONAL RELATIONSHIPS AS CONTEXTS OF DEVELOPMENT

Since the beginnings of developmental science, less than 40 years after Darwin's 1859 *Origin of Species*, there has been clear recognition that interpersonal relationships matter for growth and adjustment as well as for conflict and dysfunction. Initially, there was no consensus on which relationships were most important for adjustment, when they were most important, or even the fundamental stance of the developing individual toward a developing society. Over the years there has been a melding of once distinct approaches to form the backbone of contemporary perspectives on interpersonal relationships and developmental psychopathology.

Sigmund Freud and James Mark Baldwin were the most prominent theorists of personality and social development at the turn of the twentieth century, and the influence of both is clear in contemporary thinking. Freud and Baldwin were contemporaries but otherwise not especially similar. For Freud (1916), one's psychic makeup was determined by early experiences; for Baldwin (1897, p. 338), "personality remains after all a progressive, developing, never-to-be-exhausted thing." In Freudian theory, parent–child bonds constitute by far the most influential relationships for development, but to Baldwin all of society impacts the individual. Freudian theory places the core of psychopathology within the person, with antecedents to psychopathology in the intrapsychic and intrafamilial conflicts of the early years, which the adult was basically helpless to change without intensive, professional help. In contrast, to Baldwin the individual was not battered about by conflict, but instead was motivated and in constant interaction with society (Kohlberg, 1982). What makes Baldwin the archetypal interpersonal theorist is that he saw boundaries between people as permeable and viewed life in terms of social networks. Baldwin is perhaps best remembered for what some might call his early version of Piagetian theory. Developmental growth is spurred on by synergies between child and environment, which bend and shape (accommodate and assimilate) to one another's needs. But where Piaget's child is an intellectual abstraction, a cool epistemologist, Baldwin's child is emotional, willful, engaged—"his self is that of a shared social self" (Kohlberg, 1982, p. 312).

As Cairns (1998) notes, Baldwin's (1897) transactional themes are apparent (though rarely cited) in statements by major thinkers across the psychological landscape. Gessell (1928, p. 375) wrote that "even the maladjustments between parent and child are adaptations in a psychobiological sense . . . the roots of the growth of the infant's personality reach into other human beings." The centrality of modeling in social learning (Bandura & Walters, 1959) is a popularization of Baldwin's emphasis on *imitation* as the fundamental interactional process. From ethology, Hinde (1979, p. 23) notes that: "What A responds to in B is in part a function of what A is."

With American psychology increasingly drawn to reductionist behavioral approaches, the transactional models that Baldwin drew out made their reappearance in other disciplines, such as sociological symbolic interactionism (Cooley, 1908; Mead, 1934) and European gestalt psychology. The theoretical underpinnings of social ecological models are in gestalt psychology, the trio of Köffka, Kohler, and Wertheimer who came out of classical German empiricism in perceptual psychology. A hallmark of gestalt is *emergence*, which is top-down in contrast to more bottom-up reductionist approaches. Here, active causal agents are to be found in what can sometimes seem to be more amorphous, intangible higher levels of analysis relative to the concreteness of smaller elements from which larger wholes are built.

By the mid 20th century, a branch of gestaltism became concerned with aspects of social and personality psychology, and to a lesser extent social and personality *development*. In 1939, the psychiatrist Kurt Goldstein wrote *The Organism*, an influential holistic approach to personality that influenced gestalt therapy. A second German émigré, Kurt Lewin (1933), adapted gestalt psychology for the study of social development. In accordance with the basic ideas of the old gestalt psychology, Lewin preferred to see the person and his or her environment as one irreducible unit, called a *lifespace*. The lifespace itself was graded and contoured into different regions of significance to the person, with areas that were easier or more difficult to reach, and that expanded and differentiated with development.

Any interpersonal perspective on the development of psychopathology would have to give a standing ovation to the founder of *sociometry*, Jacob Moreno (Moreno, 1934). Sociometry is the measurement of social relationships; it is a technique for revealing the structure or psychological geography of human relationships, a similar metaphor to that of Lewin's lifespace, which represents a psychological map of the social environment from the perspective of a motivated person, or Baldwin's (1897, p. 484) *socionomics*—"the science of the relation of social life to its environment, including other social groups." Sociometry was a way of making visible the intangible social forces, operating at the levels of friends, enemies, and peer group structures, that influence adjustment. The care and meticulousness of the sociometric approach provided a method for describing and understanding the pattern of social influences that may impinge upon the person in larger social units beyond the family. With the coming of age of more sophisticated social network techniques, principles of sociometry are still highly relevant to studying the pattern of relationships in which individuals participate over time.

By the advent of World War II, psychoanalysis had clearly become the dominant framework of interpersonal relationships, development, and psychopathology. Psychoanalytic theory was incorporated into empirical developmental models by forming hybrids with Hullian drive-reduction, leading to social learning theory, and with ethology, leading to attachment theory. As the pages ahead will show, both social learning (e.g., Patterson, 1967) and attachment (e.g., Bowlby, 1969) theories have been enormously influential as two dominant interpersonal frameworks on developmental psychopathology.

The foundational psychoanalytic theories of the era before World War II and behavioral theories of the 1970s focused on early experience in the family as the causative agent for later psychopathology. However, it was always clear that relationships beyond the family, and at any point in the life course, could lead people to great personal fulfillment or to deep misery or anger. Although some of these impactful relationships involve a level of hierarchy and age differential that can also characterize family relationships, most other relationships beyond the family involve no such role-defined or hierarchical distinctions, and are so said to involve peers. A peer is an equal, of the same social standing as oneself (Hartup, 1983). It is this aspect of equality that allows for the healthy conflict and cognitive-moral growth perspective of Piaget (1932), opportunities for positive intergroup relationships as specified in contact theory (Allport, 1954), and the ability to develop empathy and perspective-taking, a sense of the generalized other (Mead, 1934). How we get along with peers is a key indication of how the individual fits into society. Of course, then, troubling aspects of peer relationships form a breeding ground for psychopathology.

Henry Stack Sullivan, a neopsychoanalytic psychiatrist, pointed out as early as the 1940s that peers could be as great an influence on development as parents, and that, in fact,

the right kind of friend, or chum, in preadolescence could smooth out the warps and woofs of ineffectual parenting. In Sullivan's eyes, as reflected in his 1953 posthumous volume *The Interpersonal Theory of Psychiatry*, the friend is the most exquisite of all human relationships. Even before Harlow claimed to be capturing the origins of love in the rhesus monkey's spring toward the cloth mother (Harlow & Zimmerman, 1959), Sullivan wrote that full-blown love requires that kind of secure relationship to a same-sex juvenile peer, characterized by the stance of equal status and a deep empathy and support. Sullivan's work heralded a rapprochement between symbolic interactionism (i.e., views of the generalized other and how they impinge upon the self) and psychoanalysis (Cairns, 1998), and he opened up the way for considering interpersonal influences beyond parenting in the early years for development and psychopathology.

Urie Bronfenbrenner (1979), who began his career in the sociometric perspective of Moreno (e.g., Bronfenbrenner, 1944), presented an integrative perspective that grants precedence to neither family nor peers but considers the unification and interplay among social-ecological contexts. The major tenet of Bronfenbrenner's person-process-context model is that individual development is situated in a system of contexts that are nested within one another. Most developmentally proximal to the individual is a microsystem, which involves face-to-face interactions and relationships between an individual and others in the social environment (e.g., parent–child, peers) that directly affect the developing individual. Proximal microsystems are linked together in mesosystems that constitute the interactions between settings in which the developing individual is situated. Individuals are also situated in exosystems that include interactions between proximal and more distal systems that may operate indirectly on the individual (e.g., parents' work environments and experiences). Micro, meso, and exosystems are situated within macrosystems that encompass cultural beliefs, opportunities, and knowledge structures. Finally, at the broadest level, chronosystems situate macrosystems within historical time and capture processes that can account for cohort effects in development. These systems were heuristics by which psychological events occurring in multiple contexts could be linked from the point of view of growth of the developing child. In this way, social-ecological models are inherently cross-contextual, dealing with peer, family, and more distal (e.g., society) contexts. At the time Bronfenbrenner first proposed his model, he characterized the study of human development to that point as being the "science of the strange behavior of children in strange situations with strange adults for the briefest possible periods of time" (Bronfenbrenner, 1977, p. 513). One of the chief contributions Bronfenbrenner made to developmental science was to situate understanding of development as being embedded within multiple real-life interpersonal contexts. The core of ecological models comes from the transactional, gestalt ideas of Baldwin and Lewin. Ecological models continue to be updated (Sameroff, 2014) and represent many contemporary principles of developmental psychopathology within an interpersonal context.

PRINCIPLES OF DEVELOPMENTAL PSYCHOPATHOLOGY WITHIN AN INTERPERSONAL CONTEXT

The field of developmental psychopathology (DP) provides a comprehensive framework for conceptualizing the role of interpersonal relationships in the development of psychopathology. Integrating key principles of this perspective can enrich interpersonal theories, generate novel hypotheses, stimulate innovative and sophisticated research paradigms, and organize the interpretation and integration of empirical findings. Below we discuss four principles of DP that serve as useful guides for model-building and empirical inquiry in the context of interpersonal theories of psychopathology.

Intersection of Normative and Atypical Development

The DP paradigm seeks to elucidate the intersection of normative and atypical development (Cicchetti, 1993; Cicchetti & Cohen, 2006; Cicchetti & Toth, 2009; Rutter, 2014). Within an interpersonal context, this principle fosters questions such as (1) How do challenging social experiences undermine typically developing interpersonal competencies and age-appropriate relationships to heighten risk for psychopathology? and (2) How does the experience of psychopathology disrupt emerging interpersonal skills and relationships? To evaluate youths' adaptation, we must understand which stage-salient tasks emerge across development and how failure to accomplish these tasks sets the stage for psychopathology.

As will be discussed within each section, children progress through various stages in their relationship development, each of which requires the acquisition of more advanced skills and presents new expectations and challenges. From infancy and early childhood into middle childhood, youth must amass skills for the independent coordination of interpersonal interactions and

the formation of more complex peer relationships. During adolescence, youth must successfully navigate the process of individuation from the family and potential conflict arising from balancing relatedness within the family and peer group. Entrance into dating and romantic relationships presents a host of challenges as youth learn how to manage emotional intimacy and sexual activity. Psychopathology may arise from a failure to effectively negotiate these tasks (e.g., inability to form healthy peer relationships), untimely—either too early or too late—progression through stages (e.g., early entrance into romantic relationships), or excessive focus on one task at the expense of another (e.g., exclusive reliance on peer groups accompanied by extreme detachment from the family). In turn, psychopathology early in the life course likely undermines future task achievement. Considering normative development also highlights questions such as whether (and why) there are age-related changes in youths' interpersonal risk for psychopathology as well as whether (and why) certain developmental stages are linked to susceptibility to certain disorders (Rutter, 2014).

Transactions Between Children and their Environments

The DP paradigm also emphasizes how characteristics of children and their environments dynamically transact over time to shape the course of development (Rutter, 2014). Transactional models hold that children not only are passive recipients of experience but also play an active role in selecting, shaping, and constructing their environments, resulting in feedback loops that stimulate continuous structural reorganization and change (Cicchetti, 1993; Rutter, 2014; Sameroff, 2014). Such models have a long history in the field of developmental psychology. For example, Scarr and McCartney (1983) suggested that children engage in *niche picking or niche building*, selecting and creating environments that best match their natural proclivities. Caspi and colleagues (1989) proposed that children shape their environments through processes of *cumulative continuity*—in which behaviors are sustained across time by accumulation of their own consequences—and *interactional continuity*—in which children's behavior elicits sustaining responses from others during social interactions. Boyce and colleagues (1998) used the term *mutual determination* to describe the continuous exchanges between individuals and their social contexts that guide the course of development.

Capturing these transactional perspectives, the contemporary notion of developmental cascades (Masten & Cicchetti, 2010) proposes that the progressive and cumulative collection of experiences and behaviors drives development, such that early adaptation creates lasting changes with profound effects on subsequent health. Cascade models trace the developmental mechanisms through which risk factors affect outcomes over time, and examine spillover from one domain to others. Within an interpersonal context, early adverse environments or skill deficits can propel children along increasingly maladaptive pathways; risk for psychopathology escalates as the effects of early difficulties snowball into more severe intra- and interpersonal challenges. Once psychopathology emerges, this risky pathway becomes increasingly canalized and resistant to change.

As transactional models gain traction in the field, scientists are exerting significant efforts toward identifying the precise ways in which children contribute to their environments. In this vein, it has long been proposed that gene-environment correlations (rGE) account for individual differences in children's creation or selection of their environments (Plomin, DeFries, & Loehlin, 1977). *Passive effects* models assert that genetic factors shared by parents and children shape the environment in which children develop (e.g., exposure to certain parenting styles or family stress), which then influence youth development; that is, youth inherit not only genes but also genetically mediated environments. *Evocative effects* models assert that genetically mediated characteristics (e.g., temperament) elicit interpersonal reactions that promote and maintain youth outcomes. *Active effects* models assert that genetic liability induces characteristics (e.g., social motivation) that influence how youth select or shape particular environments. Passive effects likely wane, and active effects likely strengthen, across development as youth gain increasing control over their environments (Scarr & McCartney, 1983). A mounting body of evidence supports rGE as a contributor to social experience (for a review, see Rutter, 2014), with recent research on epigenetics suggesting even more complex processes whereby environmental forces actually drive gene expression (Meaney, 2010). Such child–environment interplay should certainly be kept in mind when considering the interpersonal context of psychopathology.

Interacting Systems and Levels of Development

According to a DP perspective, development is energized by synergistic interactions among multiple systems (biological, cognitive, emotional, and behavioral) and levels (personal, interpersonal, societal) of adaptation (Cicchetti & Cohen, 2006; Rutter, 2014). Within an

interpersonal context, multiple characteristics of youth and their environments determine how experiences are encoded, resulting in complex and continuously evolving interactions among genetic, biological, psychological, social, and cultural risk and protective factors. Consistent with this principle, interpersonal theories of psychopathology must consider how various factors jointly determine developmental trajectories. Developmental scientists have proposed several models of *person–environment (PxE) interactions* to explain individual differences in sensitivity to social contexts (Figure 7.1). Broadly, these models take a diathesis–stress form, wherein the interaction between individual susceptibility and stressors determines risk for psychopathology (Sameroff, 1987). However, these theories differ in their precise predictions about the nature of this interaction.

According to *vulnerability* models (Figure 7.1a), such as the dual risk (Belsky, Bakermans-Krannenburg, & van IJzendoorn, 2007; Sameroff, 1987) or stress-amplification (Rudolph & Flynn, 2007) models, heightened sensitivity predisposes children to the harmful effects of stress, making them more vulnerable to psychopathology over time. According to *plasticity* models (Figure 7.1b), such as the biological sensitivity to context (Boyce & Ellis, 2005; Bush & Boyce, 2014) or differential susceptibility (Belsky et al., 2007) models, individual differences in sensitivity influence children's reactivity to both adverse and beneficial contexts. Specifically, sensitivity to context confers health risks in the context of adversity but health benefits in the context of support. According to *stress–sensitization* models (Monroe & Harkness, 2005), early adversity and its consequences for individual sensitivity reduce an individual's threshold for reactions to subsequent stress, such that less severe stress is required to trigger psychopathology in youth with than without a history of adversity (Figure 7.1c). According to *stress–inoculation model*s (Garmezy, 1986; Rutter, 2014), adversity actually buffers or steels youth (e.g., through the development of strong coping skills) against the debilitating effects of subsequent stress—that is, youth with a history of adversity would show stress resistance or reduced stress reactivity (Figure 7.1d).

Understanding PxE contributions to psychopathology can be enhanced by considering the various ways in which individual reactivity to the environment is translated into risk or resilience. Most theory and research on interpersonal models of psychopathology assume a vulnerability perspective; however, mounting evidence implicates plasticity and stress-sensitization models, suggesting the need to broaden current perspectives to consider variability in how individual differences arise. A broad array of individual difference variables have been investigated as possible determinants of youths' reactivity to interpersonal

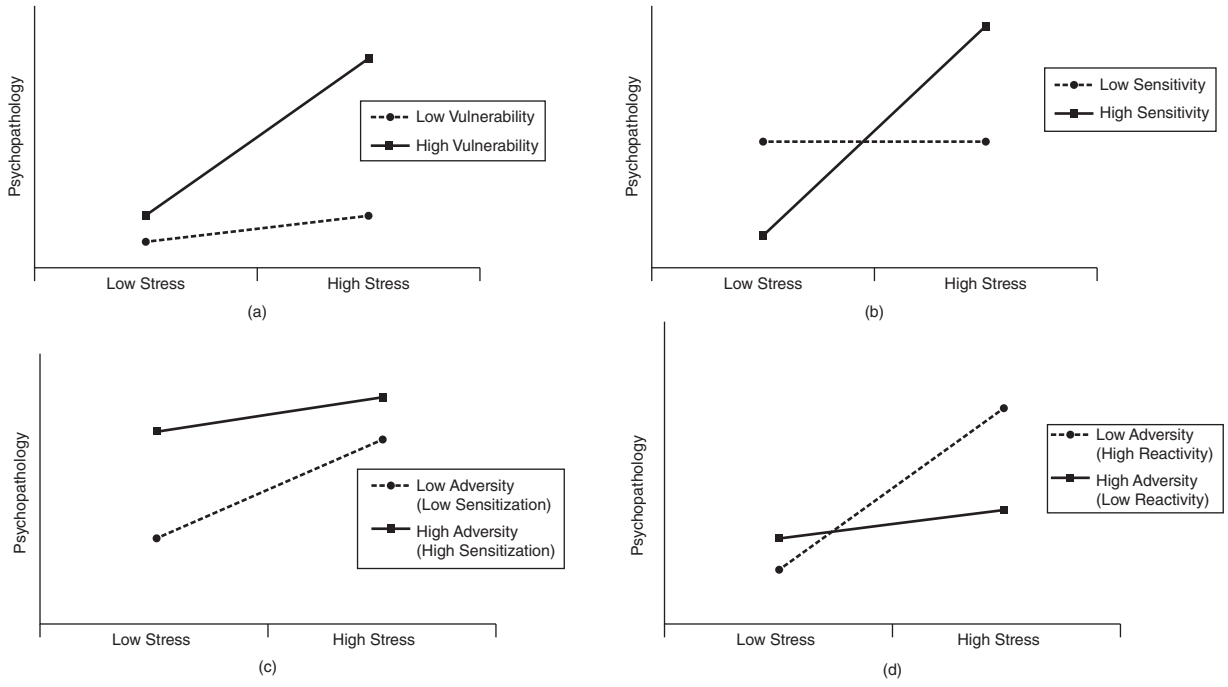

Figure 7.1 Models of person–environment (PxE) interactions. Childhood adversity and youth depression: The role of gender and pubertal status. *Development and Psychopathology, 19*, 497–521. *Source:* Adapted from K. D. Rudolph & M. Flynn, Childhood adversity and youth depression: The role of gender and pubertal status, *Development and Psychopathology, 19*, 499, 2007.

adversity, including genetic variability, temperamental and biological characteristics, cognitive styles, and coping and emotion regulation processes.

Continuity and Discontinuity in Development

Finally, the field of DP espouses an organizational approach, assuming that development unfolds in a predictable way as earlier experiences and abilities are re-organized into more complex behaviors over time. Key to this perspective is appreciating not only homotypic continuity (similarity in the overt expression of adaptation) but also heterotypic continuity (similarity in the underlying organization of adaptation) over time (Rutter, 2014). Thus, both competence and maladaptation are carried forward across development in a continual process of hierarchical integration (Cicchetti & Schneider-Rosen, 1986). From an interpersonal perspective, continuity may be expressed in terms of predictable patterns of functioning within developmentally salient relationships. That is, optimal social health will differ dramatically when considering how youth function within different relationship domains at different life stages, but there will be predictability in youths' general manifestation of competence or incompetence as related to the accomplishment of stage-salient interpersonal tasks.

Despite this emphasis on developmental continuity, the DP perspective also allows for discontinuity, perhaps prompted by significant normative transitions (e.g., progression through puberty) or non-normative challenges (e.g., death of a parent). That is, development unfolds in a lawful and predictable, but not deterministic, manner. Discontinuity can be driven by the acquisition of new competencies (e.g., acquiring self-regulation skills) or by critical events or changes in social contexts that either provide new resources (e.g., acquiring a new peer group during a school transition) or undermine existing resources (e.g., losing support following a romantic break-up), thereby creating turning points in development. The fact that early interpersonal experiences are not necessarily deterministic—for better or worse—of subsequent development is reflected in the concepts of *multifinality* (when similar risk factors contribute to varying outcomes) and *equifinality* (when varying risk factors contribute to similar outcomes; Cicchetti & Rogosch, 1996). Consistent with multifinality, children exposed to highly similar early adverse interpersonal environments can follow divergent pathways, ranging from adaptation to diverse types of psychopathology. For instance, youth exposed to maltreatment during childhood may be susceptible to later anxiety, depression, or externalizing disorders or alternatively may show resilient outcomes. Consistent with equifinality, different interpersonal experiences can lead to similar long-term outcomes. For instance, antisocial behavior in adolescence may stem from harsh parenting, chronic exposure to peer victimization, or affiliation with deviant peer groups. Interpersonal theories of psychopathology must incorporate this multiple pathways perspective that accounts for the possibility of both continuity and discontinuity across individuals, contexts, and time and must explain the mechanisms underlying stability and change (Rutter, 2014).

GENERAL INTERPERSONAL THEORIES OF DEVELOPMENTAL PSYCHOPATHOLOGY

Theories Focused on the Parent–Child and Family Context

Because families are among children's most powerful socializing influences, many notable theories describe their contribution to the development of psychopathology. Families exert an influence through both direct (explicit) and indirect (implicit) pathways. With regard to direct pathways, parents serve as socialization agents who encourage children to think, feel, or act in particular ways and who exert control over children's experiences and opportunities. Children also learn from observing and modeling their family members and receiving reinforcement to act in particular ways. With regard to indirect pathways, families implicitly convey messages about children (e.g., whether they are competent, worthy, ineffective) and the world (e.g., whether it is supportive, rejecting, dangerous) through the nature of parent–child relationships and the emotional quality of socialization efforts. Both direct and indirect pathways can help to explain the transmission of interpersonal vulnerability and psychopathology across generations. Parent- and family-oriented theories variously focus on specific aspects of the parent–child bond, more general parenting contexts, and the broader family environment. Each of these dimensions is considered in turn.

Attachment Theory

Theoretical Underpinnings. Originally developed by John Bowlby (1969, 1973, 1980) and elaborated by Mary Ainsworth (Ainsworth, Blehar, Waters, & Wall, 1978), attachment theory provides one of the most comprehensive and undoubtedly influential frameworks for understanding the normative emergence of social bonds as well as individual differences in patterns of social and emotional development (for reviews, see Cassidy & Shaver, 2008;

Roisman & Groh, 2011). Beyond its theoretical propositions regarding the normative unfolding of development, attachment theory has been widely invoked to explain how disturbances in early caregiver–child bonds can presage the emergence of psychopathology (for reviews, see Cicchetti, Toth, & Lynch, 1995; DeKlyen & Greenberg, 2008; Kobak, Cassidy, Lyons-Ruth, & Ziv, 2006).

Consistent with its evolutionary heritage, attachment theory proposes that infants engage in relationship-enhancing behaviors (e.g., orienting, crying, clinging) whereas their caregivers engage in complementary attachment-promoting behaviors (e.g., touching, holding, rocking); these behaviors presumably are guided by instinctive drives and confer benefits for survival as they maximize proximity to and protection by caregivers in the face of separation or threat. For humans, effective synchrony between these behaviors cultivates a secure caregiver-infant bond, which in turn fosters adaptive patterns of relatedness throughout the life span. Specifically, Bowlby (1969, 1973, 1980) believed that a secure attachment evolves through caregivers' display of sensitive, consistent, and warm responses to their infant. Through this contingent responsiveness, the attachment figure serves as a secure base by promoting exploratory behavior in the infant. Moreover, a secure infant demonstrates separation protest by resisting separation from, and seeking proximity to, the attachment figure. In turn, the attachment figure represents a haven of safety to which the infant can return when distressed. Thus, the attachment bond serves as a behavioral control system that organizes and regulates infants' reactions to the environment, particularly under conditions of threat or stress. Through this bond, the infant learns to balance support seeking with self-reliance and to develop independent strategies for the regulation of emotion. In a complementary fashion, when caregiving conditions are compromised through rejecting, inconsistent, distant, or abusive parenting, the infant fails to develop a sense of security and trust that lays the foundation for healthy adjustment. Rather than using the caregiver as a secure base, the infant avoids or resists comfort by the caregiver or does not develop a coherent, effective strategy for managing negative emotions and stress (Ainsworth et al., 1978).

Developmental Significance and Change. Bowlby theorized that this foundational attachment bond influences development across the life course. To account for this developmental continuity, he proposed that early caregiver–infant ties are internalized in the form of internal working models (1973, 1980) or cognitive representations of the attachment figure, the attachment relationship, and the self in the context of this relationship. The presumption is that as children gain more sophisticated cognitive and language abilities and an accompanying capacity for abstraction, the attachment system transforms from an overt and concrete behavioral manifestation of the infant's response to immediate threat into a symbolic consolidation of repeated experiences that guides the interpretation of ongoing interpersonal encounters as well as expectations for future relationships (Bowlby, 1973; Cicchetti, Cummings, Greenberg, & Marvin, 1990; Thompson, 2008). These working models most likely function outside of immediate awareness and may filter or distort incoming information, thereby increasing their resistance to change. In this way, internal working models serve as the vehicle through which early experiences are carried forward across the life course and trigger the recapitulation of early interpersonal themes in the context of developmentally salient relationships.

To illustrate this continuity, an infant who receives consistent comfort and support from his or her attachment figure would (1) develop an image of others as accepting and dependable; (2) value close relationships; and (3) perceive the self as worthy of love (Cassidy, 1988). This securely attached child would be competent and effective when faced with challenge and would cultivate close and trusting relationships with others. In contrast, an infant who experiences unpredictable or hostile caregiving would (1) develop an image of others as unavailable or rejecting; (2) deny the significance of close relationships; and (3) perceive the self as worthless or incompetent (Cassidy, 1988; Weinfield, Sroufe, Egeland, & Carlson, 2008). This insecurely attached child would be overwhelmed and ineffective when faced with challenge and would develop either an avoidant or hostile approach toward the social world.

By attempting to explain the changing nature yet enduring effects of attachment, as embodied in the construct of internal working models, attachment theory epitomizes the organizational approach to development (Cicchetti et al., 1990). Although the early caregiver–infant bond presumably serves as a profound organizational force across the life course, the manifestation of healthy (secure) or unhealthy (insecure) attachment shifts in developmentally meaningful and predictable ways as related to stage-salient tasks and competencies. Indeed, contemporary perspectives consider the diverse nature and consequences of attachment across developmental stages as it transforms in both its form and its organization (Cicchetti et al., 1990). First, the target of attachment-related cognitions and behaviors may shift or spread across development,

with peers and romantic partners taking on prominent roles as attachment figures. Second, although the function of attachment behaviors remains constant, the overt expression of attachment organization will vary over time. Third, the attachment system may increasingly integrate behavioral, cognitive, and affective components. As such, a healthy attachment may be expressed as secure base behavior with caregivers during infancy, confidence in peer availability during middle childhood, comfort with intimacy in romantic relationships during adolescence, and provision of sensitive caregiving to one's own child during adulthood.

Reflecting this developmental perspective, individual differences in attachment have been conceptualized, measured, and classified in varying ways at different life stages. These approaches are described in detail elsewhere along with critiques of their construct validity and utility for testing key theoretical propositions of attachment theory (Cassidy & Shaver, 2008; Roisman & Groh, 2011). Here, we briefly summarize each approach for the purpose of providing a methodological overview and introducing key concepts and terms as a basis for later discussion.

Ainsworth and colleagues (1978) developed the first research paradigm and classification system for studying variation in infant attachment. The Strange Situation involves a series of increasingly stressful separations and reunions between infants and their caregivers; coding of these episodes focuses on the organization of infants' responses in the presence of the caregiver (engaging in secure base behaviors, such as exploration) and during reunion following separation (engaging in safe haven behaviors, such as proximity seeking and effective use of caregiver comfort). Secure infants show exploratory behavior in the caregiver's presence, seek out their caregivers when distressed (following separation), and are easily comforted by their caregivers. Anxious-avoidant infants show little overt distress (despite physiological indications of distress) when separated and fail to seek—or even actively avoid—comfort from their parents upon reunion. Anxious-ambivalent or -resistant infants show high levels of distress when separated and simultaneously display approach behavior but resistance to comfort upon reunion. Disorganized infants (Main & Solomon, 1986) fail to show a coherent strategy for seeking proximity or comfort and may show anomalous or disoriented behaviors upon reunion (e.g., fearful or freezing behavior).

During middle childhood, attachment typically is assessed using a modified version of the Strange Situation (Main & Cassidy, 1988) or the Attachment Q-Set (Posada, Waters, Crowell, & Lay, 1995), which involves characterizing children on the basis of naturally observed secure base behaviors in the home setting. To tap internal working models during childhood, several methods also assess internalized representations of the attachment relationship. These assessments elicit open-ended verbal and behavioral responses through the use of story prompts or drawings (for a review, see Kerns, 2008). Attachment behavior and representations are coded using categorical classification schemes or continuous measures of security.

In adults, the most common assessment method is the Adult Attachment Interview (Main & Goldwyn, 1998), a semi-structured interview probing adults' state of mind regarding attachment with their caregivers. Based on the coherence of adults' narratives about their early attachment-related experiences (Roisman, Padrón, Sroufe, & Egeland, 2002), they are classified into one of four categories that parallel the infant classifications: secure/autonomous, dismissing, preoccupied, and unresolved. Complementing the developmental psychology tradition of assessing adults' state of mind with respect to early attachment experiences, social and personality psychologists have extended attachment theory to conceptualize romantic bonds in adolescence and adulthood. This perspective presumes that romantic relationships serve attachment functions parallel to those of the parent–child bond (Hazan & Shaver, 1987; for a review, see Mikulincer & Shaver, 2007). Social-personality assessments of adult attachment style involve self-report questionnaires regarding explicit thoughts and feelings within close adult (often romantic) relationships. Adults are characterized along two dimensions of attachment (in)security (Brennan, Clark, & Shaver, 1998; Hazan & Shaver, 1987; Roisman et al., 2007): attachment avoidance (discomfort with closeness and intimacy; reluctance to rely on others for support) and attachment anxiety (desire for extreme closeness and intimacy but fear of abandonment).

Considerable research has tested the key tenets of attachment theory (for reviews, see Cassidy & Shaver, 2008; Roisman & Groh, 2011). There is consistent evidence that parental sensitivity is associated, albeit modestly, with infant attachment security (De Wolff & van IJzendoorn, 1997) although distinct parenting correlates of specific types of insecure attachment have not been clearly established (Roisman & Groh, 2011). Meta-analytic evidence also supports the intergenerational transmission of attachment (van IJzendoorn, 1995) as well as a modest but significant degree of continuity in security from infancy through adulthood (Fraley, 2002).

Documenting the enduring effects of attachment, an impressive corpus of research links security of early

attachment, attachment representations, and adult attachment with a range of indicators of well-being, including self-reliance and self-image, emotion understanding and regulation, personality, and competence within peer and romantic relationships (for reviews, see Roisman & Groh, 2011; Thompson, 2008; Weinfield et al., 2008). Despite this support, the magnitude of effects often lies in the small to moderate range. Also of note, despite their presumed common theoretical origins, developmental and social-psychological assessments of adult attachment share little variance and predict somewhat distinct aspects of functioning within adult relationships (Roisman et al., 2007), suggesting they tap different aspects of attachment.

Application to Psychopathology. There is consistent (although sometimes modest and qualified) support for many of the central tenets of attachment theory with regard to its role in normative development and its contribution to individual differences in competence. Reflecting the generative nature of attachment theory, insecure attachment also has been implicated as a key contributor to psychopathology (for reviews, see Cicchetti et al., 1995; Davila, Ramsay, Stroud, & Steinberg, 2005; DeKlyen & Greenberg, 2008; Kobak et al., 2006). Collectively, these conceptualizations are based on the notion that early secure attachment arising from warm and sensitive caregiving lays the foundation for effective emotion regulation, healthy relationships, and positive working models of the self and others, which foster optimal long-term mental health. In contrast, it is theorized that early insecure attachment arising from unpredictable or rejecting caregiving undermines the formation of interpersonal competence and relationships, generates maladaptive working models of the self and others, and heightens risk for psychopathology.

Reflecting the principle of multifinality, these perspectives incorporate pathways between attachment insecurity and multiple forms of psychopathology. Reflecting the principle of equifinality, these perspectives implicate diverse avenues through which insecure attachment may foster similar outcomes. Proposed mediating pathways include (1) maladaptive internal working models incorporating views of the self as unworthy and ineffective as well as negative expectations of relationships (e.g., lack of support, hostility); (2) ineffective emotion regulation and poor coping skills; (3) cognitive biases (e.g., maladaptive interpretations, attributions, and expectancies); (4) inadequate internalization of social norms; (5) poor modulation of biological stress responses; (6) ineffective behavioral self-regulation (e.g., poor self-control and reciprocity); and (7) a negative social orientation (for reviews, see Brumariu & Kerns, 2010; Davila et al., 2005; DeKleyen & Greenberg, 2008; Weinfield et al., 2008).

In the next few sections, we present some specific representative attachment-based theories of psychopathology and we discuss the status of empirical evidence. Of note, many other theories consider attachment as a central construct. Some of those that implicate attachment within the context of integrative models are discussed in a later section. Overall, an extensive research base supports the proposed association between insecure attachment and multiple forms of psychopathology, with more limited evidence implicating a prospective contribution of insecure attachment to future psychopathology. Many comprehensive summaries of this research are available (Brumariu & Kerns, 2010; Davila et al., 2005; DeKlyen & Greenberg, 2008; Kobak et al., 2006); thus, we present a brief summary of results from recent qualitative and quantitative reviews.

Depression and Anxiety From the seminal work of Bowlby (1973, 1980) to contemporary perspectives (Brumariu & Kerns, 2010; Cassidy, 1995; Cummings & Cicchetti, 1990), attachment theory has been integral to many theories of anxiety and depression. According to Bowlby (1973), family environments that elicit concerns about rejection or abandonment or about the caregivers' or child's well-being prompt insecurity about caregiver availability along with heightened fear and vigilance. These concerns create a vulnerability to anxiety, particularly in the face of subsequent separation or challenge. Bowlby (1980) further asserted that uncontrollable and prolonged caregiver loss—whether symbolic or actual—conveys a sense of hopelessness and failure and invokes an internal working model of the self as unlovable and incompetent and of others as unloving. This working model creates a vulnerability to depression, particularly in the face of subsequent loss or disappointment. Building on these ideas, several contemporary models suggest that insecure attachment constitutes a significant risk factor for internalizing psychopathology. These theories integrate key aspects of Bowlby's original conceptualization while also refining and elaborating on pathways linking insecure attachment with anxiety and depression. Moreover, many of these models attempt to explain the contribution of specific subtypes of insecure attachment to anxiety versus depression, or even to subtypes of anxiety.

According to one model proposed by Sroufe and colleagues (Sroufe, 2003; Weinfield et al., 2008), children with an anxious-ambivalent attachment, who have pervasive concerns about caregiver availability, will be challenged by novel and complex social situations and consequently

will be prone to anxiety. Manassis (2011) speculated that each type of insecure attachment will heighten vulnerability to different types of anxiety. Specifically, children with an anxious-ambivalent attachment would show reduced exploratory behaviors and would be preoccupied with obtaining the caregiver's attention and comfort, thereby promoting separation anxiety. Children with an anxious-avoidant attachment would show heightened fear of rejection and avoid social contact, thereby promoting social phobia; alternatively, their restricted expression of negative emotions could trigger the indirect expression of distress through somatic complaints. Children with a disorganized attachment would be excessively concerned about their caregiver's well-being, potentially leading to separation anxiety and school phobia. Cassidy (1995) proposed that insecure attachment also can serve as a developmental antecedent of generalized anxiety disorder due to emergence of a cognitive style centered on chronic vigilance and ineffective responses to threat (see also Weinfield et al., 2008).

Presenting an attachment-based model of depression, Cummings and Cicchetti (1990) proposed that insecure attachment undermines children's self-esteem, felt security, coping resources, and confidence in the availability of others, thereby promoting long-term risk for depression. This model focuses in particular on the intergenerational transmission of depression, wherein the offspring of depressed parents experience high levels of caregiver psychological unavailability, thus heightening risk for the development of early insecurity, negative working models of self and others, and later disorder. Drawing from Bowlby's ideas, Egeland and Carlson (2004; see also Weinfield et al., 2008) articulated different pathways through which certain types of insecure attachment would lead to depression. Specifically, they suggested that (1) children with an anxious-ambivalent attachment, who feel unable to fulfill their caregivers' demands, develop a sense of helplessness; (2) children with an anxious-avoidant attachment, who perceive themselves as unlovable and inadequate and perceive others as hostile and unsupportive, develop a sense of alienation and hopelessness; and (3) children with a disorganized attachment, who feel overwhelmed by challenge, develop a low sense of self-efficacy. Depression represents the final common pathway of helplessness, hopelessness, and low self-efficacy. Several other theorists have proposed attachment-based models of depression, hypothesizing that insecure attachment confers vulnerability through the development of negative views of self and the social world, ineffective affect regulation and coping, and heightened generation of, or reactivity to, stress within close relationships (e.g., Cole-Detke & Kobak, 1996; Hammen et al., 1995).

Brumariu and Kerns (2010) provide speculative models of differentiated processes through which insecure attachment may contribute to both anxiety and depression. According to the first model, insecure attachment interacts with overcontrolling parenting to predict heightened threat sensitivity, difficulties in emotional understanding and expression, avoidance coping, and low self-efficacy, which heighten vulnerability to anxiety in the face of anticipated threat and in interaction with parental anxiety and temperamental vulnerability (high negative affect, high behavioral inhibition). According to the second model, insecure attachment interacts with rejecting parenting to predict a depressogenic cognitive style, difficulties in emotional understanding and expression, ruminative coping, and low self-worth, which heighten vulnerability to depression in the face of experienced disappointment or loss and in interaction with parental depression and temperament vulnerability.

In a recent narrative review of research on attachment and internalizing symptoms, Brumariu and Kerns (2010) concluded that attachment insecurity is consistently associated with anxiety and depressive symptoms, with stronger associations in preadolescence/adolescence than in earlier childhood. However, they noted the scarcity of prospective longitudinal research, particularly studies that examine changes in internalizing symptoms over time. Effect sizes across studies ranged from small to large, with effects stronger for studies that used questionnaire rather than observational or representational assessments of attachment and significant variability within and across studies depending on the specific comparisons (e.g., general insecurity vs. specific subtypes), informants, or age of symptom assessment. Although a useful preliminary summary of the state of the field, a more definitive quantitative estimate was provided by a recent meta-analysis that incorporated only studies using state-of-the-art observational measures of attachment during early childhood (Groh, Roisman, van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012). This analysis yielded a significant, albeit small, effect size for the association between attachment and internalizing symptoms, which was not significantly moderated by age of symptom assessment, child gender, economic risk or clinical status of the sample, type of attachment measure, or type of internalizing symptom measure.

Externalizing Psychopathology Attachment theory also has been invoked to explain the emergence of externalizing psychopathology. According to Bowlby (1973), prolonged

caregiver separation, rejection, or the threat of abandonment invoke intense anger in children. Originally directed toward the attachment figure, children may learn to redirect anger toward other targets, resulting in hostile and aggressive behavior. Building on these ideas, Sroufe (2003; Weinfield et al., 2008) proposed that both avoidant and ambivalent attachment would promote risk but for different reasons and with different manifestations. Whereas children with an avoidant attachment may develop aggressive and antisocial behavior (e.g., bullying, blaming, insensitivity) in response to anger stemming from rejection by their caregiver and resulting alienation and lack of social trust, children with an ambivalent attachment may develop behavior problems (e.g., impulsivity, restlessness) as a result of overstimulation and poor self-regulation. Disorganized children also are viewed as at risk for anger and aggression due to their struggles over attachment to a frightened or frightening caregiver (Weinfield et al., 2008).

Greenberg and colleagues (1993; Dyklen & Greenberg, 2008) elaborated on four specific pathways through which insecure attachment can heighten risk for disruptive behavior disorders. First, insecurely attached children may develop working models of relationships characterized by anger and mistrust, resulting in cognitive biases (e.g., hostile attributions) that set the stage for reactive forms of aggression. Second, insecure attachment may promote maladaptive regulatory behaviors (e.g., whining, noncompliance) aimed at seeking attention and proximity to the caregiver, which later consolidate into general patterns of externalizing behavior. Children with disorganized attachment, in particular, may aim to take control of the parent–child relationship in an effort to create a more coherent and predictable environment, resulting in dominating social behaviors. Third, insecurity may undermine effective emotion regulation processes, such that avoidant children minimize, and ambivalent children exaggerate, negative affect, both of which may cause problems dealing with later stress. Fourth, insecurely attached children may develop a resistant social orientation, making them less amenable to moral directives and social norms that would inhibit deviant behavior. Acknowledging the complexity of the proposed processes, however, these theorists note the improbability that insecurity exerts main effects on behavior problems, instead taking a multiple pathways perspective that considers how attachment security likely interacts with other risk and protective factors concurrently and later in development to determine behavioral trajectories.

Two recent meta-analyses examined the link between attachment and externalizing psychopathology. One (Fearon, Bakermans-Kranenburg, van IJzendoorn, Lapsley, & Roisman, 2010) yielded a medium effect for the link between general attachment insecurity and externalizing symptoms. Moreover, the predictive significance of attachment insecurity remained constant across the age of symptom assessment but was stronger for boys and for clinical samples. The other (Hoeve et al., 2012) yielded a small-to-moderate effect for the link between insecure attachment and delinquency. However, this effect was moderated by a number of factors, including age (larger for younger than older children), attachment figure (larger for mother–child than father–child attachment), and match between sex of the parent and child (larger for same-sex than cross-sex pairs). Discrepancies across these two reviews (e.g., absence vs. presence of a moderating effect of age) may be due in part to a focus on externalizing symptoms more broadly in the former study versus delinquency specifically in the latter study as well as the inclusion of studies using a broader array of attachment measures in the latter than former study. Of note, Groh et al. (2012) found that the meta-analytic effect for externalizing symptoms in the Fearon et al. (2010) study was significantly larger than their effect for internalizing symptoms.

Eating Pathology Attachment also plays a central role in several theories of eating disorders. Dating back to the early writings of Bruch (1973), integral to these theories is the idea that eating pathology emerges in the context of poor self-individuation from attachment figures, anxiety about the availability of attachment figures, and efforts to ensure proximity to caregivers. Demands for heightened autonomy from caregivers during adolescence are believed to trigger extreme confusion and anxiety, as insecurely attached youth struggle to develop a sense of self as competent and self-sufficient when facing psychological separation (i.e., individuation) from their caregivers. Armstrong and Roth (1989) proposed that eating disorder symptoms serve to regulate negative affect and anxiety about this separation and to maintain connectedness to caregivers; as such, symptoms provide insecurely attached youth with a sense of control in the face of perceived helplessness. The assumption is that insecurely attached youth not only have excessive concerns about separation but they also lack effective emotion regulation skills necessary to cope with the challenges of adolescence. Thus, disordered eating may reflect an attempt to control one's world by directing attention away from attachment toward more attainable and less anxiety-provoking goals (Cole-Detke & Kobak, 1996). O'Kearney (1996) suggested that symptoms of anorexia and bulimia function to regulate proximity to

caregivers. For youth with a dismissing (avoidant) attachment, symptoms cause an altered physical appearance that diverts attention away from distressing aspects of the attachment relationship. For youth with a preoccupied (ambivalent) attachment, a focus on appearance is thought to reflect hypervigilance to the judgments of others.

Most of the research examining the association between insecure attachment and eating disorders involves adult samples (for a review, see Davila et al., 2005). Overall, this research suggests high rates of concurrent insecure attachment in women with eating disorders. Attempts to identify links between specific subtypes of attachment and specific types of eating disorders have not yielded a consistent pattern, with some studies suggesting strong links with preoccupied attachment and others with dismissing attachment. These discrepancies may be due in part to different patterns of comorbidity within the eating disorder groups (Davila et al., 2005). Unfortunately, much of this research relies on non-standard measures of attachment; moreover, prospective research has not yet investigated whether early attachment predicts long-term risk for eating disorders, making it difficult to draw definitive conclusions about its etiological status.

General Parenting and Family Theories

Theoretical Underpinnings. Beyond the level of the parent–child attachment bond, parenting and family theories focus on three primary types of influence. One set of theories emphasizes parenting practices and styles, including parents' behavior toward children and the emotional climate of the parent–child relationship. Another set of theories focuses on parental modeling, reinforcement, and instruction, which can entail both negative influences (e.g., parental modeling of aggressive behavior) and positive influences (e.g., parental coaching in adaptive coping strategies). A third, family systems theory, expands beyond the parent–child dyad to include other subsystems within families such as interparental and sibling relationships.

Parenting Practices and Styles Parenting theorists distinguish between parenting practices (what parents do) and styles (how they do it). Several theoretical perspectives draw similar conclusions about the major dimensions underlying parenting practices and styles. Early theories emphasized the importance of acceptance versus rejection and dominance versus submission (Symonds, 1939); warmth versus hostility and detachment versus involvement (Baldwin, 1955); warmth and permissiveness versus strictness (Sears et al., 1957); love versus hostility and autonomy versus control (Schaefer, 1959); and warmth versus hostility and restrictiveness versus permissiveness (Becker, 1964). These theories share a framework focusing on dual dimensions of parenting: emotional (captured in the constructs of acceptance and warmth vs. hostility and rejection) and behavioral (captured in the constructs of involvement and autonomy vs. restrictiveness and control). Contemporary theories view these as orthogonal dimensions of parenting.

Baumrind's (1967) well-known conceptualization incorporated these two key dimensions of parenting into a typology of three styles: authoritarian, authoritative, and permissive. Authoritarian parents are highly controlling, giving directives for their children to follow without an opportunity to provide input or make independent choices. Permissive parents are warm and affectionate but highly lenient, giving children a great deal of freedom to do as they please. Authoritative parents share a mixture of these characteristics; they are affectionate but also provide clear rules along with explanations for why children should follow them. Compared to children whose parents are authoritarian or permissive, children of authoritative parents show the highest levels of subsequent social competence and academic achievement and the fewest behavior problems (Baumrind, 1971). Lewis (1981) reinterpreted Baumrind's work to emphasize that reciprocal communication and children's empowerment to negotiate rules in authoritative families, rather than high control, promotes children's autonomy and social competence.

Building on Baumrind's perspective, Maccoby and Martin (1983) conceptualized parenting in terms of a two-by-two matrix reflecting high versus low levels of demandingness (control, supervision) and responsiveness (warmth, acceptance). Authoritarian parents were high on demandingness but low on responsiveness, and authoritative parents were high on both demandingness and responsiveness. However, Maccoby and Martin differentiated permissive parents into indulgent parents, who were low on demandingness but high on responsiveness, and neglecting parents, who were low on both demandingness and responsiveness. Following this distinction, Baumrind (1991) later incorporated into her own framework a rejecting-neglecting style in which parents were low on both demandingness and responsiveness. Baumrind (1991) also differentiated the nature of demandingness such that authoritative parents use firm control but are not highly restrictive, whereas authoritarian parents use firm control but are also highly restrictive.

Baumrind's differentiation of restrictiveness from firm control foreshadowed what has become an important distinction between psychological and behavioral control

(Barber, 1996). Psychological control involves manipulation and intrusion into children's emotional and cognitive world through invalidating children's feelings and pressuring them to think in particular ways. These psychologically controlling behaviors are associated with worse adolescent adjustment, such as more delinquency, more depression, and poorer academic achievement (Barber, 2002). Behavioral control involves parents' attempts to regulate children's behavior through monitoring, guidance, and supervision; this regulation can be accomplished through parents' behaviors (e.g., setting rules such as curfew times) and parents' knowledge about adolescents' whereabouts, companions, and how they spend their time, which can be a function of parents' own efforts as well as adolescents' willingness to disclose information to their parents (Stattin & Kerr, 2000). In contrast to psychological control, behavioral control generally is associated with better adolescent psychological and behavioral adjustment (Pettit, Laird, Bates, Dodge, & Criss, 2001).

In part in response to inconsistent findings regarding how specific parenting practices are related to children's adjustment, another set of theories emphasizes parenting style as a context that moderates the link between specific parenting practices and children's adjustment. Darling and Steinberg (1993) distinguished three aspects of parenting: parents' goals for their children's socialization, parenting practices, and the emotional climate in which parents socialize their children (i.e., style). They argued that parenting style moderates the effectiveness of specific parenting practices and modifies children's openness to being socialized. These three aspects of parenting comprise a model with five components. Parenting goals and values (component 1) influence both parenting style (component 2) and parenting practices (component 3), which directly affect child outcomes (component 4); however, the relation between parenting practices and child outcomes is moderated by parenting style and children's willingness to be socialized (component 5), which also is affected by parenting style.

Several other contemporary models also introduce the role of parents' and children's emotions as well as children's subjective perceptions of parenting as key mediators of parenting effects. Davies and Cummings (1994) summarized research on two broad categories of parenting problems—parental rejection (including negative emotions) and poor child behavior management—in the context of their emotional security hypothesis. According to this framework, children's emotional security mediates the link between parenting and children's adjustment. Parents' negative emotions, including intrusiveness, withdrawal, and rejection, contribute to children's anger, dysphoria, social withdrawal, noncompliance, and externalizing problems. In terms of poor child behavior management, Davies and Cummings described two problematic parenting patterns. The first is characterized by lax supervision and discipline, whereas the second is characterized by harsh discipline. Both are predictive of children's externalizing and internalizing problems. Davies and Cummings interpret these links in the context of an emotional security hypothesis, which posits that when parents are unavailable or unpredictable, children's sense of emotional security and ability to regulate their own emotions are compromised. Most of their research focuses on children's emotional insecurity in the face of marital conflict, but the proposed mechanisms share features of attachment theory and other prominent parenting theories, which propose that children's interpretation of parents' behavior is a key factor in the link between parenting and children's adjustment.

In a similar vein, Rohner's (2004) parental acceptance–rejection theory posits that children's interpretation of their parents' behavior as indicating acceptance or rejection determines its effects on development. Meta-analyses and systematic reviews of data from many countries support this proposition (e.g., Khaleque & Rohner, 2002). In one investigation, Rohner, Bourque, and Elordi (1996) found children's perceptions of the harshness and justness of their parents' physical punishment did not have direct effects on their psychological adjustment; instead, these effects were fully mediated by children's perceptions of their parents' acceptance and rejection. Similarly, Rohner, Kean, and Cournoyer (1991) found that parents' use of physical discipline negatively affects children's adjustment in part through its effect on children's perception of being rejected. Thus, the effect of a particular parenting behavior may depend on the context in which it is employed and the meaning it delivers for the parent and child.

Dix (1991) describes three types of processes in an emotion-focused model of parenting. Activation involves when emotion is experienced, what emotion is experienced, and how strongly it is experienced. Engagement orients people to events in a way that is consistent with the emotion and affects their cognition about the event, physiological state, behavioral orientation, expression of emotion, and motivation. Regulation involves processes that help people understand and control their emotions, including how emotions are expressed (e.g., by augmenting positive emotions or inhibiting negative emotions). Emotions are activated in parent–child interactions because these interactions are important to parents. Parents often

have particular short-term (e.g., get the child to school on time) and long-term (e.g., promote honesty, responsibility, and empathy) goals in parent–child interactions; emotions often hinge on whether parents' goals in a particular interaction are promoted or thwarted. When parents and children have compatible concerns and behaviors, emotion generally will be positive; when they have divergent concerns and behaviors, emotion often becomes negative. Parents can manage this divergence with a variety of strategies. They can use cooperative strategies such as negotiating and reasoning. Alternatively, parents can use forceful strategies by imposing their will; because this approach does not reconcile children's and parents' wants, children are likely to resist more and, therefore, these strategies may undermine future cooperation and support in parent–child relationships. Finally, parents can use empathic strategies by accommodating to the child's desires.

The strength of a given emotion depends on parents' perceptions of whether the event that induced the emotion is important, stable, and controllable. Too little emotion can lead to parenting that is disengaged or unresponsive, but too much emotion can lead to parenting that is too harsh or intrusive, both of which characterize distressed parents. Emotion regulation is important for parents because it ensures that parents do not display counterproductive emotions (e.g., parents may suppress expressions of their own fear to avoid making their young children fearful) or that are poorly matched to a particular parenting situation (e.g., if parents bring home anger from an interaction at work and take it out on the child). Dix (1991) argued that parenting will be most effective when children's concerns activate stronger emotion than parents' concerns because parents will then act empathically in the child's interests even if it is not personally convenient or easy to do so.

Parental Modeling, Reinforcement, and Instruction Social learning models focus on exposure to healthy versus pathogenic learning environments within the family (for a review, see Davies & Sturge-Apple, 2014). Learning can occur through observational (vicarious), enactive (reinforcement), and instructional processes. In observational learning, children adopt cognitive, emotional, and behavioral repertoires through imitation and the internalization of schemas or scripts. In risky family environments, parents may express unhealthy cognitive biases (e.g., negative attributions, hypervigilance to threat), show high levels of emotional distress (e.g., extreme anxiety), and engage in maladaptive behaviors (e.g., poor coping, aggression) due to their own psychopathology or other personality characteristics, thereby transmitting unhealthy patterns to their offspring. In enactive learning, parents may manage children's behavior using reinforcement contingencies that purposefully or inadvertently reinforce either salutary or deviant behaviors. Inept parenting behaviors (e.g., lax or inconsistent discipline; poor communication of expectations) can have the effect of failing to reward prosocial behaviors and failing to punish antisocial behaviors, thereby conveying confusing messages about appropriate behavior. Unfortunately, parenting behaviors aimed at protecting children (e.g., limiting contact with anxiety-inducing situations; permitting or encouraging avoidance) can serve to negatively reinforce maladaptive emotions and behavior. Parents also provide direct instruction regarding appropriate modes of functioning, encouraging children to cope with emotions and stress in ways that foster either healthy or unhealthy patterns (Abaied & Rudolph, 2010). Collectively, these learning processes result in the intergenerational transfer of unhealthy cognitive, emotional, and behavioral styles that heighten risk for psychopathology.

Family Systems Theory Family systems theory posits that the entire family, rather than just individual dyads within families, should be the unit of analysis when trying to understand links between family functioning and children's development (Davies & Cicchetti, 2004). Dyadic parent–child, interparental, and sibling relationships are all important, but family systems theory advocates an approach to families that goes beyond individual dyads. Key concepts in family systems theory include holism, interpersonal boundaries, and embeddedness (Cox & Paley, 1997).

The concept of *holism* encompasses understanding families as consisting of interdependent parts (Davies & Sturge-Apple, 2014). Families include subsystems of interconnected relationships (e.g., mother-child, father-child, brother-sister, mother-father, etc.) that, as a unit, represent more than the additive sum of these subsystems (Cox & Paley, 1997). Functioning within one relationship, or subsystem, can affect all other individuals and relationships, and relationships are bidirectional. Within the family system, individuals can have direct effects on one another or can have indirect effects when dynamics from one relationship influence dynamics in another relationship, such as when interparental conflict spills over into hostile parent–child interactions (Schoppe-Sullivan, Schermerhorn, & Cummings, 2007). Because of this interdependency, disturbances in any subsystem can have implications for other subsystems.

The concept of *interpersonal boundaries* also plays a key role in family systems theory. The exchange of resources

and information within families has been described in relation to four patterns of boundaries: cohesive, disengaged, enmeshed, and triangulated (Davies & Sturge-Apple, 2014). Cohesive families have flexible and well-defined boundaries that give children access to resources such as warmth and guidance yet also enable children to retain autonomy and individuality. In cohesive families, conflict and distress tend not to spill over from one relationship subsystem to others and are typically mild and well managed. Children in cohesive families generally have better developmental outcomes than do children in other types of families. Disengaged families have rigid and inflexible boundaries that prevent children from gaining access across family subsystems to resources such as support and protection (Davies & Sturge-Apple, 2014). Consequently, individuals in disengaged families often feel emotionally detached and alienated. Children in disengaged families are at risk for developing psychopathology characterized by externalizing problems, social withdrawal, and interpersonal disregard (Jacobvitz, Hazen, Curran, & Hitchens, 2004). Enmeshed families have weak boundaries in which children lack autonomy and are exposed to discord in multiple family subsystems (Davies & Sturge-Apple, 2014). For example, in enmeshed families, children may not be shielded from marital conflict, and parents may use psychological control that intrudes on adolescents' ability to gain age-appropriate independence from the family. Children in enmeshed families are at risk for anxiety, other internalizing problems, and interpersonal dependency (Jacobvitz et al., 2004). Triangulated families share characteristics of both disengaged and enmeshed families as reflected in defensive alliances between some family members who are pitted against others from whom they are disengaged. Children who form coalitions with a parent may take on developmentally inappropriate roles as a confidante or caregiver, placing them at psychological risk (Johnson, 2010). Sometimes, children's psychological symptoms themselves serve a function within the family of bringing other family members into an alliance against the child (Davies & Sturge-Apple, 2014).

Families are embedded in the larger world, and this larger context affects what occurs within families. Cultural, social, and economic events can have a tremendous effect on the nature of families and interactions among family members (Bronfenbrenner, 1977). Ecological models are clear in documenting that understanding children's development in family systems is not independent of what is happening outside the family. For example, Elder's (1974) classic study of children of the Great Depression demonstrated that children's developmental outcomes were contingent not only on family processes but also on economic strain resulting from the Depression as well as children's age at the time, with individuals who were adolescents during the Depression faring more favorably than those who were children.

Family systems theory has the potential to contribute to an understanding of children's adjustment above and beyond parenting theories. As described previously, several parenting theories emphasize the importance of parental warmth and affection in fostering positive developmental outcomes. Family systems theory contextualizes this idea by emphasizing that parental warmth might have different meanings in the context of different types of families. For example, parental warmth may be a manifestation of healthy family functioning, an attempt by a parent to compensate for other forms of adversity in the family, or a coalition-building attempt by one parent against the other (Davies & Cicchetti, 2004).

Even within family systems theory, the majority of attention is devoted to interparental and parent–child subsystems rather than to sibling subsystems. Nevertheless, sibling relationships are an important interpersonal context and can play a meaningful role in children's development. In the United States, approximately 80 percent of children have at least one sibling (Livingston, 2011). On average, children spend more time with their siblings than with their parents (McHale & Crouter, 1996). Chronic and physical conflict between siblings is related to children's internalizing (Milevsky & Levitt, 2005) as well as externalizing problems (Ensor, Marks, Jacobs, & Hughes, 2010). In contrast warmth and cohesion between siblings is related to fewer externalizing problems (Branje, Van Lieshout, Van Aken, & Haselager, 2004) and more positive psychological functioning (Stocker, 1994).

Expressed emotion (EE) theory provides another lens through which to understand links between family functioning and psychopathology (Brown, Birley, & Wing, 1972). Originally developed to explain the course of severe mental illness such as schizophrenia, this theory has been extended to understand the development of other disorders, including mood and eating disorders (Butzlaff & Hooley, 1998). The assumption of EE theory is that emotions operate as a salient socializing force within the family; a particular emphasis is placed on the dimensions of hostility, criticism, and emotional over-involvement. Hostility and criticism often involve either blaming an individual for problems in the family or blaming a family member for not controlling his or her disorder. Emotional over-involvement often involves family members blaming themselves for another family member's disorder. In a

meta-analysis of 27 studies, EE was a significant predictor of relapse in schizophrenia, mood disorders, and eating disorders (Butzlaff & Hooley, 1998).

Integrative Parenting/Family Model Integrating diverse parenting and family theories of psychopathology, Davies and Sturge-Apple (2014) proposed a comprehensive, developmental family risk model. In their model, family dynamics include both family risk factors (quality of relationships within the parent–child, interparental, and child-sibling subsystems) and systemic organizing parameters (interdependency, holism, and boundaries). The systemic organizing parameters describe how the subsystems relate to one another, such as interdependency related to spillover of conflict from the interparental relationship to parent–child relationship and whether there are well-defined boundaries between family members. Family risk factors and systemic parameters are thought to influence child psychopathology through cascade mechanisms (interpersonal, neurobiological, neuropsychological, and stage-salient tasks). Bidirectional associations between family dynamics and child adjustment trajectories operate via family risk mechanisms (child attachment insecurity, child defensive reactivity, and child affiliative styles) and can be moderated by regulatory conditions (parent characteristics, ecological factors, and child attributes).

Developmental Significance and Change. Different aspects of parenting and family relationships are salient at different stages of development (for a review, see Grusec & Davidov, 2007). During infancy, responsiveness and sensitivity are essential to foster healthy parent–child attachment relationships. During early childhood, children's social and emotional development is encouraged by parents' scaffolding of children's experiences in a way that promotes their self-regulation and emotion socialization as well as their development of executive function skills. During middle childhood, behavioral control becomes more salient as parents attempt to effectively prevent and respond to misbehavior. Normative development is promoted via parents' setting and enforcing appropriate limits, proactive behavioral management, and provision of warmth and acceptance. In adolescence, it is important for parents to continue providing warmth and acceptance and appropriate behavioral regulation. At the same time, promoting autonomy and independence are increasingly important. During adolescence, distal monitoring and psychological control become more salient as adolescents spend more time outside the direct control of parents and in the presence of their peers. The transition through puberty also may significantly transform and challenge family relationships as parents and youth attribute different meaning to advancing maturation, with parents focusing on increasing responsibility and risk, and youth focusing on increasing privilege and autonomy. Negotiating the push and pull of parent–child relationships as adolescents seek autonomy yet retain connections with the family can serve as a significant stressor to the family system.

Early theory and research focused largely on how parents affect children's development during each of these developmental stages. However, the seminal writings of Bell (1968) and Scarr and McCartney (1983) spurred a new scientific tradition focused on understanding transactions between children and their parents. These reciprocal effects can unfold moment by moment (Bell, 1968) or over longer periods of time (Sameroff, 1975). Sameroff's (1975) model asserts that children and their parents mutually affect one another when children elicit particular types of responses from their parents and when parents' behavior induces children to behave in particular ways. Parent effects can be accounted for by mechanisms discussed earlier, such as parenting practices and styles, learning processes, and family dynamics. Child effects can be accounted for by mechanisms such as temperamental eliciting of particular parenting behaviors and rGE effects. As children develop and are given more opportunities to act independently on the environment, rGE effects move from being driven primarily by passive processes to more evocative and active ones (Scarr & McCartney, 1983). Although some research suggests the primacy of child or parent effects, there is more empirical support for reciprocal relations (see Special Section of *Journal of Abnormal Child Psychology*, 2008).

Along with transformations within parent–child relationships, entire families are dynamic. Some family changes involve normative transitions as children develop (and therefore require change within the family to accommodate their new capabilities and needs) and as parents develop (for example, once they have progressed beyond the transition to parenthood and have moved into a more established parenting role). Sources of change also can include events inside families such as the birth of a new baby, parental divorce, or illness or death of a family member. Finally, changes can be instigated by outside forces, such as a parent's job loss or a child's academic difficulties or successes.

Normative development often is distinguished from non-normative development by virtue of disruptions in family relationships. For example, parent–child relationships that are physically, emotionally, or sexually abusive are non-normative and confer risk for negative developmental outcomes. Likewise, family experiences that

are off-time by virtue of their occurrence either before or after they would be expected normatively also confer developmental risk. For example, teen parenthood often is associated with academic, psychological, and behavioral difficulties in both the teen parents and their offspring.

Application to Psychopathology. Parenting and family theories offer several explanations regarding why problems in parent–child relationships predict certain types of psychopathology. Reflecting *multifinality*, theories delineate ways in which the major dimensions of parenting affect multiple forms of psychopathology. Reflecting *equifinality*, theories suggest that different aspects of parenting and family relationships ultimately may be related to similar forms of psychopathology via several mediators (e.g., children's emotion regulation, emotional insecurity, perceptions of their parents' rejection). In the next few sections, we present some representative parenting and family systems theories as related to psychopathology.

Depression Driven by robust evidence for the intergenerational transmission of depression, many theories of youth depression consider the idea that depressed parents contribute not only genetic and neurobiological liability but also socialization contexts conducive to the development of depression in offspring. Specifically, several theories (Abaied & Rudolph, 2014; Goodman & Tully, 2008; Hammen, Rudolph, & Abaied, 2014) propose a transmission process wherein maternal depression and its cognitive and emotional sequelae disrupt parenting behavior and parent–child relationships, creating stressful contexts and functional deficits that predispose youth to depression. These perspectives collectively focus on the contribution of multiple parenting dimensions thought to characterize both depressed parents and the parents of depressed youth: (1) high levels of hostility, rejection, and criticism; (2) low levels of support, warmth, and positive affect; (3) high levels of psychological control and intrusiveness; and (4) maladaptive socialization of emotion and coping (e.g., frequent expression of negative emotion or punitive responses to children's emotional displays; encouragement for children to avoid stress and negative emotions). Exposure to these parenting environments (among other early adversities) is thought to impair biological, emotional, cognitive, and interpersonal development in ways that leave youth vulnerable to depression (Hammen et al., 2014). Moreover, transactional processes may emerge in which depressive symptoms color perceptions of the parent–child relationship and induce discomfort and stress in relationships, thereby disrupting future parenting (Abaied & Rudolph, 2014).

Sheeber and colleagues (2001) proposed a model that incorporates similar elements but also considers conditioning within the parent–child relationship, suggesting four pathways to depression. First, the presence of stress and absence of support in parent–adolescent relationships is a risk factor for the development of depression. Second, parents may inadvertently condition their adolescents to exhibit depressive symptoms via negative and positive reinforcement (e.g., reducing parent-to-child aggression or increasing supportiveness in the face of adolescents' depressive behaviors). Third, depressive cognitive styles and ineffective problem-solving skills in children may mediate the relation between problematic parenting and adolescents' depressive symptoms. Finally, parents of depressed adolescents are less skilled at teaching their adolescents to regulate negative affect in constructive ways. In concert, these mechanisms contribute to links between problematic parenting and the development of depression.

Supporting these theories, prospective research using multiple methods (e.g., self- and parent reports, interviews, observations) implicates parenting disruptions as consistent predictors of youth depression and, less frequently, as mediators between maternal and youth depression (for reviews, see Abaied & Rudolph, 2014; Goodman & Tully, 2008; Hammen et al., 2014). At a macro-level (reflecting general parenting practices and style), depressed mothers have particular difficulty with the emotional aspects of parenting, showing less warmth, positive affect, and supportiveness along with more criticism, hostility, and guilt induction (for a meta-analysis, see Lovejoy, Graczyk, O'Hare, & Neuman, 2000). Exposure to these contexts, in turn, predicts youth depression, perhaps in part as a process of social contagion as depressed mothers model maladaptive affect and cognition. At a micro-level (reflecting moment-to-moment contingencies), maladaptive conditioning processes occur, wherein coercive parent–child interchanges heighten youths' vulnerability to subsequent depression. Supporting reciprocal-influence models, some research links depressive symptoms to increasingly negative perceptions and stress within parent–child relationships, although this evidence is mixed.

Anxiety Parents can influence the development and maintenance of anxiety in their offspring through several pathways (for a review, see Vasey, Bosmans, & Ollendick, 2014). In one conceptualization, Murray, Creswell, and Cooper (2009) proposed three such pathways: (1) genetic vulnerability; (2) modeling of anxious cognitions and behavior; and (3) socialization efforts that lead children to believe the world is dangerous and they are unable to cope. Theories of anxiety also propose indirect pathways

through which parents convey anxiety-inducing messages about children and the world, with a particular focus on the parenting dimensions of psychological control or intrusiveness, overprotectiveness (e.g., limiting exposure to challenging or fear-provoking stimuli), and rejection-criticism (Creswell, Murray, Stacey, & Cooper, 2011; Davila et al., 2010; Vasey et al., 2014; Whisman & Beach, 2010). These parenting practices and styles are believed to instill anxiety by lowering children's perceptions of control, compromising their feelings of competence and mastery, restricting their sense of autonomy, heightening their threat sensitivity, and interfering with their emotion regulation (Albano, Chorpita, & Barlow, 2003; Vasey et al., 2014; Whisman & Beach, 2010). Anxiety is then maintained through parental reinforcement (e.g., encouraging or allowing avoidance and escape of a phobic stimulus) and accommodation (e.g., participating in compulsive rituals), which result in a failure to habituate to anxiety-inducing stimuli and to acquire age-appropriate coping and social skills (Kraper, Soto, & Carter, 2014; Whisman & Beach, 2010). Although well intentioned, such reinforcement and accommodation can have the unintended effect of supporting and perpetuating anxiety.

Reflecting transactional processes, children with anxious temperaments or early symptoms of anxiety also may elicit protective or critical behavior or encouragement to avoid stressful situations from their parents (Albano et al., 2003; Kraper et al., 2014), and parent and child displays of anxiety may become mutually reinforcing (Davila et al., 2010). Many of these processes are likely exacerbated in the context of parental anxiety, contributing to the intergenerational transmission of disorder (Albano et al., 2003; Davila et al., 2010; Kraper et al., 2014; Vasey et al., 2014).

A recent meta-analysis (McLeod, Wood, & Weisz, 2007) supports a significant, albeit relatively small, linkage between parenting and anxiety, with larger effects for the dimensions of overcontrol and low autonomy-granting relative to parental rejection and lack of warmth. Overall, research suggests that the magnitude of parenting-anxiety associations varies according to several parameters (e.g., age, informant, sample, methodology; Creswell et al., 2011) and is moderated by child temperament (Vasey et al., 2014). Stronger effects emerge when youth rather than parents serve as informants (McLeod et al., 2007), consistent with the emphasis of some theories on mediation of parenting effects by children's subjective perceptions. Of note, much of the evidence on parenting-anxiety linkages comes from cross sectional research, although some recent longitudinal research supports bidirectional associations between parenting and child anxiety (Vasey et al., 2014).

Externalizing Psychopathology Parenting and family relationships play a key role in most theories of externalizing psychopathology. Patterson and colleagues' (Patterson, Capaldi, & Bank, 1991) coercion theory has been particularly influential in efforts to understand the development of aggressive and antisocial behavior. Coercive exchanges are bidirectional processes in which children influence their parents and parents influence their children in an escalating cycle of negative affect and behavior. As a result of these cycles, aversive behaviors in children (e.g., whining, yelling, hitting) are inadvertently reinforced through parental withdrawal of discipline; likewise, parental ineffective discipline is reinforced through children's temporary reduction in aversive behaviors. These coercive patterns are generalized to interactions between children and others in their environments (e.g., peers, teachers) as children learn to use aversive behaviors to attain rewards or avoid unpleasant experiences, resulting in the perpetuation and exacerbation of aggressive and antisocial behavior (Dishion, 2014).

Other social learning models also explain emerging risk for externalizing psychopathology. Children exposed to corporal punishment may observe and imitate parents' use of aggression; indeed, parents' use of corporal punishment is a robust predictor of children's externalizing behavior (for a review, see Gershoff, 2002). Similarly, according to Huesmann and Guerra (1997), children develop normative beliefs about aggression based on experiences within the family. If children experience aggression in parents, they may come to perceive aggression as being an acceptable and legitimate way of handling problems. More generally, parenting styles characterized by high levels of rejection, high levels of psychological control, and low levels of parental warmth may provide models of hostility and aggression as well as insufficient opportunities for children to learn prosocial behavior, creating risk for externalizing behavior (Barber, 1996). Poor monitoring and lack of supervision may allow adolescents to engage in risky environments and behaviors, promoting and maintaining antisocial behavior (Barber, Stolz, & Olsen, 2005).

Beyond the parent–child dyad, a large body of research links disruptions in family systems or subsystems within families to children's externalizing psychopathology. There is some evidence that taking into account the full family system leads to better prediction of children's externalizing psychopathology than does attention to any single component of the family. For example, Ingoldsby, Shaw, and Garcia (2001) found that children's aggression at school was predicted by exposure to distress in more than one family subsystem rather than exposure to distress in just one. Overall, there is considerable theoretical and empirical

work implicating the linkage between family functioning and the development of externalizing psychopathology (for a review, see Davies & Sturge-Apple, 2014). Developmental cascade models capture well how minor problems in self-regulation during infancy can develop into major problems in externalizing psychopathology through a series of maladaptive transactions between parents and children and noxious family environments (Dishion, 2014).

Of course, it is essential to consider transactional processes wherein children with predispositions toward aggression and antisocial behavior elicit adverse parenting and disrupt the family system. Children with irritable temperaments and high levels of negative emotionality may evoke rejection and hostile or inconsistent discipline from parents and may react in more adverse ways to parent socialization efforts (Bates, Schermerhorn, & Goodnight, 2010). Indeed, consistent with theories of rGE correlations, genetically influenced conduct problems are implicated in an evocative child effect on maternal sensitivity (Deater-Deckard, 2009).

Eating Pathology Family systems theory concepts of enmeshment, overprotectiveness, rigidity, and avoidance of conflict/unresolved conflict have played a prominent role in attempts to understand the development of eating pathology (Minuchin, Rosman, & Baker, 1978). In families characterized by these patterns, eating disorders sometimes develop as a way for children to attempt to exert control and boundaries that are not established in other ways within the family (Blinder, Chaitin & Goldstein, 1988). More broadly, control has emerged as a key issue for individuals with eating disorders, who often attempt to exert control over their lives by controlling their food intake (in the case of anorexia) or who feel out of control with respect to food (in the case of bulimia), both of which have been theorized to stem from inappropriate control within the parent–child relationships (Bruch, 1978). Furthermore, as social learning theory would predict, parents model attitudes and behaviors related to food, eating, and weight (Bruch, 1973).

In part, eating pathology may be transmitted from parents to children in ways that do not directly involve the child's eating. For example, when mothers with bulimia are binging and purging, they are more likely to ignore the child or to become irritable and physically violent (Stein & Fairburn, 1989). Thus, equifinality may characterize the development of eating pathology, with both general parenting problems such as authoritarian control or lack of affection as well as eating-specific problems such as modeling unhealthy attitudes about food leading to children's eating pathology.

Directions for Future Research on Parent–Child and Family Theories

With regard to attachment theory, reviews and meta-analyses support a reliable and enduring, albeit modest, effect of insecure attachment on psychopathology, with a particularly strong effect for externalizing behavior. However, future research will need to address several unanswered questions to provide a more nuanced perspective on the role of early attachment in the development of psychopathology.

First, the jury is still out regarding the validity of theoretical predictions regarding the contribution of specific types of attachment to specific types (or subtypes) of disorder. Thus far, despite some evidence for specificity of effects, contradictory evidence and a lack of consensus abound within the field. In their narrative review, Brumariu and Kerns (2010) concluded that ambivalence poses a higher risk for preadolescence/adolescence anxiety and global measures of internalizing symptoms than do other subtypes of attachment (consistent with some theoretical predictions; Sroufe, 2003; Weinfield et al., 2008), and that avoidance was not consistently associated with internalizing symptoms. They also concluded that disorganization was moderately associated with depression. Yet, in their meta-analytic review, Groh and colleagues (2012) found that avoidance but neither resistance nor disorganization significantly predicted internalizing symptoms. There are likely several reasons for these differences, most notably the inclusion of additional studies and the focus on standardized observations of attachment organization in the meta-analysis (vs. the inclusion of self-report and representational measures of attachment during later childhood and adolescence in the narrative review). With regard to externalizing symptoms, Fearon et al. (2010) found a significant effect for disorganization, a small but significant effect for avoidance, and a nonsignificant effect for ambivalence. Disorganization was significantly more strongly associated with externalizing than internalizing symptoms (Groh et al., 2012). Thus, there is not yet a consensus regarding links between specific types of attachment and specific disorders.

Second, adaptations of attachment theory to explain the development of psychopathology often fail to consider the probabilistic nature of the theory's assumptions regarding attachment continuity (Roisman & Groh, 2011). Both theoretical accounts and empirical investigations need to better reflect this aspect of attachment theory by considering characteristics of children or their environments that may account not only for continuity but also for change in attachment organization across development.

Indeed, Bowlby's original conceptualization allows for the possibility that working models can be updated across development based on attachment-relevant experiences, resulting in change over time (Bowlby, 1973; Thompson, 2008). Consistent with this idea, research reveals only moderate stability in attachment organization across the life span (Fraley, 2002). Research therefore needs to consider how changes in the attachment context—either the development of new secure attachments or the loss of previous secure attachments—have the potential to trigger discontinuity between early attachment and subsequent psychopathology.

Third, theory and research need to consider more fully potential individual differences in the contribution of attachment security to psychopathology. Given that attachment theory is a theory about the normative development of, and the emergence of individual differences in, response to threat or challenge, it is logical to conclude that attachment patterns would have a particularly large impact in such contexts. Illustrating this idea, Davila and colleagues (2005) presented an overarching vulnerability-stress model of insecure attachment as a risk factor for psychopathology, suggesting that attachment insecurity can be viewed as a vulnerability or risk within this framework. Consistent with the concept of multifinality, this type of model helps to explain when or for whom attachment insecurity will confer risk for psychopathology. Conceptualized as a stressor, insecurity would trigger psychopathology in youth with predisposing vulnerabilities (e.g., genetic predisposition, temperamental vulnerability). Conceptualized as a vulnerability, insecurity would promote psychopathology in the face of adversity (e.g., normative developmental transitions, life stressors). Similarly, Cummings and Cicchetti (1990) suggest that the contribution of insecure attachment to depression is multidetermined, depending on potentiators (factors that increase the probability of insecure attachment leading to depression) and compensators (factors that decrease the probability of insecure attachment leading to depression) and on the dynamic transactions between children and their environments. Indeed, reviews of empirical support linking insecurity with psychopathology have concluded that evaluating main effects of attachment, particularly in low-risk samples, is likely a futile endeavor as this approach does not appreciate the complexity of attachment theory or its qualified assumptions regarding continuity across development (DeKlyen & Greenberg, 2008).

With regard to more general dimensions of parenting, theory and research consistently implicate a variety of forms of problematic parenting in the development of diverse problematic outcomes. A challenge for future research will be to understand the parameters that shape the contribution of specific forms of parenting to specific forms of psychopathology. Research has begun to move in this direction; for example, appropriate behavioral control primarily has been related to less externalizing behavior, whereas high levels of psychological control and low levels of warmth have been related to more internalizing problems (Gray & Steinberg, 1999). Likewise, in the McLeod et al. (2007) meta-analysis, parental autonomy granting accounted for 18% of the variance in the association between parenting and child anxiety, whereas parental warmth accounted for less than 1% of the variance. Using person-centered rather than variable-centered analyses and considering potential moderators may facilitate progress toward accomplishing this objective because such analyses would be better poised to discover if particular forms of parenting are related to specific child outcomes only in children with certain predispositions, for parents with certain characteristics, or in socioecological contexts with certain features.

Future research also will need to devote more attention to understanding dynamic reciprocal processes between family systems and children's psychopathology. With the advent of sophisticated statistical modeling procedures, research can now move beyond vague disclaimers about a lack of knowledge about the direction of effects between family risk and psychopathology to conduct theoretically guided examinations of transactional effects and pathways of influence. These analyses will capture the dynamic, interdependent processes that are central to contemporary parenting and family theories of psychopathology.

Theories Focused on the Peer Context

There is a long history of research establishing that early disturbances within the peer group forecast proximal as well as long-term risk through adolescence and adulthood (for a review, see Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006). Drawing from a developmental psychopathology perspective, several overarching models have been proposed to explain this well-established link (for a review, see Rudolph & Asher, 2000). These models alternately view peer difficulties as indicators, antecedents, or consequences of maladjustment and psychopathology.

An incidental model (Parker & Asher, 1987) frames peer disturbances as a by-product of underlying pathogenic processes arising from genetic or early environmental factors. According to this model, peer relationships serve as a detection system that indicates the presence or absence of

psychopathology, a type of litmus test for children's general well-being. Disturbances in the peer system are believed to reflect early risk and ensuing emotional and behavioral maladjustment. Within this model, the observed association between early peer difficulties and subsequent psychopathology is considered an epiphenomenon resulting from developmental continuity in adjustment. This model does not discount the importance of peer difficulties—indeed, they are viewed as key markers of risk for mental health problems—but rather assumes that peer disturbances themselves are not making an active contribution to subsequent psychopathology.

Although the peer system likely does serve as an effective detection system for underlying disturbances, contemporary causal models view early peer difficulties as active contributors to subsequent psychopathology (Choukas-Bradley & Prinstein, 2014; Parker et al., 2006). Consistent with a developmental psychopathology perspective, these models emphasize the role of peer relationships in the context of normative and atypical development. Whereas healthy peer relationships serve as positive socialization forces that enhance normative development, unhealthy peer relationships serve as negative socialization forces that foster psychopathology. Considering that youth learn critical age-appropriate competencies in the context of the peer group, those who are marginalized from such relationships or who experience relationship adversity would fail to develop the necessary resources to maintain healthy developmental trajectories and would not benefit from the health-promoting effects of positive relationships (Parker et al., 2006). Moreover, the peer group can act as a direct source of deviant influence that heightens risk for psychopathology (Prinstein & Dodge, 2008). Causal models therefore view peer group experiences as direct or indirect contributors to mental health.

Over the past two decades, theories of peer-psychopathology linkages have become increasingly sophisticated. Recent models consider how youth and their peer environments jointly contribute to psychopathology by incorporating ideas about interactive processes (e.g., peer disturbances predict the most severe psychopathology in youth with preexisting vulnerabilities; Rudolph, 2009) as well as transactional processes (e.g., early behavioral disturbances set in motion adverse peer processes, which then perpetuate and exacerbate risk; Dishion, 2014). According to these models, disruption within each risk domain (interpersonal and intrapersonal) and interactions among domains gain momentum over time, setting youth upon a developmental trajectory to disorder. Causal models, in sum, approach peer group experiences as making direct or indirect contributions to mental health. In the ensuing discussion of peer-oriented theories, we first consider the interpersonal nature of peer social ecologies (close bonds, broader social networks, and status in the peer group) and then move on to the intrapersonal motivations that drive these social relationships.

Theories of the Peer Ecology

Theoretical Underpinnings. As within families, peer ecologies operate at multiple levels and exert both direct and indirect socialization influences on the development of psychopathology. Without a natural attachment figure, peer social ecologies do not come pre-established with a secure base. Nonetheless, such bases for safety and support can be found among peers in the form of friendships. Friendship is the foundational interpersonal tie within the peer group. High quality dyadic friendships are of great comfort and significance (Bukowski, Motzoi, & Meyer, 2009; Hartup & Stevens, 1997; Ladd, 2005). However, peer relations can vary in the type of interpersonal tie they concern—friendships, affiliations, liking, even antipathy—and in the number of individuals involved. Influence flows through these multidimensional social networks of interpersonal affiliations.

A defining characteristic of peer relations is that of equality (Bukowski, 2011; Hartup, 1983; Sullivan, 1948/1953), but such is the nature of society that status is rarely equally distributed among all (Moreno, 1932). Children come to recognize the importance of social status, to more or less prioritize its attainment in their lives (LaFontana & Cillessen, 2011; Rodkin, Ryan, Jamison, & Wilson, 2012), and to both adapt and attempt to increase their place in the social order. Status differentials are another basic channel through which influence flows (Brechwald & Prinstein, 2011).

We elaborate on these two interrelated axes of peer social ecologies (Rodkin, 2004; Rodkin & Gest, 2011)—*social networks* and *social status*—with an eye toward understanding their contribution to the development of psychopathology. Exploration of these ideas reveals the multifaceted and often paradoxical effects of peer relationships on mental health. Phenomena of social networks and social status surround children whether they move toward, against, or away from the world (Caspi, Elder, & Bem, 1987). Even children who feel negatively toward society or toward their peer cohort can find and construct niches of interpersonal support. From the standpoint of the child coping with the stressors of living, a welcoming social network may be an unmitigated resource. From

the standpoint of the developmental psychopathologist, concerned with long-term trajectories of youth, network influences can vary dramatically, attenuating or exacerbating adjustment problems. The type of friendships and networks in which youth participate can determine their salutory versus toxic effects; youths' position within their peer groups can determine their access to resources, which can serve as either risk or protective factors. Even youth with high social status may be susceptible to adverse influence, engaging in risky activities, and the temptation to abuse their status by harassing others.

Social Networks The dyadic friendship is the starting point of any discussion of peer social networks. Many have written on the features of friendships (Bukowski et al., 2009; Hartup & Stevens, 1997; Ladd, 2005; Parker et al., 2006; Rubin et al., 2006), which include reciprocated liking, an egalitarian relationship characterized by cooperation, and similarity in at least some aspects of affect and behavior. Friends provide each other with emotional support, validation, tangible assistance, and enjoyment. Within-species friendships may have an evolutionary function and significance just as has been posited in classical attachment theory (Seyfarth & Cheney, 2011).

Many have theorized that simply having a reciprocal or close friend can protect against the hazards of everyday life, thereby reducing risk for psychopathology (Ladd, 2005). Indeed, having a best friend present during a negative experience can dampen the deleterious effects of that experience on self-worth and HPA activity (Adams, Santo, & Bukowski, 2011) and protect against dysregulated cortisol patterns in youth who face exclusion by peers (Peters, Riksen-Walraven, Cillessen, & de Weerth, 2011). Yet Hartup and Stephens (1997) noted that it is informative to know not simply whether a child has a friend but also the identity and behavioral characteristics of these friends and the quality of the friendship. We return to these topics when considering the role of social networks in specific forms of psychopathology.

Antipathy, or relationships of mutual dislike, can be seen as akin to the opposite of friendship. Antipathy is a natural human feeling, surely not to be celebrated, but not to be pathologized either. At the same time, it is obvious that strong currents of dislike running through peer social networks is trouble waiting to happen. Although controversial, asking children whom they like least reveals information that the absence of liked most nominations simply cannot. The liked least question was critical to the sociometric status categories of Coie, Dodge, and Coppotelli (1982) and is central to a literature on children's antipathies, or mutual nominations of dislike (Hodges & Card, 2003). Card's (2010) meta-analysis of studies of children's antipathies revealed three findings: (1) approximately 35% of children and adolescents have an antipathetic relationship; (2) antipathies are associated with externalizing and internalizing problems; and (3) almost half of children's mutual antipathies are mixed-gender, between a boy and a girl (see also Rodkin, Pearl, Farmer, & Van Acker, 2003). An antipathetic relationship between two children can lead to negative thoughts about the other, such as hostile attributional biases, as well as to negative behaviors, such as aggression (Peets, Hodges, & Salmivalli, 2008), possibly laying the groundwork for emerging psychopathology in both members of an antipathetic dyad.

Social ties involving more than two individuals can be conceptualized as a more complex social network. The most common type of network studied involves friendships, but networks can be organized around a variety of social ties beyond friendships, such as whom children hang around (Rodkin & Ahn, 2009), want to be like, or even do not like (Berger & Dijkstra, 2013). In a broad review of social dynamics within networks, Rivera, Soderstrom, and Uzzi (2010) make a distinction between three types of mechanisms that unite individuals into groups: (1) assortative, centered on the importance of individuals' attributes (e.g., social behavior, personality, ethnicity, gender); (2) relational, emphasizing the importance of existing relationships in the network—some ties in a social network come to exist because of social ties that already exist; and (3) proximity, focused on aspects of physical organization, such as propinquity (e.g., being neighbors).

Theories concerning youth social networks can be considered analogous to a quantitative mapping of microsystemic processes. Building on early studies of sociometry, which quantified properties of peer social ecologies in relation to success and failure, developmental scientists have long been interested in understanding how youth sort into social networks as well as how these networks influence development, including risk for psychopathology (for reviews, see Prinstein & Dodge, 2008; Veenstra & Steglich, 2013). A well-documented phenomenon in social networks is *homophily*, or the tendency for youth to affiliate with similar peers (McPherson, Smith-Lovin, & Cook, 2001).

Theorists also emphasize the concept of complementarity or an opposing tendency to have differentiation in group skills or roles (Farmer et al., 2002). It makes sense that in well-functioning groups individuals will share some characteristics and attitudes while having unique skills. Homophilic processes may differ for particular types of ties (e.g., friendships, affiliations) and behavioral types

(e.g., aggression, substance use, depression; Brechwald & Prinstein, 2011). Social network theory proposes several processes through which similarity might emerge: (1) active selection processes (e.g., an active or affirmative preference or birds of a feather flock together effect—the tendency for individuals to select like-minded friends); (2) passive or default selection processes (e.g., a marginalization effect—marginalization from a mainstream network and losing positive ties with normative others leaves only social isolation or affiliation with other marginalized peers; Choukas-Bradley & Prinstein, 2014; Van Zalk, Kerr, Branje, Stattin, & Meeus, 2010a); and (3) peer influence processes—peers socialize network members to adopt similar beliefs and behaviors through reinforcement, modeling, internalization, and group identification, such that network members become more similar over time (Prinstein & Dodge, 2008). Socialization mechanisms could vary according to the extent of group identification, which promotes internalization of, and not just compliance with, group norms.

The selection vs. socialization antithesis resembles the incidental vs. causal models of peer influence outlined at the opening of this section: Is homophily due to interpersonal influence, or were youth already similar before they started getting to know one another? Disentangling selection from socialization is a longstanding pursuit with respect to peer influences on risk-related behavior and is filled with methodological complications. Moreover, when friendship ties are embedded, as they most often are, in a larger social network, then endogenous network processes are potential confounds. That is, social networks entail structural characteristics and mechanisms that are inherent to any social system, including network closure, the well-known phenomenon that friends of friends are likely to become friends in the future; reciprocity, the tendency for unilateral perceptions, such as of friendship, affiliation, or enmity, to eventually be returned; density, the proportion of interconnected ties within a social network; and hierarchy or centralization, the degree to which social capital (e.g., friendship nominations) is centered upon a small, favored few or distributed in a more broad and egalitarian manner throughout the network. Contemporary longitudinal social network modeling techniques allow selection and socialization processes to be assessed net of these endogenous phenomena (Veenstra & Steglich, 2013).

Social Status Despite the egalitarian connotations of the word *peer*, not all social niches are created equal. Just as there can be a large variety of ties that connect youth into social networks, status can be considered along a number of dimensions. Children and youth differ in their material resources, physical attractiveness, physical size and strength, athleticism, and other peer-valued characteristics that may have different levels of importance in male and female peer cultures (Adler & Adler, 1998; Maccoby, 1998). The classic measures of social status have been the number of children's friendships (e.g., Sherif, 1956) or the number (or proportion) of peers nominating or rating a child as someone whom they like the most (Moreno, 1934).

Coie et al. (1982) proposed an influential framework where the difference between acceptance and rejection (i.e., liked least nominations) formed a measure of social preference, which in turn was considered with the sum of acceptance and rejection (termed *social impact*) to yield various sociometric categories: popular, controversial, rejected, neglected, average (and unclassifiable). This taxonomic system focused only on positive and negative nominations, disregarding social network ties between peers (Cairns, Leung, & Xie, 1998). Of the five sociometric categories, the rejected grouping received by far the most attention from a developmental psychopathology perspective. Indeed it is safe to say that the research attention focused on the peer-rejected child represented the effective entrée of peer relations research to the modern discipline of developmental psychopathology (e.g., Coie et al., 1992). Who are peer-rejected children? Rejected children, those who are widely disliked and hardly liked, have varied behavioral profiles—many are aggressive, more still are anxious and withdrawn (French, 1988, 1990)—but they clearly are at risk for concurrent and future adjustment problems. Sometimes, though not a traditional concern of developmental psychopathology, children are excluded because of the group to which they belong, be it a gender or racial group (Killen, Mulvey, & Hitto, 2012). Peer rejection is the construct around which incidental versus causal models of peer relations for later maladjustment were constructed by Parker and Asher (1987). The 1990 edited volume, *Peer Rejection in Childhood* (Asher & Coie, 1990), delineated many of the challenges that rejected children face, and set in motion a focus on prevention that continues to form a critical corpus in peer relations research (Bierman, 2005; Prinstein & Dodge, 2008).

It seems sensible enough to equate dislike with peer rejection, but problems become evident when popular children are defined as the most liked and least disliked, as they were in the Coie et al. (1982) system. As described in our developmental significance section, at some point, be it middle childhood or early adolescence (Rodkin et al., 2012), children come to differentiate being likeable (or preferred) from being popular. Preference expresses a personal sentiment (i.e., who do *you* like?),

but popularity represents a judgment about what others value and the consensual norms of the peer ecology. Children high in preference have an untroubled set of behavioral characteristics—cooperative, friendly, prosocial, nonaggressive, and sociable (Rubin et al., 2006)—and so they were never much focused on in developmental psychopathology research of the 1980s and 90s. In contrast, popularity has only modest (in some cases positive, in other cases negative) correlations with aggression (Rodkin & Wilson, 2007; Rodkin et al., 2000). Neal (2010) suggested that distinctions between preference and popularity are especially important for socially aggressive behaviors such as relational aggression (Crick et al., 1999).

Some popular youth, or youth hoping to be popular, want to publically demonstrate their social prowess and avoid the pitfalls of social vulnerability, even if this means resorting to aggressive and antisocial behavior. Popular children, because of their heavy engagement in social networks, might be highly susceptible to social influence from peers (Haynie, 2001). They may be tempted to abuse their high social position by bullying peers, demonstrating their dominance through harassment and humiliation. They may devalue academic efforts, as budding scholars, nerds, and straight A students rarely have high social status unless they are also attractive and athletic (Coleman, 1961). In sum, although low social status is well-known as a potential marker of poor adjustment, youth with high social status are not invariably well adjusted.

Developmental Significance and Change. Peer social ecologies begin small but get larger and more differentiated with time, and are shaped by institutional structures, such as daycares and schools. The importance of social networks can be seen even at the earliest ages of nursery school (e.g., Merei, 1949). Schaefer et al. (2010) considered fundamental properties of social network formation over a school year and found evidence for a cascading mechanism in which a simpler network process, such as reciprocity, emerged before the establishment of a more complex network process, namely status hierarchies, which in turn emerged before still more complicated network processes such as triadic closure. Thus, Schaefer et al. (2010) provide support for the proposition that popularity becomes increasingly important for the structure of preschoolers' interactions throughout the school year. By the ages of four and five, children are highly susceptible to peer influence (Haun & Tomasello, 2011).

Some of the most innovative work on social status and its behavioral correlates has occurred with preschool children. Roseth, Pellegrini, Bohn, Van Ryzin, and Vance (2007) reported that some preschool children use aggression effectively to establish social dominance, and that once a social order is established, overt aggression tends to decrease. Some high status preschoolers and adolescents, termed *bistrategic controllers*, can flexibly employ aggressive and prosocial strategies to achieve instrumental aims (Hawley, Little, & Card, 2007).

White (1996) called the biological, psychological, and social transition between the ages of 5 and 7 an entry into an age of reason, when children become especially open to assimilating the traditions and demands of society. It is during this age when formal schooling begins and theory of mind comes into play. White (1996) saw the 5-to-7 shift as intrinsically neurobiological, including the completion of myelinization across major circuits in the body, cortical energy consumption peaks, stabilization of electroencephalographic rhythms into an adult pattern, and more. Konner (2010) notes the evolutionary relevance of middle childhood, a period of life unique to our species, to the development of the human capacity for social relations and cognitive growth. Indeed, Piaget (1932) saw this time as the beginning of heteronomous morality (i.e., moral judgments based more on inferences of intent than the severity of outcomes) and the beginning of cooperative, collaborative social relations. Maccoby (1998) noted that by 7 years of age the two cultures of male and female peer groups are firmly in place, when children are ready to learn society's rules about gender roles and social status more broadly.

Middle childhood peer social ecologies are highly developed, and preadolescents engage in a gamut of relational ties. It is during middle childhood that Sullivan (1948/1953) wrote of the great, protective powers of a chum. Children form antipathies (Card, 2010), affiliative social networks (Cairns & Cairns, 1994), and groups with a strong sense of identity that can influence behavior and moral judgment (Killen & Rutland, 2011). Social status continues to be an axis of the peer social ecology during middle childhood. By fifth grade, popularity is a prime organizing force of children's social networks, perhaps more influential in determining affiliative homophily than aggressive or prosocial behavior (Dijkstra, Berger, & Lindenberg, 2011; Logis, Rodkin, Gest, & Ahn, 2013). Pre- and early adolescent children describe popular boys as cool, athletic, funny, and defiant, and popular girls as attractive, sociable, snobby, mean, and rude. Not surprisingly, unpopular children have particularly negative attitudes toward their popular peers (Adler & Adler, 1998). Although boys and girls may express negativity in different ways, dominance-related beliefs and behaviors are related to positive peer regard for both girls and boys (Hawley, Little, & Card, 2008).

Hawley et al.'s (2008) myth of the alpha male is that girls too can strive for a balance between prosocial and coercive interpersonal strategies in search of a dominant position in the peer group (see also Crick et al., 1999). By the late elementary school years, the differences described earlier between preference and popularity become more easily distinguishable (Rodkin et al., 2012). The behavioral correlates of popularity change from being relatively more prosocial early in development to relatively more aggressive as youth reach adolescence (Cillessen & Mayeux, 2004).

Peer social influence is often thought to be at its apex during adolescence, when youth crave attention and status (LaFontana & Cillessen, 2010), are easily swayed into deviant peer groups, and form an adolescent culture (Mintz, 2004). Indeed, during adolescence, peer relationships become a highly salient source of socialization and self-evaluation (Choukas-Bradley & Prinstein, 2014). By adolescence, status differences appear to be quite consequential. *Crowds*, which may be a type of social relationship particular to adolescence in the modern high school, are groups that are based on reputation, not necessarily affiliation or friendship (Brown & Dietz, 2009). Youth who are identified by their peers or themselves as belonging to a particular crowd appear to be of the same type. Placement in a crowd identifies youth as engaging in certain behaviors but also can denote ethnicity, class, and social status. As with peer groups and friendships, however, effects of crowd membership on adjustment will vary depending on the kind of crowd it is, and possibly how crowd membership overlaps with friendship and other social networks.

In recent years, developmental scientists have increasingly considered how brain reorganization during adolescence may guide further changes in peer relationships (Murray-Close, 2012). Puberty is marked by alterations in physiological systems guiding self-regulation, motivation, and emotion, with accompanying implications for youths' social orientation. For example, Steinberg (2008) proposed that puberty-related changes in the brain's incentive-processing system, driven by alterations in the dopaminergic system, trigger more reward-seeking in the presence of peers and consequent increases in risky behavior. Susceptibility to peer influence and ensuing risky behavior declines between adolescence and adulthood because of maturation in the brain's cognitive control system, which results from structural changes in the prefrontal cortex and its connectivity to other brain regions, along with a decline in reward seeking. Increases in testosterone during puberty also may heighten dominance-related behaviors linked to peer aggression. Furthermore, linkages between sex-linked hormone systems that develop across puberty (e.g., estrogen, androgens) and the HPA axis may trigger developmental changes in peer relations, such as heightened reactivity to peer stressors.

Biologically driven changes may intersect with psychosocial influences across puberty to alter the peer system in ways that influence risk for psychopathology (for a review, see Rudolph, 2014). Somatic changes signal approaching maturity with implications for peer status and selection into particular social networks and crowds. According to the peer socialization hypothesis (Stattin, Kerr, & Skoog, 2011), these effects may be especially salient for youth who mature off-time, particularly early, relative to their peers. Reflecting selection effects, early-maturing youth may seek out friendships and romantic relationships with similarly mature peers, who will be other early-maturing and older youth. Because these youth on average engage in more norm-breaking behavior, early-maturing youth are more susceptible to early risk for antisocial behavior. Thus, biological, psychological, and social aspects of puberty influence and interact with peer selection and socialization processes in ways that can shape trajectories of psychopathology.

During the pubertal transition, sex-typed peer relationship processes also may intensify as a result of differential socialization elicited by signs of physical maturation. For example, Rose and Rudolph (2006) proposed a model wherein immersion in same-sex peer groups early in development contributes to sex-linked behavioral and social-cognitive styles, which interact and transact with sex-linked stress and coping processes within peer relationships to contribute to heightened risk for internalizing psychopathology in girls and externalizing psychopathology in boys. The adolescent transition is presumed to amplify these sex-linked processes, leading to increasing divergence between female and male peer groups. Developmental changes in relationships may be a particular burden for adolescent girls. Although distinctive attributes of adolescent female relationships (e.g., heightened intimacy and disclosure) provide a strong sense of social connectedness and belonging, they also come with some costs. Specifically, girls' focus on connection-oriented goals (e.g., intimacy, nurturance) may be accompanied by heightened vulnerability and strife, especially during adolescence when interpersonal roles and expectations undergo significant redefinition and disruption. Adolescent girls also report higher levels of interpersonal sensitivity, reflected in both concerns about approval, evaluation, and abandonment as well as empathy for others. This stronger interpersonal engagement may heighten the salience and adverse impact of disruption in the peer groups of adolescent girls

compared to boys (Crick & Zahn-Waxler, 2003; Rose & Rudolph, 2006).

Application to Psychopathology. In classical ecological theory, there can be a dystopia and social chaos around the idea of youth forming their own peer social ecologies that are poorly regulated or not regulated by adults. Bronfenbrenner (1979) was clear that peer microsystems were prone to problem behavior, and suggested that the developmental sequelae of accumulated peer group processes, particularly within educational settings, can narrow future life opportunities. It is the recognition that peer ecologies can have a negative influence on children that promotes prevention-oriented research on how to consider ecologies as a malleable factor, and interpersonal relationships such as friendship as a protective factor and source of social capital. Building on this historical perspective concerning the potential adverse influence of the peer group, well-articulated theories have emerged concerning the contribution of peer relations to multiple forms of psychopathology.

Externalizing Psychopathology As Cairns and Cairns (2001, p. 32) stated: "The development of aggressive strategies grows out of close affiliations and relationships, not because of their absence." The risky nature of interpersonal influence among aggressive and antisocial peers is captured in the theory of deviancy training (Dishion, Spracklen, & Patterson, 1996), which explicates the coercive processes that emerge when aggressive children congregate together, contributing to the development of antisocial behavior. Deviancy training occurs when a youth engages in or discusses antisocial behavior and peers reinforce that behavior by granting approval or high status. Other peers are then likely to reciprocate by engaging in antisocial behavior as well. In addition to verbal and nonverbal reinforcement through deviancy training, associating with deviant peers can increase adolescents' own antisocial behavior in very tangible ways by providing opportunities for antisocial behavior. Affiliating with deviant peers also may foster the perception that antisocial behavior is the norm, thereby reinforcing such behavior. Adolescents who associate with deviant peers by the age of 13 are more likely to behave in antisocial ways and use drugs during young adulthood (Dishion & Tipsord, 2011).

Deviancy training may play a particularly important role in the development of antisocial behavior because a group of peers acting jointly is much more likely to engage in antisocial behavior than is a single individual acting alone. The strongest correlate of adolescents' delinquency is the delinquency of their peers (Warr, 1993). Consistent with active selection processes, adolescents who engage in antisocial behaviors select friends who engage in similar behaviors (e.g., McPherson et al., 2001). However, studies that statistically control for the effects of peer selection demonstrate that once antisocial peers are in a group together, they incrementally increase one another's engagement in a wide range of antisocial behaviors including early and high-risk sexual behavior, violent offenses, and substance use (Dishion, 2000). Along these lines, Schulenberg, Patrick, Maslowsky, and Maggs (2014) describe a process of progressive accommodation, wherein adolescents select like-minded friends who engage in alcohol use, who in turn provide strong socialization influences. These negative outcomes even extend to potentially adverse effects of intervention programs that group together antisocial youth (Dishion et al., 1999). Peer network effects can vary by the type of interpersonal tie studied (e.g., peer groups vs. best friendships; Cruz, Emery, & Turkheimer, 2012), gender (Fujimoto, Unger, & Valente, 2012), and the phenomenon under investigation (Brechwald & Prinstein, 2011).

Theories of the deviant peer group were originally quite constrained to deal with adolescents. In early classic conceptualizations, children who engage in coercive cycles of violence with their caregivers during early childhood and who then generalize these dysfunctional interactional patterns upon entering school become rejected and set up for academic failure, falling through the cracks until forming groups, presumably through passive selection or deselection processes, with similarly marginalized (or deviant) youth in adolescence. However, peer deviancy processes have been shown in children as young as first grade, with unique relations to aggressive behavior patterns in fourth grade (Snyder, Schrepferman, Bullard, McEachern, & Patterson, 2012). Even in early childhood, social networks are multidimensional, and so it is possible for children to be widely rejected but to have a friend, or to lack a reciprocated friend but be part of an affiliative peer group (e.g., Kinderman, 2007). Social network effects stemming from the absence of peer support (i.e., peer rejection) and the presence of peer support (i.e., affiliative peer groups) can operate concurrently and have cascading effects over time.

There also is some question as to whether the kinds of processes specified to operate among deviant peers are limited to cases of deviance. Dysfunctional deviant peer group processes have in fact some functionality. Dishion (2014, p. 458) argued that deviant peer clustering can be viewed as "an evolutionary-based adaptation to marginalization and stress in families and the school environment" that emerges in part from "the biologically driven survival

function of procreation and group affiliation." The mechanisms involved in deviancy training—laughing, smiling, reinforcing, or granting high status to the peer who engages in antisocial behavior—are by no means restricted to a small subgroup of already at-risk children. These same processes are implicated in discussions of why youth bully. As Olweus (1979) noted, some bullies are socially integrated and networked (see also Rodkin, 2011). These youth affiliate with a wide variety of peers, in which case there is an unhealthy potential for widespread acceptance of bullying in some classrooms and schools. This is what Pepler and colleagues call the theater of bullying (Pepler, Craig, & O'Connell, 2010), encompassing not only the bully–victim dyad but also children who encourage and reinforce bullies (or become bullies themselves), others who silently witness harassment and abuse, and hopefully still others who intervene to support children being harassed (see also Salmivalli et al., 2010). As Pepler and colleagues (2010, p. 470) wrote, "Bullying is a social event" with an audience of peers in almost 90% of observed cases. This silent, mocking audience grows exponentially, in frightening anonymity, with cyberbullying (Rodkin & Fischer, 2013). Epitomizing the developmental psychopathology principle of intersections between normal and atypical development, therefore, the mechanisms driving the acceptance of aggression in deviant peer groups may in fact be deeply rooted and broadly based.

Indeed, there is still some question as to whether bullying is a form of psychopathology rather than an instance of normative development (Dodge & Albert, 2012), but there is a more widespread consensus that high social status, and not just low social status, is a relevant construct to the developmental psychopathologist (Dodge & Albert, 2012; Ellis et al., 2012). It is still relatively new to consider high social status as an attribute that could contribute to any form of psychopathology, including externalizing problems. However, evidence is accumulating that popularity, like unpopularity, can be a risk factor associated with drinking (Crosnoe, 2006), smoking (Mayeux, Sandstrom, & Cillessen, 2008), and disruptive and aggressive behavior (Lansford et al., 2009). Linkages between popular-aggressive youth and Moffit's (1993) adolescence-limited trajectory seem clear, but there has been no formal comparison in the literature and empirical linkages between social status and aggression have often been reported in the pre-adolescent years (Rodkin et al., 2000). Causal linkages between low social status—peer rejection or isolation—and aggressive behavior, one of the most studied topics of peer relations scholarship, play a central role in the most influential frameworks for understanding childhood aggression, such as dynamic cascade models (e.g., Bierman, 2005; Dodge, Greenberg, Malone, & the CPPRG, 2008; Dishion & Tipsord, 2011; Lansford, Malone, Dodge, Pettit, & Bates, 2010).

Depression and Anxiety Developmental scientists are becoming increasingly interested in characterizing the peer worlds of youth with internalizing symptoms in an effort to understand how adverse conditions contribute to risk as well as how symptoms interfere with the maturation of normative peer relationships. Although it has long been argued that healthy peer relationships can serve as protective forces in development—buffering youth with risks due to genetic liability, tumultuous family circumstances, and the like—contemporary theoretical perspectives have turned to mapping out the possible dark side of peer relationships for youths' emotional health (Choukas-Bradley & Prinstein, 2014; Rose & Rudolph, 2006). Later, we describe the adverse effects of specific stressors within peer relationships (rejection, victimization, exclusion). In this section we discuss other aspects of youths' peer ecologies that may contribute to risk for internalizing symptoms.

At a dyadic level, failure to develop intimate friendships can cost youth the rewarding provisions of enjoyment, support, and trust that protect against emotional distress. It is not surprising that anxious and depressed youth have poorer quality friendships and are members of smaller social networks, thereby undermining their access to such resources (for reviews, see Choukas-Bradley & Prinstein, 2014; La Greca, Davila, Landoll, & Siegel, 2011). Exposure to friendship conflict and dissolution or friendlessness can contribute to internalizing symptoms (Davila et al., 2010; La Greca et al., 2011; Rudolph, 2002) and, in turn, symptoms can further interfere with the establishment of close and supportive friendships (Davila et al., 2010; La Greca et al., 2011).

Beyond poor access to resources or the pathogenic effects of conflictual relationships, however, unhealthy processes may emerge even within the context of relatively healthy or close friendships. Rose (2002) proposed that corumination, a process wherein friends frequently and extensively discuss their problems, may heighten closeness but also contribute to anxiety and depression by focusing attention on negative affect and stress. Moreover, corumination occurs more often in adolescent female than male friendships and predicts anxiety and depressive symptoms in girls but not boys, perhaps helping to account for girls' higher levels of internalizing symptoms (Rose, 2002). Giletta and colleagues (2012) distinguished best friendships and friendship networks in a study of peer socialization of alcohol use and depressive behaviors in

ninth through eleventh grades. They found that network effects were stronger for the socialization of alcohol use, but for girls there was additional socialization of depressive behaviors within best friendship dyads.

The growth of sophisticated approaches to social network analysis also has spurred an interest in deconstructing the phenomenon of homophily for social network members sharing similar levels of symptoms (Prinstein, 2007). This work aims to determine whether homophily arises through peer selection or influence as well as to identify underlying processes. Several mechanisms may drive selection effects in the networks of depressed youth (for a review, see Schaefer, Kornienko, & Fox, 2011). Consistent with a misery loves company scenario, homophily may arise through active selection into friendships or peer groups with other depressed youth, perhaps due to preference for similar others or negative feedback seeking. Homophily also may result in dissolution of relationships with dissimilar friends (Kiuru, Burk, Laursen, Nurmi, & Salmela-Aro, 2012). Alternatively, depressed youth may sort into groups through default selection when other friendship options are constrained. Depressed youth show many unappealing characteristics as interaction partners and friends (e.g., excessive reassurance seeking, hostility, poor conflict resolution); being friends with depressed youth may therefore be unpleasant and stigmatized. Indeed, depressed youth elicit negative reactions from peers (for a review, see Rudolph, Flynn, & Abaied, 2008) and are less likely to be selected, and more likely to be deselected, as friends over time (Van Zalk et al., 2010a). Conflict with friends and exclusion by the mainstream peer group may lead them to seek out other depressed youth. Beyond this active peer exclusion, social withdrawal may cause depressed youth to detach from peers, marginalizing themselves in the social system and thereby leaving only an impoverished pool of other depressed youth as viable interactional partners (Schaefer et al., 2011). Consistent with this idea, youth with depressive symptoms are more likely to deselect friends over time (Van Zalk et al., 2010a), thereby leading to social isolation.

Homophily in internalizing symptoms also may stem from peer influence processes, wherein youth become more similar to their network members over time. The dynamics of peer influence may differ depending on the underlying processes. Direct contagion could occur if friends overtly encourage or adopt one another's depressive affect and behavior (Coyne, 1976; Kiuru et al., 2012). One might imagine a similar process occurring in the networks of anxious youth, as heightened worry and arousal spread among friends. Indirect contagion could operate in a more subtle way through adoption of group norms to obtain acceptance or status (Kiuru et al., 2012), negative affect induced by excessive reassurance seeking (Joiner & Timmons, 2009), absence of enjoyable social interactions between friends, or shared exposure to depressed friends' problems. Peer selection and influence processes are embedded within a broader set of dynamics driving the coevolution of social networks and depressive symptoms composed of individual level effects (personal risk factors), depression feedback (the self-perpetuating nature of symptoms), and endogenous network processes (Schaefer et al., 2011).

Research confirms that peer selection, deselection, and influence all contribute to depression homophily within friendship networks (Kiuru et al., 2012; Schaefer et al., 2011; Van Zalk et al., 2010a), with particularly strong effects for girls (Van Zalk, Kerr, Branje, Stattin, & Meeus, 2010b); social network effects also emerge for related internalizing psychopathology such as anxiety (Mercer & DeRosier, 2010) and self-injury (Prinstein et al., 2010). There is some indication that peer selection occurs through a process wherein depressed youth withdraw from peer relationships, resulting in affiliation with other marginalized youth; thus, depression homophily may occur as an endogenous product of other network forces rather than through a preference effect (Schaefer et al., 2011). With regard to peer influence, there is evidence for a convergence effect in which youth develop depressive symptoms at levels comparable to those in their networks (i.e., youth become either more or less depressed over time to resemble the average symptom level of their peers), leading to increasing similarity within networks (Kiuru et al., 2012). Peer influence effects may be due in part to co-rumination (Schwartz-Mette & Rose, 2012) and transmission of negative cognitions (Stevens & Prinstein, 2005; Van Zalk et al., 2010b) among friends. Such findings highlight the importance of distinguishing peer selection and influence mechanisms driving the structure and evolution of social networks. Moreover, youth may be differentially sensitive to depression contagion effects (Prinstein, 2007), suggesting the need to consider individual differences in these processes.

At the level of the broader peer group, it is intuitive that high social status should serve a protective function against internalizing symptoms. However, a more nuanced perspective on risk has emerged as contemporary theories have distinguished likeability or peer preference from popularity (Sandstrom & Cillessen, 2006), as discussed earlier. Low peer preference is associated with more depressive symptoms (Zimmer-Gembeck, Waters, & Kindermann, 2010), especially in girls (Oldehinkel, Rosmalen, Veenstra, Dijkstra, & Ormel, 2007), perhaps because of the psychological implications (e.g., loneliness,

low self-esteem) of being isolated from the social group (Oldehinkel et al., 2007) along with the distinct affiliative needs of girls (Rose & Rudolph, 2006). However, popularity may harbor its own emotional costs, particularly for popular girls who are viewed in more negative ways by peers than popular boys (Rose, Glick, & Smith, 2011).

Eating Pathology Risk-related changes in body image and eating behavior often emerge in the context of the pubertal transition, a stage during which peer influence becomes pronounced as adolescents increasingly rely on the judgments of peers. Puberty brings about physical changes that are open to scrutiny by peers and are often subject to commentary and harassment (Rudolph, 2014). Adolescents who fail to meet the ideal norms for their gender (thinness for females; lean muscularity for males) may be especially sensitive to social conformity pressures, aiming to meet explicit or implicit social norms and to reduce discrepancies between themselves and their peers (Rancourt, Conway, Burk, & Prinstein, 2012). In this way, peers can serve as active agents in the socialization of eating pathology by modeling and reinforcing group-endorsed attitudes (e.g., body image concerns) and behaviors (e.g., dieting, excessive exercise, muscle gaining). Of note, the gender composition of peer groups may moderate these peer influence processes, such that belonging to a same-gender peer group enhances socialization effects (Rancourt et al., 2012). Of course, youth also may show a preference for befriending peers of a similar weight; in particular, overweight youth may be stigmatized and marginalized by peers thereby creating strong selection (or de-selection) effects (de la Haye, Robins, Mohr, & Wilson, 2011).

Socialization also may occur within the context of specific adolescent crowd affiliations. For example, affiliating with Brains is associated with more healthful eating and dieting, whereas affiliating with Popular and Burnout crowds is associated with more unhealthful eating and, for the latter, food preoccupation/bulimic behaviors (Mackey & La Greca, 2007). However, processes of peer selection versus influence within these crowds have not yet been disentangled through longitudinal analysis, making it difficult to determine whether affiliating with certain crowds promotes change in eating attitudes and behaviors or whether youth gravitate toward crowds with similar norms in this domain.

Social Motivation Theories

Theoretical Underpinnings. The human needs of belonging, acceptance, affiliation, and influence are basic motivational strivings (McClelland et al., 1953). All involve interpersonal relationships—we wish to be accepted by others, to affiliate with others, to influence others. To fulfill these needs, children develop specific goals for social interaction (e.g., nurturance, intimacy, companionship, domination; Rodkin & Ryan, 2012), cognitive representations of what they want to accomplish, which provide direction and energy for behavior.

Both classic (McClelland et al., 1953) and contemporary (Dweck & Leggett, 1988; Gray, 1994) theories of motivation suggest that individual differences in behavior are regulated by two systems: an approach (appetitive) system, sensitive to reward or success, and an avoidance (defensive) system, sensitive to punishment or failure. Approach-avoidance dispositions are manifested across many domains, including temperament, personality, affect, and coping (Gable, Reis, & Elliot, 2003). As such, approach and avoidance motivation are embodied in terms of general needs or strivings as well as more specific goal orientations that underlie and shape behavior. Within the interpersonal sphere, social approach motivation involves sensitivity to social rewards (e.g., obtaining social approval, positive judgments, acceptance, status, intimacy) whereas social avoidance motivation involves sensitivity to social punishments (e.g., avoiding social disapproval, negative judgments, rejection, loss of status, alienation) (Rodkin et al., 2012; Rudolph, Abaied, Flynn, Sugimura, & Agoston, 2011; Rudolph & Bohn, 2014; Rudolph et al., 2005; Rudolph, Troop-Gordon, & Llewellyn, 2013; Ryan & Shim, 2008).

At a dispositional level, children may be motivated by general strivings toward achieving social success or avoiding social failure. As one example, need for approval has been conceptualized as a motivational striving through which children are driven by a desire to obtain positive judgments by peers that enhance their self-worth (approach oriented; e.g., feeling proud of oneself in the face of approval) or to avoid negative judgments by peers that deplete their self-worth (avoidance oriented; e.g., feeling ashamed of oneself in the face of disapproval) (Rudolph & Bohn, 2014; Rudolph et al., 2005). Approach-oriented need for approval is viewed as driving an adaptive orientation toward the world that promotes positive engagement (prosocial behavior, peer acceptance) and suppresses conflictual engagement (aggression, victimization) and disengagement (withdrawal, exclusion). Avoidance-oriented need for approval is viewed as driving a maladaptive orientation toward the world that suppresses positive engagement, promotes disengagement, and may

promote some forms of conflictual engagement such as relational aggression (Rudolph & Bohn, 2014).

General social motives or strivings may, in turn, be translated into specific goal orientations. Youth with a strong approach-oriented need for approval may endorse goals that focus on eliciting signs of approval from peers (i.e., approach goals) whereas youth with a strong avoidance-oriented need for approval may endorse goals that focus on avoiding signs of disapproval from peers (i.e., avoidance goals) (Rudolph & Bohn, 2014). Drawing from achievement goal theory (Dweck & Leggett, 1988), researchers (Elliot, Gable, & Mapes, 2006) have conceptualized social goals within a similar framework that distinguishes developing competence (i.e., mastery goals) versus demonstrating competence (i.e. performance goals).

Reflecting one type of approach motivation, *social mastery (development)* goals involve improving relationships and social skills (e.g., gaining insights into friendships or learning how to get along with others). With social mastery goals, intrapersonal standards are used for evaluating one's competence and judging whether involvement in a relationship is valuable. The motivation for building relationships and forging connections with others is distinct from any specific reward such as status. Success is judged by whether one is improving social skills, deepening the quality of one's relationships, or developing one's social life in general (Rodkin et al., 2012; Rudolph, Abaied et al., 2011; Ryan & Shim, 2008). This goal is similar to what Ojanen, Grönroos, and Salmivalli (2005) term a *communal* goal orientation. Social goals that pertain to developing relationships tend to be associated with prosocial behavior (Rodkin et al., 2012; Rudolph, Abaied et al., 2011).

With social performance (demonstration) goals, interpersonal standards are used for evaluating one's competence and judging whether a relationship is valuable. Attention is focused on one's self, and the reason for effort is to demonstrate competence or self-worth (Rodkin et al., 2012; Rudolph et al., 2012; Ryan & Shim, 2008). This goal is similar to what Ojanen and colleagues (2005) term an agentic goal orientation. Performance goals can be further distinguished along the approach-avoidance dimension. Social performance-approach goals involve garnering positive feedback and gaining social status (e.g., being seen as cool or popular); social performance-avoidance goals involve avoiding negative judgments from others and losing social status (e.g., not being seen as a geek or a loser). Success is evaluated in terms of having a good reputation and high social status for a performance-approach goal, and in terms of avoiding a reputation as socially awkward or ineffective for a performance-avoidance goal. Social performance-approach goals tend to be associated with more aggression whereas social performance-avoidance goals tend to be associated with less aggression and more passive behavior (Rodkin et al., 2012; Rudolph, Abaied et al., 2011).

Developmental Significance and Change. Mapping onto social mastery versus social performance goals, adolescents clearly distinguish who is preferred, with its basis in affiliation and intimacy, from who is popular, with its roots in power and influence (Bukowski, 2011). Although distinctions among goals of affiliation versus status or intimacy versus power may be most salient during adolescence, research reveals clear goal structures as young as fifth grade (Ojanen et al., 2005; Rodkin et al., 2012) and even second grade (Rudolph, Abaied, et al., 2011). Moreover, the behavioral correlates and consequences of social goals appear similar across different ages (Rodkin et al., 2012; Rudolph, Abaied et al., 2011; Ryan & Shim, 2008), suggesting developmental uniformity in the meaning and implications of these goals. Overall, relatively little research has directly investigated developmental continuity and change in social motivation, an area much in need of attention. In this context, it is important to consider the possibility that puberty-driven changes in the neural substrates underlying reward systems (Forbes & Dahl, 2005) result in increasing shifts toward approach motivation during adolescence—whether those shifts are toward a focus on mastery and intimacy or toward a focus on dominance and status may be determined by characteristics of youth and the contexts in which their goals develop (peer groups, classrooms) prior to or during the pubertal transition, suggesting a potential window of opportunity for intervention.

Application to Psychopathology. Motivation has emerged as a key component of many interpersonal theories of psychopathology. In some theories, motivation is viewed from a social-information processing perspective, with a focus on identifiable goals and attributional biases presumed to drive behavior. In other theories, motivation is instantiated in neurocognitive and neural biases presumed to reflect dimensions of temperament or personality. Common across these perspectives runs the idea that motivation may guide individuals' movement toward, against, or away from the world (Caspi et al., 1987).

Externalizing Psychopathology Aggressive children, particularly those who are also rejected, have a unique motivational stance to many interpersonal relationships,

characterized by hostile attributional biases in the face of ambiguity (Crick & Dodge, 1994), retaliation goals in the face of social obstacles (Troop-Gordon & Asher, 2005), and a high value placed on demonstrating competence and status (Rodkin et al., 2012). Regardless of the precise focus, the motivation of youth with externalizing psychopathology epitomizes an emphasis on approach—moving *against* the world in ways that exert influence, garner power, and optimize one's position in the peer group.

Evolutionary and ethological theories form one conceptual backdrop for understanding how social motivation relates to aggression. Aggression, like its close cousin attachment, has deep phylogenetic roots (Cairns & Cairns, 2001; Ellis et al., 2012). Individuals aggress to get what they want and to change the behavior of others. Peer social structures exist within the boundaries of dominance hierarchies, in which some members are more central, popular, powerful, and likely to control resources than are others. Individuals may gain and maintain status, power, and prestige by using aggression, alone or in combination with more prosocial means of control, to dominate their peers. This may be done, for example, by selectively targeting lower status peers or by bullying in the presence of others who support bullying behavior (Kärna et al., 2011; Veenstra et al., 2010).

Socially integrated aggressors may be motivated by goals that orient them to demonstrate social status (Rodkin et al., 2012). Children who aggress might encourage group members to rally around them, to define themselves by excluding deviants, and to maintain cohesion and identity for their clique (Faris & Felmlee, 2011). Dominance hierarchies are neither static nor stable—there can be, and often is, flux in the hierarchy. This flux can occur as a result of changes in behaviors, interactions, and relationships as members try out new roles, as developmentally normative transitions happen (e.g., movement from elementary to middle school), or as idiosyncratic changes emerge in the group structure (e.g., some children move in or out of the peer group). Thus, children who have moderate levels of social status and children who are attempting to increase their status may be motivated to proactively aggress against others to demonstrate their power, establish their social position, and push others downward.

Socially marginalized aggressors may be motivated by a desire to achieve a status that they lack, or in classic frustration-aggression parlance, to displace the aggression that they receive onto targets whom they perceive as weak. Aggressive and coercive behaviors may be viewed by peers as attempts to establish dominance, thereby triggering peers to respond with aggression of their own (Hanish, Sallquist, DiDonato, Fabes, & Martin, 2012). Those who are most effective in using aggression to gain and maintain power tend to rise in the social hierarchy whereas those who are the least effective fall. In these cases, the psychological processes involved in aggression entail the recognition, though not necessarily an accurate understanding, of who is the target of harassment and of the networks in which aggressors and victims are embedded.

Contrasting with these motivations for proactive forms of aggression, in the form of bullying, Carver, Johnson, and Joormann (2008) provide a theory of risk for impulsive (i.e., reactive) aggression and conduct problems. In particular, they suggest these behaviors stem from an imbalance between the behavioral activation (approach) and behavioral inhibition (avoidance) motivational systems—that is, youth with an overactive approach orientation and an underactive avoidance orientation would disregard social norms or potential consequences of their actions to pursue their own self-interest, increasing the likelihood of impulsivity, aggression, and antisocial behavior. These adverse effects are presumed to be potentiated in the presence of poor self-regulation, as reflected in an inefficient top-down effortful control system. Recent work extends these ideas into a social context, such that aggression is prompted by high levels of sensitivity to social reward (social approach) and low levels of sensitivity to social punishment (social avoidance) in the face of poor self-regulation (Rudolph et al., 2013).

Depression In many ways depression is a disorder of motivation, reflecting an inability to upregulate approach-oriented emotions (positive affect or enjoyment) and behavior (effortful engagement with the environment) and an exaggeration of avoidance-oriented emotions (negative affect) and behavior (withdrawal). Many theories of depression therefore consider the contribution of motivational factors at a behavioral level, such as compromised reward-seeking behaviors (Forbes & Dahl, 2005); a social-cognitive level, such as diminished approach strivings/goals and heightened avoidance strivings/goals (Rudolph et al., 2013); and a physiological level, such as underactivation of brain regions involved in approach and overactivation of brain regions involved in inhibition/avoidance (Davidson, Pizzagalli, & Nitschke, 2009).

Contrasting their theory of risk for externalizing psychopathology, Carver et al. (2008) suggested that depression stems from an overactive avoidance orientation and an underactive approach orientation. According to the theory, poor self-regulation combined with a sensitive reactive avoidance or an insensitive reactive approach system is reflected in cognitive perseveration (e.g., rumination),

absorption in emotions, and consequent depression. A significant amount of research from multiple levels of analysis (behavioral, social-cognitive, physiological) has been devoted to understanding the role of the behavioral activation (approach) and behavioral inhibition (avoidance) systems in depression (for a review, see Carver et al., 2008), with some application of these ideas specifically to approach and avoidance motivation within a social context (Rudolph et al., 2013). Overall, this research supports theoretical frameworks linking low approach motivation and heightened avoidance motivation with depression.

Depression also may emerge from more basic social motivational strivings in youth. For example, a heightened avoidance-oriented need for approval may serve as a risk for depression. Youth whose self-worth is threatened by disapproval may experience more frequent fluctuations in their self-views; moreover, when faced with perceived or actual negative feedback from peers, heightened avoidance-oriented need for approval may foster self-disappointment, shame, and sadness, leading to depression (Rudolph et al., 2005). In contrast, youth who use positive feedback as a source of self-enhancement may be protected from depression. Such youth may focus on rewarding social encounters, discount adverse encounters, and feel less self-doubt and hopelessness; those with a diminished approach-oriented need for approval may fail to receive such benefits and be more prone to depression (Rudolph et al., 2005).

Anxiety Applying Gray's (1994) reinforcement sensitivity theory to the peer context, anxiety (particularly social anxiety) also has been conceptualized with regard to its social motivational underpinnings. This line of thinking has distinguished, in particular, the types of motivation that discriminate different forms of withdrawn behavior in youth (Rubin, Coplan, & Bowker, 2009). Shy, inhibited, or reticent children are believed to suffer from an approach-avoidance conflict in that they are high in both types of motivation (they wish to interact with peers but are inhibited by fear and anxiety). This group is believed to experience heightened internalized feelings of social anxiety and to be at risk for social phobia. Avoidant children are characterized by a combination of low social approach and high social avoidance motivation. Unsociable or socially disinterested children, in contrast to both groups, are low in both types of motivation and, therefore, likely do not experience high levels of anxiety. These groups of socially withdrawn children differ in terms of their short- and long-term risks (for a review, see Rubin et al., 2009), suggesting the importance of integrating social motivation into interpersonal theories of anxiety.

Directions for Future Research on Peer Theories

One potentially fruitful direction for research is to take a more ecological approach to understanding individual-level psychopathology by measuring the mental health of peer settings, quantifying measurement along both social network and social status dimensions. This is both an age-old mission of sociometric research (e.g., Bronfenbrenner, 1944) and an exciting new goal given advances in theories and measures of youth settings (Gest, Osgood, Feinberg, Bierman, & Moody, 2011; Seidman, 2011) together with analytic advances in the estimation of selection and socialization processes (Veenstra et al., 2013). Interestingly, this research goal based in community and social psychology has joined with evolutionarily oriented work on the functionality of behavior patterns, including aggressive and antisocial behavior (Cairns & Cairns, 2001). For example, from their life history approach, Ellis et al. (2012, pp. 605–606) suggested setting-level interventions that consider "proactively how to 'engineer' social networks in early adolescence . . . promoting group structures and behavioral strategies that enable adolescents to earn status for prosocial behaviors . . . and avoiding dynamics that confer social status and peer reward for antisocial behavior." Similarly, Dodge and Albert (2012, p. 627) noted that we should "use our evolved capacity to engineer environments in ways to enhance individual development."

An issue, then, is to encourage adults (e.g., clinicians, educators) to attend productively to issues of status and to promote inclusion and integration into social networks. Mikami, Lerner, and Lun (2010) point out that there also exists a social context of rejection: Children can be rejected for not fitting into peer group norms, due to the reputational biases and stereotypes of the majority, or when classroom social networks are marked by hierarchy and stratification (Ahn, Garandeau, & Rodkin, 2010; Garandeau, Ahn, & Rodkin, 2011). In schools and other settings where youth congregate, social network data could be used to design classroom assignments that mix high-risk and low-risk youth (Ellis et al., 2012), identify incipient peer leaders (Gest et al., 2011), correct unhealthy settings where antipathies outweigh friendships (Gest & Rodkin, 2011), identify when the social norms of a peer ecology support unhealthy behavior, and track along social network lines patterns of diffusion across which spread attitudes, values, and behaviors (Dishion, 2014).

Considering motivations that drive children's social interactions and relationships also may be essential for fully understanding the peer context of psychopathology. How can youth be motivated to behave less aggressively when aggression brings social rewards (Hawley, Little, &

Rodkin, 2007)? How can youth suffering from anxiety and depression be motivated to approach a world in which they perceive few social rewards and are exquisitely sensitive to anticipated, perceived, or actual social punishments? One answer may be to focus more specifically on children's motivations regarding social interaction rather than their observable behaviors.

Integrating ecological and motivational theories, what is needed are syntheses that consider the motivations of youth in tandem with measures of their social status and social network position within their actual peer ecologies. This will help foster theories of the peer context that feature, like in the lifespaces of Lewin and sociograms of Bronfenbrenner, a motivated, goal-directed child with beliefs about peers and the social world interacting with a complex social system of friends, acquaintances, enemies, and others. Psychopathology can enter this system via the child's developing beliefs, stance toward the developing society, whether or not a niche is found, and whether the peers that provide proximal support also promote positive adjustment in the long term.

Stress-Based Interpersonal Theories

Multiple theoretical perspectives emphasize the potent contribution of life stress exposure to the development of psychopathology. These perspectives variously focus on the role of early adversity, recent stress, or a combination of the two. Although life stress theories encompass a wide range of acute and chronic stressors, many either emphasize the impact of interpersonal stressors or involve interpersonal mechanisms through which stress undermines development and heightens risk for psychopathology. As such, many of these theories interface with family- and peer-based theories of psychopathology. We will first describe general conceptualizations of life stress and its role in psychopathology and then turn to disorder-specific and stressor-specific models of risk.

General Stress-Based Theories

Theoretical Underpinnings. The study of stress has a long and rich history in efforts to understand the emergence and perpetuation of psychopathology. Across this history, the field's conceptualization of life stress and its impact has undergone several transformations as theories have progressed from fairly simplistic views to more complex perspectives that acknowledge interactions and transactions among stressful life experiences and multiple vulnerability and protective factors (for reviews, see Grant et al., 2003; Grant et al., 2014). Advances also are reflected in the elucidation of developmentally sensitive models that consider the crucial role of early adversity and salient stage-specific stressors across childhood and adolescence. Accordingly, scholars have made efforts to conceptualize and explore the role of life stress within the context of integrative, dynamic, and developmental frameworks.

In one early conceptualization, Holmes and Rahe (1967) advocated a stimulus-based approach, viewing stress as exposure to disruptive or demanding environmental circumstances, thus emphasizing the objective experience of stress (see also Brown & Harris, 1978). In contrast, Selye (1974) conceptualized stress in terms of external events that elicit certain distress responses, called the general adaptation syndrome. This type of response-based approach is reflected in current neuroscience perspectives that view stress in terms of the type and magnitude of physiological response elicited by an event or circumstance (McEwen & Seeman, 2006). Advocating a transactional approach, Lazarus and Folkman (1984) noted the importance of considering not only environmental events and conditions but also individuals' subjective appraisals of these circumstances (e.g., as harmful, threatening, or challenging). According to this perspective, individual perceptions of events determine their stressfulness. These differing perspectives have pushed the field forward, highlighting distinct yet related aspects of life stress, yet each has been critiqued for focusing on only limited aspects of stressful experiences.

Integrating across these perspectives, Grant and colleagues (2003, 2014) have presented a comprehensive developmentally sensitive stress-based etiological model of psychopathology. Emphasizing the need to distinguish external environmental stressors from internal stress responses, this model defines stressors as "environmental events or chronic conditions that objectively threaten the physical and/or psychological health or well-being of individuals of a particular age in a particular society" (p. 449). In this definition, the term *stressors* serves as a global umbrella incorporating chronic environmental conditions (e.g., ongoing peer rejection), major life events (e.g., death of a parent), and minor life events (e.g., arguing with a friend); although not specified, these stressors also may include normative developmental challenges (e.g., entering into romantic relationships). Objective stressors are believed to undermine biological, psychological, and social processes (i.e., mediators) in ways that heighten risk for psychopathology. This model also elaborates possible characteristics of children and their environments (e.g., age, sex, social support, cognitive or coping styles) that moderate the associations among stressors, mediational

processes, and mental health outcomes. Another proposition focuses on specificity in the association between particular stressors, mediators, moderators, and psychopathology. Finally, the model proposes reciprocal and dynamic influences among stressors, mediators, and moderators that predict the onset and exacerbation of psychopathology. Thus, this framework incorporates both objective conditions and subjective reactions yet distinguishes their etiological status, such that cognitive and emotional appraisals and physiological responses to stress are viewed as potential mechanisms through which objective stressors trigger psychopathology or as moderators that determine the direction and strength of influence of stress on psychopathology.

Beyond the conceptualization of life stress as a proximal contributor to psychopathology, over the past few decades developmental psychopathologists have focused intense attention on the adverse long-term consequences of early social adversity (Boyce & Ellis 2005; Bush & Boyce, 2014; Esposito & Gunnar, 2014). Early adversity has been broadly construed, incorporating experiences such as exposure to socioeconomic disadvantage, parental psychopathology, deprivation, maltreatment, neighborhood violence, insecure attachment, and cumulative lifetime family disruption (for reviews, see Bush & Boyce, 2014; Goodman & Brand, 2009; Goodman & Tully, 2008; Gunnar & Loman, 2011). Although each type of early social adversity may have unique implications for children's development (for some examples, see later sections), common risk processes also have been identified across these experiences in an effort to understand their etiological contribution to future psychopathology.

O'Connor (2003) distinguished two models accounting for individual differences in the long-term impact of early experience. An experience-adaptive or developmental programming model holds that biological systems adapt to environment input, particularly during sensitive periods of development; moreover, this malleability is developmentally constrained such that systems have difficulty readjusting to later changes in the environment. A cumulative effects model holds that early experiences have a long-term impact to the extent that these effects are reinforced or maintained by later events; this model includes both an additive effects variant (the effects of later adversity add to the effects of earlier risks) and an interactive effects variant (the effects of later adversity depend on the history of earlier risks). Stress-sensitization models, discussed earlier, represent one example of this interactive effects variant. According to these models, stressful early experiences are encoded in the brain in the form of memory traces that heighten reactivity of biological stress-response systems, thereby lowering their threshold for reactivity (for a review, see Monroe & Harkness, 2005). Boyce and Ellis' (2005) biological sensitivity to context (BSC) model combines elements of the experience-adaptive and cumulative effects models; specifically, the BSC model holds that early adversity calibrates the stress-response system, such that youth exposed to stressful early social environments show heightened biological sensitivity to later stress. Departing somewhat from other risk models, this sensitivity is thought to exert risk-augmenting effects under subsequent stressful conditions but risk-protective effects under subsequent supportive conditions (Bush & Boyce, 2014).

Refining these stress-based models of psychopathology, contemporary theory and research are aimed toward articulating specific pathways through which risk processes unfold (for reviews, see Esposito & Gunnar, 2014; Goodman & Brand, 2009; Gunnar & Loman, 2011). One line of research, consistent with stress-sensitization and BSC theories, focuses on the idea that a history of prolonged or severe social adversity sensitizes developing brain systems so as to create more pronounced reactivity to stress later in life (for reviews, see Bush & Boyce, 2014; Gunnar & Loman, 2011). Another line of research suggests that early adversity induces risk through exposure to maladaptive parent socialization patterns and stressful interpersonal contexts that weaken youths' developing sense of self, emotion regulation and coping skills, and interpersonal competencies, leaving them vulnerable in the face of future stress or even causing them to generate stressful events and circumstances (for reviews, see Goodman & Tully, 2008; Hammen, 2009; Rudolph et al., 2008).

Developmental Significance and Change. Stress-based theories uniformly emphasize the long-term developmental significance of early social adversity and proximal life stress as instantiated in subsequent biological, cognitive, emotional, and interpersonal risk. However, consistent with a developmental psychopathology perspective, it is vital to consider how stress-linked risk dynamically evolves across the life course in tandem with changes in the occurrence and meaning of particular stressors as well as how early stress intersects with normative developmental tasks and challenges in ways that amplify—or perhaps dampen—earlier risk.

Considerable transformations occur in the nature, role, and consequences of close relationships across development, resulting in changing demands and standards for interpersonal success. Each developmental stage carries new challenges, with the potential to endow satisfaction

from achieving new interpersonal goals (e.g., developing strong friendships during middle childhood) or to induce stress from failing to meet new social demands (e.g., having difficulty balancing connectedness vs. autonomy within parent–child relationships during adolescence). In particular, adolescence often is characterized as a tumultuous period, fraught with novel interpersonal stressors induced by physical-maturational, cognitive-developmental, and social-contextual transitions (Rudolph, 2014). Youth who struggle with these transitions may be at particular risk for interpersonal disruptions that pose a threat for psychopathology. Moreover, developmental changes in relationships may be a particular burden for adolescent girls in light of their stronger interpersonal engagement and sensitivity (for a review, see Rose & Rudolph, 2006). Indeed, research suggests that the transition through adolescence is characterized by a pileup of stressful events and circumstances, especially in the interpersonal domain, with girls showing heightened stress exposure and reactivity compared to boys (e.g., Rudolph & Hammen, 1999; Shih, Eberhardt, Hammen, & Brennan, 2006; for reviews, see Hammen, 2009; Rudolph, 2002). These findings suggest that interpersonal stress-based theories of psychopathology must consider relevant developmental and sex differences in risk over time.

Beyond greater stress exposure, the adverse impact of interpersonal stress may be intensified during adolescence by puberty-linked changes in brain structure and function (for a review, see Dahl, 2004). Contemporary affective and cognitive neuroscience perspectives focus on a growing disjuncture between brain systems involved in the regulation of arousal, motivation, and emotion and those involved in cognitive modulation of behavior (e.g., executive functions that guide judgment and decision making). Specifically, these theories propose an emerging imbalance during puberty reflected in increasing reactivity of sublimbic regions involved in emotion processing (e.g., amygdala, ventral striatum) accompanied by a lag in the maturation of the prefrontal cortex and associated cognitive control processes. This maturational gap is thought to trigger biological sensitivity, emotion dysregulation, risk-taking behavior, and associated risks during adolescence (Dahl & Gunnar, 2009). Thus, heightened stress reactivity may potentiate risk associated with increasing levels of interpersonal stress exposure during this stage. Risk may be most salient in youth exposed to early adversity, who likely enter the adolescent transition with compromised social skills and interpersonal resources (Rudolph, 2009).

Although prevailing interpersonal stress theories of psychopathology focus on this notion that early adversity and escalating interpersonal stress at puberty promote continuity—and perhaps intensification—of maladaptive developmental pathways across adolescence, stress theorists recently are considering possible mechanisms driving discontinuity in risk across development. This perspective is predicated upon the assumption that puberty represents a period of developmental plasticity during which considerable reprogramming occurs in stress-response systems (Dahl, 2004). The adaptive calibration (DelGiudice, Ellis, & Shirtcliff, 2011) or pubertal stress recalibration (Esposito & Gunnar, 2014) hypothesis argues that puberty provides a window of opportunity during which stress-response systems can be recalibrated based on current demands, such that youth who were exposed to early social adversity but then experience supportive, low stress conditions during adolescence may rebound, allowing for protection against psychopathology. Validation of this hypothesis awaits support from rigorous prospective longitudinal research, but it provides a possible explanation for variations in the developmental consequences of early social adversity.

Application to Psychopathology. Exposure to interpersonal stress occupies a prominent position in many developmental psychopathology theories of disorders. The fundamental assumption common across stress-based risk models is that heightened stress exposure overwhelms youths' personal resources and compromises multiple systems of development, thereby precipitating mental health problems. Once again, this line of research highlights the possibility of multifinality (exposure to similar stressors predicts different mental health outcomes) as well as equifinality (exposure to different stressors predicts the same mental health outcome) in youths' developmental trajectories. For the most part, interpersonal stress is incorporated into broader models of psychopathology that implicate diathesis-stress interactions, wherein exposure to stress differentially affects youth depending on prior vulnerabilities (e.g., cognitive biases, emotional deficits) and supports (e.g., risky vs. protective social environments). In the following sections, we focus chiefly on the role of stress itself; the interface between stress and other risks will be described more fully in a later section.

We again present representative examples of relevant models and rely, where possible, on integrative summaries and reviews to cull empirical evidence regarding the role of interpersonal stress in psychopathology. Of note, despite the incredible proliferation of life stress-psychopathology research in youth (over 2000 studies in the past 20 years; Grant et al., 2014), quantitative analyses are not available to estimate the strength of stress-psychopathology linkages. However, in the most comprehensive set of

reviews to date (Grant et al., 2003, 2006; Grant, Compas, Thurm, McMahon, & Gipson, 2004; McMahon, Grant, Compas, Thurm, & Ey, 2003), Grant and colleagues conclude that there is unequivocal support for the prospective contribution of stressors, both cumulative and specific severe stressors (e.g., divorce, poverty), to internalizing psychopathology (e.g., anxiety and depression) and externalizing psychopathology (e.g., aggression and delinquency). Unfortunately, these reviews often do not distinguish specific types of stressors, thereby making it impossible to discern the precise contribution of interpersonal stress to various forms of psychopathology.

Depression Early life stress theories of depression focused on how exposure to adverse life events or circumstances triggers depression onset, persistence, or recurrence (Brown & Harris, 1978). Following this emphasis on the contribution of life stress to depression, research aimed to disentangle symptom-related stress from fateful or independent life events, or events whose occurrence is beyond one's control. This theoretical perspective drove the development of contextual threat (Brown & Harris, 1978) approaches to stress assessment that filtered out individuals' subjective perceptions of threat—which may be biased by depressive symptoms—focusing instead on the objective impact of stress on adjustment. Challenging this traditional view of depressed individuals as passive recipients of experience, Hammen (2006) asserted that understanding the social context of depression requires a consideration of how individuals contribute to stressful environments. Specifically, disorder-induced impairment and stable characteristics of depressed and depression-prone individuals may create stress, which then perpetuates and exacerbates symptoms. This stress-generation process can help explain the continuity and recurrence of depression over time (Rudolph, Flynn, Abaied, Groot, & Thompson, 2009). Although stress exposure and generation can occur within noninterpersonal contexts, life stress theories of depression emphasize the potent role of interpersonal stress.

Collectively, these theories presume that interpersonal stress, conflict, and disruption, particularly stressors that deplete one's self-worth, interfere with the normative acquisition of competencies that emerge in the context of adaptive relationships, such as forming a healthy sense of self and others and learning how to effectively regulate emotions and behavior. Interpersonal stress also can overwhelm youths' coping resources and erode their social networks, creating a sense of helplessness and loneliness. Moreover, interpersonal stress can sensitize biological stress-response systems, thereby heightening reactivity to subsequent stress. These impairments create a vulnerability for depression, which then causes further deterioration in relationships and the generation of more stress (Hammen, 2009; Rudolph et al., 2000, 2008). Thus, consistent with developmental psychopathology principles, interpersonal life stress theories of depression implicate transactional processes through which social disruption and depression become intimately linked within a self-perpetuating cycle over time. Developmental elaborations of these models focus on interpersonal stress as a specific context for the emerging sex difference in depression during adolescence, suggesting that girls are particularly sensitive to disruption in their relationships (Rudolph, 2002, 2009; Rudolph, Hammen, & Daley, 2006; Shih et al., 2006).

A sizeable body of research provides convincing support for life stress as a precursor to depressive symptoms and, to a lesser extent, the onset of depressive disorders in youth. Much of this research relies on composite measures of cumulative events across multiple domains, making it difficult to determine the specific role of interpersonal stress. However, individual studies do indicate that chronic interpersonal stress, cumulative interpersonal life events, and specific types of interpersonal events prospectively predict depression. A growing body of evidence also supports the notion that depressive symptoms predict the generation of interpersonal stress (for reviews, see Hammen, 2009; Rudolph et al., 2006). In their broad review, Grant and colleagues (2006) generally found stronger associations between cumulative or specific life stressors and internalizing symptoms in girls than in boys, qualified some by the type of stressor. Moreover, one recent study indicated that self-generated interpersonal (but not noninterpersonal) stress accounted for the continuity of depression in girls but not boys, supporting transactional interpersonal life stress models of depression and the sex difference therein (Rudolph et al., 2009). Confirming the importance of developmentally sensitive life-stress models, research also reveals an intensification of the interpersonal life stress-depression link at puberty. In particular, early maturation interacts with family and peer stress to predict subsequent depression, and depression interacts with early maturation to predict subsequent interpersonal stress generation (for a review, see Rudolph, 2014). Finally, research supports theoretical models asserting that exposure to early social adversity heightens risk for subsequent youth depression, often through stress-amplification or stress-sensitization processes (for reviews, see Goodman & Brand, 2009; Hammen, 2009; Hammen et al., 2014).

Anxiety Exposure to stressors also is an integral component of many etiological theories of anxiety. Early

perspectives linking stressors with anxiety emerged from classical conditioning theories suggesting anxiety resulted from pairing of a neutral stimulus with a traumatic event. Attempting to explain individual differences in the presence of a conditioned stimulus in individuals with anxiety, more contemporary accounts consider the role of preexisting vulnerabilities, previous learning experiences and stressors, and poststressor experiences (Murray, Creswell, & Cooper, 2009).

Barlow and colleagues (Albano et al., 2003) presented a multifaceted model that emphasizes the crucial role of life stressors as setting into motion a causal chain eventuating in anxiety. It is believed that early exposure to stress fosters changes in neural systems underlying stress responses and engenders a psychological vulnerability characterized by a diminished sense of control, which in turn drives anxiety. The model does not specify whether stressors occurring within the interpersonal domain are particularly relevant to anxiety; rather, the focus is on early stressful events or conditions that predispose children to acquiring a cognitive template characterized by a weakened sense of predictability, control, or mastery. Of note, this model proposes that the actual nature of life events becomes less influential across development, as this cognitive template strengthens subjective appraisals of stress.

Whisman and Beach (2010) provided a framework for understanding the specific role of early interpersonal stress in the development of anxiety. They propose that stressors viewed as being intentionally inflicted are more likely to undermine mental health, thus implicating the salient role of interpersonal stressors. Furthermore, they suggest early severe and cumulative exposure to interpersonal stressors will sensitize individuals to subsequent stress, thereby heightening risk for anxiety, although they allow for the possibility that moderate levels of stress may induce resilience. Similar to interpersonal life stress theories of depression, this framework integrates the ideas that (1) interpersonal stressors pose particular risk for anxiety in girls compared to boys (see also Davila, La Greca, Starr, & Landoll, 2010); (2) sensitivity to interpersonal stressors increases during developmentally salient life transitions, such as puberty; and (3) anxiety symptoms contribute to the generation of future interpersonal stress (e.g., through avoidance, missed opportunities for socialization, and consequent failure to develop adequate social skills; Davila et al., 2010), resulting in a self-sustaining cycle of symptoms and stress-inducing behavior.

Supporting interpersonal stress models of anxiety, both early social adversity and recent stressors predict anxiety symptoms and disorders in youth, with some specificity for anxiety versus depression (for reviews, see Davila et al., 2010; Grant et al., 2014). As noted earlier, some evidence supports stronger links between stress and internalizing symptoms, broadly construed, in girls than in boys (Grant et al., 2006). Although little research implicates specific types of interpersonal stressors, there is some evidence that threat events (e.g., threat of caregiver loss, physical jeopardy, psychological challenge) are uniquely associated with youth anxiety compared to depression (Eley & Stevenson, 2000). Finally, preliminary evidence supports stress-generation processes in anxiety (Murray et al., 2009; Whisman & Beach, 2010).

Externalizing Psychopathology The frustration–aggression hypothesis (Dollard, Doob, Miller, Mowrer, & Sears, 1939) postulates that aggression emerges from emotional arousal elicited by aversive events that thwart one's desired goal attainment. Although aspects of this hypothesis have undergone significant critique, the idea that exposure to aversive or stressful events induces aggression (and other types of externalizing psychopathology) has remained a part of many theoretical models. The assumption is that stress exposure leads to arousal and negative affect (e.g., anger, hostility), which are expressed in the form of aggressive and delinquent behavior.

Integrating aspects of the frustration–aggression hypothesis, many contemporary stress-based accounts of externalizing psychopathology represent variants of strain theory. The core assumption of strain theory is that youth who live in aversive environments (e.g., those characterized by poverty, neighborhood disadvantage, and associated chronic stressors) are unable to achieve valued goals via legitimate channels and, therefore, turn to delinquency and crime (Agnew, 1985). Responding to critiques of this theory and some empirical failures to support its assumptions, Agnew (1985) proposed a revised strain theory, which proposes that youth who are embedded in aversive social environments become frustrated not only in reaction to the blockage of goal-seeking behavior but also in reaction to the blockage of pain-avoidance behavior. That is, youth often have no legitimate options for escaping from stressful social environments (e.g., parental rejection; teacher conflict), resulting in aggressive or illegal escape attempts (e.g., fighting with peers to reduce harassment; running away to escape stressful home environments) or in anger-based aggression and delinquency. The former would incite proactive, instrumental antisocial behavior and the latter would incite reactive, emotionally driven antisocial behavior. The likelihood of social strain contributing to antisocial behavior would be contingent on other factors, such as youths' beliefs about delinquency, integration into deviant peer groups, and level of social control (internalization of conventional norms and values).

Some effort has been made to elucidate specific types of social stressors most likely to predict externalizing psychopathology. Agnew (2001) suggested several broad characteristics of strain that enhance its likelihood of promoting delinquency and criminality; these include strains that (1) are perceived as unjust (which induces anger and a desire for revenge, inhibits guilt, and impedes adaptive coping); (2) are perceived as severe in magnitude (which interferes with adaptive coping, attenuates its likelihood of success, and increases the perceived cost of the strain); (3) are associated with low social control (which reduces the perceived cost of delinquency and one's ability to engage in adaptive coping); and (4) create pressure or incentives to engage in criminal coping (e.g., exposure to others who model or reinforce crime or to conditions that diminish the utility of adaptive coping and maximize the benefits of aggression and delinquency; see also Attar, Guerra, & Tolan, 1994). According to Agnew (2001), some interpersonal strains with these characteristics include parental rejection, harsh discipline, peer maltreatment, and other forms of victimization and discrimination.

Similar to interpersonal stress theories of depression and anxiety, strain theory has been applied to understanding sex differences in stress and externalizing psychopathology. Briefly, Broidy and Agnew (1997) proposed that males may show higher rates of delinquency and criminality than females in reaction to strain because (1) they experience more of the types of strain associated with violence and delinquency; (2) although both males and females respond to strain with anger, females experience the associated emotions of depression, guilt, and anxiety, which inhibit aggressive reactions; and (3) anger more likely provokes aggression and delinquency in males because of their typical coping strategies, weaker affiliative tendencies, involvement in peer group networks that promote physical confrontation and risk taking, and experience of fewer societal inhibitions against aggression. Focusing on life stress more generally, Leadbeater and colleagues (1995) proposed that adolescents with an individualistic orientation (who are sensitive to criticism), which is more characteristic of boys than girls, are more likely to respond to stress—particularly stress that threatens the self—with externalizing psychopathology in order to maintain personal power and deflect perceived criticism.

Consistent with stress-based theories, exposure to a variety of social stressors (e.g., neighborhood disadvantage and violence, aversive family and school environments, cumulative life events) predicts externalizing psychopathology (Attar et al., 1994; for reviews, see Agnew, 1985, 2001; Grant et al., 2006); consistent with strain theory, some of these effects are accounted for by heightened levels of anger (Agnew, 1985). There is some evidence supporting links between certain types of strain and externalizing psychopathology (for a review, see Agnew, 2001) as well as stronger links between stress and externalizing psychopathology in boys than in girls (for a review, see Grant et al., 2006; cf. Attar et al., 1994; Hoffmann & Su, 1997), although more research of this type is needed.

Stressor-Specific Theories

Although some theoretical models focus on cumulative life stress exposure, others postulate how specific severe interpersonal stressors heighten risk for psychopathology. These conceptualizations often integrate other interpersonal models of psychopathology to explain how stress exposure exerts long-term toxic consequences on mental health. For example, theoretical models often assert that specific life stressors contribute to psychopathology via disruptions in family processes (e.g., insecure attachment, poor parenting, family conflict) or peer processes (e.g., affiliation with deviant peers, disruption in social networks). Below we describe a few such models; this summary is not exhaustive but rather provides representative examples of theories concerning how specific stressors increase the likelihood of multiple forms of psychopathology within an interpersonal context.

Family Adversity. Some interpersonal stressors impinge directly upon youth by threatening parent–child bonds and family relationships; others exert indirect influences on youth by limiting family resources, creating parenting strain, and compromising parents' mental health in ways that impair their ability to act as support systems for youth. Regardless of the specific form, family adversity exposes youth to punitive, stressful, or unpredictable family environments. In the following sections we discuss four exemplars of such stressors that have received significant attention in interpersonal theories of psychopathology.

Socioeconomic Risk Several related theoretical models contend that exposure to poverty heightens risk for psychopathology through interpersonal mechanisms (e.g., Conger, Ge, Elder, Lorenz, & Simons, 1994; Wadsworth, Raviv, Santiago, & Etter, 2011). These models share the idea that economic strain compromises family health, resulting in maladaptive parenting (e.g., harshness, rejection, inconsistent discipline), parental depression, and family conflict; this family disruption then puts youth at risk for multiple forms of psychopathology. In a meta-analytic review of this pathway, Grant et al. (2003) provided evidence for the validity of family process models of socioeconomic risk. In particular, poverty predicted poor parenting, which predicted heightened internalizing

and externalizing symptoms over time. The overall model fit the data somewhat better for girls than for boys; moreover, the association between poverty and poor parenting was stronger in boys than in girls, whereas the association between poor parenting and internalizing symptoms was stronger in girls than in boys. More recent work focuses on understanding how some families and youth are resilient in the face of economic strain. For example, Wadworth and colleagues (2011) proposed a model wherein effective coping and stress reduction mitigate the adverse effects of economic strain on family functioning, thereby reducing long-term risk for psychopathology. Overall, this line of theory and research provides a global perspective on risk for psychopathology—particularly anxiety, depressive, and externalizing symptoms—arising from poverty and ensuing family disruption, with little indication of circumstances accounting for differential risk for specific types of disorder.

Maltreatment Exposure to maltreatment is a traumatic form of family adversity that can forebode future psychopathology. Cicchetti and Banny (2014) proposed an ecological-transactional model in which maltreatment is viewed as a pathogenic relational environment that compromises the achievement of key developmental milestones, propelling children along a pathway of risk for repeated developmental failures and the emergence of psychopathology. This model allows for *multifinality* in the developmental trajectories of maltreated youth, with some moving toward compromised development and psychopathology and others toward healthy adaptation. Perturbations in diverse stage-salient developmental processes are implicated as potential paths through which maltreatment instills risk: (1) maltreatment fosters an aberrant emotional environment in the context of the parent–child relationship; early exposure to this environment compromises the emergence of skills for differentiating and modulating emotions, thus resulting in deviant emotional expression (e.g., excessive negative or blunted affect), attention (e.g., a bias toward angry faces), and arousal processes (e.g., under- or over-controlled); (2) exposure to insensitive and hostile care provokes the emergence of insecure (particularly disorganized) attachment and negative internal working models; (3) maltreated children show deviant self-system development, reflected in negative (for neglected) or grandiose (for abused) self-representations, low self-esteem, and dissociative symptoms; (4) maladaptive interactional patterns developed within a maltreating relationship create ongoing interpersonal problems within the peer group, such as aggression, victimization, and poor quality friendships; (5) certain subtypes of maltreatment foster deviant memory processes (e.g., defensive processes, overgeneral autobiographical memory); and (6) chronic physiological activation resulting from maltreatment disrupts biological systems regulating stress reactivity, resulting in allostatic overload. Collectively, disruptions across multiple domains create a cascade of developmental challenges that potentiate long-term liability for multiple forms of psychopathology, including mood and anxiety disorders, dissociation, suicidal behavior, substance use, antisocial behavior, psychosis, and personality pathology (Cicchetti & Banny, 2014). Of importance, this model emphasizes that maltreatment represents only a probabilistic risk for psychopathology that is contingent upon genetic liability.

Presenting an integrative developmental model specifically linking early maltreatment with depression, Harkness and Lumley (2009) stipulate that exposure to abuse and neglect promotes the development of core negative belief systems (e.g., negative attributional style, maladaptive cognitive schema) and dysregulation of the HPA axis (hippocampal atrophy and cortisol hypersecretion). These processes interact and stabilize throughout adolescence, coalescing into rigid structures that prime sensitivity to future stress and even cause the generation of stress, thereby heightening risk for depression. Although accumulating research supports parts of this model (e.g., effects of maltreatment on cognitive and biological vulnerability; stress sensitization in maltreated youth; for a review, see Harkness & Lumley, 2009), the model has not yet been tested in full.

Family Conflict Focusing on family conflict as a severe stressor, Davies and Sturge-Apple (2014) proposed that repeated exposure to interparental conflict or hostility in parent–child relationships sensitizes children to sources of threat, which compromises their sense of security and puts them at risk for psychopathology. In the face of these threats, children may show self-protective behaviors such as triangulation or alliance formation, avoidance, and hypervigilance to threat cues, all of which are developmental precursors to psychopathology.

The process of triangulation in the context of interparental conflict has received much attention as a stressor. Fosco and Grych (2008) reviewed three main forms this triangulation can take. First, children may become involved in their parents' disputes to try to help resolve them. Second, children may form an alliance with one parent against the other. Third, children may misbehave to direct parents' attention toward them and away from the marital discord.

Becoming involved in interparental conflict has the potential to undermine children's adjustment because forming an alliance with one parent might reduce their access to support from the other parent, redirecting parents' anger toward themselves might increase children's emotional distress, and behavior problems themselves might become habitual as children try to keep parents' focus away from their marital problems. Many aspects of these theoretical models of family and interparental conflict as risk factors for psychopathology are bolstered by empirical support (for a review, see Davies & Sturge-Apple, 2014).

Early Deprivation One of the most profound interpersonal stressors experienced by youth is exposure to extreme deprivation in the context of severely inadequate caregiving environments. Spurred by a surge in children exposed to global deprivation within institutional care settings abroad, scientists have scrutinized the implications of this early experience for the development of psychopathology (for a review, see Esposito & Gunnar, 2014). This line of research takes advantage of a natural experiment, in that many youth exposed to early deprivation typically enter into supportive environments (through adoption) during infancy or early childhood, affording the opportunity to ascertain the enduring effects of early social adversity and to better understand processes of recovery and resilience.

Esposito and Gunnar (2014) illustrated two theoretical perspectives on the impact of early deprivation. Theories of experience-expectant development suggest that stimulus depletion associated with deprivation interferes with neural development during sensitive periods, creating delays or deficits in cognitive, emotional, and motor development. A life stress perspective suggests that early deprivation and the accompanying absence of caregivers to provide regulatory input serves as a chronic stressor that causes dysregulation in the HPA axis, stress-related neuropeptides, and neurotransmitters or even creates epigenetic changes in the stress-regulatory systems that manage threat and challenge. These two perspectives are not mutually exclusive and may account for different adverse effects of early deprivation.

More specifically, characteristics of early deprivation (e.g., lack of environmental stimulation, absence of a close caregiving relationship) are thought to result in a failure to succeed on salient development tasks such as establishing a secure attachment, an advanced theory of mind, and cognitive and emotional regulatory skills (e.g., executive function, attentional control) during earlier childhood. Deprivation also predicts compromised biological functioning (e.g., impaired cellular growth and repair; growth delays; HPA axis dysregulation; delayed neural maturation; abnormalities in brain structure and connectivity). Highlighting the importance of a developmental perspective, Esposito and Gunnar (2014) suggest that deprivation-induced impairment may interact with heightened challenges in adolescence to forecast emerging psychopathology during this stage, yet adolescence also may represent a period of opportunity during which biological systems rebound, and risk for psychopathology decreases in the context of a supportive environment. Despite the compelling findings documenting adverse sequelae of early deprivation, few studies explicitly examine whether these processes mediate between deprivation and subsequent psychopathology or whether adolescence brings heightened risk or resilience.

Peer Adversity. Challenging conventional wisdom suggesting that exposure to adversity within the peer context represents a normative part of growing up, theoretical perspectives increasingly view these experiences as traumatic stressors with the potential to set youth upon trajectories of risk for psychopathology. Indeed, many forms of peer adversity share characteristics of family adversity (e.g., exposure to negative self-referent feedback, demeaning treatment, and even emotional and physical abuse) that can jeopardize the achievement of key developmental tasks and heighten vulnerability across multiple systems of development.

Peer Rejection Exposure to peer rejection can be viewed as a developmentally salient interpersonal stressor that threatens youths' well-being by compromising their sense of self (La Greca et al., 2011; Prinstein & Aikens, 2004), priming cognitive biases (Dodge et al., 2003) and emotion dysregulation (Bierman & Wargo, 1995), and forcing youth outside of the mainstream peer group (Dishion, 2014), thereby increasing their likelihood of developing psychopathology (Choukas-Bradley & Prinstein, 2014; Parker et al., 2006). Consistent with vulnerability models, it has been proposed that exposure to peer rejection will predict depressive symptoms in youth with but not without predisposing cognitive vulnerabilities (Prinstein & Aikins, 2004). In the context of problem behavior (externalizing psychopathology, substance use, risky sexual behavior), it has been proposed that early aggression will predict subsequent symptoms in youth exposed to low social preference (peer rejection) but not high social preference (peer acceptance) (Prinstein & La Greca, 2004). Consistent with stress-generation models, peer rejection also has been conceptualized as a potential consequence of depressive symptoms (Agoston & Rudolph, 2013; Kochel, Ladd, & Rudolph, 2012) and aggression (Dishion, 2014). This perspective highlights the continuous transactions between interpersonal stressors and psychopathology.

More broadly, contemporary theories consider how social rejection gets under the skin (e.g., Slavich, Donovan, Epel, & Kemeny, 2010) to heighten risk for psychopathology, processes that will be explored further.

Peer Victimization Conceptualizing peer victimization within a life stress perspective, Rudolph and colleagues (Troop-Gordon, Rudolph, & Sugimura, 2015; Troop-Gordon, Rudolph, Sugimura, & Little, 2015) proposed a model wherein victimization serves as a form of early social adversity that interferes with the normative development of self-regulatory processes in ways that heighten risk for psychopathology. Typically, peers help shape emerging self-regulatory abilities by modeling and providing feedback about effective coping and acting as support systems that encourage effective self-regulation. Because victimized youth are marginalized from the mainstream peer group, they have limited opportunity for positive socialization; moreover, their coping resources may become overwhelmed, impairing their ability to manage reactions to social stress. Youth who anticipate aggression or humiliation from peers due to a history of victimization also may show heightened vigilance and consequent biological reactivity to social threat. According to this model, therefore, early exposure to peer victimization will predict heightened stress reactivity over time, as reflected in involuntary, dysregulated cognitive, emotional, behavioral, and physiological responses to social challenges. This heightened stress reactivity, in turn, enhances risk for psychopathology.

Preliminary research supports this model. Specifically, early exposure to peer victimization and increasing victimization over time predict maladaptive growth patterns of involuntary engagement (e.g., rumination, impulsive action) and disengagement (e.g., emotional numbing, escape) responses to stress over time (Troop-Gordon et al., 2015). Moreover, involuntary engagement and disengagement responses to stress mediate the prospective contribution of peer victimization to subsequent depressive symptoms (Troop-Gordon et al., 2015). Research also links victimization to heightened biological reactivity in response to social challenge (Kliewer, Dibble, Goodman, & Sullivan, 2012). More generally, research supports a prospective contribution of victimization to multiple forms of psychopathology, including general and social anxiety, depression, and externalizing symptoms (Davila et al., 2010; Rudolph, Troop-Gordon, Hessel, & Schmidt, 2011). Consistent with stress-generation models, internalizing and externalizing psychopathology also contribute to subsequent peer victimization (Davila et al., 2010; Rudolph, Lansford et al., 2014).

Peer Exclusion Persistent exclusion from the peer group also has been viewed as an interpersonal stressor that heightens risk for psychopathology (Davila et al., 2010; Gazelle & Rudolph, 2004). Exclusion may occur through direct actions (e.g., refusing a child's bid to participate in group activities) or through indirect actions (e.g., failing to involve a child in the peer group). Drawing from diathesis-stress models of psychopathology, Gazelle and Rudolph (2004) suggested that exposure to peer exclusion may exacerbate risk associated with a tendency toward anxious solitude, characterized by shy, verbally inhibited, and solitary behavior among familiar peers (Rubin et al., 2009). Specifically, they reasoned that when the beliefs of anxious solitary children (e.g., fears about negative evaluation or maltreatment) are confirmed through peer exclusion, they will progress from worrying about the possible occurrence of negative peer events and their ability to respond effectively (a risk for anxiety symptoms) to being certain about the occurrence of negative peer events and convinced of their inability to cope (a risk for depressive symptoms). In support of this theory, a prospective study revealed that children who were both anxious solitary and excluded reported higher stable levels (for girls) or increasing levels (for boys) of depressive symptoms over time. Peer exclusion also has been implicated in social anxiety (Davila et al., 2010). Thus, peer exclusion represents a specific interpersonal stressor that can pose a risk for internalizing psychopathology, particularly in youth with a heightened sensitivity to exclusion.

Romantic Relationship Stressors Romantic involvement represents a normative process with the potential to provide opportunities that enhance well-being or to present challenges that undermine healthy development. Although increasing involvement in romantic relationships is typical across mid- to late adolescence, emerging theory and research suggest this involvement also heightens risk for psychopathology. Dating and romantic relationships can create stressful experiences and events (e.g., harassment, breakups, conflict) that threaten youths' mental health. However, several theoretical models propose that romantic involvement even in the absence of specific stressors can have adverse effects (for a review, see Davila, 2008).

According to a normative trajectory model (Davila, 2008), youth who become involved in dating and romance during early adolescence (considered to be early and thus off-time) are failing to conform to developmental norms, which compromises their adjustment. According to an attention impairment model (Joyner & Udry, 2000), romantic involvement deflects attention from other key

developmental tasks (e.g., attaining academic success, sustaining strong friendships and family relationships), which has adverse mental health effects. According to a stress and coping model (Davila, 2008), novel activities and experiences (e.g., initiation of sexual behavior, development of intimacy) and intense, novel emotions (e.g., romantic love, passion, sexual attraction) emerging within romantic relationships may pose challenges for youth, particularly those with inadequate coping resources and other vulnerabilities. Theoretical models of puberty and psychopathology further propose that premature entrance into dating and romantic relationships, especially for early-maturing girls, paves the way for affiliation with older and more deviant peers, which facilitates the onset or progression of antisocial behavior and substance use (for a review, see Rudolph, 2014).

Supporting models of romantic risk, romantic stressors, attraction, involvement, and activities (e.g., flirting, dating, sexual activity) predict symptoms of depression (for a review, see Davila, 2008). Contrary to a purely normative trajectory model, this risk occurs not only in early adolescence but also at older ages. However, romantic involvement and stress do help to account for the association between early pubertal timing and multiple forms of psychopathology, including depression and externalizing psychopathology (for a review, see Rudolph, 2014). Poor-quality romantic relationships also are associated with higher levels of anxiety (for a review, see Davila et al., 2010). Reflecting a transactional process, psychopathology, such as depression, also predicts subsequent disruption within romantic relationships (Daley & Hammen, 2002).

Directions for Future Research on Stress-Based Theories

Significant empirical advances provide compelling evidence for the prospective contribution of interpersonal stressors to psychopathology. This research documents the adverse effects of both cumulative stressors and specific adverse life events, including early as well as more proximal experiences. The field also has progressed in its understanding of personal and contextual characteristics that amplify or dampen stress reactivity. Yet, this line of research still provides a surprisingly broad—and often atheoretical—perspective. Of particular interest here is whether stressors within interpersonal relationships serve as robust predictors of specific forms of psychopathology and, if so, why and for whom?

Despite recent progress (Grant et al., 2014), there is a dearth of conceptually driven research examining specific stressor-psychopathology linkages (McMahon et al., 2003), making it difficult to determine the particular contribution of interpersonal stressors. Progress on this front will require building and testing more sophisticated theoretical models to explain why certain stressors heighten risk for certain disorders. Addressing this issue may be facilitated by considering the pathways through which interpersonal stressors exert their effects as well as characteristics of youth and their environments that determine specific adverse—or even beneficial—consequences of stress (Grant et al., 2006). For example, interpersonal stressors that threaten one's sense of control (e.g., parental divorce) may heighten risk for anxiety; those that deplete one's self-worth (e.g., social rejection) may heighten risk for depression; and those that threaten one's social status (e.g., peer victimization) may heighten risk for externalizing psychopathology. However, the picture is likely more complicated given that individual differences in the mental health consequences of interpersonal stressors undoubtedly depend on personal characteristics such as genetic liability, temperament, or cognitive style as well as environment contexts, such as family or peer support. Thus, advances in the field will require considering how particular stressors contribute to particular types of psychopathology through particular pathways in particular youth under particular circumstances at particular points in development.

Reflecting this approach, interpersonal life stress theories of depression, perhaps the most well-developed and well-tested life stress theories, propose a detailed account concerning how relationship disruptions heighten vulnerability to depression and why these effects may be particularly robust in certain youth (e.g., girls, those with heightened investment in relationships) at certain stages (e.g., adolescent transition) as well as the processes through which depression and associated characteristics contribute to subsequent interpersonal stress (for reviews, see Hammen, 2009; Rudolph, 2009). The field would benefit from the articulation of similar conceptual models guiding assertions about the contribution of interpersonal stressors to other forms of psychopathology. Rigorous prospective and multiwave research designs then will be needed to systematically test these models, including explicit exploration of the pathways through which early social adversity and proximal interpersonal stressors are translated into long-term risk. This research would be aided by systematic quantitative summaries of the field. Future research also will need to take a developmentally sensitive approach that considers whether the adverse mental health consequences of stressors emerge, intensify, or even subside at certain life stages as well as when and how sensitivity to

stress stemming from early adversity represents an asset that confers benefits for development; this research can take advantage of exciting developments in neuroscience that provide insight into how stress exposure interfaces with normative changes in brain development to trigger psychopathology. Finally, interpersonal stress theory and research would benefit from a careful consideration of how early and recent stressors intersect with other domains of risk or resilience, as embodied in various theoretical models (e.g., stress amplification, plasticity, stress sensitization, stress inoculation), to predict psychopathology or even positive youth development.

INTERSECTION BETWEEN INTERPERSONAL THEORIES AND ALTERNATE THEORIES OF PSYCHOPATHOLOGY

Considering how interpersonal vulnerability is linked to other domains of risk (genetic, biological, cognitive, and contextual) can advance the field's understanding of multifinality in developmental pathways as well as clarify the processes through which interpersonal vulnerability contributes to psychopathology. Although our discussion of individual theories inevitably alluded to both moderators and mediators of the consequences of interpersonal experiences, this section provides a more integrative summary of key theories.

Moderators of the Impact of Interpersonal Relationships on Psychopathology

As reflected in our previous discussions, many interpersonal theories form the basis for predicting that interpersonal disruptions can foster diverse forms of psychopathology. In some cases, predictions about specific outcomes may lie in distinguishing particular dimensions of risk (e.g., overprotective parenting that elicits heightened vigilance vs. rejecting parenting that undermines self-worth). In other cases, it is difficult to predict the precise outcomes. To understand individual differences in emerging risk, it is therefore necessary to consider which youth under which conditions will show which forms of psychopathology (or resilience). Throughout the description of individual theories, we mention such possibilities. Here we briefly describe two levels of moderating factors—the molecular (genes and their expression) and the molar (culture and its expression)—that may determine how interpersonal risk is translated into particular outcomes.

Molecular-Level Moderators—Genes and Their Expression

At the molecular level, genes may moderate the contribution of interpersonal environments to psychopathology, conforming to a vulnerability model (genes heighten sensitivity at high levels of interpersonal risk), plasticity model (genes make youth more susceptible to both positive and adverse interpersonal environments), stress-sensitization model (genes sensitize youth such that they require lower levels of interpersonal risk to express psychopathology), or stress-inoculation model (genes bolster resilient outcomes in the face of stress). Identifying specific genetic markers of risk for psychopathology has been a subject of great debate; regardless of the empirical yield of this approach, it reveals little about the processes involved in the development of disorders. Contemporary theoretical models are therefore turning to a focus on endophenotypes—or intermediate level biological, neural, or psychological characteristics—through which genetic risk is translated into psychopathology.

As one example, a polymorphism in the serotonin transporter gene, which moderates the impact of interpersonal risk (e.g., family and peer maltreatment and stress) on depression (Benjet, Thompson, & Gotlib, 2010; Cicchetti, Rogosch, & Sturge-Apple, 2007) and aggression (Brendgen et al., 2008), also is associated with cognitive risk (e.g., biased information processing; Beevers, Wells, Ellis, & McGeary, 2009), biological risk (e.g., HPA reactivity; Gotlib, Joormann, Minor, & Hallmayer, 2008), and individual differences in temperament (e.g., negative emotionality; Pauli-Pott, Friedl, Hinney, & Hebebrand, 2009); these endophenotypes in turn directly moderate the contribution of interpersonal risk to psychopathology (Brendgen, Wanner, Morin, & Vitaro, 2005; Rudolph, Troop-Gordon, & Granger, 2011; Sugimura & Rudolph, 2012). Moreover, there is some tantalizing indication of plasticity genes, which account for differential susceptibility to both adverse and positive environments, although more evidence is needed (Rutter, 2014). Scientists also have identified both genetic variability and specific neural profiles that heighten susceptibility or resistance to peer influence, either amplifying or dampening risk for psychopathology (Brechwald & Prinstein, 2011).

Essentially, genes and their expression can influence how individuals encode, interpret, and react to interpersonal experiences, thereby altering their impact on development. Comprehensive interpersonal theories of psychopathology therefore increasingly consider genetic variations—and perhaps more importantly, their accompanying endophenotypic implications—in how interpersonal adversity is translated into risk for psychopathology.

Molar-Level Moderators—Culture and Its Expression

At the other extreme, broad contextual features of individuals' environments may moderate the association between interpersonal factors and psychopathology by determining the meaning attributed to particular social interactions and relationships. Culture shapes individuals' expectations regarding the normativeness of particular experiences. Attribution theory (Dodge, 2006) posits that individuals' interpretations of behavior are dependent on how frequent the behavior is within a culture as well as a culture's relevant laws, customs, and ideology. Individuals who perceive themselves as experiencing non-normative compared to normative relationships are more likely to personalize an attribution about the experience, thereby heightening their risk for psychopathology (Lansford et al., 2005).

Bornstein (1995) proposed a model differentiating the forms of parenting (i.e., specific behaviors of parents toward children) and the functions of parenting (i.e., the meaning imparted to children). On the one hand, a given form of parenting can serve different functions depending on the cultural context (e.g., parents' derogatory comments about a child may convey hostility in most cultures but love in cultures where they are viewed as protective; DeLoache & Gottlieb, 2000). On the other hand, different forms of parenting can serve the same function (e.g., parents may use direct, such as physical affection and praise, vs. indirect, such as food preparation, behaviors to convey warmth; Bornstein, 1995). Thus, the meaning of particular parent–child interactions and their implications for children's development depend on the cultural context.

In part, cultural meanings are dependent on overarching goals of individuals within the cultural group (Pomerantz & Wang, 2009). For example, despite the documented association between authoritative parenting and optimal development, authoritarian parenting may be more adaptive for children in some cultural groups. Although authoritarian parenting is associated with European American children's fearful behavior, it is associated with African American girls' assertiveness (Baumrind, 1972). Grusec, Rudy, and Martini (1997) theorized that in collectivist cultural groups, in which the needs of the group are given primacy over individual needs, authoritarian parenting may be more adaptive. In such cultural groups, authoritarian parenting is associated with less negative parental affect and cognition than in individualist cultural groups, suggesting that the association between parenting style and children's adjustment depends on the larger cultural context in which families are situated (Rudy & Grusec, 2006).

Similar principles apply to understanding the impact of cultural norms and values on peer-psychopathology linkages. For example, shyness and inhibition relate to psychopathology in Western cultures but to positive indicators of adjustment in China (for a review, see Chen et al., 2014). The conceptual model invoked to explain these differences proposes that the consequences of particular social behaviors depend on how those behaviors fit into patterns that are positively valued within a cultural context. In China, where children's dependence, inhibition, and self-restraint are valued, a child who behaves in a shy or sensitive manner will be regarded more positively than would such a child in a Western culture that values independence and self-expression; in turn, children will be less likely to proceed along a pathway to psychopathology in a cultural context that is consistent with their exhibited behaviors. Of interest, as China has become more Westernized, these cultural differences have diminished (Chen et al., 2014).

Mediators of the Impact of Interpersonal Relationships on Psychopathology

Although the field has witnessed enormous strides in documenting the insidious effects of interpersonal adversity on psychopathology, considerably less is known about how or why this process occurs—that is, the oft-cited question of How do social experiences get under the skin? Most interpersonal theories of psychopathology incorporate ideas about candidate pathways through which social disruption creates risk for psychopathology. Specific pathways are discussed as relevant throughout earlier sections of the chapter; in this section we highlight some of the common themes on which these theories converge.

Biological Pathways

As discussed earlier, development programming theories propose that biological systems adapt to environmental demands, resulting in potentially enduring changes in brain organization (Boyce & Ellis, 2005; O'Connor, 2003). Although potentially adaptive in the short-term, through the process of entraining (Boyce & Ellis, 2005) altered biological systems may constrain possible future developmental pathways followed by youth exposed to early stress, thereby launching them onto trajectories of psychopathology. A notable trend in the field is to explore this biological embedding of experience as a risk mechanism (Bush & Boyce, 2014; Rutter, 2014).

Broadly, many contemporary theories share in common the notion that severe or chronic exposure to social

adversity—including insecure attachment, parent psychopathology, toxic family environments, parent and peer maltreatment, and early social deprivation—taxes physiological systems (e.g., HPA axis, autonomic nervous system, immune system) involved in maintaining homeostasis, thereby intensifying or attenuating their sensitivity. These potentially enduring changes in biological systems underpinning emotion regulation, stress reactivity, and cognitive self-regulation can eventuate in psychopathology (for reviews, see Cicchetti & Rogosch, 2012; Davies & Sturge-Apple, 2014; Esposito & Gunnar, 2014; Goodman & Brand, 2009; Pollak, 2008). Indeed, the recent explosion of theory and research linking social experiences with biological processes has spawned the newly emerging field of social affective neuroscience. Likewise, the field of epigenetics is beginning to unravel how interpersonal experiences guide individual differences in the biological and phenotypic expression (or silencing) of genes (Meaney, 2010).

As one example, social pain theory (Eisenberger, 2012) suggests intriguing possibilities for one biological pathway through which interpersonal adversity is internalized as risk for psychopathology. Building on the idea that social bonding and belonging serve a vital evolutionary role in human well-being, social pain theory suggests that threats to these social needs trigger activation in the same neural circuitry as that underlying physical pain. Supporting this theory, experimental exposure to social injury (e.g., loss, exclusion, rejection, negative social evaluation) activates the dorsal anterior cingulate cortex (dACC) and anterior insula, areas implicated in the affective component of physical pain. Suggesting the importance of individual differences in social orientation, perhaps shaped by past experience, these effects are heightened for individuals with high rejection sensitivity and an anxious attachment. A complementary line of research reveals that the experience of being liked by others activates neural regions involved in reward motivation (Davey, Allen, Harrison, Dwyer, & Yucel, 2010). Moreover, individuals who report feeling more rejected in their everyday social interactions show more social pain (Eisenberger, Gable, & Lieberman, 2007) whereas a history of engagement in positive social experiences protects against social pain (Masten et al., 2010). Collectively, this research suggests that stressful or supportive interpersonal experiences can be instantiated in specific patterns of neural function, which can confer risk for, or protection against, psychopathology. Contemporary theories also suggest social rejection can lead to activation of stress–response systems (HPA and sympathetic-adrenal-medullary axis) and a pattern of pro-inflammatory processes that heighten risk for psychopathology (Slavich et al., 2010), providing promising leads for future research.

Building on the historical work of Harlow (Harlow & Zimmerman, 1959), another fascinating line of research focuses on meaningful differences in the biological profiles of nonhuman primates reared under adverse social conditions (i.e., those that threaten healthy attachment, such as being reared by mothers who are under stress, abusive/rejecting mothers, or peer age-mates). Monkeys raised under these conditions demonstrate dysregulation of the HPA axis (both heightened and blunted reactivity), atypical patterns of neurotransmitter metabolism and cerebral blood flow, and differences in growth hormone levels and immune response. Notably, these atypical biological profiles are linked to behavioral indexes of compromised social and mental health, including poor relationships with age mates (less social affiliation, more affective withdrawal, more subordinate behavior), heightened manifestations of emotional distress and anxiety, impulsive and aggressive behavior, and alcohol tolerance. Of interest, the adverse biological and behavioral consequences of early social experience appear to be moderated by genetic variation, such that only monkeys with certain genetic profiles show these effects (for a review, see Suomi, 2008).

Despite these groundbreaking advances, far less effort has been dedicated to documenting directly (through longitudinal studies of mediation) whether socially driven biological reorganization accounts for the mental health consequences of early social adversity. Moreover, the possibility of rGE correlations and epigenetic effects lends further complexity to theoretical models, as experiences thought to independently create changes in the brain may themselves be constructed through evocative or active genetic effects on the environment or may merely activate underlying genetic propensities toward biological dysregulation, calling for research designed to tease apart these alternative developmental processes.

Social-Cognitive Pathways

Diverse theoretical perspectives share the proposition that social-cognitive processes serve as long-term carriers of early interpersonal experience and as potential vehicles of risk for psychopathology. Common across these perspectives is the notion that individual differences in cognitive formulations of the social world find their roots in past interpersonal experiences. Prior experiences are believed to be transformed into abstract, intrapsychic representations, variously described as internal working models (Bowlby, 1980), cognitive-interpersonal schemas (Baldwin,

1992), or mental databases (Crick & Dodge, 1994). These cognitive-affective structures, which incorporate beliefs and evaluations about the self and others, are encoded in memory early in life and become increasingly intransigent over time. As they consolidate, they become a lens through which future interpersonal experiences are encoded, interpreted, and retrieved, thereby coloring individuals' perceptions and expectations about themselves and their social worlds. When formed in the context of stressful interpersonal experiences, these mental models presumably foster adverse responses to the environment and a consequent vulnerability to psychopathology. Indeed, maladaptive social-cognitive processes are implicated in theories of many forms of psychopathology, including depression, anxiety, and aggression/antisocial behavior.

According to cognitive theories of depression, risky early family environments (e.g., insensitive caregiving, interpersonal loss, maltreatment, parent psychopathology) foster mental models of the self as incompetent, unlovable, and helpless and of the world as hostile (for reviews, see Abela & Hankin, 2008; Gibb & Coles, 2005; Rudolph & Flynn, 2014). These maladaptive schemas may take one of two forms. Autonomous (Beck, 1987) or self-critical (Blatt & Homan, 1992) individuals adopt perfectionistic standards and suffer from fears of criticism, inferiority, and failure. Sociotropic (Beck, 1987) or dependent (Blatt & Homan, 1992) individuals adopt feelings of helplessness and suffer from fears of loss, rejection, and abandonment. These schemas are believed to create vulnerability to depression in the face of relevant life stressors (e.g., failure vs. rejection). Cognitive theories of anxiety assert that exposure to uncontrollable social experiences or adverse family contexts (e.g., insecure attachment, overprotective parenting) foster mental models characterized by low self-efficacy and vigilance to threat (Kerns, 2008; Nolte, Guiney, Fonagy, Mayes, & Luyten, 2011). Cognitive theories of aggression postulate that family adversity (e.g., harsh parenting, maltreatment) and peer adversity (e.g., rejection) are internalized as social information-processing biases characterized by hostile processing of social cues and deviant social goals (Dodge, Bates, & Pettit, 1990). Collectively, these theories presume that social-cognitive schemas and associated information processing biases become engrained over time and modulate how individuals react to future social experiences, serving as proximal contributors to psychopathology.

Despite the prevalence of theories suggesting that early interpersonal experiences shape social-cognitive processes, there is evidence for genetic, biological, and temperamental contributions to cognitive biases (Dodge & Pettit, 2003; Hammen et al., 2014; Nolte et al., 2011). Future theory development and validation must therefore consider the extent to which a common genetic liability underlies exposure to stressful interpersonal experiences, maladaptive social-cognitive processes, and particular forms of psychopathology as well as how genetic and environmental factors independently or interactively contribute to social-cognitive risk processes.

Emotion Pathways

Emotion processing can be construed as a range of processes involved in the recognition, understanding, regulation, and expression of emotional cues (Pollak, 2008). Difficulties processing and regulating emotions lie at the core of psychopathology. Efforts to understand the interpersonal origins of such difficulties have focused on identifying how social adversity shapes psychological, neural, and biological processes central to emotional experience, which in turn serve as proximal risks for disorder.

At a phenomenological level, relationships are thought to shape emotions through both explicit and implicit pathways. Emotional tendencies may be directly transmitted from parents to offspring through modeling (e.g., emotional contagion), instruction (e.g., scaffolding and socialization of emotion), and reinforcement (Davies & Sturge-Apple, 2014), creating an avenue for the intergenerational transmission of psychopathology (Abaied & Rudolph, 2014; Vasey et al., 2014). Interpersonal experiences also may indirectly foster certain patterns of emotion regulation and expression. Attachment theory provides one prototype of this process. The attachment relationship is presumed to provide children with a context in which they learn strategies for identifying, regulating, and expressing emotions. Avoidant attachment confers a tendency toward deactivating responses to stress, in which youth suppress negative emotions, whereas anxious attachment involves a tendency toward hyperactivating responses to stress, in which youth amplify outward signals of distress (Weinfield et al., 2008). Insecure attachment and problematic family environments (e.g., conflict exposure) also may undermine youths' emotional understanding and sense of emotional security (Davies & Sturge-Apple, 2014; Thompson, 2008). These maladaptive patterns of emotional experience and regulation can coalesce into psychopathology (Abaied & Rudolph, 2014; Davies & Sturge-Apple, 2014).

Adverse interpersonal experiences also alter sensory thresholds for the processing of emotion. Youth exposed to maltreatment show heightened sensitivity to facial cues of anger (but not other emotions), suggesting their emotion

processing systems become attuned to cues that are salient within their unique interpersonal contexts (Pollak, 2008). This perceptual salience influences attention control processes involved in emotion as reflected in rapid orienting to, and delayed disengagement from, anger cues. Perceptual sensitivity to threat cues, hypervigilance, and associated self-protective emotional processes also may emerge in other risky family contexts (Davies & Sturge-Apple, 2014). In turn, cognitive regulatory biases in emotion processing (e.g., heightened attention to anger cues and diminished attention to fear and sadness cues) may serve as proximal risks for aggression and antisocial behavior. In a similar fashion, youth exposed to maternal depression show emotion processing biases characterized by selective attention to negative versus positive facial expressions, a pattern that likely places these youth at risk for depression (Joormann, Eugene, & Gotlib, 2009).

Social adversity also can contribute to risk for psychopathology by undermining developing neural circuitry guiding emotion regulation and processing (for a review, see Gunnar, 2010). Youth exposed to stressors such as maltreatment and parent psychopathology show characteristic differences in the neuroanatomical and neurophysiological substrates of emotion that presage risk for psychopathology. Maltreated youth display smaller prefrontal cortex and right temporal lobe regions, disrupted neural processing of emotional stimuli, heightened autonomic reactivity to conflict, and atypical patterns of hormones involved in stress reactivity and affiliative bonding, all differences with potential implications for emotion processing and responding; monkeys raised in isolation show decreased white matter in parietal and prefrontal cortices, areas linked to emotional modulation (for reviews, see Cicchetti & Banny, 2014; Pollak, 2008). Offspring of depressed mothers show dysregulation of the HPA axis, which in turn predicts subsequent youth depression, and atypical activation in brain regions (e.g., amygdala, nucleus accumbens, prefrontal cortex) associated with emotion regulation (for a review, see Joormann et al., 2009).

From a developmental perspective, understanding emotional pathways linking interpersonal experience and psychopathology becomes particularly important during adolescence, a stage marked by notable changes in the neural and cognitive systems underlying emotions (Lewis, Lamm, Stieben, & Zelazo, 2006) along with increases in many forms of psychopathology. Moreover, it is important to consider that emotional sensitization may change across development, as chronic exposure to stressful interpersonal experiences can eventually result in habituation of psychological and biological response systems and consequent inhibition of reactivity (Davies & Sturge-Apple, 2014). Thus, profiles of emotional risk may shift across development with ongoing exposure to social adversity. Long-term research must track the emotional consequences of social adversity over time to determine whether effects are enduring and crystallize into identifiable forms of psychopathology.

Summary

This section summarizes several intermediary processes that can serve as mechanisms through which exposure to social adversity crystallizes into psychopathology across development. Despite supportive circumstantial evidence (i.e., social adversity predicts disruptions in biological, social-cognitive, and emotional processes; these disruptions instill risk for psychopathology), definitive tests of these models need to directly examine the proposed mediational pathways and to evaluate potential changes in the transactions among social risk, mediators, and psychopathology across development. To determine the strength of psychosocial transmission of risk, research also needs to sort out the rGE correlations and epigenetic effects that could account for linkages between the social environment and mediating processes.

DISORDER-SPECIFIC INTEGRATIVE INTERPERSONAL THEORIES OF PSYCHOPATHOLOGY

Despite the insights afforded by the aforementioned interpersonal theories, each solves only one piece of the multifaceted puzzle of psychopathology. Embracing the defining axioms of developmental psychopathology, integrative interpersonal theories consider how risk and protective factors within youth and their environments along with relevant moderators and mediators contribute through additive, multiplicative, and transactional processes to trajectories of risk or resilience across contexts and over time. Integrative developmental models also consider how risk evolves across different stages, determining the timing of onset and trajectories of psychopathology at certain points in the life course. Although the literature is rich with many integrative models of developmental psychopathology, we focus selectively on those that have a core interpersonal component. Given their abundance in the literature, we present integrative models of three groups of disorders: depression, anxiety, and externalizing psychopathology.

Integrative Interpersonal Theories of Depression

In many ways, it is difficult to disentangle youth depression from the interpersonal context in which it evolves. Although the depressive syndrome incorporates many subjective and internal experiences—such as sadness, boredom, low self-worth, concentration difficulties, and fatigue—these symptoms often are expressed within, and intricately linked to, interpersonal interactions and relationships. Indeed, depressed youth experience a wide assortment of personal deficits and social disturbances that illustrate the interpersonal nature of the disorder (for reviews, see Rudolph, 2009; Rudolph et al., 2008). Their self-views are marked by feelings of social inadequacy and perceived rejection; significant others also view them as lacking in key social skills and as undesirable relationship partners. Moreover, depressed youth often encounter either overt conflict and rejection or social isolation. Given these many forms of social disruption, it is not surprising that contemporary theory and research on youth depression incorporate a strong interpersonal focus. Because interpersonal models have their grounding in early clinical and research perspectives on adult depression, we briefly describe these pioneering theories and then explore developmentally sensitive adaptations and extensions.

In one of the first cohesive interpersonal theories of depression, Coyne and colleagues described a "depressive social process" (Coyne, 1976, p. 187) wherein depression-linked characteristics and behaviors disrupt social relationships by eliciting negative responses from social network members, which contribute to the onset, maintenance, and recurrence of depression (Joiner & Timmons, 2009). The process begins when depressed individuals seek encouragement and reassurance of their worth. Because of their low self-worth and skepticism, depressed individuals question the encouragement and reassurance provided by others and thus they continue to seek reassurance. Failure to accept offered support eventually causes frustration and rejection by relationship partners. As depressed individuals observe inconsistencies between others' reassurances of support and their rejecting behavior, depressive symptoms increase. An ongoing cycle emerges, fueled by continued rejection and validation of negative self-views accompanied by ensuing intensification of depressive symptoms.

Paradoxically, depressed individuals also engage in negative feedback seeking, a process wherein they explicitly seek out negative feedback and criticism. According to self-verification theory (Swann, 1990), individuals are motivated by a need to maintain consistent self-views, causing them to seek information that confirms these views. In the case of depressed individuals, they elicit feedback consistent with their negative self-schemas, perhaps by affiliating with people who evaluate them negatively, despite the potential pain they experience when this feedback is provided (Swann, Wenzlaff, Krull, & Pelham, 1992). Of course, this negative feedback undoubtedly reinforces their low self-worth. Thus, the continuity of depression can be explained by a "self-propagatory process" (Joiner & Timmons, 2009, p. 332), wherein behavioral manifestations and consequences of depressive symptoms elicit maintaining responses from the environment (rejection, withdrawal of social support, negative feedback), which lengthen episodes and trigger recurrence of symptoms.

This pioneering theory, along with its extensions (Joiner & Timmons, 2009) and intellectual relatives (e.g., Hammen, 2006), provide a useful grounding for understanding the interpersonal context of youth depression but are constrained by their adevelopmental focus. Specifically, they fail to (1) articulate the origins of interpersonal vulnerability; (2) consider which interpersonal processes are relevant during particular life stages; and (3) elucidate how normative developmental changes interact with individual differences in interpersonal traits and experiences to account for the emergence of depression. To address these conceptual lacunae, recent developmentally sensitive interpersonal theories offer several innovations. First, these theories provide dynamic frameworks that consider how complex interactions and transactions among youth and their social contexts contribute to the emergence and expression of interpersonal vulnerability over time. Second, they consider how the interpersonal antecedents and consequences of depression crystallize during developmentally salient stages, particularly the transition through adolescence, with a focus on how normative challenges set the stage for interpersonal vulnerability to depression. In this vein, these theories address two well-established developmental features of depression: the surge in depression and the emergence of a sex difference in depression during adolescence. Third, interpersonal theories of youth depression clearly account for continuity in depression over time, explaining how characteristics of depressed youth shape their social contexts in ways that perpetuate and exacerbate symptoms in the short- and long-term.

Nolen-Hoeksema and Girgus (1994) provided one of the first broad frameworks for understanding the emerging sex difference in depression across adolescence. According to this framework, girls carry greater vulnerability than boys prior to adolescence; this vulnerability interacts with girls' heightened exposure to challenges relative to boys during adolescence to predict a sharper surge in

depression. Although this framework focuses on a broad range of vulnerabilities and adolescent challenges, personal and contextual influences of an interpersonal nature (e.g., interpersonal orientation, exposure to social challenges such as sexual abuse) assume a central position (see also Nolen-Hoeksema, 2001).

Two other theories focus on more precise interpersonal processes through which sex-linked vulnerability to depression unfolds across the adolescent transition. Cyranowski, Frank, Young, and Shear (2000) highlighted how girls' affiliative needs, driven by both social and hormonal forces, interact with social challenges during the transition to foster depression in at-risk females. Similarly, Rudolph (2002) suggested that girls' heightened exposure to, generation of, and reactivity to interpersonal stress contribute to the emergence and maintenance of a sex difference in depression during adolescence. Female-linked relational orientation styles (e.g., a heightened psychological and emotional investment in relationships) are presumed to account in part for the sex difference in stress reactivity and depression. These two models shed light on interpersonal vulnerability in adolescent girls but are somewhat limited in scope.

Considering a wider spectrum of interpersonal vulnerabilities and challenges, Rudolph and colleagues (Rudolph, 2009; Rudolph et al., 2008) recently offered a broader developmentally based, interpersonal model explaining the emergence of depression and the sex difference therein during adolescence (Figure 7.2). This model proposes that early family adversity (e.g., insecure parent–child attachment, parental depression, maltreatment) fosters the development of maladaptive appraisals of relationships and social-behavioral deficits. These appraisals and deficits heighten vulnerability to depression, particularly in the face of relationship disturbances, and cause youth to generate stress in their existing relationships and to select into more stressful social contexts. The contributions of maladaptive relationship appraisals and social-behavioral deficits to depression are intensified during the passage through adolescence, especially in girls, due to accompanying maturational changes. Finally, depression exacerbates interpersonal dysfunction, accounting for the continuity of depression over time.

Within this model, maladaptive relationship appraisals are conceptualized as negative conceptions of relationships (negative perceptions of self and others,

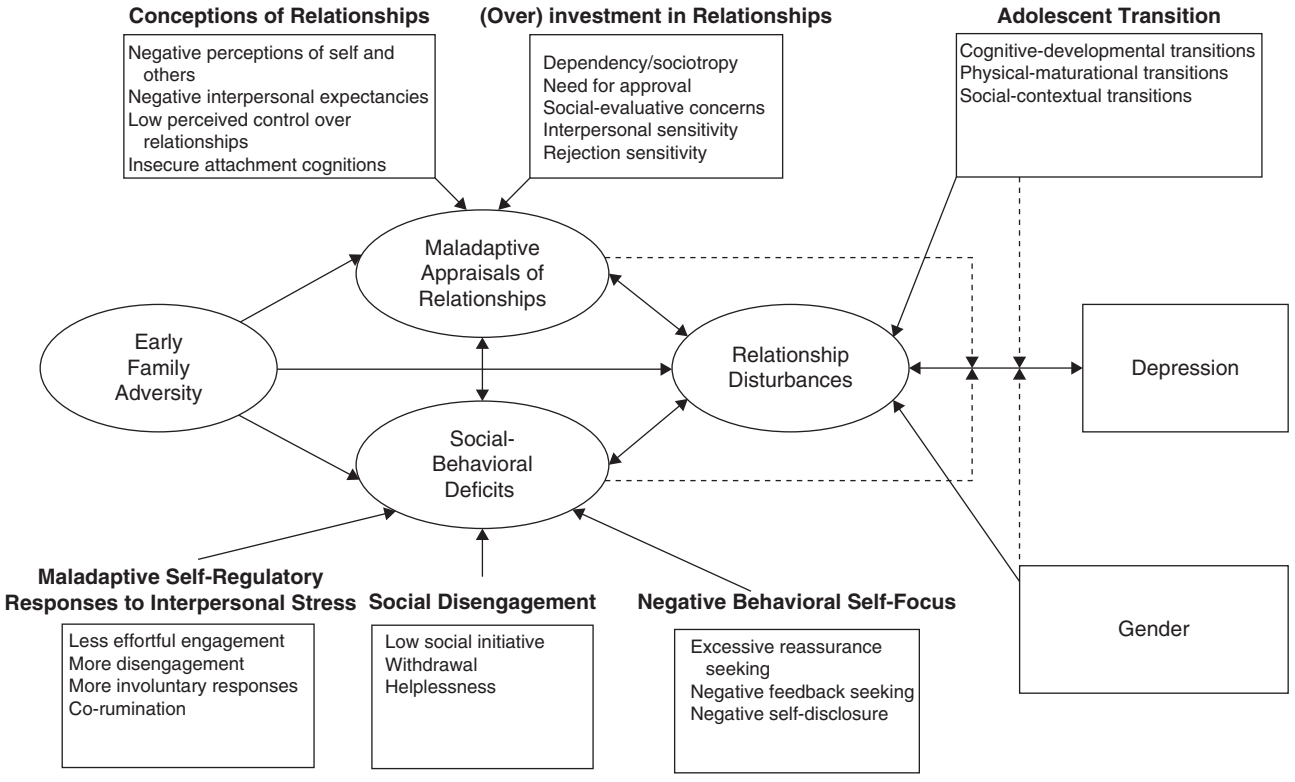

Figure 7.2 Theoretical model of the interpersonal context of adolescent depression. *Source:* Reprinted from K. D. Rudolph, The interpersonal context of adolescent depression, in S. Nolen-Hoeksema & L. M. Hilt (Eds.), *Handbook of depression in adolescents (*pp. 377–418), New York, NY: Routledge, 2009.

pessimistic interpersonal expectancies, low perceived control over relationships, and insecure attachment cognitions) and an overinvestment in relationships (dependency/sociotropy, need for approval, social-evaluative concerns, and interpersonal/rejection sensitivity). Social-behavioral deficits are conceptualized as maladaptive self-regulatory responses to interpersonal stress (less effortful engagement and more effortful disengagement; involuntary, dysregulated responses; and co-rumination), social disengagement (low social initiative, withdrawal, and helplessness), and a negative behavioral self-focus (excessive reassurance seeking, negative feedback seeking, and negative self-disclosure). Relationship disturbances include low social status (e.g., less peer acceptance and more peer rejection), negative responses from interaction partners, poor friendship quality, disturbances in romantic and family relationships, and general interpersonal stress.

Despite having some roots in interpersonal theories of adult depression, this model departs from these theories in several ways. First, it incorporates the direct and indirect effects of maladaptive relationship appraisals, proposing that they help to account for the generation of stress and conflict in relationships and they moderate the effect of relationship disturbances on depression. Second, this model focuses on developmentally salient interpersonal processes, emphasizing those particularly relevant to girls' increasing risk relative to boys across adolescence (e.g., social-evaluative concerns and interpersonal sensitivity). Third, this model articulates how the social-contextual, physical-maturational, and cognitive-developmental transitions of adolescence intensify interpersonal vulnerability and depression, particularly in girls, during this stage. Specifically, it is proposed that the following changes trigger depressive symptoms in youth with prior interpersonal vulnerability: (1) broader and more proximal changes in social contexts (e.g., school transitions, increasing individuation from the family and immersion in the peer group, entrance into romantic relationships); (2) physical, psychological and social effects of puberty (e.g., hormonal changes, alterations in self- and other-perceptions, changing social roles and stressors); and (3) advancing cognitive abilities (e.g., heightened social comparison, generalization across situations and time, and perspective taking). Each of these transitions is presumed to pose particular challenges to girls, who experience more social challenges, more adverse effects of puberty, and heightened investment in the quality of relationships and judgments of others. Finally, this model considers how, in developing youth, symptoms can create proximal disturbances in relationships as well as long-term interpersonal scars that threaten future development and adaptation (Rudolph, 2009).

Hammen and colleagues (2004) proposed a model describing interpersonal processes that account for the intergenerational transmission of depression. This model focuses on the stressful family environment associated with maternal depression and its consequences for youths' interpersonal functioning. In particular, maternal depression manifests in interpersonal stress and poor parenting in mothers; through modeling and socialization processes, offspring develop social deficits that precipitate their generation of stress within relationships; these deficits and stressors serve as proximal predictors of youth depression.

Taking a broader perspective, Cicchetti and Toth (1998) presented an integrative ecological transactional model of depression that incorporates the interface among multiple biological, psychological, and social systems. This model espouses an organizational approach to development, considering how challenges to the achievement of four stage-salient tasks (biological regulation, affective differentiation and modulation of arousal and attention, secure attachment and positive representational models, and a healthy self-system) along with predisposing genetic characteristics increase the likely emergence of a depressotypic organization. Interpersonal themes permeate this model, as reflected in the prominent role of parent–child interactions in guiding adaptation within each of these domains and the potential enduring pernicious effects of biological, affective, and psychological disruptions on the development of adaptive interpersonal relationships. Moreover, the emergence of depression is considered within the context of the microsystem (family transmission of psychopathology and other stressors in family relationships), exosystem (school and community contexts), and macrosystem (e.g., cultural values and beliefs).

Integrative Interpersonal Theories of Anxiety

Traditional etiological theories of anxiety focused on intrapersonal (e.g., cognitive, affective, behavioral, physiological, and genetic) processes; yet, like depression, many symptoms of anxiety manifest within an interpersonal context and undoubtedly influence youths' interpersonal relationships. In some anxiety disorders (e.g., social phobia), interpersonal dysfunction is a fundamental feature; in others, interpersonal worries may be a central characteristic (e.g., generalized anxiety disorder) or symptoms may prevent the development of healthy relationships or cause tension within existing relationships (e.g., separation

anxiety disorder, agoraphobia). Indeed, anxious youth experience many social disturbances, including problems in parent–child relationships, social withdrawal and avoidance, fear of rejection, lower levels of peer acceptance, and peer exclusion and victimization (for reviews, see Davila et al., 2010; La Greca & Landoll, 2011). The interpersonal context of anxiety may become particularly salient during formative stages, such as the adolescent transition, when relationships become more diversified, complex, and challenging.

One recent model (Murray et al., 2009) considers the interactive influences of (1) genetic and biological vulnerability (expressed in the form of temperamental behavioral inhibition as well as information processing biases, such as attentional bias to threat and biased interpretation of ambiguous information); (2) exposure to adverse life events that heighten perceptions of threat and dampen perceptions of control; (3) parental anxiogenic modeling, instruction, and transfer of information about threat; and (4) parenting characterized by overinvolvement and discouragement of autonomy. These risk factors are thought to stem, in part, from parental anxiety, accounting for the intergenerational transmission of disorder. However, the model also assumes transactional processes wherein parental behaviors are elicited by pre-existing vulnerabilities in youth, a process that is particularly likely in families with anxious parents.

Another contemporary model (Nolte et al., 2011) provides a compelling multidisciplinary developmental framework integrating attachment and parenting theories of anxiety with perspectives drawn from the fields of social neuroscience, genetics, and neurobiology (Figure 7.3). At the core of this framework lie stress-regulatory strategies that enhance reactivity to threat-related cues and experiences. These individual styles of threat response and stress regulation are believed to develop and continuously operate within the context of caregiving experiences as instantiated in attachment relationships. Thus, attachment experiences are viewed as an organizational system that modulates the expression of genetic/temperamental, epigenetic, and environmental risks for anxiety.

In particular, attachment relationships characterized by inconsistency and unpredictability in caregivers and anxious-ambivalent attachment in offspring drive hyperactivation in the child, as reflected in an overly sensitive HPA axis and allostatic overload, altered fronto-limbic neural circuitry, attentional bias to threat, low personal agency, poor mentalization (ability to perceive the mental states of others), and hypervigilance; this hyperactivating profile compromises youths' ability to accommodate to future stressors, setting the stage for anxiety. This model also addresses the intergenerational transmission of anxiety, proposing that parents' own anxiety-prone risk profile—characterized by low social support, insecure

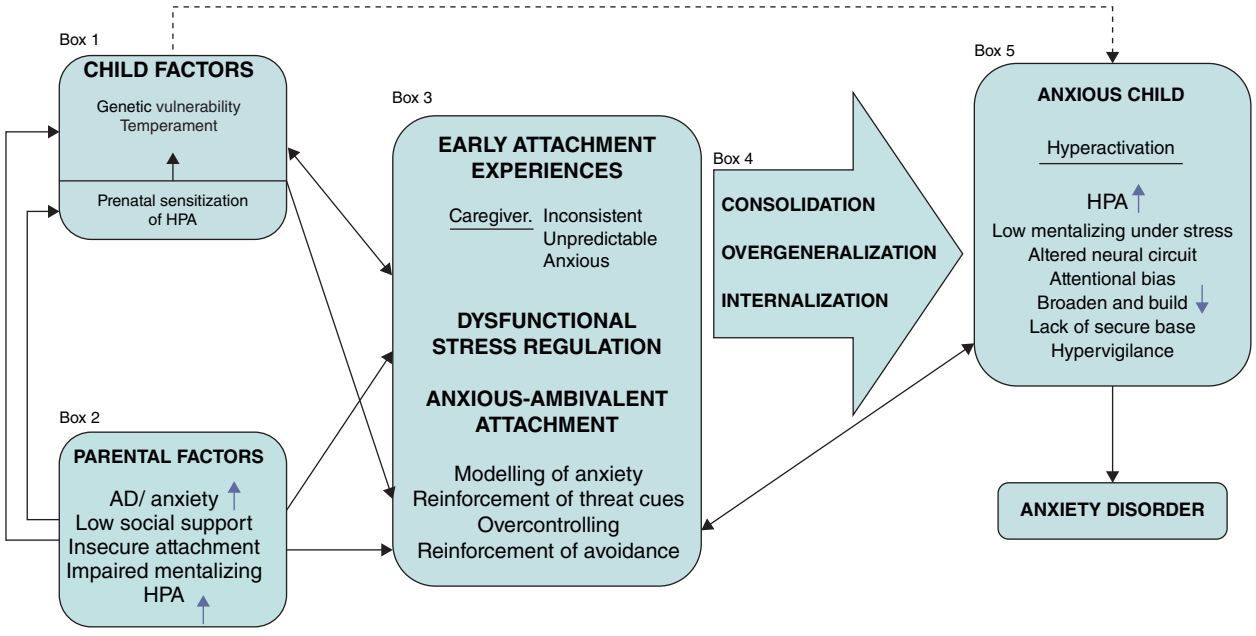

Figure 7.3 A developmental model of the attachment-moderated interaction of risk factors in the development of anxiety disorders. See footnote 1. *Source:* Reprinted from T. Nolte, J. Guiney, P. Fonagy, L. C. Mayes, & P. Luyten, Interpersonal stress regulation and the development of anxiety disorders: An attachment-based developmental framework, *Frontiers in Behavioral Neuroscience, 5*, 1–21, 2011.

attachment, impaired mentalization, and heightened HPA reactivity—interferes with adaptive parent–child co-regulation of distress and drives the development of poor self-regulation in offspring. Moreover, maternal anxiety may influence the developmental programming (i.e., sensitization) of the HPA axis through its effects on maternal stress and ensuing levels of prenatal cortisol. This constitutionally based reactivity in offspring interacts with later attachment experiences and parenting styles (e.g., modeling and reinforcement of avoidance, overcontrol) to determine risk for impaired stress regulation processes.

Arising from a distinct intellectual tradition, developmental scientists offer theoretical explanations for how anxiety develops within the context of temperamental risk, maladaptive parenting practices, and ensuing compromised relationships with peers. Such models emerge from efforts to understanding the precursors and consequences of social withdrawal, particularly as motivated by shyness, inhibition, harm-avoidance, and fear. Rubin and colleagues (2009) presented one such model, wherein a cascade of transactions among youth vulnerabilities, parental responses, and peer difficulties eventuate in social anxiety and social phobia by adolescence. The cascade begins with infant temperamental risk in the form of a lowered threshold for arousal and difficulty to soothe. This temperamental style elicits vigilance and overly solicitous behavior by parents, which maintains or intensifies the child's constitutional tendency toward wariness and inhibition during the toddler and preschool years. As children enter more complex and evaluative social relationships during elementary school, the behavioral expression of this inhibition (e.g., social reticence, avoidance of peer interactions) elicits peer rejection and victimization, which reinforce social concerns, amplify withdrawal, and trigger negative self-regard (e.g., self-blame, hopelessness). Socially withdrawn youth then enter into poor quality friendships with similar peers, further inhibiting their development of adaptive social skills. Parents respond through overprotective and power-assertive behavior (e.g., discouraging independence, controlling social activities), which reinforces children's sense of insecurity and low social efficacy and interferes with their learning of coping and problem-solving skills. Ultimately, social inhibition and negative self-regard transform into social anxiety and social phobia during adolescence. Of note, this model allows for a deflection from this escalating trajectory of risk in the presence of responsive and warm parent–child relationships or school contexts (e.g., positive teacher-child relationships or classroom environment).

Integrative Interpersonal Theories of Externalizing Psychopathology

Patterson and colleagues' (1991) early versus late starter model of the development of aggressive and antisocial behavior has been one of the most influential integrative models guiding the understanding of the development of externalizing psychopathology. This model distinguishes youth whose antisocial behavior begins during childhood (early starters) versus adolescence (late starters). According to the theory, early starters are at greater risk for long-term antisocial behavior that extends into adulthood than are late starters.

This theory stresses the importance of coercive exchanges between parents and children over time in the development of aggressive behavior. These early coercive exchanges serve as a basis for early-starting antisocial behavior. Children may generalize to interactions with peers' coercive interaction styles initially learned through parent–child interactions. Many children who have experienced coercive episodes in the family have social skill deficits that contribute to rejection by peers during elementary school. Peer rejection then further contributes to early starting antisocial behavior. Patterson et al.'s (1991) model thus describes how coercive parent–child interactions and peer rejection set the stage for aggressive children (early starters) to remain chronically antisocial into adulthood.

Late starters who become antisocial during adolescence are theorized to experience poor parental monitoring and supervision, aspects of parenting that become more salient during adolescence. Poor monitoring and lack of supervision contribute to increasing involvement with deviant peers, which in turn promotes adolescents' own antisocial behavior. In contrast to early starters, late starters have developed sufficient social and academic skills so they can desist from antisocial behavior when changes in the environment make other options more appealing.

Moffitt's (1993) life-course persistent versus adolescent limited model shares several key features with Patterson et al.'s (1991) model. Both theories differentiate between the etiology of externalizing problems that begin in childhood versus adolescence, and both include family and peer risk factors for externalizing psychopathology. However, whereas Patterson's theory emphasizes coercive parenting during childhood, Moffitt's theory emphasizes early emerging neuropsychological deficits such as poor verbal skills, inattention, and impulsivity. These characteristics make children more difficult to parent; in environments of risk and adversity, parents may lack the psychological and physical resources to manage a difficult child.

In Moffitt's theory, this dual risk of a difficult child situated in an adverse environment lays the foundation for life-course-persistent antisocial behavior. When these children enter school, they often struggle academically and socially, furthering their risk for the development of externalizing problems.

In contrast to Patterson et al.'s (1991) focus on poor parental monitoring and supervision along with deviant peer affiliation as the driving forces behind late starting antisocial behavior, Moffitt (1993) regarded adolescent-limited antisocial behavior as resulting from a maturity gap between adolescents' dependence on and control by adults and their desire to demonstrate their freedom from adult constraint. However, as they continue to develop, and legitimate adult roles and privileges become available to them, there are fewer incentives to engage in antisocial behavior. Because these adolescent-limited offenders do not have the neuropsychological deficits or problematic family environments characteristic of life-course-persistent offenders, they are able to take advantage of new opportunities with the transition to adulthood. Thus, adolescent-limited antisocial behavior is regarded as resulting from normative forces to which all adolescents are exposed if they are in a maturity gap. Of note, some more recent evidence does suggest that late-starting and adolescent-limited forms of antisocial behavior may not be as innocuous as once believed, and in some cases adolescents with these profiles proceed along long-term trajectories of risk (Marmorstein & Iacono, 2005).

Both Patterson et al.'s (1991) and Moffitt's (1993) theories could be considered forms of a broader category of developmental cascade models that describe how a constellation of interpersonal and other risks unfold over time to confer risk for the development of externalizing psychopathology. For example, Dishion (2014) presented a cascade model in which defiance and self-regulation difficulties in early childhood develop into overt and covert antisocial behavior during middle childhood and into substance use, risky sexual behavior, and serious problem behaviors during adolescence. As part of this cascade, academic problems, peer rejection, and affiliation with at-risk peers during childhood along with school failure and deviant peer contagion during adolescence perpetuate and augment these cascades of externalizing problems. Poor family management, insufficient parental monitoring, and other ecological risks also contribute to the cascade. Likewise, Dodge et al. (2009) delineated a developmental cascade model for the onset of illicit substance use in which difficult child characteristics and an adverse sociocultural context contribute to early parenting problems, which lead to early child behavior problems and consequent peer adversity, which contribute to parenting problems during adolescence, which lead to adolescent peer problems and eventually to illicit substance use. In these integrative cascade models, intergenerational continuity in externalizing problems can result from genetic risk conferred by parents who themselves have externalizing problems as well as from environmental risk created by parents with externalizing problems, who are more likely to use harsh, inconsistent discipline and less likely to be warm, responsive, and sensitive.

These recent cascade models are foreshadowed by other multifactorial developmental models. For example, Greenberg and colleagues (1993) presented one early integrative interpersonal model for conceptualizing the early onset of disruptive behavior problems (see also DeKleyen & Greenberg, 2008). Focusing on multiple pathways and levels, this model includes four domains of risk: insecure attachment, ineffective parenting (e.g., harsh and ineffective discipline, lack of warmth), high family adversity (e.g., low SES, marital conflict, trauma, poor social support), and atypical child characteristics (e.g., poor executive function, temperamental reactivity). An emphasis is placed on the creation of person-centered profiles that consider how these risks combine additively or multiplicatively to determine behavioral trajectories, with the assumption that no one risk factor is necessary or sufficient for the development of psychopathology. The model also allows for early and emerging associations among risk factors, significant changes in risk status across development, and ongoing transactions between risks and disruptive behavior over time. These complex processes presumably result in multiple pathways to disorder that depend on the number, type, and combination of risk factors present and their developmental timing.

Dodge and colleagues (e.g., Crick & Dodge, 1994; Dodge et al., 1990) enriched integrative models of externalizing psychopathology by specifying the role of social-cognitive processes. Like many other integrative theories, Dodge and Pettit's (2003) biopsychosocial model (Figure 7.4) of the development of chronic conduct problems includes children's biological predispositions, the sociocultural context, parenting, and peers as risk factors for the development of conduct problems. However, their model further posits that mental processes, including social knowledge structures and social-information-processing patterns, mediate the links between these early risks and subsequent conduct problems. That is, biological predispositions, sociocultural contexts, and previous social experiences shape children's knowledge about the world in ways that have implications for their future behavior. On the basis of these knowledge structures, children

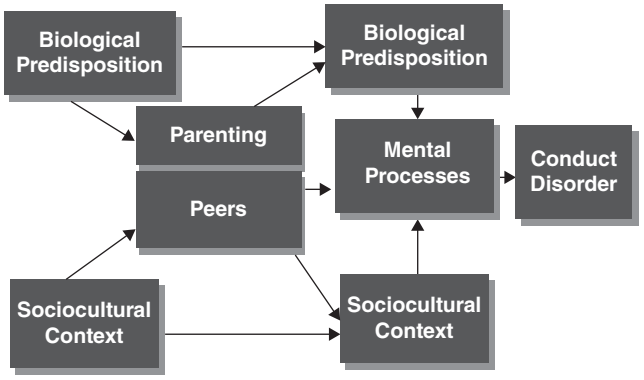

Figure 7.4 A biopsychosocial model of the development of conduct disorder. *Source:* Reprinted from K. A. Dodge & G. S. Pettit, A biopsychosocial model of the development of chronic conduct problems in adolescence, *Developmental Psychology, 39*, 349–371, 2003.

engage in a series of cognitive steps when they encounter new social stimuli, including encoding social information, making attributions about the causes of others' behavior, generating possible responses, and evaluating responses. Biases at any of these processing steps increase the risk of antisocial behavior.

Although sex differences in externalizing psychopathology are well documented (Archer, 2004), it is unclear whether etiological pathways differ for boys and girls. Patterson's theory was developed on the basis of an exclusively male sample. The sample that formed the basis of Moffit's (1993) theory included both males and females, yet the theory itself was intended as an explanatory framework for understanding the development of antisocial behavior among boys. Silverthorn and Frick (1999) reviewed the literature on the development of antisocial behavior in girls and concluded that modifications to the distinction between early and later onset of antisocial behavior may be needed. In particular, the authors concluded that girls' antisocial behavior may not emerge until adolescence, despite the presence of risk factors such as neuropsychological deficits and dysfunctional family environment that would predict childhood onset for boys. Silverthorn and Frick liken this delayed onset pathway for girls to the childhood-onset pathway for boys. Furthermore, they posit that an adolescent-onset path with relatively benign consequences (as proposed by Moffit) does not exist for girls. These interesting theoretical propositions await rigorous empirical testing.

FUTURE DIRECTIONS

Reflecting historical perspectives on the integral role of interpersonal relationships in human adaptation, the field of developmental science has long emphasized early experience within relationships as a context and a catalyst for psychological growth. It is increasingly clear that interpersonal relationships throughout childhood, adolescence, and beyond also can play an important role in individual adjustment. In a recent summary of research on resilience and positive psychology, Luthar, Lyman, and Crossman (2014) concluded that the most salient theme to emerge from these fields is the fundamental value of human relationships. If a need to belong is at the heart of psychological health and well-being, interpersonal alienation and disruption likely lie at the core of psychopathology. Indeed, this notion has permeated the field since the early writings of Freud (1916), Bowlby (1969), and many others, and continues to characterize many contemporary theories of developmental psychopathology. As such, it is now widely accepted that a variety of interpersonal perturbations can create significant obstacles to healthy development. How, then, can and should the field progress as we continue to unravel the mystery of why, how, and when psychopathology emerges, develops, and persists within interpersonal contexts? Within each of the earlier sections, we pointed out several specific areas for advancement; here we focus on more general directions that we believe should serve as a cornerstone for interpersonal theories of psychopathology in the next decade.

Developing and Testing Multilevel Conceptualizations

One of the most universally recognized and commonly cited contemporary themes in the field of developmental psychopathology is the need for multilevel conceptualizations, reflecting mounting pressure for interdisciplinary perspectives that consider the interface among biological, psychological, behavioral, and interpersonal systems of development (Cicchetti, 2008). At the risk of sounding mundane, we propose that this venture should indeed be one of the driving forces for upcoming development of interpersonal theories and for designing effective empirical investigations to test these theories.

As we briefly mention in the chapter, the field has made promising inroads into documenting gene–environment correlations and interactions as well as beginning to understand epigenetic processes within interpersonal contexts. What this means is that there is good reason to believe that genes influence both exposure and reactivity to social experiences and that social experiences influence gene expression, thus dramatically enriching our understanding of the interpersonal context of psychopathology. In the coming years we will likely see interpersonal theories evolve to further postulate the biological and psychological endophenotypes through which early social adversity and contemporaneous interpersonal experiences leave their

legacy on gene expression. This elaboration will require specific, testable mechanisms amenable to direct validation, thereby bolstering our increasingly conceptually rich theories with equally compelling empirical evidence.

Elucidating Developmental Pathways

Building upon multilevel interpersonal theories also will require more precise explication of developmental timing effects and the possibility of developmental plasticity in the face of interpersonal adversity. Several questions will need to be addressed in this regard. What is the relative contribution of early versus chronic versus acute interpersonal adversity on psychopathology? Do early adverse interpersonal experiences have enduring effects beyond those linked to ongoing stressors? Are there stages of development (e.g., puberty, transition to adulthood) during which the pernicious effects of early adversity are intensified or open to reversal? What factors promote resilience against these effects? What are the mediating processes that account for long-term effects of gene–early environment interactions and how do these processes unfold over the course of development? Answering these questions will refine interpersonal models of psychopathology in ways that make them truly developmental in nature.

Emphasizing the Parent–Peer Interface

Theories of the peer context historically have been juxtaposed against theories of the parent/family context, and a parent versus peer model seems to come naturally to mind in the same kind of antithesis seen in classic nature versus nurture arguments. Early on, Sullivan's (1948/1953) psychiatric interest in peer influence was framed as an alternative to classical Freudian models where the child's personality is shaped in the home. Later, Harris's (1995) group socialization theory played up the importance of peer influence for personal adjustment at the expense of family-related phenomena. To this day, there is an element of catch-up to theories of the peer context, which historically have been less well developed than the 60-year-old tradition of research on parent–child attachment.

As demonstrated in this review, however, theories of peer influence can be organized around ecological and motivational perspectives that are broadly sympathetic to cardinal principles of developmental psychopathology, such as the importance of transactions between children and their environments as well as multiple, nested levels of influence. Behaviors like peer-directed aggression are more likely than in previous years to be seen as having both adaptive and maladaptive components, straddling boundaries between normative and atypical development. From a developmental psychopathology perspective, parent/family and peer influences on individual adjustment share the common element of constituting interpersonal systems, albeit embedded in different ecological systems with unique developmental trajectories. As with nature and nurture, parent and peer influences are likely to interact and synergistically shape individual pathways.

Another useful feature of a developmental psychopathology framework is the ease with which it can conceptualize parent and peer influences as ecologies in transaction with one another (e.g., Dishion, 2014; Parke & Ladd, 1992). In line with ecological postulations of mesosystemic and exosystemic factors involving multiple contexts, the synchronies (or lack thereof) between developing peer and family social ecologies, as for instance in coercive cycles generalized from home to school (Dishion & Tipsord, 2011), remain an important point of departure for future research. Further elaboration of cascade perspectives may help elucidate emerging risk across development and also link psychopathological processes arising within the family and peer contexts.

Moving from Theory to Practice

Moving from theory to practice not only in addressing psychopathology, but also in supporting youths' development in positive ways, will benefit from taking an integrative theoretical approach encompassing a number of interpersonal domains. An important future direction will be to evaluate the effectiveness of theory-based interventions designed to prevent or alleviate psychopathology. As Lewin (1952) wrote, "There is nothing more practical than a good theory" (p. 169). In this context, rather than focusing only on reversing the effects of earlier social adversity, interpersonal relationships can viewed as sources of social capital that can be harnessed to bolster children's development.

Many interventions attempt to change youth outcomes indirectly by improving parenting. Some of these interventions are driven by clear theoretical rationales; others are not. Using theory to guide interventions and then rigorously examining their effectiveness has the potential to maximize the benefits of parenting interventions in addressing risk factors for psychopathology. The success of a number of interventions such as the nurse–family partnership (Olds et al., 1998), functional family therapy (Alexander, Pugh, & Parsons, 1998), and Triple P (positive parenting program; Prinz, Sanders, Shapiro, Whitaker, & Lutzker, 2009), as well as others described as model or

promising programs in the Blueprints for Violence Prevention (Center for the Study and Prevention of Violence, 2012), suggests the promise of integrating theory, empirical research, and intervention.

With respect to peer relationships, as Ladd (2005, p. 1) stated, peers are an essential resource for children's development. Indeed, a central goal of child socialization is social integration (Maccoby, 1992), finding a supportive niche in one's contacts in the social world, and eventually, as Sullivan (1948/1953), Erikson (1950), or Bronfenbrenner (1979) might have it, being in a position to care for, sustain, and restructure that world for the better. At the same time, these theorists and others (e.g., Coleman, 1961; Mintz, 2004) often have viewed the peer social ecology with a wary eye—as bad company, far from the constraints of competent adult monitoring, and liable to lead the young person astray. A consequence of this tension is that whereas peers often are looked to as potential resources in intervention attempts—creating buddies, encouraging friendships, empowering bystanders, promoting social skills—peer-based interventions have had, since the days of the 1930s Cambridge-Somerville Project (McCord, 2003), limited success and the potential for backfiring (Dishion & Tipsord, 2011). If peers are essential ingredients to trajectories of social adjustment, can they be harnessed for positive purposes, and how can the power of peers be used to enhance individual development?

More recently in the peer domain, prevention programs such as All Starts, or Project Alert, have begun to use network perspectives that enhance social integration and the prevention of problem behaviors (Gest et al., 2011). With the advent of stochastic actor-based modeling (Veenstra et al., 2013), hopes are that researchers will be able to transcend simple declarations of homophily and be in a position to specify developmental cascades in which peer factors reflect, contribute to, and readjust life trajectories of youth (Brechwald & Prinstein, 2011; Cairns & Cairns, 1994). Within schools as well as other peer contexts (e.g., neighborhood clubs, peer group interventions), a critical question concerns the extent to which adults—such as parents—can and should scaffold and monitor peer relationships and, if so, how to do so effectively without encouraging negative effects. Even in elementary school, high status aggressive children can be an alternative authority structure to educators, parents, and other adults, challenging traditional socialization goals. Moreover, it may not be sufficient to intervene only in microsystems at the level of the peer social ecology; rather, multilevel interventions aimed at altering macrosystems (e.g., schools, communities) in which these relationships are embedded may be needed to ensure lasting effects. Research aimed at examining such assumptions in the context of specific prevention and intervention programs is sorely needed to determine the optimal way to increase the quality of social environments for a wider variety of youth, bringing out latent social capital and opportunities for growth.

Conclusion

If healthy, supportive, and emotionally satisfying relationships form a sturdy foundation on which to build the architecture of future mental health, interpersonal disruption and estrangement weaken these structures, allowing collapses in psychological well-being. Theory aimed at understanding the reasons for these breakdowns in concert with interventions aimed at bolstering interpersonal foundations hold great promise for building strong youth, communities, and societies.

INTRODUCTION

> Why should we think upon things that are lovely? Because thinking determines life.
>
> —William James

Psychology is standardly defined as the study of thoughts, behaviors, and emotions. Developmental psychopathology includes the investigation of both normal and abnormal phenomena and processes in psychology. This chapter centers on thoughts, that is, cognition, in developmental psychopathology. Cognition means different things to different scholars. We focus on, and organize our review around, central mental *processes*, including attention, memory, and executive functioning, alongside core cognitive (sometimes considered social-cognitive) *products*, including attributions, attitudes, rumination, and reappraisal (see Ingram, Miranda, & Segal, 1998, for discussion of differentiating cognitive products and processes as risks to psychopathology). First, we start with a brief modern historical overview concerning the progression of how cognitive factors and processes have been conceptualized and examined from both a normal and abnormal perspective. Next, we introduce some logical conceptual models to organize our ensuing review of evidence. Then, we review the dominant cognitive risks, structured by processes and products, for several prevalent and impairing psychopathologies (internalizing disorders of depression and bipolar disorder (BD) as well as anxiety disorders, externalizing disorders of attention-deficit/hyperactivity disorder (ADHD) and conduct disorders, and schizophrenia). Space limitations did not permit a review of every cognitive risk; rather, we summarize knowledge on those main theoretically specified and empirically investigated products and processes. Finally, we discuss several points that emerged from this review and present some future research directions: (1) developmental issues; (2) the integration of cognitive products and processes within cognitive/affective neuroscience and genetics frameworks; (3) transdiagnostic versus disorder-specific models of psychopathology; and (4) translational implications.

History

The history of cognitive approaches in psychopathology has followed a curious path, best illustrated as mostly parallel play, between two predominantly independent scientific traditions: clinical psychology/psychiatry and experimental psychology/cognitive science. This theme of parallel play between clinical and cognitive science is

largely reflected up to the present, and is also mirrored in the organization of our review of cognitive influences in developmental psychopathology. More specifically, cognitive clinical scientists have tended to emphasize and study more easily accessible, self-reportable cognitive products (e.g., attributions, automatic thoughts, and dysfunctional attitudes), whereas experimental cognitive scientists have predominantly focused on cognitive processes (e.g., memory and attention) that are typically assessed via experimental tasks. Moreover, cognitive clinical scientists have tended to be more interested in and study individual differences in cognitive risks and associations with psychopathology, whereas experimental cognitive scientists have leaned more toward group differences in cognitive processes.

Both clinical and cognitive scientists followed the paradigmatic shift observed in the broad history of psychology, with the transition from psychodynamic to behaviorism and then the cognitive revolution. Broadly speaking, cognitive approaches to psychopathology have progressed through five stages: (1) descriptions and observations of how cognition is perturbed in psychopathology (Beck, 1967); (2) experiments focused on cognitive processes in aggression (e.g., Bandura, Ross, & Ross, 1961; Bandura, 1977); (3) emphasis on cognitive products (e.g., Abramson, Seligman, & Teasdale, 1978; Dodge, 1980); (4) investigations using cognitive science tasks and methods (Ingram et al., 1998) and a focus on information processing grounded in social psychology (e.g., Bandura, 1986) and emotion (e.g., Gross & Thompson, 2007); and (5) emphasis on integrating genetics (Feder, Nestler, & Charney, 2009; Gibb, Beevers, & McGeary, 2013; Swanson et al., 2007) as well as cognitive and affective neuroscience models and approaches (Beck, 2008; e.g., Bishop, 2007; De Raedt & Koster, 2010; Nigg & Casey, 2005; Posner, Russell, & Peterson, 2005).

Perhaps the most recognized clinical scientist to advance cognitive approaches to psychopathology, Aaron Beck, initiated clinical cognitive studies of psychopathology via description and observation. As a psychodynamically trained psychiatrist, he was searching for classic psychoanalytic themes of anger turned inward among the dreams of his depressed patients, but instead accurately recognized that these patients described themes of loss, failure, hopelessness, and pessimism. Beck's work, based on his astute clinical observations with depressed adults revealing negative thoughts of the self, world, and future, led to his ground-breaking book on cognitive therapy (Beck, 1967) and initial theorizing focusing on etiology and treatment approaches involving cognitive schemas, content, and process in depression. About this same time, Albert Ellis was promoting his cognitive approach called rational emotive behavior therapy (Ellis, 1957). Also about this time, an instrumental theoretical and empirical figure, Bandura, was advancing beyond psychoanalytic doctrine and was initiating his classic line of inquiry investigating behavioral (e.g., Bandura et al., 1961), and what ultimately became social-cognitive (e.g., Bandura, 1977), processes using a more experimental approach.

Progressing firmly as the cognitive revolution was in full swing, several theoretical advances in clinical cognitive understanding of psychopathology unfolded with an emphasis on cognitive products. Building on the basic behavioral understanding of learned helplessness approaches to human depression (Miller & Seligman, 1975), Abramson and colleagues underscored how attributions can affect depression (e.g., Abramson et al., 1978). Dodge and colleagues also applied attributional models to explicate aggression and conduct disorder (e.g., Crick & Dodge, 1994; Dodge, 1980).

About this same time, various experimental cognitive scientists were conducting more controlled experiments with core cognitive processes, including attention, memory, and executive functioning, using between groups comparison designs, sometimes with psychopathologically disordered groups. Relatedly, other experimentalists, using more social psychology and emotion traditions (e.g., Gross & Thompson, 2007) were similarly investigating cognitive processes and information processing, using experimental tasks developed in cognitive psychology, with clinical applications in aggression, anxiety, and mood (Joormann, 2010). At the present time, the state of the field is focused on integrating cognitive processes and products with either genetic influences or neuroscientific principles and findings (e.g., Beck, 2008; Disner, Beevers, Haigh, & Beck, 2011; Nigg & Casey, 2005).

Logical Models

Before initiating our review of cognitive processes and products in common psychopathologies, it is important to discuss several ways that can be used to more formally model the relationship between cognitive factors and psychopathology. The following section will discuss several logical models that could be used to conceptualize the role of cognitive influences in developmental psychopathology: correlate, consequence, risk factor/vulnerability, and causal risk factor. We draw on prior work articulating logical models that can more formally describe relations between a risk and psychopathology (e.g., Kazdin,

Kraemer, Kessler, Kupfer, & Offord, 1997; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). As we discuss later, a general shortcoming of the broad field of cognitive risks in developmental psychopathology across the life span is the lack of consideration and application of such logical models to more formally organize cognitive risks and try to rule out, or in, particular models based on the evidence. This is a goal of the chapter and our review. In addition, this section will also describe how cognitive factors might work together with other influences to contribute to psychopathology through the following mechanisms: moderation, mediation, and dynamic/transactional.

The simplest type of relationship characterizes a cognitive factor as a *correlate* of psychopathology, in that the two are associated (Kazdin et al., 1997). In addition, cognitive influences may also be a *consequence* of maladjustment, such that they accompany or follow directly from psychopathology. Correlates can be identified using cross sectional or retrospective study designs. Establishing cognitive correlates of mental health outcomes can act as the first step to inform future research designs, as discussed later, which are better able to address the temporal or potential causal relationship among cognitive influences and developmental trajectories of psychopathologies.

Within the conceptualization of a correlate, a cognitive construct may also act as a risk factor, or vulnerability, to psychopathology, such that the cognitive influence is associated with an increase in the probability of the outcome over the population base rate of the outcome (Kazdin et al., 1997). A risk factor is therefore a specific type of correlate that must temporally precede the outcome. Risk factors can be identified using only a prospective longitudinal design. Within risk factors, there are two categories: variable and fixed risk factors. Variable risk factors may change within an individual (e.g., age, height), whereas fixed risk factors do not change (e.g., race, sex). Cognitive influences are mutable variables, and therefore fall under the category of variable risk factors. For example and as we review later, a body of research that has utilized multiple time point designs has found that a negative inferential style predicts, especially in interaction with stressors, depression. In addition, as discussed in the literature review, prospective longitudinal studies suggest that impairments in EF, memory, attention and related brain systems predict later psychosis, ADHD, and PTSD, suggesting that cognitive deficits may be a risk factor for many disorders. A recent, relatively specific type of risk factor is an endophenotype (Gottesman & Gould, 2003), which is an intermediate trait (e.g., cognitive products and processes) that is relatively stable over time (e.g., present even during remission from illness) and present in healthy family members, thus linking genetic risk to later psychopathology.

Finally, a subset of risk factors may act as causal risk factors, such that the manipulation of these risk factors changes the probability of the outcome (Kazdin et al., 1997). The only study designs that are sufficient to identify causal risk factors include naturalistic experiments, laboratory experiments (e.g., randomized control trials, animal studies), or studies that examine dose-response relationships. Studies that have manipulated cognitive reappraisal in a laboratory setting, for instance, have demonstrated that this cognitive construct is associated with less sadness and general negative affect among both clinical and nonclinical participants (Perry & Henry, 2012). Likewise, training to reduce attentional bias toward negative information has been shown to reduce risk for depression recurrence (e.g., Browning, Holmes, Charles, Cowen, & Harmer, 2012), and experimental modification of cognitive emotion recognition at the perceptual level reduced anger and aggression in ambiguous contexts (Penton-Voak et al., 2013).

As part of a developmental, interdisciplinary approach to the study of cognitive risks to psychopathology, it is safe to assume that cognitive risk factors do not operate in isolation, but rather work together with other influences to engender risk to psychopathology. One possibility is moderation. In this type of relationship, a moderator B changes the relationship between independent variable A and the outcome O (Kraemer et al., 2001). It is important to note that, strictly speaking, the moderator B does not affect the level of A or the probability of A. Statistical analysis that examines moderators may seek to evaluate hypotheses of differential susceptibility to psychopathology as well as resiliency that buffers against these maladaptive outcomes.

A second mechanism that models how risk factors work together is mediation. In this type of relationship, a mediator B is caused to vary by the independent variable A. B, in turn, causes variation in the outcome O (Kraemer et al., 2001). Therefore, unlike in moderation, A does indeed affect the mediator B. Statistical analysis that examines mediators may seek to identify an intermediate variable in the causal pathway from A to a negative mental health outcome, thereby explaining how and why A influences that outcome.

A final model that explains how risk factors work together is the transactional model (e.g., Sameroff, 1975). In this model, variables are recursive, such that variables can serve both as an antecedent and as an outcome. For example, in the cognitive vulnerability-transactional stress model for depression (Hankin & Abramson, 2001),

a negative life event contributes to initial elevations in negative affect (e.g., sadness, anger), which interacts with cognitive risk factors (e.g., negative cognitive style) to maintain and amplify negative affect, thereby increasing risk for depression, which in turn contributes to future dependent negative life events (e.g., fight with a friend), perpetuating this recursive cycle. It is important to note that these logical models are not mutually exclusive. Indeed, it is highly likely that different models will hold true for different cognitive products and processes, or even for the same cognitive process or product at different times or for different individuals.

Overview and Plan for the Literature Review

The following sections review the evidence of core cognitive risks to psychopathology. There are several initial points to highlight. First, we do not review every single cognitive risk (process or product) that has ever been investigated. Rather, we concentrate this review on the main theoretically specified and empirically investigated factors and processes. Second, we do not review all forms of psychopathology, but rather focus on several of the most investigated and prevalent forms of psychopathologies—depression, BD, schizophrenia, anxiety (primarily posttraumatic stress disorder (PTSD), social anxiety disorder (SAD), generalized anxiety disorder (GAD), panic, and obsessive compulsive disorder (OCD), and externalizing disorders (primarily ADHD) and conduct disorders). Third, we organize this review mainly around prior reviews and meta-analyses, as well as essential individual papers that establish associations between these cognitive influences and those selective psychopathologies. It is important to emphasize, as became evident in conducting this review of core cognitive risks and psychopathologies, that not all of the cognitive products and processes have been studied with all of the main psychopathological disorders we reviewed. As such, our review covers associations between cognitive risks and psychopathology for those links for which there is a sufficient evidence base.

From this review, certain general conclusions can be reached that illustrate well-established principles of developmental psychopathology (see Cicchetti & Toth, 2009). First, it is clear that a variety of cognitive processes and products are linked to each of the psychopathologies reviewed here, thus reflecting the idea that there are multiple cognitive pathways to a given disorder (i.e., equifinality; Cicchetti & Toth, 2009). For example, research has linked both cognitive processes (e.g., deficits in executive functioning, biased attention for negative information) as well as cognitive products (e.g., negative inferential style, rumination) to depression. Additionally, evidence is consistent with the view that cognitive processes are perturbed across disorders (i.e., multifinality; Cicchetti & Toth, 2009), whereas cognitive products may operate as relatively more specific risks to particular psychopathologies based on the content and affective tone of the cognition and disorder. Still, this relatively broad conclusion requires additional research to substantiate, and it is a point to which we return to and expand upon later in the Discussion. For example, while the data suggest many processes may be relatively general risks to psychopathology transdiagnostically, future research may find greater specificity in cognitive processes when examined in greater detail (e.g., different neurotransmitter systems implicated in the underlying neural processes, or different strategies employed in cognitive tasks assessing these core processes). Likewise, seemingly specific cognitive products (e.g., rumination and worry) may share common underlying processes.

Second, the data reveal significant associations between cognitive risks and psychopathology, but the current state of knowledge is not consistently and systematically organized around the logical conceptual models presented in the previous section. To the extent possible, we present the evidence in this review in a manner that attempts to adjudicate among these potential logical models. Can certain ones be ruled out (e.g., purely concomitant association) for certain cognitive risks and particular forms of psychopathology? Are other models (e.g., risk factor/vulnerability) presently more favored and supported by the evidence?

Third, throughout the review we will point out the age group of the samples (e.g., child, adolescent, adult), some basic design features (e.g., cross sectional, longitudinal; case-control), and methods (e.g., questionnaires/self-reports in much of the product literature; cognitive tasks in most of the process studies). From the review it became clear that the majority of the work has focused on adult samples, although this generality varies and depends on the particular cognitive process and product investigated along with disorder. Research on cognitive processes and products that was conducted at different ages and developmental stages (e.g., infancy, childhood, adolescence, adulthood) with prospective longitudinal study designs can help to determine the developmental trajectories of these cognitive constructs, including emergence, stabilization, and change over time. For example, research has found that hostile attribution bias, a cognitive product linked to conduct disorder, is negatively associated with age (Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002). We return to discuss and comment

on developmental/age features and design considerations later in the chapter.

A final key theme that emerged from this review is that there has generally been an independent, silo approach underlying inquiries into cognitive risks to development of psychopathology, as opposed to a more integrative approach across multiple levels of analysis (Cicchetti & Toth, 2009). To our knowledge no prior review has covered both cognitive products and processes together and development of several main psychopathologies, including both internalizing and externalizing problems. Many investigators focus on one product or process and one disorder only, and there has been little connection across multiple levels of analysis in cognition (i.e., lack of process and product integration) and across different forms of psychopathology (i.e., possibly transdiagnostic vs. specific disorder prediction). Just as young children interact together in parallel play, there has not been much cross talk between the cognitive products and process literature, or between literatures on cognition in different clinical disorders. Cognitive constructs at different levels inevitably constrain and influence one another in a bidirectional, transactional manner (Cicchetti & Toth, 2009), so future research should examine more than just one construct in isolation. For instance, cognitive theories of depression have begun to link deficits in inhibition with repetitive negative thought in depression (e.g., Zetsche, Avanzato, & Joormann, 2012). We organized our review by cognitive processes and products, rather than by clinical disorder, purposefully to begin to facilitate this conceptual shift focused on cognitive influences, which may be transdiagnostic risks to development of psychopathologies. We hope that this review will stimulate future research to move beyond the current silo approach and begin to integrate studies across cognitive products and processes and examine how these multiple cognitive influences predict development of several psychopathologies.

COGNITIVE PROCESSES

Executive Function

Executive function (EF) processes enable us to respond flexibly to the environment and regulate our thoughts and behaviors, allowing us to break out of habits, make decisions and evaluate risks, plan for the future, prioritize and sequence our actions, and cope with novel situations. EF is composed of a set of cognitive control processes, mainly supported by the prefrontal cortex (PFC), which regulate lower level cognitive processes (e.g., perception, motor responses) and thus enable self-directed behavior toward a goal (e.g., Miyake & Friedman, 2012). Given the breadth of the EF construct, many different tasks have been used to assess EF in the laboratory (Table 8.1). EF appears to be especially vulnerable to disruption, as evidenced by EF impairments associated with most forms of psychopathology, as discussed below. Thus, it has been proposed that EF deficits may be transdiagnostic intermediate phenotypes or risk factors for emotional, behavioral, and psychotic disorders (Susan Nolen-Hoeksema & Watkins, 2011). There is strong evidence that multiple aspects of EF are indeed impaired across most diagnostic groups, although the magnitudes of these deficits vary, both across disorders and across aspects of EF.

Core Components of EF: Shifting, Updating, and Inhibition

EF is best characterized as consisting of separable but related cognitive processes, with both unique and shared individual differences, genetic influences, and neural substrates (Miyake & Friedman, 2012). One influential model which has been applied to understanding the effects of psychopathology on EF, the *unity/diversity model*, has identified three fundamental aspects of EF: (1) shifting, (2) inhibition, and (3) updating working memory, as well as a common EF ability which is involved in all aspects of EF and may subsume inhibition (Miyake & Friedman, 2012). Shifting is defined as switching between task sets or response rules. For example, you may need to shift from reading this chapter to responding to an urgent email and back again. Inhibition is defined as suppressing or resisting a prepotent (automatic) response to make a less automatic but task-relevant response. For example, you may want to want to resist the automatic response of checking those not-so-urgent emails to complete reading the chapter. Updating is defined as monitoring and coding incoming information for task-relevance, and replacing no longer relevant information with newer, more relevant information. For example, as you read this chapter, you may be monitoring for a relevant piece of information you are looking for (say, the definition of updating), hold this information in working memory while you write it down, then replace it with the next relevant piece of information. Common EF is defined as what is shared across all EF tasks, and is posited to be the ability to monitor for and maintain goal and context information (e.g., the goal of finishing this section of the chapter; Miyake & Friedman, 2012). This theory is compatible with the view that the central role of the frontal lobes is active maintenance of goals, plans and other task-relevant information,

TABLE 8.1 Examples of Commonly Used EF Tasks

Construct	Task	Description	Outcome measure(s)	Methods citation[1]
Shifting	Intradimensional–extradimensional shift	Learn from feedback to select a stimulus based on one dimension, switch to the previously nonrewarded stimulus (intradimensional shift), then to a different stimulus dimension (extradimensional shift)	**1.** Perseverative errors in intradimensional and extradimensional shifts **2.** # of shifts achieved **3.** Time to complete	Robbins et al. (1998)
	Trail Making B[2]	Alternately connect letters and numbers in sequence (e.g., A-1-B-2) Often compared with Trail Making A (connect letters or numbers only, does not require shifting)	**1.** Trail Making B–Trail Making A time **2.** Errors in B **3.** Time to complete B	Strauss, Sherman, and Spreen (2006)
	Object Alternation	Find object hidden alternately under two different cups	Errors	Kuelz, Riemann, Zahn, and Voderholzer (2004)
	Wisconsin Card Sorting Task (WCST)	Learn from feedback to sort cards by one dimension (e.g., color), and then switch to a different dimension (e.g., shape) when given negative feedback on the first dimension (repeats with multiple sorting rules)	**1.** Perseverative errors **2.** # of rules achieved **3.** Time to complete	Strauss et al. (2006)
	Cued task switching	Perform one of two tasks depending on cue before each trial (e.g., color/shape, addition/subtraction, number/letter, categorize by size/categorize by living vs. nonliving)	**1.** Switch cost (switch–repeat RT) **2.** Perseverative errors	Friedman et al. (2008)
Inhibition	Color-word Stroop (experimental version)	Identify the color ink a color word is printed in; trials are incongruent (e.g., red written in blue ink) and congruent (e.g., red written in red ink) or neutral (noncolor word); trial types are randomly intermixed	**1.** Stroop interference (incongruent–neutral RT) **2.** Incongruent–neutral errors	Silton et al. (2010)
	Color-word Stroop (neuropsychological version)	Separate blocks of word reading, color naming, and incongruent (e.g., red written in blue ink) trials	**1.** Incongruent–color naming time **2.** Incongruent block time **3.** Incongruent block errors	Strauss et al. (2006)
	Stop-signal	Quickly categorize and respond to stimuli (e.g., left and right pointing arrows), unless a stop signal appears, signaling to withhold a response	**1.** Stop signal RT (time needed to stop a response) **2.** Commission errors	Band, Van der Molen, and Logan (2003)
	Antisaccade	Look in the opposite direction of visual cue	Errors (detected by eye tracking or failure to detect briefly presented target on correct side)	Friedman et al. (2008)
	Go/No-Go	Quickly categorize and respond to some stimuli and withhold a response to other stimuli	Commission errors	Rubia et al. (2001)
	Hayling	Read sentences where the final word is omitted but highly predictable; first complete sentences correctly (Part A), then with an unrelated word (part B)	**1.** Part B–Part A RT **2.** Part B errors	Strauss et al. (2006)
Working memory updating	Keep Track	Remember last exemplar word presented in several target categories and report these words at the end of the trial	Accuracy	Friedman et al. (2008)
	Letter Memory	Remember and repeat the last three letters in a letter string, adding the most recent letter and dropping the 4th letter back	Accuracy	Friedman et al. (2008)
	Verbal n-back	Indicate if the stimulus (usually letter) matches the stimulus *n* (e.g., 3) items back	Accuracy	Braver, Cohen, Nystrom, Jonides, and Smith (1997)
	Spatial n-back	Indicate if the spatial location of a stimulus matches the location *n* (e.g., 3) items back	Accuracy	Friedman et al. (2008)

TABLE 8.1 (*Continued*)

Construct	Task	Description	Outcome measure(s)	Methods citation[1]
Visuospatial working memory	Corsi block tapping/ Spatial Span	Tap irregularly arranged blocks/squares in the same order as experimenter (Corsi blocks) or computer (Spatial Span).	Span (max. length of sequence correctly performed)	Strauss et al. (2006)
	Self-Ordered Pointing	Search an array of boxes for hidden tokens; token is only in each location once	**1.** Errors (return to previous location) **2.** Strategy score (how often search is initiated from same starting box)	Owen, Downes, Sahakian, Polkey, and Robbins (1990)
	Sequential Comparison	View an array of colored squares and after a delay, indicate if any squares have changed colors in a test array	Span (see reference)	Luck and Vogel (1997)
Verbal working memory	Digit Span (Forward and Backward)	Repeat sequence of numbers in forward or reverse order	Span (max. length of sequence correctly performed)	Strauss et al. (2006)
	Letter-Number Sequencing	Repeat list of alternating letters and numbers, resequenced into numbers first, then letters	Span (max. length of sequence correctly performed)	Strauss et al. (2006)
	Reading Span	Read a serious of unrelated sentences, then recall the last word of each sentence.	# correctly recalled words	Friedman and Miyake (2004)
	Operation Span	Read aloud and verify simple math equations, then read aloud a presented word; at end of trial, recall all words	# correctly recalled words	Miyake et al. (2000)
Verbal fluency	Semantic Verbal Fluency/Category Fluency	Say as many words from a semantic category (e.g., animals) as possible in 1 (or 3) min	**1.** Switches between subcategories **2.** # of words	Troyer, Moscovitch, and Winocur (1997)
	Phonemic Verbal Fluency/Controlled Oral Word Association (COWA)	Say as many items starting with a certain letter (usually F, A, S) as possible in 1 (or 3) min	# of words	Troyer et al. (1997)

[1]Citations are for sources that provide a full description of the task and outcome measures of the most recent or recommended version of the task, not necessarily the first publication to report the task.
[2]Not recommended for future research because it has poor construct validity (e.g., effect sizes are equal for the Trail Making Test Part A measures; Snyder, 2013).

which may be essential for all aspects of EF (Miller & Cohen, 2001).

The largest deficits on these core aspects of EF are found for individuals with schizophrenia. Meta-analyses have found large impairments on measures of shifting, inhibition, and updating (Table 8.2). A recent meta-analysis also found that adolescents with psychosis risk syndrome have small but significant deficits in EF, which are somewhat larger in those who go on to convert to schizophrenia (Giuliano et al., 2012). EF deficits increase during the prodrome, and increase again with the first psychotic episode, then appear to be fairly stable over time (e.g., see Lewandowski, Cohen, & Ongur, 2011 for review), with little evidence that individuals with schizophrenia experience greater age-related declines in EF than healthy individuals (Irani, Kalkstein, Moberg, & Moberg, 2011). However, there is some evidence that EF deficits are sensitive to symptom levels. Specifically, EF impairments in schizophrenia are associated with negative symptoms and disorganization, but not with positive symptoms (Dibben, Rice, Laws, & McKenna, 2009).

These EF processes are also impaired in individuals with mood disorders, although the magnitude of these deficits is somewhat smaller than those in schizophrenia. Meta-analytic evidence demonstrates that individuals with depression are significantly impaired on measures tapping shifting, inhibition, and updating, with medium effect sizes, while individuals with BD have somewhat larger impairments in shifting and inhibition, while there is little research on updating in individuals with BD (Table 8.2). More research is needed to determine how EF deficits change over the life span in individuals with depression and BD. A meta-analysis of children with BD found fairly comparable effect sizes to those in adults (Walshaw, Alloy, & Sabb, 2010), suggesting that EF deficits are already present early in BD and may be relatively stable across the life span. EF deficits in individuals with depression appear to be relatively stable from adolescence through older adulthood (Snyder, 2013), but there has been little research in younger adolescents or children with depression. EF deficits in BD and depression also appear to be fairly stable across current mood state, as most measures of EF

[1] Summary of meta-analyses conducted in the last ten years. Weighted mean effect size (Cohen's *d*) comparing healthy control participants to the clinical group. All effect sizes have been recoded such that positive values represent worse task performance by the clinical group. When a meta-analysis reported effect sizes for multiple individual tasks within an EF component, the average of these effect sizes is reported.

[2] Composite measures including some tasks we would not classify as shifting (verbal fluency, design fluency, and WAIS similarities) in addition to traditional shifting tasks.

[3] Includes updating tasks.

Manip. = manipulation. Maint. = maintenance. VF = verbal fluency.

remain equally impaired in euthymic individuals with BD (Kurtz & Gerraty, 2009; Table 8.2) and individuals with depression in remission (Snyder, 2013). On the other hand, some EF deficits increase with symptom severity (e.g., see McDermott & Ebmeier, 2009 for meta-analysis). However, longitudinal research is needed to determine whether EF tracks changes in depression severity, or whether preexisting EF abilities affect depression severity. Preliminary evidence suggests that the latter may be the case: individuals who had more severe EF (shifting/inhibition) deficits during their first MDD episode were more likely to relapse within a year (Schmid & Hammar, 2013).

Individuals with OCD have impaired performance across these core EF domains, with small effect sizes for shifting and inhibition, but large effect sizes for updating (Table 8.2). Importantly, while depression frequently co-occurs with OCD, EF deficits in OCD are not driven by co-occurring depression, as even those with low levels of depressive symptoms show the same level of EF deficits (Snyder, Kaiser, Warren, & Heller, 2015). While there have been few studies of EF in children and adolescents with OCD, they appear to have EF deficits similar to those of adults with OCD (e.g., Andrés et al., 2007; Shin et al., 2008), suggesting that EF deficits are present from soon after illness onset. EF deficits appear to be fairly stable through adulthood (Snyder et al., 2015), but there has been little research on older adults with OCD.

Evidence for impairments in these core EF domains is less consistent for other anxiety disorders. A recent meta-analysis found that compared with trauma-exposed individuals who did not develop PTSD, individuals with PTSD had worse performance on measures of shifting, with a medium effect size, but not the Stroop measure of inhibition (Table 8.2; Polak, Witteveen, Reitsma, & Olff, 2012). However, a review of the literature including a wider range of inhibition tasks suggests that individuals with PTSD do experience inhibition deficits (Aupperle, Melrose, Stein, & Paulus, 2012). EF impairments in individuals with PTSD do not seem to be clearly influenced by current mood state, suggesting that they are trait-like (Aupperle et al., 2012). However, unlike OCD, co-occurring depression may account for EF deficits in individuals with PTSD, although more research in individuals without severe depressive symptoms is needed to confirm this finding (Polak et al., 2012). While most research has focused on adults, a few studies in children and adolescents have also found EF impairments associated with trauma and PTSD (Carrion, Wong, & Kletter, 2012). However, in adults there is some evidence that EF deficits associated with PTSD increase with age from early to middle adulthood, although this finding is based on cross sectional studies, leaving the possibility that cohort effects (e.g., in type of trauma exposure) could account for these findings (Polak et al., 2012).

In contrast with OCD and PTSD, there is not strong evidence for broad EF impairments associated with other anxiety disorders, and there have been no published meta-analyses. While a few studies have found impairments in shifting associated with PD, SAD and GAD in adults (Airaksinen, Larsson, & Forsell, 2005; Cohen et al., 1996; Mantella et al., 2007), others have found no evidence of impairment in shifting (Airaksinen et al., 2005; Boldrini et al., 2005; Purcell, Maruff, Kyrios, & Pantelis, 1998), or inhibition (Price & Mohlman, 2007a; van den Heuvel et al., 2005; Van der Linden, Ceschi, Zermatten, Dunker, & Perroud, 2005). In sum, there is limited and inconsistent evidence for EF impairments on traditional neuropsychological tasks in individuals with anxiety disorders other than OCD and PTSD.

However, research in nonclinical samples suggests that trait anxiety, and especially anxious apprehension (worry) is associated with impairments in a specific aspect of EF, inhibiting competing responses. A number of studies have found that high trait anxiety is associated with impaired inhibition task performance (e.g., Bishop, 2008; Eysenck & Derakshan, 2011; Snyder et al., 2010), although others have not (e.g., Avila & Parcet, 2001), likely due to differences in the types of tasks, and potentially most critically, the measures of anxiety used. Recent research suggests that anxious apprehension, but not anxious arousal, is associated with an impaired ability to inhibit competing verbal responses (Snyder et al., 2010). Since anxious apprehension and anxious arousal can both be present to different degrees in individuals with anxiety disorders, more specific measures of anxious apprehension, as well as more sensitive and specific measures of inhibition, may be beneficial in detecting EF deficits in such individuals.

Finally, ADHD is associated with impairments in shifting and inhibition, while updating has not been widely studied. While earlier theories posited a core inhibitory deficit that secondarily disrupts other aspects of EF (e.g., Barkley, 1997), recent meta-analyses demonstrate that only motor response inhibition tasks (stop signal and go/no-go) show substantial deficits, while the Stroop measure of inhibition shows only a small effect size (Table 8.2). EF is also impaired in other externalizing disorders, including ODD/CD, but these deficits may be accounted for at least in part by co-occurring ADHD (see Ogilvie, Stewart, Chan, & Shum, 2011 for meta-analysis). EF deficits occur in individuals of all ages with ADHD,

from preschoolers (Pauli-Pott & Becker, 2011) through mid-adulthood (Boonstra, Oosterlaan, Sergeant, & Buitelaar, 2005). However, effect sizes are somewhat larger in meta-analyses of adults with ADHD than those with children and adolescents (Table 8.2). It is possible that the subset of individuals who continue to experience ADHD symptoms into adulthood have a more severe form of the disorder, contributing to greater EF deficits, or that poor EF is a risk factor for continued ADHD symptoms in adulthood. However, this must be interpreted with caution because different tasks or task variants are often used with different age ranges, precluding direct comparisons.

Working Memory

While shifting, inhibition, and updating are important aspects of EF, this model in no way posits that these are the only components of EF. For example, working memory is often considered a component of EF. Working memory (WM) is defined as actively maintaining (i.e., 'holding on line') or manipulating information across a short delay. Manipulating information in WM places heavier demands on EF (i.e., the *central executive* component of WM) than simple maintenance (Repovs & Baddeley, 2006). WM maintenance can further be divided into verbal (e.g., words, letters, and numbers) and visuospatial (e.g., shapes, patterns, and spatial locations) stores), while the central executive component of WM is believed to be domain-general (e.g., Repovs & Baddeley, 2006).

Working memory deficits are widespread across forms of psychopathology, but vary in magnitude both across disorders and across components of WM. Visuospatial WM is consistently impaired, with large effect sizes for individuals with schizophrenia, and medium-small effect sizes for BD and ADHD, and small but significant effect sizes for depression and OCD (children and adolescents for ADHD, mainly adults for all other disorders; Table 8.2). Verbal WM is also widely impaired, but deficits are smaller for simple verbal working memory maintenance (e.g., digit span forward) than verbal working memory manipulation (e.g., digit span backward). Specifically, meta-analyses show verbal WM manipulation deficits with large effect sizes for schizophrenia, medium effect sizes for BD, MDD, and ADHD (somewhat larger for children/adolescents than adults), and small but significant effect sizes for PTSD and OCD. In contrast, simple verbal WM maintenance tasks show only medium effect sizes for schizophrenia, small effects for BD, depression, and ADHD (only adults meta-analyzed), and no significant impairment in OCD (Table 8.2). There has been very little research on WM in individuals with anxiety disorders other than OCD, but there have been reports of impaired visuospatial WM in individuals with PD (Boldrini et al., 2005), and impaired verbal WM manipulation, but not maintenance, in individuals with GAD (Christopher & MacDonald, 2005).

The finding that manipulation is more impaired than maintenance, along with evidence that visuospatial and verbal WM manipulation are equally impaired, both support the view that working memory deficits in these disorders are due to impairment in the central executive aspect of working memory, rather than the content-specific maintenance systems (Barch, 2005). This suggests that verbal WM deficits may arise from difficulty with encoding and/or manipulating information in working memory, rather than maintenance of information. Supporting this, a meta-analysis found that working memory deficits associated with schizophrenia do not increase with the delay interval over which material must be maintained (Lee & Park, 2005), while studies have found that increasing presentation time or stimulus saliency to aid encoding improves working memory performance in individuals with schizophrenia (Lee & Park, 2005). However, this more fine-grained analysis of the factors driving WM impairments has not been performed for other forms of psychopathology.

Complex Tasks: Verbal Fluency and Planning

Many complex tasks may also tap multiple aspects of EF. For example, verbal fluency tasks (generating words starting with a certain letter or from a category) likely tap several cognitive processes (Rende, Ramsberger, & Miyake, 2002). Planning tasks are also complex, involving multiple cognitive demands (Goel & Grafman, 1995), and so may not represent a single EF ability. Notably, verbal fluency and planning tasks are frequently used in clinical studies. Such tasks may be commonly implemented in clinical research because they are viewed as more ecologically sensitive: the complexity of verbal fluency and planning tasks may make them more relatable to real-world tasks that require similar skills. Thus, there are both disadvantages (in terms of interpretability) and advantages (in terms of ecological validity) in the use of such complex EF tasks.

Deficits in verbal fluency are widespread across disorders. Indeed, meta-analyses show that the largest deficit for adults with schizophrenia and depression is found on the semantic verbal fluency task, with large and medium effect sizes respectively (Table 8.2). Semantic verbal fluency is also impaired in individuals with BD (all ages, with medium effect sizes), OCD (mainly adults, with small effect sizes), and ADHD (all ages, with small effect sizes), while there is

inconsistent evidence for verbal fluency in individuals with PTSD (Aupperle et al., 2012; Table 8.2). For schizophrenia, BD, and MDD, effect sizes for phonemic verbal fluency are somewhat smaller than those for semantic, although still significant (Table 8.2). In contrast, individuals with OCD have equal impairments in the two forms of verbal fluency, and verbal fluency deficits associated with ADHD appear to be larger for phonemic verbal fluency than semantic verbal fluency (Table 8.2). There has been little research on verbal fluency in anxiety disorders other than OCD: one study reported impaired phonemic verbal fluency in individuals with PD (Gladsjo et al., 1998), while others found no impairment in individuals with GAD (Airaksinen et al., 2005) or SAD (Hood et al., 2010). However, conclusions are premature given the paucity of evidence.

Why might semantic and phonemic verbal fluency tasks be differentially affected in different disorders? Verbal fluency tasks impose multiple EF demands (e.g., shifting among subcategories, monitoring for repeated words, memory retrieval). One possibility as to why semantic verbal fluency is more impaired in individuals with schizophrenia, BD, and depression is that it may place heavier demands on shifting, and particularly on selecting what to switch to, since category cues are likely to lead to the activation of many category members, which then compete for production (Snyder & Munakata, 2010). Another possibility is that deficits in semantic memory retrieval may contribute to semantic verbal fluency impairment, particularly in individuals with schizophrenia. For example, a meta-analysis found that individuals with schizophrenia have large deficits on semantic verbal fluency both for switching between subcategories, an index of EF ($d = 1.02$), and semantic clustering, and index of semantic memory ($d = 0.93$) (Doughty & Done, 2009). In contrast, the larger effect for phonemic verbal fluency in individuals with ADHD could potentially be due to deficits in phonological processing in many individuals with ADHD, since ADHD and reading disabilities frequently co-occur (Willcutt, Pennington, Olson, & DeFries, 2007). Thus, deficits in verbal fluency may arise from a variety of sources, and illustrate the difficulty of interpreting results from complex tasks.

Planning has been much less studied. Individuals with BD have significant impairments in planning, with one meta-analysis finding a small effect size in adults and another finding a large effect size in children and adolescents (Table 8.2). Adults with depression also have significant, but small, impairments on planning tasks (Table 8.2). In individuals with ADHD, two meta-analyses, both in children and adolescents, found quite different effect sizes for planning tasks, one small, one medium (Table 8.2). Likewise, two meta-analyses of individuals with OCD found different effect sizes for planning, two small and one medium (Table 8.2). Finally, there is inconsistent evidence for planning deficits associated with PTSD (Aupperle et al., 2012). Thus, while planning tasks in theory tap multiple aspects of EF, standard measures of planning may be less sensitive than other EF tasks in detecting more subtle EF deficits associated with some disorders.

Attention

What is attention? Despite William James's (1890) famous assertion that "everyone knows what attention is" (pp. 403–404), attention has been conceptualized and defined in many ways, and is best thought of as an umbrella term for a set of processes that filter incoming information and allocate processing resources, including *sustained attention, selective attention,* and *divided attention*. Problems with attention can arise either because there are deficits in attentional processes themselves (e.g., difficulty maintaining any attentional focus), or because attention is allocated in a way that is not adaptive (*attentional bias,* e.g., focusing on negative information). There is evidence for both attentional deficits and attentional biases associated with psychopathology, with the strongest evidence for attentional deficits in schizophrenia, bipolar disorder and ADHD, and attentional biases in depression and anxiety disorders.

Sustained Attention

Sustained attention or *vigilance* maintains alertness continuously over time. For example, sustained attention is what enables you to stay focused on reading this chapter instead of drifting off into a daydream. Sustained attention is usually measured with continuous performance tests (CPTs), in which a stream of stimuli must be monitored for several minutes to detect infrequent and nonsalient targets (e.g., a particular number sequence in a stream of numbers). Sustained attention involves subcortical brain systems that maintain basic arousal and alertness (e.g., reticular activating system), but also the frontoparietal cognitive control network that also supports EF. This is probably because sustaining attention on tasks like the CPT, while seemingly simple, requires EF processes such as maintaining the task goal and monitoring for task-relevant stimuli. Sustained attention is particularly impaired in individuals with schizophrenia, BD, and ADHD. In contrast, there is limited evidence for sustained attention impairments in individuals with depression or anxiety disorders.

Recent meta-analyses have found impairments with large deficits on sustained attention tasks for individuals with schizophrenia, medium deficits for individuals with BD and MDD, and small to medium deficits for individuals with OCD (Table 8.3). While most research has focused on adults, deficits in sustained attention have been reported in children and adolescents with schizophrenia (e.g., Groom et al., 2008; Thaden et al., 2006; but see Ueland, Øie, Inge Landrø, & Rund, 2004) and BD (Table 8.3). A recent meta-analysis also found that adolescents with psychosis risk syndrome have small but significant deficits in sustained attention, which are somewhat larger in those who go on to convert to schizophrenia (Giuliano et al., 2012). Sustained attention deficits appear to be relatively stable over the course of illness: they do not vary with age in individuals with schizophrenia through adulthood and older adulthood (Bozikas & Andreou, 2011; Irani et al., 2011), and persist during euthymia in individuals with BD (Table 8.3) and in remission for individuals with MDD (Rock et al., 2013).

As for EF, there is some evidence that sustained attention impairments may be risk markers for psychosis and BD. Adolescents scoring in the high-risk range on a questionnaire for psychotic-like experiences had impaired sustained attention (Kim et al., 2012). Furthermore, unaffected first-degree relatives of individuals with BD also have significant, though milder, deficits in sustained attention (Bora et al., 2009). On the other hand, there

TABLE 8.3 Summary of Recent Attention Meta-Analyses[1]

	Meta-analysis	Group	Sustained attention	Biased attention: dot-probe	Biased attention: emotional Stroop
Depression	Peckham et al. (2010)	MDD	–	0.70	0.16
	Epp et al. (2012)	MDD			0.24
	Rock et al. (2013)	MDD	0.65		
Average					**0.20**
BD	Arts et al. (2008)	Euthymic BD (all)	0.58		
	Bora et al. (2009)	Euthymic BD ((all)	0.83		
	Kurtz and Gerraty (2009)	Euthymic BD ((all)	0.69		
	Kurtz and Gerraty (2009)	Manic/mixed BD (all)	0.79		
	Robinson et al. (2006)	Euthymic BD (all)	0.60		
	Torres et al. (2007)	Euthymic BD (all)	0.74		
	Walshaw et al. (2010)	Pediatric BD (all, clinical status not specified)	0.40		
Average			**0.66**		
Anxiety Disorders	Bar-Haim et al. (2007)	OCD, GAD, PTSD, SAD, PD, and simple phobia	–	0.38	0.45

Children and adolescents only			0.57		
Adults only			0.57		
Average (all)			0.58		

[1]Summary of meta-analyses conducted in the last ten years. Weighted mean effect size (Cohen's *d*) comparing healthy control participants to the clinical group. All effect sizes have been recoded such that positive values represent worse task performance by the clinical group. When a meta-analysis reported effect sizes for multiple individual tasks within an attention component, the average of these effect sizes is reported.

is some evidence that sustained attention impairments develop over the course of psychotic illness: early-onset schizophrenia patients show a failure to improve performance on attention tasks during adolescence, while healthy adolescents do improve performance, suggesting that schizophrenia is associated with a failure in the developmental trajectory (Frangou, 2009).

Inattention symptoms obviously play a central role in ADHD. However, the diagnostic criteria for ADHD in the DSM-IV are not specifically defined in cognitive terms, and behaviors labeled as *inattentive* may not always arise from deficits in attentional processes per se (e.g., behavior labeled inattentive might be due to poor EF; Huang-Pollock, Nigg, & Carr, 2005). Nonetheless, some diagnostic criteria do appear to describe difficulty sustaining attention. Indeed, there is strong meta-analytic evidence that children, adolescents, and adults with ADHD all have impaired performance on laboratory sustained attention tasks, with equal effect sizes across ages, including preschool, suggesting that attentional processes are affected from early in development (Table 8.5). Specifically, individuals with ADHD discriminate between targets and distracters more slowly and less accurately, and show an increasing number of omission errors over time during task performance, consistent with difficulty sustaining attention, but do not show a bias to make more target responses which would be consistent with impulsive responding (Huang-Pollock, Karalunas, Tam, & Moore, 2012).

There is much less evidence for sustained attention impairments associated with anxiety disorders other than OCD, with mixed evidence of impairments in sustained attention associated with PTSD (e.g., Jenkins, Langlais, Delis, & Cohen, 2000; Vasterling et al., 2002, but see, e.g., LaGarde, Doyon, & Brunet, 2010; Twamley, Hami, & Stein, 2004), and no evidence of impairment in PD (e.g., Galderisi et al., 2008; Gladsjo et al., 1998).

Selective Attention

Selective attention filters incoming information to select relevant information for further processing. This selection can occur on the basis of sensory modality (e.g., pay attention to visual, not auditory, information), sensory attributes (e.g., look for something blue) or spatial locations (e.g., pay attention to the left side of space). (Selecting information on the basis of more abstract processes or goals is covered under executive function). For example, if you are reading this chapter in a busy coffee shop, selective attention enables you to attend to the words on the page while filtering out the conversations going on around you. Selective attention, especially in the visuospatial domain, is largely supported by the dorsal attention network (also called the orienting network), which consists of the posterior parietal cortex and frontal eye fields, and is involved in voluntary orienting of attention based on cues (e.g., Posner & Rothbart, 2007). Somewhat surprisingly given impairments in seemingly more basic sustained attention, selective attention deficits do not appear to be strongly associated with psychopathology, with the possible exception of auditory selective attention in individuals with schizophrenia.

There is some evidence that auditory selective attention may be impaired in individuals with schizophrenia. Specifically, several studies have found that adults with schizophrenia or schizotypal personality disorder were worse at selective attention in dichotic listening tasks, in which two different verbal stimuli are presented simultaneously, one in each ear, with instructions to identify the stimuli in only one ear (Egeland et al., 2003; Hugdahl et al., 2003; Voglmaier et al., 2009). However, these deficits may not be present in younger and stabilized patients (Løberg, Jørgensen, & Hugdahl, 2002).

Unlike auditory selective attention, there is not strong evidence for impairments in visuospatial selective attention associated with schizophrenia. While individuals with schizophrenia are slower overall on measures of selective attention, they generally perform as well as healthy control participants at excluding distracters from attention (Gold, Hahn, Strauss, & Waltz, 2009). Specifically, in Posner spatial cueing tasks, in which a visual cue indicates the probable location of an upcoming stimulus, individuals with schizophrenia are slower to respond overall, but benefit as much from valid cues, and are slowed as much by invalid cues, as healthy control participants (Gold et al., 2009). Similar findings have been reported for visual search tasks, in which targets of a certain shape and color, rather than spatial location, must be selectively focused on (for review, see Gold et al., 2009). Event related potential (ERP) evidence further suggests that individuals with schizophrenia are as fast as healthy participants to allocate attention to a target, even though their subsequent motor response is slowed (Luck et al., 2006).

Mirroring the findings in schizophrenia, there is not clear evidence for impaired visuospatial selective attention in individuals with ADHD despite impaired sustained attention. Specifically, while children with ADHD are slower to respond to cued targets, children with and without ADHD have a similar pattern of response slowing when distracters are present or cues are invalid (Friedman-Hill et al., 2010; Huang-Pollock et al., 2005). Meta-analytic

evidence suggests only small differences in cued visuospatial selective attention between children with ADHD and healthy children (d =0.22–0.27, (Huang-Pollock et al., 2005). This suggests that children with ADHD are not specifically impaired at visually selecting target items or locations. While there is some evidence that children and adults with ADHD have difficulty selectively attending to auditory information (Gomes et al., 2012; Shafritz, Marchione, Gore, Shaywitz, & Shaywitz, 2004), the possibility that these findings could also be due to general slowing rather than selective attention deficits per se requires further investigation.

Interestingly, there is some evidence that children and adults with ADHD do as well has healthy controls at filtering out distracters when task demands are high, but show deficits when task demands are low (easy target discrimination and low distracter salience), suggesting that individuals with ADHD may have trouble endogenously sustaining attention in easy tasks, rather than selective attention per se (Friedman-Hill et al., 2010). Thus, as in schizophrenia, it appears that individuals with ADHD may not have a core deficit in filtering irrelevant visual information, but rather problems with recruiting and sustaining attentional control. This view is consistent with the finding that individuals with ADHD are reliably impaired on sustained attention tasks, which are relatively undemanding and may therefore lead to more lapses in attention.

There has been little research on selective attention in other forms of psychopathology, with mixed reports of impaired and unimpaired selective attention in adults with depression (Egeland et al., 2003; Hammar, Kildal, & Schmid, 2012; Hugdahl et al., 2003, but see, e.g., Desseilles et al., 2009; Godard et al., 2011; Reppermund, Ising, Lucae, & Zihl, 2009), BD (Burdick et al., 2009), PTSD (Johnsen, Kanagaratnam, & Asbjørnsen, 2011, but see, e.g., Leskin & White, 2007; Vasterling et al., 2002) and OCD (Clayton, Richards, & Edwards, 1999), but only reports of unimpaired performance in PD (Clayton et al., 1999) and SAD (Sachs, Anderer, Doby, Saletu, & Dantendorfer, 2003). Furthermore, it is not clear if those deficits that have been reported might result from general slowing, as in schizophrenia and ADHD.

Divided Attention

Divided attention allocates processing resources to more than one task at once. To return to our coffee shop example, divided attention enables you to continue reading the chapter while at the same time listening for your order to be called. In the laboratory, divided attention is generally assessed with tasks that require dividing attention between two simple tasks at once (e.g., identifying visual and auditory targets). Coordinating two tasks in this way activates the frontoparietal cognitive control network, even when the individual tasks do not (Collette et al., 2005), suggesting that, like sustained attention, it places demands on EF.

There has been less research on divided attention than other forms of attention. However, those studies which have examined this domain found divided attention impairments in adults (e.g., Daban et al., 2005; Raffard & Bayard, 2012) and adolescents (Boutin, Gingras, & Rouleau, 2010) with schizophrenia, adults with BD (Godard et al., 2011), adults with depression (Godard et al., 2011; Reppermund et al., 2009), and both children/adolescents (e.g., Greimel et al., 2011; Kaufmann et al., 2010; but see Koschack, Kunert, Derichs, Weniger, & Irle, 2003) and adults (Müller et al., 2007) with ADHD. In addition, nonpsychotic relatives of individuals with schizophrenia have impaired divided attention (Faraone et al., 1999), as do adolescents scoring in the high-risk range on a questionnaire for psychotic-like experiences (Kim et al., 2012), suggesting it may be an endophenotype or risk factor. However, there has been no research that could shed light on the causal links between divided attention impairments and other forms of psychopathology.

Biased Attention

Biased attention is the tendency to direct attention toward, and have difficulty disengaging attention from particular type of affective stimuli, often those that are mood-congruent. Attentional biases can arise both from increased bottom-up salience of the affective stimuli (e.g., because it is mood-congruent) and reduced top-down control of attention. In the laboratory, attentional bias is usually measured in dot-probe tasks, in which visual attention must be directed away from affective stimuli to detect a target, and emotional Stroop tasks in which the meaning of affective words must be ignored to respond based on the color of the ink the words are written in (see Table 8.4).

The tendency to inappropriately allocate attention to emotional cues is central to cognitive models of mood disorders (e.g., Beck, 2008). Meta-analytic evidence demonstrates that individuals with depression have an attentional bias toward negative information, with medium effect sizes on dot-probe tasks, but only small effect sizes on emotional Stroop tasks (Table 8.4), and may have a bias away from positive stimuli (Peckham, McHugh, & Otto, 2010). Interestingly, attentional biases on the emotional Stroop and dot probe tasks do not appear to be significantly correlated, suggesting that they

TABLE 8.4 Examples of Commonly Used Attention Measures

Construct	Task	Description	Outcome measures	Methods citation[1]
Sustained attention	X-Type Continuous Performance Test	Stimuli (letters, numbers, or pictures) are presented continuously on the computer screen, participant presses a button whenever the target (e.g., X) appears.	Multiple measures including: **1.** Commission errors (false alarms) **2.** Omission errors **3.** RT **4.** Changes in RT and accuracy over time	Riccio, Reynolds, Lowe, and Moore (2002)
	AX-Type and Identical Pairs Continuous Performance Test	Stimuli (letters, numbers, or pictures) are presented continuously on the computer screen, participant presses a button whenever the target (e.g., X) appears, proceeded by a specific other stimulus (e.g., A), or when two identical stimuli appear in a row.	Multiple measures including: **1.** Commission errors (false alarms) **2.** Omission errors **3.** RT **4.** Changes in RT and accuracy over time	Riccio et al. (2002)
	Conners' Continuous Performance Test	Letters presented continuously on the computer screen, participant presses a button whenever any letter other than X appears.	Multiple measures including: **1.** Commission errors (false alarms) **2.** Omission errors **3.** RT **4.** Changes in RT and accuracy over time	Strauss et al. (2006)
	Integrated Visual and Auditory Continuous Performance Test (IVA)	Two stimuli (e.g., 1, 2) are presented pseudorandomly, alternating between visual and auditory presentation, participants press a button for targets, regardless of modality.	Standardized indexes calculated by the program, based on error and RT patterns	Strauss et al. (2006)
Selective attention	Ruff 2 & 7 Selective Attention Task	Draw lines through targets (2 & 7) while ignoring other numbers and letters.	**1.** Correct hits within time limit **2.** Errors	Strauss et al. (2006)
	Visual Search (e.g., Test of Everyday Attention search tasks)	Many versions. Search for target stimuli (e.g., a number, letter, shape, or picture) in an array of distracter stimuli.	Vary between versions, generally search time or number of correct hits within a time limit.	Strauss et al. (2006) for Test of Everyday Attention
	Dichotic Listening	Many versions. Two separate auditory stimulus streams (words or syllables) presented, one to each ear, via headphones. Participants asked to pay attention to one ear and repeat aloud the content.	**1.** Correct hits from attended ear **2.** Intrusions (false alarms) from unattended ear	Hugdahl (2003)
	Posner Cueing task and similar spatial cueing tasks	Participants must detect targets presented to the left or right of a fixation point, with or without a preceding cue. Cues are endogenous (central arrows pointing to the left or right) or exogenous (highlighting the left or right target box). On valid trials (usually 80%), the cue indicates the correct target location, on invalid trials (usually 20%), the cue indicates the incorrect target location.	Multiple measures including: **1.** Target detection RT **2.** Congruent RT—uncued RT (cueing benefit) **3.** Incongruent RT—uncued RT (incongruent cueing cost)	Posner, Snyder, and Davidson (1980)
Divided attention	Dual Task paradigms (e.g., Test of Everyday Attention Telephone Switch While Counting; Test of Attentional Performance divided attention task)	Many versions. Require completing two simple tasks at once, usually one visual and one auditory (e.g., visual search while counting tones in TEA). Performance compared with each task performed separately.	RT or accuracy difference between dual task and single task conditions	Strauss et al. (2006) for Test of Everyday Attention
Biased attention	Dot-Probe	Two stimuli (usually faces or other pictures) of differing valence are briefly presented (usually 500 ms) simultaneously on either side of a fixation point, followed by an emotionally neutral probe (e.g., dot, arrow, or letter) at one location, which must be detected/identified.	RT difference to detect/identify the probe in the previous location of the valences vs. the neutral stimulus	Yiend (2010)
	Emotional Stroop	Report the color of emotional words and neutral words written in colored ink.	RT difference between emotional and neutral words	Yiend (2010)

[1]Citations are for sources that provide a full description of the task and outcome measures of the most recent or recommended version of the task, not necessarily the first publication to report the task.

may index different attentional processes (Dalgleish et al., 2003). This could potentially be due to the need to shift visuospatial attention away from negative stimuli in the dot-probe tasks, in comparison to the emotional Stroop task, in which negative information is integral to the task stimuli. Depression is associated with extended maintenance of gaze to dysphoric stimuli in free viewing tasks, as measured with eye tracking (Armstrong & Olatunji, 2012), suggesting difficulty shifting visuospatial attention away from negative stimuli could potentially account for the stronger effects seen in dot-probe tasks. In contrast to depression, there is limited and mixed evidence for attentional biases toward negative and manic stimuli individuals with BD on emotional Stroop (Besnier et al., 2011; Lyon, Startup, & Bentall, 1999) and dot-probe (Lyon et al., 1999; but see Whitney et al., 2012) tasks. Thus, more research is needed on attentional biases associated with BD.

Attentional biases associated with depression and BD do not seem to be driven by current mood state, and may be risk markers. Negative attentional bias does not occur after sad mood induction (Epp, Dobson, Dozois, & Frewen, 2012) but is present in adults (Peckham et al., 2010) and youth (Hankin, Gibb et al., 2010) with depression in remission, and unaffected relatives of individuals with BD (Besnier et al., 2009; Gotlib, Traill, Montoya, Joormann, & Chang, 2004). Further supporting the hypothesis that attentional biases may be a risk factor, training to modify attentional biases by directing attention toward positive stimuli has been shown to reduce the risk of depression recurrence (Browning, Holmes, Charles, Cowen, & Harmer, 2012). However, one study did find that only depressed BD patients, and not euthymic BD patients or unaffected relatives of BD patients, demonstrated attentional bias away from positive stimuli (Jabben et al., 2012). Thus, more research is needed to determine if some attentional biases may be mood state dependent.

Like mood disorders, there is evidence for biased attention in anxiety disorders, specifically toward threatening stimuli. In emotional Stroop and dot-probe tasks, individuals with anxiety disorders have a bias toward threat information, with similar effect sizes across disorders, and for children and adults (Table 8.4). Likewise, individuals with PTSD have biased attention toward PTSD-specific threat words in the emotional Stroop task compared with nontrauma exposed individuals, though they do not differ significantly from trauma-exposed individuals without PTSD (Cisler et al., 2011). These attentional biases may be driven largely by initial orienting toward threat, as evidenced by larger effects at shorter stimulus durations (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & Van IJzendoorn, 2007) and more frequently initial orienting toward threat during free viewing and visual search (Armstrong & Olatunji, 2012). In contrast, there is not consistent evidence for increased subsequent maintenance of gaze toward threat, although it may occur in some task contexts (Armstrong & Olatunji, 2012). Thus, the factors that influence initial orienting of attention toward threat may be distinct from those that influence later maintenance or shifts of attention (Shechner et al., 2012).

Attentional biases have been relatively infrequently studied in individuals with schizophrenia, but the extant research suggests that schizophrenia may be associated with attentional biases toward disorder-specific stimuli. There is some evidence that individuals with paranoid schizophrenia have increased interference from paranoia-related and threat words in the emotional Stroop task (Besnier et al., 2011; Kinderman, Prince, Waller, & Peters, 2003), but not negative or positive words more generally (Besnier et al., 2011; Demily et al., 2010; Waters, Badcock, & Maybery, 2006). However, it is possible there is a more general bias toward negative stimuli in schizotypy (Mohanty et al., 2005). There has been almost no research on attentional biases in individuals with ADHD, with one recent study finding that children with ADHD did not exhibit the attentional bias toward threat shown by those with anxiety disorders (Weissman, Chu, Reddy, & Mohlman, 2012). More research is needed in this area, especially with stimuli that may be more affectively relevant to those with ADHD, such as reward stimuli.

Memory

Much of what we do in our daily lives, and indeed, who we are, depends on memory. There are multiple memory systems and memory processes, including *episodic memory* (memory for specific events), *semantic memory* (memory for facts and concepts), and *autobiographical memory* (memory for specific life events and facts about the self).[1] Memory problems are common in psychopathology, but the nature and magnitude of these impairments vary across disorders. While most forms of psychopathology are associated with impairments in episodic memory, only schizophrenia is associated with substantial impairments in semantic memory, and autobiographical memory

[1] Here we focus on explicit (episodic and semantic) memory, which has been most often studied in relation to psychopathology. Skill learning and conditioning can also be considered forms of memory (implicit memory), but are beyond the scope of this chapter. Working memory is covered in the section on executive function.

may be particularly affected in schizophrenia, depression and PTSD.

Episodic Memory

Episodic memory refers to memories for specific events within a spatio-temporal context (e.g., yesterday, I sat in my office and read papers about episodic memory), and relies heavily on the hippocampus and surrounding areas of the medial temporal lobe (e.g., Eichenbaum, 2004). In the laboratory, episodic memory is assessed by asking participants to study stimuli (e.g., word lists or complex designs), then recall or recognize them after a delay (Table 8.5). These tasks thus allow pure episodic memory to be separated from autobiographical memory for personally significant events. Many forms of psychopathology are associated with episodic memory impairments on these tasks, although the magnitude of these impairments varies both across disorders and across memory tests.

Adults with schizophrenia and bipolar disorders have similar profiles of episodic memory impairments, albeit with larger effect sizes for individuals with schizophrenia. Meta-analytic evidence demonstrates that individuals with schizophrenia and BD have large and medium impairments respectively in episodic memory (Table 8.6). Impairments are similar for recall of verbal and nonverbal information, and for recall after short and long delays (Table 8.6). There is some evidence that deficits in recognition are somewhat smaller than those for recall, although recognition memory has been less studied (Table 8.6). While there have been relatively few studies of episodic memory in children and adolescents with BD or early-onset schizophrenia, they seem to have somewhat comparable levels of impairment as adults with these disorders (Frangou, 2009; Joseph, Frazier, Youngstrom, & Soares, 2008). A recent meta-analysis also found that adolescents with psychosis risk syndrome have small but significant deficits in both verbal and nonverbal episodic memory, which are somewhat larger in those who go on to convert to schizophrenia (Giuliano et al., 2012).

There is some evidence that episodic memory impairments may be a stable trait in individuals with schizophrenia and BD. Deficits in individuals with BD are not closely tied to current mood state, as they occur in euthymic BD (Table 8.6), although there is some evidence that they may be somewhat larger in manic/mixed and depressed BD (Kurtz & Gerraty, 2009). In addition, in individuals with schizophrenia, meta-analyses of longitudinal studies have found no increase in deficits over relatively brief periods (Irani et al., 2011; Szöke et al., 2008). However, declines may occur over a longer time period, or may have already occurred since many studies included individuals with chronic schizophrenia.

There has been less research on episodic memory in other forms of psychopathology, but the available evidence points to episodic memory impairments in most other disorders as well. Adults with depression appear to have impairments in both verbal and nonverbal episodic memory (Table 8.6; but see Lee, Hermens, & Porter, 2012 for evidence of impaired nonverbal but not verbal episodic memory in first episode MDD). The one meta-analysis that included both recall and recognition measures for nonverbal memory found roughly equal effect sizes (Rock et al., 2013, Table 5). There has been no systematic examination as to whether verbal recall and recognition are differentially affected. In addition, there has been little research on episodic memory in children/adolescents with or at risk for depression, although a few studies have found deficits in verbal (Günther, Holtkamp, Jolles, Herpertz-Dahlmann, & Konrad, 2004; Horan, Pogge, Borgaro, Stokes, & Harvey, 1997) and nonverbal (Matthews & Coghill, 2008) episodic memory.

At least some anxiety disorders are also associated with episodic memory impairments. Individuals with PTSD have impairments in verbal episodic memory recall (after both short and long delays), but only small impairments in nonverbal recall (Brewin, Kleiner, Vasterling, & Field, 2007). An important question is whether these deficits are due to PTSD per se, or the traumatic experiences themselves. Both appear to contribute: individuals with PTSD have significant verbal episodic memory impairments even compared with trauma-exposed individuals without PTSD, but have larger impairments compared with healthy, nontrauma-exposed control participants (Table 8.6; Johnsen & Asbjørnsen, 2008). While most research included in these meta-analyses is on adults, studies in children with maltreatment-related PTSD have also reported episodic memory impairments (Carrion et al., 2012). However, there is some evidence that co-occurring depressive symptoms may account for episodic memory impairments in individuals with PTSD (Burriss, Ayers, Ginsberg, & Powell, 2008), and more research is needed to disentangle to what extent memory impairments are driven by factors specific to PTSD versus co-occurring depression or transdiagnostic processes.

Meta-analyses of adults with OCD found small but significant effect sizes for verbal memory and medium effect sizes for nonverb memory, but did not systematically analyze all specific aspects of memory (Table 8.6). A meta-analysis of compulsive checkers (most with a diagnosis of OCD) found significant, albeit moderate, impairments in verbal and nonverbal recall, and nonverbal

TABLE 8.5 Examples of Commonly Used Memory Measures

Construct	Task	Description	Outcome measures	Methods citation[1]
Verbal episodic memory	California Verbal Learning Test (CVLT)	Semantically structured list of 16 items presented for five learning trials, each followed by recall. Then a second 16 word interference list is presented for one trial, followed by free and cued recall of the first list. After 20 min. of distracting tasks, first list free and cued recall or repeated, then recognition test.	Many outcome parameters, including: **1.** Short delay free and cued recall **2.** Long delay free and cued recall **3.** Recognition (hits, false alarms, discrimination index)	Straus et al. (2006)
	Rey Auditory Verbal Memory Test (RAVLT)	List of 15 words read aloud by experimenter for five learning trials, each followed by recall. Then a second 15 word interference list is presented for one trial, followed by free recall of the first list. After a 20 min. delay, free recall of first list repeated, then recognition of first list words.	Many outcome parameters, including: **1.** Short delay free and cued recall. **2.** Long delay free and cued recall. **3.** Recognition (hits, false alarms, discrimination index).	Straus et al. (2006)
	Wechsler Memory Scale (WMS-III) Word List	Recall a list of 12 words after each of four learning trials, after presentation of an interference list, and again after a delay. Finally, a recognition trial is given.	**1.** Immediate recall **2.** Delayed recall **3.** Recognition	Straus et al. (2006)
	Wechsler Memory Scale (WMS-III) Logical Memory	Recall two paragraphs read aloud by the experimenter immediately and after a delay, followed by a yes/no recognition test.	**1.** Immediate recall **2.** Delayed recall **3.** Recognition	Straus et al. (2006)
	Wechsler Memory Scale (WMS-III) Verbal Paired Associates	Experimenter presents a list of word pairs, then reads the first word in each pair and participant must respond with the second word. Recall is re-tested after a delay, followed by a recognition test.	**1.** Immediate recall **2.** Delayed recall **3.** Recognition	Straus et al. (2006)
Nonverbal episodic memory	Benton Visual Retention Test (BVRT)	Geometric figure is displayed for 10 s and then withdrawn. Participant must copy figure from memory.	**1.** Number of correct reproductions **2.** Error score	Straus et al. (2006)
	Brief Visuospatial Memory Test (BVMT)	Participant views six simple geometric patterns in a grid for 10 s, which is then withdrawn. Participant must reproduce figures in correct locations from memory. Followed by two more learning and recall trials with same stimuli, then recall again after 25 min. of distracting tasks, followed by recognition trial.	Many outcome parameters, including: **1.** Recall on first three trials (short delay recall) **2.** Delayed recall **3.** Recognition (hits, false alarms, discrimination index)	Straus et al. (2006)
	Rey-Osterrieth Complex Figures Test (ROCF)	A complex geometric figure is presented. Administration procedures differ, but usually participants are asked to copy the figure, then it is withdrawn and participants must reproduce it from memory after a 3 min. delay and again after a 30 min. delay, which may be followed by a recognition trial.	Many outcome parameters, including: **1.** Short and long delay recall accuracy (points for each part of figure correctly reproduced). **2.** Recognition (points for each part of figure recognized correctly).	Straus et al. (2006)
	Wechsler Memory Scale (WMS-III) Visual Reproduction	Participant must reproduce geometric figures both immediately and after a delay. Recognition can also be tested.	**1.** Immediate recall **2.** Delayed recall **3.** Recognition	Straus et al. (2006)
	Wechsler Memory Scale (WMS-III) Faces	Participant must recognize faces both immediately after presentation and after a delay.	**1.** Immediate recognition **2.** Delayed recognition	Straus et al. (2006)
Semantic memory	Expressive Vocabulary Test (EVT), Boston Naming Test, and similar picture naming tests	Label pictures with increasing item difficulty. Some tests (e.g., EVT) also require providing synonyms for some items.	Scores based on number of items correct	Straus et al. (2006)
	Peabody Picture Vocabulary Test (PPVT) and similar picture recognition tests	Point to pictures corresponding to a label from an array of four pictures.	Scores based on number of items correct	Straus et al. (2006)

TABLE 8.5 (*Continued*)

Construct	Task	Description	Outcome measures	Methods citation[1]
	Wechsler Adult Intelligence Scale (WAIS) Vocabulary and similar vocabulary tests	Combination of naming pictures and defining words.	Standardized scores following scoring manual	Straus et al. (2006)
	Wechsler Adult Intelligence Scale (WAIS) Information and similar semantic information tests	Answering questions about a broad range of general knowledge, including scientific and geographical facts, history, and literature.	Standardized scores following scoring manual	Straus et al. (2006)
	Pyramid and Palm Trees/ Camel and Cactus	On each trial, point to one of four pictures that goes best with a target picture (e.g., target = bottle of wine, choices = apple, banana, grapes, pear).	Accuracy	Bozeat, Lambon Ralph, Patterson, Garrard, and Hodges (2000); Howard and Patterson (1992)
	Categorization/Sorting tasks	A variety of tasks, involving asking whether an item belongs to a certain category or not, or sorting items into categories, at different category levels (e.g., animals vs. plants; birds vs. mammals)	Accuracy	Doughty et al. (2009)
	Semantic Priming	A simple task, usually lexical decision (word or nonword) is performed, with each word proceeded by a semantically related word (prime) or unrelated word. Primes can be direct (e.g., tiger-lion) or indirect (e.g., stripes-lion).	Difference in RT between primed and unprimed words	Perea and Rosa (2002)
Autobiographical memory	Autobiographical Memory Interview	Semi-structured interview assessing semantic autobiographical memory (e.g., names of teachers) and episodic autobiographical memory (e.g., describing specific events) from childhood, early adulthood, and recent past.	**1.** Number of semantic facts recalled from each time period **2.** Points based on number and detail (time and place) of episodic events recalled from each time period	Straus et al. (2006)
	Autobiographical Memory Test	Participants are presented with words (e.g., safe, clumsy) and asked to retrieve a memory specific to time and place and describe it for 30–60 s.	Memories scored as categoric (repeated event), extended (lasting more than one day), or specific (reflect a unique occurrence lasting no longer than a day)	Williams and Broadbent (1986)
	TEMPau Task	Participants instructed to recall specific events (lasting less than one day) from different life periods, and classify them as remember (specific episodic details, sense of mental time travel), know (semantic details, sense of familiarity only), or guess (not certain about any details).	**1.** Overall and episodic specificity scores **2.** What, where, and when remember and know scores **3.** Self-perspective (field vs. observer)	Piolino, Desgranges, and Eustache (2009)

recognition, although verbal recognition was not impaired, possibly due to ceiling effects (Table 8.6; Woods, Vevea, Chambless, & Bayen, 2002). Research has focused almost entirely on adults, and the few studies in children and adolescents with OCD again show mixed findings of impaired (Andrés et al., 2007) and unimpaired (Ornstein, Arnold, Manassis, Mendlowitz, & Schachar, 2010; Shin et al., 2008) episodic memory. There has been very little research on memory function in individuals with other anxiety disorders. One study found significant verbal episodic memory impairments associated with PD and SAD, but not generalized anxiety disorder or specific phobias (Airaksinen et al., 2005; Galderisi et al., 2008). However, the lack of significant effects for specific phobias and generalized anxiety disorder must be interpreted with caution since the very small sample sizes limited power.

Finally, meta-analytic evidence demonstrates that adults with ADHD also have impairments in verbal episodic memory recall (after both short and long delays), and recognition (Table 8.6). While there has been no meta-analysis, individual studies have also found episodic verbal memory deficits in children and adolescents with

TABLE 8.6 Summary of Memory Meta-Analyses[1]

[1] Summary of meta-analyses conducted in the last ten years. Weighted mean effect size (Cohen's *d*) comparing healthy control participants to the clinical group. All effect sizes have been recoded such that positive values represent worse task performance by the clinical group. When a meta-analysis reported effect sizes for multiple individual tasks within a memory component, the average of these effect sizes is reported.

[2] This older meta-analysis is included due to the lack of more recent meta-analyses covering multiple aspects of memory in individuals with MDD.

ADHD (Cutting, Koth, Mahone, & Denckla, 2003; Udal, Øygarden, Egeland, Malt, & Groholt, 2012; but see Kibby & Cohen, 2008; Vakil, Blachstein, Wertman-Elad, & Greenstein, 2012). However, there is little evidence of deficits in nonverbal episodic memory (Table 8.6). This pattern suggests that factors other than episodic memory per se may be contributing to the verbal memory deficits in individuals with ADHD. Since reading and language disorders frequently co-occur with ADHD (e.g., Willcutt, Pennington, & DeFries, 2000), it is possible that difficulty processing verbal information may play a role, although even children without co-occurring reading disabilities have been reported to have verbal episodic memory impairments (Cutting et al., 2003; Kibby & Cohen, 2008).

Overall, the pattern of episodic memory impairments across disorders suggests a domain-general deficit in encoding or retrieval. First, deficits are not greater for recall after a longer delay compared with a shorter delay in any disorder where this has been investigated. This suggests that psychopathology is associated with difficulty in encoding and/or retrieval, rather than forgetting more information over time (storage). Second, in most disorders, memory for both verbal and nonverbal materials is impaired, suggesting deficits are mostly domain general, although the magnitude of deficits occasionally differs between domains, perhaps due to additional domain-specific deficits (e.g., visuospatial processing in OCD (Rampacher et al., 2010). There are two possible exceptions, PTSD and ADHD, in which there is little evidence for nonverbal episodic memory impairments; however, as there has been less research on nonverbal memory in these disorders, it is premature to conclude that it is not impaired. Third, in some cases recall is more impaired than recognition. While recall requires retrieval processes supported by the hippocampus and PFC, recognition can be accomplished based on familiarity, which is supported by areas surrounding the hippocampus (Yonelinas, 2002).

Thus, it has been proposed that impaired hippocampal binding and prefrontally mediated use of strategies for encoding and retrieval lead to particular impairments in episodic recall for individuals with psychopathology (e.g., Barch & Ceaser, 2012). Indeed, there is meta-analytic evidence for reduced hippocampal volume and/or alterations in hippocampal functional activation in individuals with multiple forms of psychopathology, including schizophrenia (Adriano, Caltagirone, & Spalletta, 2012), BD (Frey et al., 2007), depression (Arnone, McIntosh, Ebmeier, Munafò, & Anderson, 2012), and PTSD (compared with both trauma-exposed and unexposed controls; Kühn & Gallinat, 2013; Woon, Sood, & Hedges, 2010; although effects have been much less consistently found in children; Carrion et al., 2012).

There is some evidence suggesting that hippocampally mediated memory problems may be risk factors or endophenotypes for psychopathology, rather than a neurodegenerative effect of illness. Hippocampal volume is reduced in at-risk individuals before psychosis onset (Fusar-Poli, Radua, McGuire, & Borgwardt, 2012), and is equally reduced in first episode and chronic schizophrenia (Adriano et al., 2012; Mesholam-Gately et al., 2009; Pelletier, Achim, Montoya, Lal, & Lepage, 2005) for increased recognition deficits with illness duration). Likewise, individuals who had lower episodic memory recall performance pre-trauma subsequently developed more PTSD symptoms following a natural disaster (Parslow & Jorm, 2007) or deployment to a war zone (Marx, Doron-Lamarca, Proctor, & Vasterling, 2009). Moreover, unaffected relatives of individuals with schizophrenia, BD, and PTSD also have smaller hippocampal volumes and moderate impairments in episodic memory (Arts et al., 2008; Barch, 2005; Bora et al., 2009; Gilbertson et al., 2006).

While this evidence suggests that hippocampal dysfunction may be an endophenotype, there is some evidence that neurodegenerative processes may also play a role. Specifically, stress has neurotoxic effects on the hippocampus, which has a particularly high concentration of glucocorticoid receptors (MacQueen & Frodl, 2010), suggesting that stress associated with psychopathology may contribute to hippocampal dysfunction. However, there is mixed and inconclusive evidence that hippocampal dysfunction increases with longer illness duration (MacQueen & Frodl, 2010), although there is evidence for progressive loss of temporal lobe grey matter (Vita, De Peri, Deste, & Sacchetti, 2012). Thus, hippocampal dysfunction may arise from a combination of neurodegenerative processes and genetic factors and early life stress which in turn increase risk for psychopathology (Pechtel & Pizzagalli, 2010).

Why might poor memory function serve as a risk factor? One possibility is that the ability to effectively solve problems depends in part on retrieval of information about similar past situations, and that poor problem solving increases stress and risk for psychopathology (e.g., Sutherland & Bryant, 2008). Moreover, under stress memories become more rigid and habitual, potentially contributing to a lack of flexibility in thinking and problem solving which could contribute to psychopathology (Schwabe, Wolf, & Oitzl, 2010).

Semantic Memory

Semantic memory is knowledge of facts and concepts, which are not tied to a particular time or place (e.g., knowing what semantic memory means, without remembering where and when you learned this). Semantic memory is generally assessed by asking people to define words, answer general factual questions, or sort items based on semantic categories or similarity (Table 8.5). Semantic memory depends on a distributed network of cortical areas that represent specific sensory properties (e.g., shapes and colors in visual association cortex, sounds in auditory association cortex) as well as anterior lateral temporal lobe and prefrontal areas involved in more abstract semantic processing (e.g., Patterson, Nestor, & Rogers, 2007).

Unique among the disorders reviewed here, meta-analytic evidence demonstrates that schizophrenia is associated with large impairments in semantic memory (Table 8.6). What is responsible for these semantic memory impairments? First, since many semantic memory tasks assess vocabulary and factual knowledge, performance could be affected by education; however, individuals with schizophrenia are impaired even compared with education-matched healthy control participants (Doughty & Done, 2009). Second, effect sizes are generally large for picture naming and vocabulary tests requiring language production, and moderate but still significant for picture matching and sorting tasks which do not require a verbal response (Doughty & Done, 2009). This suggests that language impairments may contribute to poor performance on verbal semantic memory tasks, but do not fully account for semantic memory impairments. Third, deficits are present even for naming and picture matching tasks that have few executive function demands and are generally preserved in individuals with prefrontal damage, suggesting that semantic memory deficits are also not solely due to EF impairments (Done, 2009).

Rather, schizophrenia may be associated with abnormalities in semantic associations themselves. Individuals with schizophrenia show bizarre associations, idiosyncratic categorization during sorting tasks, and increased semantic priming (especially indirect priming, e.g., tiger-stripe; Pomarol-Clotet, Oh, Laws, & McKenna, 2008), consistent with a loosening of associations caused by excessive spreading activation through semantic networks (Doughty & Done, 2009). These abnormalities in semantic associations are more severe for those with formal thought disorder, and have been posited to play a causal role in thought disorder (Pomarol-Clotet et al., 2008). However, while large deficits in semantic memory are already present in first episode psychosis (Mesholam-Gately et al., 2009), it is not known whether they precede illness onset.

In contrast to schizophrenia, semantic memory appears to only minimally impaired at most in individuals with other forms of psychopathology. Adults with BD show no deficit in vocabulary measures of semantic memory (Table 8.6). An older meta-analysis of adults with depression suggests only a small effect size on measures of semantic memory (Zakzanis, Leach, & Kaplan, 1998; Table 8.6), and a number of more recent studies have found no impairment on measures of semantic memory (Castaneda, Suvisaari, et al., 2008; Herrera-Guzmán et al., 2010; Matthews & Coghill, 2008b; but see Portella et al., 2003; Ravnkilde et al., 2002). ADHD is also associated with small deficits in semantic memory in both adults and children (Table 8.6), but as for verbal episodic memory, these deficits could potentially be driven by language difficulties, given that semantic memory is assessed with vocabulary and other verbal measures. There has been no meta-analysis of semantic memory in individuals with OCD, but individual studies suggest that performance on measures of vocabulary and semantic knowledge are not impaired (Andrés et al., 2007; Shin et al., 2008; Tekcan, Topçuoğlu, & Kaya, 2007; but see Exner, Martin, & Rief, 2009). There has been virtually no research on semantic memory in individuals with other anxiety disorders.

Autobiographical Memory

Autobiographical memory, which refers to memory about the self and one's own life, is considered to be a mixture of episodic memory for specific life events, and semantic memory for facts about the self (e.g., Renoult, Davidson, Palombo, Moscovitch, & Levine, 2012). Autobiographical memory is usually assessed using interview methods, in which people are asked to recall a serious of autobiographical events, and responses are scored for specificity (Table 8.5). In the Autobiographical Memory Test (AMT; Williams & Broadbent, 1986), participants are asked to retrieve a memory specific to a time and place in response to a serious of positive and negative cue words (e.g., safe, embarrassed), and responses are coded as specific (reflecting a specific event lasting no longer than a day), categorical (reflecting a repeated event), or extended (reflecting events extended over a long period of time). Autobiographical memory is considered *overgeneral* when most memories retrieved are categorical or extended rather than specific. Importantly, memories scored as specific in the AMT can contain both episodic and semantic details (Levine, Svoboda, Hay, Winocur, & Moscovitch, 2002).

In contrast, the Autobiographical Memory Interview (AMI; Kopelman, Wilson, & Baddeley, 1990) and Autobiographical Interview (Levine et al., 2002) provide indexes of both episodic and semantic autobiographical memory, by asking participants to recall specific life events and facts about the self, which are scored for the level of detail.

The main focus on autobiographical memory impairments has been on individuals with depression and PTSD. Overgeneral autobiographical memory in individuals with depression and PTSD is hypothesized to arise from (1) capture of attention by self-relevant information, activating ruminative processes that interfere with retrieval, (2) avoidance of retrieval of specific memories to regulate emotion, and (3) deficits in EF that limit the ability to successfully conduct retrieval searches of memory (for review, see Sumner, 2012). Meta-analytic evidence demonstrates that individuals with depression have large deficits in reporting specific autobiographical memories ($d = 1.12$; Williams et al., 2007). It is unclear if these deficits are specific to episodic versus semantic autobiographical memory, as most studies have used the AMT, but one recent study using the AMI reported impairment only on episodic autobiographical memory (Semkovska, Noone, Carton, & McLoughlin, 2012). Deficits in autobiographical memory associated with depression are not valence specific, as they have been reported for positive, negative, and neutral memory cues (see King et al., 2010 for review). In addition, autobiographical memory impairments persist during remission from depression, and thus are not dependent on current mood state (King et al., 2010).

Overgeneral autobiographical memory has been found in individuals with depression from childhood through older adulthood, although no systematic analysis of age-related changes has been conducted (King et al., 2010). The presence of autobiographical memory impairments early in life and depression course is consistent with additional evidence that autobiographical memory deficits may be associated with risk for depression. Overgeneral autobiographical memory predicts the onset of depression (but not anxiety or externalizing disorders) in adolescents (Hipwell, Sapotichne, Klostermann, Battista, & Keenan, 2011; Rawal & Rice, 2012), and future levels of depressive symptoms in adults even controlling for baseline symptoms (see Sumner, Griffith, & Mineka, 2010 for meta-analysis), although these predictive effects are small.

Despite detailed and intrusive memories of trauma events, there is also strong evidence for overgeneral autobiographical memory of nontrauma events in individuals with PTSD. PTSD and acute stress disorder are associated with reduced specificity of autobiographical memories, and this deficit cannot be accounted for by co-occurring depression or trauma exposure alone (see Brewin, 2011; Moore & Zoellner, 2007 for review). Indeed, the majority of the literature is not consistent with the view that trauma exposure alone (independent of PTSD symptoms) either in childhood or adulthood, leads to overgeneral autobiographical memory (Moore & Zoellner, 2007). Rather, there is some evidence that poor autobiographical memory may be associated with risk for developing PTSD: trainee firefighters who had more overgeneral autobiographical memory retrieval went on to develop more PTSD symptoms after three years of firefighting experience, during which they encountered multiple traumatic events (Bryant, Sutherland, & Guthrie, 2007). As in the depression literature, studies of autobiographical memory in individuals with PTSD have relied almost entirely on the AMT, which does not provide a separate measure of semantic autobiographical memory. However, there are reports that PTSD symptoms (Moradi et al., 2008), and traumatic experiences (Hunter & Andrews, 2002; Stokes, Dritschel, & Bekerian, 2008) are associated with worse semantic autobiographical memory.

Although autobiographical memory deficits associated with schizophrenia are less discussed, individual studies find evidence of impairment. Not surprisingly given impairments in both episodic and semantic memory, individuals with schizophrenia have difficulty recalling both autobiographical episodic and semantic memories, as indexed by both the number of memories recalled and their specificity and detail (e.g., McLeod, Wood, & Brewin, 2006; Neumann, Blairy, Lecompte, & Philippot, 2007). These deficits are not attributable to co-occurring depression or differences in premorbid IQ (McLeod et al., 2006). Autobiographical memories from all life stages, including early childhood, are affected, suggesting that the primary deficit arises during retrieval or that encoding is affected from early in development (McLeod et al., 2006). However, the largest impairment is for events and facts around the time of each individual's illness onset, suggesting that poor encoding during this time may contribute to autobiographical memory deficits (e.g., Riutort, Cuervo, Danion, Peretti, & Salamé, 2003). Interestingly, individuals with schizophrenia appear to also have difficulty generating detailed descriptions of possible future events (*prospective memory;* D'Argembeau, Raffard, & Van der Linden, 2008), which involves the same brain network activated by retrospective memory processes (e.g., Schacter, Addis, & Buckner, 2008).

There is very little research on autobiographical memory in individuals with other disorders. One study found overgeneral autobiographical memory in adults with BD (Scott, Stanton, Garland, & Ferrier, 2000). One study found that individuals with OCD had overgeneral autobiographical memory, but that this was driven by co-occurring depression rather than OCD per se (Wilhelm, McNally, Baer, & Florin, 1997). In general, autobiographical memory does not appear to be impaired in individuals with other anxiety disorders, including SAD (Heidenreich, Junghanns-Royack, & Stangier, 2010; Wenzel, Jackson, & Holt, 2002), or GAD/high worry (Finnbogadóttir & Berntsen, 2011; Wenzel & Jordan, 2005). Autobiographical memory has not been investigated in individuals with ADHD.

Thus, there is strong evidence for autobiographical memory impairments only in depression, PTSD, and schizophrenia. However, given the limited amount of research in individuals with other disorders, it is premature to draw conclusions about the specificity of autobiographical memory deficits to these disorders.

Gender, Cultural, and Ethnic Differences and Considerations

Basic cognitive processes are widely assumed to be human universals, and so not to vary greatly across cultures. Thus, while the aforementioned research included participants from many countries (including Asian, European, North American, and Latin American countries), there have been no systematic comparisons of cognitive process deficits across cultures. Socioeconomic status (SES) is perhaps a more likely moderator, as low SES is associated with worse performance on many cognitive tasks in both children and adults, with executive function perhaps most affected (see Hackman & Farah, 2009 for review). While many of these effects in adults are likely driven by education, which strongly influences performance on many tasks, SES effects are also found in infants and young children, thus education cannot be the only driving factor. Rather, there are multiple candidate causal pathways, including differences in parenting and chronic stress (Hackman & Farah, 2009). Since these factors are also known to affect risk for psychopathology, it seems plausible that SES could moderate the link between psychopathology and cognitive function. However, to our knowledge this has not been directly studied.

Gender has received somewhat more attention, given the differential rates of many forms of psychopathology between males and females. However, despite gender differences in psychopathology, there is not strong evidence that gender moderates the association between psychopathology and cognitive processes. Many meta-analyses have not examined gender as a potential moderator, and some that have done so have found that gender does not moderate cognitive impairments associated with psychopathology, including EF and attentional bias in depression (Peckham et al., 2010; Snyder, 2013), EF and episodic memory BD II disorder (Bora et al., 2011), and EF in ADHD (e.g., Lipszyc & Schachar, 2010; van Mourik et al., 2005). On the other hand, some meta-analyses have reported gender differences, including larger impairments in BD samples with more female participants on two measures of the shifting component of EF (Arts et al., 2008; Kurtz & Gerraty, 2009), but larger impairments for samples with more male participants in first-episode psychosis on measures of verbal episodic memory (Mesholam-Gately et al., 2009), and in ADHD for a measure of the inhibition component of EF (Bálint et al., 2009). However, these effects are generally found for one task, are not consistent across meta-analyses, and may not remain significant if other confounding moderators are controlled for (e.g., see (Lipszyc & Schachar, 2010) for an apparent effect of gender on inhibition in ADHD, which is no longer significant controlling for age and study quality). Thus, while gender effects merit further investigation, current evidence suggests that it is not a robust moderator of cognitive process deficits associated with psychopathology.

COGNITIVE PRODUCTS

Cognitive Styles

The following section outlines well-established maladaptive patterns of explaining stressful events or situations (Table 8.7). Some cognitive styles (e.g., negative inferential style, hostile attributional bias, looming maladaptive style) are event-specific, and although the style is consistent, the particular cognitions generated in response to each event are context dependent. Conversely, other cognitive styles (e.g., dysfunctional attitudes, early maladaptive schemas) are based upon stable mental representations, and are believed to be consistent across situations. Not only do these cognitive patterns involve assigning meaning to stressful situations in the environment, but they also involve the processing of self-related concepts.

Neuroimaging studies of cognitive styles have shown activation of the medial prefrontal cortex, which is associated with autobiographical content, as well as the anterior cingulate cortex, which is responsible for labeling incoming

TABLE 8.7 Commonly Used Cognitive Product Measures

Construct	Measure	Description	Methods citation
Attributional style: attributions for the cause of life events along three dimensions: **1.** internal vs. external **2.** stable vs. unstable **3.** global vs. specific	Attributional Style Questionnaire (ASQ)	Presents 12 hypothetical events (i.e., 6 are positive, 6 are negative; in addition, 6 are interpersonal, 6 are achievement related); participants indicate a cause of the event and answer questions about the cause of the event on a 7-point Likert scale	Peterson and Semmel (1982)
	Children's Attributional Style Questionnaire–Revised (CASQ-R)	Presents 24 hypothetical negative events; participants choose between two possible explanations for this event; each item holds two dimensions of attributional style constant, while the third is varied between the explanations	Thompson, Kaslow, Weiss, and Nolen-Hoeksema (1998)
Negative inferential style: attributions for the cause, consequences, and self-worth implications of life events along three dimensions	Cognitive Style Questionnaire (CSQ)	Presents 24 hypothetical events (i.e., 12 are positive, 12 are negative; in addition, 12 are interpersonal, 12 are achievement related). Participants indicate a cause of the event and answer questions about the cause, consequences, and self-worth implications of the event on a 7-point Likert scale	Haeffel et al. (2008)
	Adolescent Cognitive Style Questionnaire (ACSQ)	Presents 12 hypothetical negative events (i.e., 6 are interpersonal, 6 are achievement related). Participants indicate a cause of the event and answer questions about the cause, consequences, and self-worth implications of the event on a 7-point Likert scale	Hankin and Abramson (2002)
Dysfunctional attitudes: core beliefs about the world, relationships with others, and self that are related to performance, perfectionism, and approval by others	Dysfunctional Attitudes Scale (DAS)	Presents 40 dysfunctional attitude statements. Participants indicate agreement on a 7-point Likert scale (e.g., totally agree to totally disagree)	Weissman and Beck (1978)
	Children's Dysfunctional Attitudes Scale (CDAS)	Presents 40 dysfunctional attitude statements. Participants indicate agreement on a 4-point Likert scale (e.g., never true to always true)	Abela and Sullivan (2003)
Early maladaptive schemas: core beliefs about the world, relationships with others, and self that are related to childhood adverse relational experiences: **1.** disconnection: expectation that need for security, acceptance, and respect will not be met **2.** impaired autonomy: concerns about ability to function competently, capably, or independently **3.** other directedness: excessive focus on desires, feelings, and response of others **4.** overvigilance and inhibition: emphasis on suppressing feelings, impulses, and choices **5.** impaired limits: deficiency in internal limits, responsibility to others, and long-term goal orientation	Young Schema Questionnaire (YSQ)	Presents 205 schemas (75 schemas in the Short Form). Participants indicate agreement on a 6-point Likert scale (e.g., describes me perfectly to completely untrue of me)	Young and Brown (1994)
Looming maladaptive style: mental representation of future threat as rapidly rising in risk, progressively worsening, and accelerating.	Looming Maladaptive Style Questionnaire	Presents 6 hypothetical events. Participants answer questions about the event on a 5-point Likert scale	Riskind et al. (2000)
Hostile attribution bias: in ambiguous provocation situations, the tendency to interpret the intentions of another as hostile	Hypothetical situation instruments (multiple versions)	Presents hypothetical provocation situations (i.e., some are instrumental, some are relational) in which the intent is ambiguous; participants answer questions about the reasons for the provocation and intent of the provocateur	See, for example, Crick (1995) for questionnaire-based vignettes; Dodge, Pettit, McClaskey, and Brown (1986) for videotaped vignettes)

(*continued*)

TABLE 8.7 (*Continued*)

Construct	Measure	Description	Methods citation
Repetitive negative thought: self-focused attention that involves repetitively and passively focusing on negative events and symptoms of distress, as well as the causes and consequences of these events and symptoms	Response Style Questionnaire–Ruminative Responses Scale (RSQ–R)	Presents 22 statements regarding tendency to ruminate. Participants indicate agreement on a 4-point Likert scale (e.g., almost never to almost always)	Nolen-Hoeksema (1990)
	Children's Response Style Questionnaire (CRSQ)	Presents 10 statements regarding tendency to ruminate. Participants indicate agreement on a 5-point Likert scale (e.g., never to always)	Abela, Rochon, and Vanderbilt (2000)
	Penn State Worry Questionnaire (PSWQ)	Presents 16 statements regarding tendency to worry. Participants indicate agreement on a 5-point Likert scale	Meyer, Miller, Metzger, and Borkovec (1990)
Reappraisal: change how one thinks about a situation or about one's capacity to manage the demands of a situation to alter its emotional significance	Emotion Regulation Questionnaire (ERQ)	Presents 10 items that assess trait use of reappraisal and suppression. Participants indicate agreement on a 7-point Likert scale	Gross and John (2003)
Distraction: engaging in thoughts or behaviors to divert one's attention away from negative mood and instead toward more positive stimuli	Response Style Questionnaire–Distractive Responses Scale (RSQ–D)	Presents 11 statements regarding tendency to distract; participants indicate agreement on a 4-point Likert scale (e.g., almost never to almost always)	Nolen-Hoeksema (1990)
	Children's Response Style Scale (CRSQ)	Presents 10 statements regarding tendency to distract. Participants indicate agreement on a 5-point Likert scale (e.g., never to always)	Abela, Rochon, and Vanderbilt (2000)

information as self-referential (for a review, see Disner, Beevers, Haigh, & Beck, 2011). Furthermore, these studies have found increased activation of the amygdala and hippocampus–limbic structures involved in emotional processing (see Disner et al., 2011). These particular regions exhibit increased activity among participants with psychopathology, such as depression (Cooney, Joormann, Eugène, Dennis, & Gotlib, 2010) and social anxiety (Blair et al., 2008). Therefore, neuroimaging studies suggest that maladaptive patterns of self-referential processing in the context of stressful life events may be associated with emotional distress, and consequently, psychopathology.

Negative Inferential Style

Broadly defined, negative inferential style refers to an individual's characteristic pattern of explaining the meaning, causes, and consequences of stressful life events. One particular type of negative inferential style was outlined originally in the reformulated learned helplessness theory of depression (Abramson et al., 1978), which maintains that individuals who attribute negative events to internal (i.e., about the self), stable (i.e., enduring), and global (i.e., widespread) causes are said to possess a negative attributional style. An extension of the reformulated learned helplessness theory is the hopelessness theory of depression (Abramson, Metalsky, & Alloy, 1989). According to this model, individuals not only possess a negative attributional style for the *causes* of stressful life events, but they also make stable and global inferences regarding the *consequences* of an event and believe that a stressful life event has negative implications for the *self* (e.g., the self is deficit, flawed, or worthless).

Empirical research examining the role of negative inferential style as a cognitive vulnerability to psychopathology has found support in children, adolescents, and adults, although relatively less research with child samples suggests that more research needs to be conducted in this early cohort to fully understand the nature of the relationship between negative inferential style and psychopathology. More importantly, a substantial body of research has found that negative inferential style interacts with negative life events to predict changes in psychopathology, including symptoms and clinical diagnosis, over time. Although originally formulated as a theory to explain vulnerability to depression, it appears as though a negative attributional style is present across other types of psychopathology, such as PTSD, ADHD, and schizophrenia.

Findings linking negative inferential style to depression, in particular, are the most robust compared with other forms of psychopathology. Numerous cross sectional studies have demonstrated a relationship between negative inferential style and depression in children, adolescents, and adults (Alloy et al., 2012; Alloy, Abramson, Walshaw, & Neeren, 2006). Although informative, cross sectional methodology makes it difficult to determine whether negative inferential style reflects a risk factor, causal risk factor, correlate, or consequence of depression. Studies that utilize more than one time point are best able to

examine whether negative inferential style precedes and prospectively predicts changes in depression over time. Such studies have found that negative inferential style predicts changes in depression in children, adolescents, and adults (e.g., Abela & Hankin, 2008; Abramson et al., 2002; Alloy, Abramson, Walshaw, & Neeren, 2006). More specifically, negative inferential style prospectively predicts levels of depressive symptoms, first onsets of depression, as well as recurrence of depression in adults (e.g., Alloy et al., 2000), which is consistent with the risk factor model. Additionally, studies with remitted depressives can also be helpful in determining whether negative inferential style is mood-state dependent, or whether it represents a stable and enduring trait. Unfortunately, studies that have examined remitted depressives have produced mixed results. A majority of studies have found that remitted depressives do not exhibit negative inferential style, whereas a few studies have shown that these individuals do in fact demonstrate this type of cognitive vulnerability after recovering from depression (see Alloy et al., 2006). Therefore, there is insufficient evidence to conclude whether negative inferential styles represent a consequence of depression.

It is also important to examine the role of stressful life events as a moderator of the relationship between negative inferential style and depression. It should be emphasized that in the cognitive vulnerability–stress model, negative inferential styles contribute to psychopathology only in the presence, not the absence, of stressful life events. Studies that examine the interaction of negative inferential style and stressful life events therefore provide a more stringent test of these models. Such studies have found consistent support for the vulnerability–stress model in predicting changes in depressive symptoms as well as the occurrence of a clinically significant depressive episode in both children and adolescents (e.g., Abela & Hankin, 2008; Jacobs, Reinecke, Gollan, & Kane, 2008; Lakdawalla, Hankin, & Mermelstein, 2007) and adults (e.g., Abramson & Alloy, 2006; Abramson et al., 2002; Ingram, Miranda, & Segal, 2006; Joormann, 2010).

A subset of research on negative cognitive style and depression has separately examined the specific role that each type of inference (e.g., cause, consequence, implication for the self) plays in the development of depression. Studies that have parsed out negative inferential style into three factors have yielded mixed findings. Some studies have found support for all three types of negative inferences as a predictor of increases in depressive symptoms when combined with hassles (e.g., Brozina & Abela, 2006). In some youth samples, researchers have found that negative inferences about the *self*, but not about the causes or consequences regarding negative events, interacted with stress to predict changes in depressive symptoms over time (Abela, McGirr, & Skitch, 2007; Cohen, Young, & Abela, 2011). However, other studies with youth have found that only inferences about the *causes* of negative events interact with stress to predict changes in depression (e.g., Conley, Haines, Hilt, & Metalsky, 2001; Lau, Rijsdijk, Gregory, McGuffin, & Eley, 2007). Still others have demonstrated that negative inferences about the *consequences* of negative events predict changes in depression (Abela, 2001; Cohen, Young, & Abela, 2011). It has been suggested that one specific type of inference may not be the strongest predictor of depression for all individuals, especially children and early adolescents. Rather, each individual is as vulnerable to depression as his or her most negative inferential style, a theory known as the *weakest link approach* (Abela & Sarin, 2002). The weakest link approach should inform studies that choose to parse out negative inferential style, such that these studies should determine a participant's most negative inference as reflective of that participant's overall cognitive vulnerability. Studies using this approach to study the cognitive vulnerability–stress model have found support (Abela & Hankin, 2008).

The relationship between negative inferential style and BD is similar to that of depression. Cross sectional studies with bipolar individuals currently experiencing a depressive episode found that negative inferential styles did not differ from those of unipolar individuals who were also currently depressed (Reilly-Harrington & Alloy, 1999; Reilly-Harrington & Miklowitz, 2010). As with studies of remitted individuals with depression, studies with remitted individuals with BD have been mixed. A majority of studies report that remitted individuals do not exhibit more negative inferential styles than healthy individuals, whereas other studies do find a significant difference between these two groups (Alloy, Abramson, Walshaw, Keyser, & Gerstein, 2006; Lex, Hautzinger, & Meyer, 2011). In a similar vein, some studies have found that negative cognitive style remained stable across different mood states in bipolar individuals, including hypomania, depression, and euthymia (Reilly-Harrington & Miklowitz, 2010). Cross sectional studies with bipolar individuals in hypomanic and manic states also found evidence for negative inferential styles (Lex et al., 2011; Reilly-Harrington & Alloy, 1999; Reilly-Harrington & Miklowitz, 2010; Scott & Pope, 2003), but these were only found in those who had a past history of depression. Those without depression did not differ from healthy controls. Longitudinal studies have found that negative cognitive styles interact with stressful life events to predict changes in

depressive symptoms, as well as manic symptoms, in individuals diagnosed with BD (Reilly-Harrington & Alloy, 1999) as well as individuals with subsyndromal levels of bipolar symptoms (Reilly-Harrington & Alloy, 1999).

Research with bipolar individuals has also found a link between positive inferential style and mania. Individuals with a positive inferential style make stable and global attributions for the causes of positive events, anticipate positive consequences as a result of these positive events, and identify positive implications for the self as a result of these events (Alloy, Abramson, Walshaw, & Neeren, 2006). Cross sectional findings show that bipolar individuals in a manic state exhibit a positive inferential style (Lex et al., 2011), which when combined with positive life events, prospectively predicts increases in hypomanic symptoms (Alloy, Abramson, Walshaw, Keyser, et al., 2006). Taken together, findings for both negative and positive inferential style in BD are consistent with the risk factor model.

Most studies with both youth and adults have shown that a negative inferential style is not associated with certain forms of anxiety symptoms or anxiety disorder either as a main effect predictor or in the context of stressful life events (e.g., Alloy, Abramson, Whitehouse, Hogan, et al., 2006; Hankin, Abramson, Miller, & Haeffel, 2004; Hankin, 2008; Joiner, 2000). However, a recent study by Alloy et al. (2012) found that negative inferential styles were concurrently associated with anxiety symptoms and diagnoses (e.g., social phobia). This discrepancy may be due to the fact that the sample in Alloy et al. (2012) was largely composed of early adolescents, which is a critical developmental period for first onset of anxiety disorders. Depression, on the other hand, typically emerges in mid- to late adolescence or early adulthood. In addition, many studies linking negative inferential style and depression found that negative inferential style was higher among individuals diagnosed with *comorbid* anxiety and depression compared with those diagnosed with only depression or only anxiety (Alloy, Abramson, Whitehouse, Hogan, et al., 2006; Fresco, Alloy, & Reilly–Harrington, 2006). Prospective longitudinal studies have demonstrated that individuals with high levels of negative attributional style were more likely to experience an onset of an anxiety disorder that was comorbid with depression compared with low-risk individuals (Alloy, Abramson, Walshaw, & Neeren, 2006).

Despite the lack of support for negative inferential style as a cognitive vulnerability for anxiety broadly defined, a small line of research has found associations between attributional style and PTSD, specifically (Elwood, Hahn, Olatunji, & Williams, 2009). Individuals who attribute interpersonal and noninterpersonal traumatic events to stable and global causes experience more severe PTSD as well as prospective increases in PTSD symptoms over time (Elwood, Hahn, et al., 2009; Palker-Corell & Marcus, 2004; Runyon & Kenny, 2002; Williams, Evans, Needham, & Wilson, 2002). In addition, some other studies have reported that individuals who attribute these events to external causes also report higher levels of PTSD (Elwood, Hahn, et al., 2009). In sum, there is little support for the role of negative inferential styles in anxiety generally, however, a line of research examining PTSD in particular has found support for an external, stable, and global style among individuals with PTSD.

There is a small body of research linking negative inferential style and ADHD (see Rucklidge, Brown, Crawford, & Kaplan, 2007 for a review). It is hypothesized that individuals with ADHD most likely experienced a higher rate of repeated experiences of failure, and if undiagnosed, teachers and parents might have attributed these difficulties to characteristics of the individual (e.g., lazy, stupid, unmotivated). As in depression, individuals with ADHD tend to make stable and global attributions for negative events as well as unstable and specific attributions for positive events (Collett & Gimpel, 2004; Rucklidge & Kaplan, 2000). In addition, another type of negative inferential style that is most commonly associated with ADHD involves a hypothesized fourth dimension, known as controllability (see Rucklidge & Kaplan, 2000 for a discussion). This dimension reflects the degree to which the causes and consequences of negative events are viewed by individuals as within their control. Researchers have found that individuals with ADHD possess an internal-uncontrollable inferential style, such that they believe that their cognitive and behavior problems are the result of variables that are internal, but also out of their control (Rucklidge et al., 2007). In line with this theory, studies have found that adults with ADHD tended to make internal and uncontrollable attributions for negative events in their childhood (Rucklidge et al., 2007) as well as for current negative events (Rucklidge & Kaplan, 2000). This pattern is also found in children and adolescents with ADHD (Rucklidge et al., 2007; Rucklidge & Kaplan, 2000). Very few studies have examined associations between negative attributional style and conduct disorder/oppositional defiant disorder (CD/ODD). These studies have found that the interaction of attributional style and stressful life events has exhibited specificity with depression, and did not predict externalizing symptoms over time (Hankin, 2008b; Robinson, Garber, & Hilsman, 1995).

Studies of negative inferential style in schizophrenia have mostly examined the internal/external domain

for attributions regarding the causes of negative events. Healthy individuals typically attribute negative events to external causes, but these causes are more likely to be universal (i.e., due to chance or circumstance), as opposed to personal (i.e., due to other individuals; Aakre, Seghers, St-Hilaire, & Docherty, 2009). Individuals with schizophrenia, especially those currently experiencing persecutory delusions, tend to attribute negative events to external personal causes (Aakre et al., 2009). Individuals with schizophrenia who are not currently paranoid, however, do not attribute negative events to external-personal causes (Aakre et al., 2009). Therefore, the attributional style of individuals with schizophrenia appears to be a state dependent correlate of schizophrenia, and not a stable and enduring cognitive pattern.

Dysfuncational Attitudes

Beck's cognitive theory of psychopathology posits that self-schemas are associated with the onset, maintenance, and recurrence of emotional disorders, such as depression (Beck, 1976). Broadly speaking, schemas are well-organized cognitive representations of the past experiences that represent an individual's knowledge of the world, relationships with others, and the self. Depressive self-schemas, in particular, represent a set of rigid core beliefs or dysfunctional attitudes related to performance, perfectionism, and self-worth, and guide the selective processing of negative information in the environment over and above positive or neutral information (Dozois & Beck, 2008). In the presence of stressful life events, these depressive self-schemata act as filters for stimuli in the environment, affecting the way an individual perceives, encodes, interprets, and remembers emotionally salient information (Beck, 1976; Dozois & Beck, 2008; Joormann & Gotlib, 2010). This selective processing of negative information contributes to negative automatic thoughts, and consequently, negative perception about oneself, the world, and the future—the negative cognitive triad (Dozois & Beck, 2008). This negatively biased information processing ultimately leads to the onset of emotional distress symptoms or disorders. Although there is conceptual and empirical overlap between dysfunctional attitudes and negative inferential style, dysfunctional attitudes represent universal beliefs and rules, as opposed to event-specific attributions inherent in negative inferential style. Indeed, studies have shown that measures of dysfunctional attitudes and negative inferential style load onto distinct latent factors (e.g., Haeffel et al., 2003; see Taxonomy and Structure of Cognitive Risks section in Discussion).

In addition to an overall cognitive vulnerability–stress model for dysfunctional attitudes, Beck (1987) has hypothesized that the experience of stressful events that are congruent with one's own particular cognitive schema should confer particular vulnerability to the development of depression (Zuroff, Mongrain, & Santor, 2004). These particular schemas are divided into two categories: sociotropy and autonomy. Individuals with a sociotropic cognitive style value intimacy, relationships, and acceptance from others, and consequently, are most vulnerable to emotional distress when they experience rejection, loss, and disappointment in the interpersonal domain (Beck, 1987). Those with an autonomic cognitive style place great importance on achievement, independence, and control, and so are at a greater risk for distress when they experience failure or are precluded from making their own choices (Beck, 1987).

Young, Klosko, and Weishaar (2003) extended the work of Beck and identified a variety of early maladaptive schemas (EMS) that underlie several forms of psychopathology. These maladaptive schemas are pervasive patterns of memories, emotions, cognitions, and bodily sensations that represent an individual's knowledge about the world, relationships with others, and the self. These schemas guide the appraisal of situations, such that the individual focuses on elements that confirm the schema and minimize or deny information that contradicts the schema, thus perpetuating the schema. Young's early maladaptive schemas fall into five domains: *disconnection/rejection*, *impaired autonomy*, *other-directedness*, *impaired limits*, *overvigilance/inhibition*. Individuals who are high on the disconnection/rejection domain believe that others will not meet their needs for security, acceptance, and respect. Such individuals fear being rejected by others and anticipate that certain negative events will lead to negative evaluation and loss of status. Those who are high on the impaired autonomy domain anticipate that aspects of the self and the environment will interfere with their ability to function independently and successfully. Other-directedness is related to an extreme focus on the desires of others, even at the expense of the individual's needs. Impaired limits encompasses characteristics such as difficulties exerting self-control. Finally, overvigilance and inhibition includes particular schemas, such as negativity/pessimism, emotional inhibition, and punitiveness.

Overall, dysfunctional attitudes and early maladaptive schemas have shown a robust relationship with depression, anxiety, BD, and schizophrenia, with fewer studies examining the relationship with externalizing disorders. As with negative inferential style, both dysfunctional attitudes and

early maladaptive schemas are linked to psychopathology as main effect predictors, as well as in the context of negative life events. Dysfunctional attitudes demonstrate the strongest associations with depression in children, adolescents, and adults both concurrently and prospectively over time (Abela & Hankin, 2008; Abramson et al., 2002; Alloy, Abramson, Walshaw, & Neeren, 2006; Jacobs et al., 2008). In addition, the interaction of dysfunctional attitudes and negative life events is linked to increases in depressive symptoms in adults (Abramson et al., 2002; Joormann, 2010) as well as adolescents (Abela et al., 2011; Hankin et al., 2009). Similar findings have been demonstrated for clinically significant depressive episodes with adolescents (Lewinsohn, Joiner, & Rohde, 2001) and adults (Hankin et al., 2004; Otto et al., 2007). This constitutes solid evidence for dysfunctional attitudes as a risk factor for the development of depression.

Studies of early maladaptive schemas in nonclinical adult samples have found that specific schemas falling under the domains of disconnection and rejection, impaired autonomy and other-directedness interacted with stressful life events to predict increases in depressive symptoms over time (Cámara & Calvete, 2011; Eberhart, Auerbach, Bigda-Peyton, & Abela, 2011). Cross sectional studies (Lumley & Harkness, 2007; Muris, 2006; Vlierberghe, Braet, Bosmans, Rosseel, & Bögels, 2009) and one longitudinal study (Calvete, Orue, & Hankin, 2012) of adolescents have found that these three domains are associated with depression in adolescents.

Dysfunctional attitudes have been shown to relate specifically to depression, and not anxiety generally, both concurrently and prospectively (e.g., Alloy, Abramson, Walshaw, & Neeren, 2006; Hankin, Abramson, Miller, & Haeffel, 2004). However, studies of early maladaptive schemas, in particular, have found that the domain of impaired autonomy, which includes vulnerability to harm and dependence, predicted increase in anxiety symptoms in the context of stressful life events (Cámara & Calvete, 2011; Glaser, Campbell, Calhoun, Bates, & Petrocelli, 2002; Lumley & Harkness, 2007; Schmidt, Joiner, Young, & Telch, 1995; Welburn, Coristine, Dagg, Pontefract, & Jordan, 2002). In terms of SAD, specifically, one study has identified the other-directedness schema domain as a significant predictor of social anxiety symptoms over time (Calvete, Orue, & Hankin, 2012). Studies in the PTSD literature have identified mistrust/abuse, defectiveness/shame, emotional deprivation, dependency, and vulnerability to harm as particularly related to early traumatic and victimization experiences (Harding, Burns, & Jackson, 2011; Price & Mohlman, 2007b).

Few studies have explored the relationship between early maladaptive schemas and BD. Nilsson, Jørgensen, Straarup, and Licht (2010) found that individuals diagnosed with BD were higher on the domain of impaired limits, especially insufficient self-control, compared with healthy controls. Hawke, Provencher, and Arntz (2011) also found that impaired limits, specifically entitlement/grandiosity and insufficient self-control/self-discipline, was associated with BD. The authors also identified a negative relationship between emotional inhibition and BD.

Although early maladaptive schemas have not been studied in individuals with externalizing disorders, a smaller number of studies have examined the link between early maladaptive schemas and aggression. Calvete (2008) found that entitlement/grandiosity was the strongest predictor of aggressive behavior. Similarly, Rijkeboer and De Boo (2010) identified defectiveness/shame, mistrust/abuse, entitlement/grandiosity, and insufficient self-control schemas in relation to aggressive mood in children.

Finally, a small body of research in dysfunctional attitudes in schizophrenia has found that these individuals demonstrate a great deal of concern with their performance and other's evaluation of their performance (Rector, 2004). Patients with schizophrenia possess maladaptive beliefs about their ability to succeed in various activities, and as a result, have low levels of interest and motivation in engaging in these activities (i.e., negative symptoms; Rector, 2004). In addition, individuals with schizophrenia also are concerned about how they are perceived by others (Grant & Beck, 2009; Horan et al., 2010; Rector, 2004).

Hostile Attribution Bias

Hostile attribution bias is a type of attributional style that is based upon social information processing theory (Crick & Dodge, 1994). Broadly speaking, social information processing involves five stages: encoding of social cues, interpretation of cues, response access, response evaluation, and response enactment (Mathieson, Murray-Close, Crick, & Woods, 2011). Hostile attribution bias is grounded in the second stage of processing: interpretation of cues. In this stage, an individual assigns meaning to social cues that have been perceived, attended to, and stored in short-term memory during the encoding stage. The interpretation of social cues is contingent upon two factors: the nature of encoded social cues (e.g., quantity, sensory modality, emotional valence), as well as the ability of the individual to utilize those social cues to infer others' intentions and beliefs. In hostile attribution bias, individuals interpret the intentions of others as hostile in ambiguous social situations (Andrade et al., 2012; Crick & Dodge, 1994; Dodge,

1980; Mathieson & Murray-Close, 2011; Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002). Therefore, a hostile attribution bias is the result of a maladaptive pattern of inferring others' intentions and beliefs.

A preponderance of evidence has demonstrated an association between hostile attribution bias and subsequent aggressive behavior. In addition, there is evidence that individuals with schizophrenia, especially those with paranoia or persecutory delusions, may exhibit hostile attribution bias. Finally, very few studies have found evidence of hostile attributional style among children who are high in depression and anxiety. To our knowledge, there are no studies of hostile attribution bias in BD.

The link between hostile attribution bias and aggressive behavior is robust and has been found among community populations of elementary and junior high school age youth (Andrade et al., 2012; Crick, Grotpeter, & Bigbee, 2002), clinical populations of youth (MacBrayer, Milich, & Hundley, 2003), incarcerated offenders (Dodge, Price, Bachorowski, & Newman, 1990), and adults (DeWall, Twenge, Gitter, & Baumeister, 2009; Dodge, 2006). Prospective longitudinal studies have also found that hostile attribution bias predicts changes in aggression over time (Dodge, 2006), which suggests that this type of bias may serve as a risk factor. Some studies that examine the link between social rejection and subsequent aggression have found that hostile attribution bias mediates this link (DeWall et al., 2009; Reijntjes et al., 2011; Yeung & Leadbeater, 2007).

There is some discussion in the hostile attribution literature of specificity between the type of provocation situation, the hostile attribution bias, and the type of retaliatory aggression. Aggressive behavior is typically classified along two specific dimensions (Crick & Grotpeter, 1995). Physical aggression involves the use or threat of physical force to influence perceptions of safety and power. Relational aggression, on the other hand, involves damage to relationships through mechanisms such as friendship withdrawal, manipulation of social status among peers, or gossiping. Researchers have found some support for this hypothesized specificity. For instance, individuals who were relationally aggressive exhibited hostile attribution biases for ambiguous provocation scenarios that were relational in nature (Bailey & Ostrov, 2007; Crick & Grotpeter, 1995; Crick et al., 2002; Yeung & Leadbeater, 2007). In addition, physically aggressive individuals demonstrated hostile attribution biases for ambiguous provocation scenarios that were instrumental or physical in nature (Bailey & Ostrov, 2007; Crain, Finch, & Foster, 2005; Crick et al., 2002). However, other researchers have not found these exact relationships. For instance, Godleski & Ostrov (2010) found that hostile attributions for instrumental provocations predicted both physical and relational aggression.

In light of evidence that children with ADHD are also particularly prone to act aggressively in social situations, a small body of literature has also explored hostile attribution bias in individuals with this disorder. Attentional difficulties in ADHD cause individuals to encode fewer social cues in experimental vignettes, and as a consequence these children do not have the same amount of relevant social cue information with which to make response decisions (Andrade et al., 2012). In negatively valenced vignettes, children with ADHD make significantly more negative intent attributions than controls (Andrade et al., 2012).

In addition to disorders characterized by externalizing behaviors, some research has explored hostile attribution bias in schizophrenia. Findings show that individuals with paranoia or persecutory delusions make hostile attributions by consistently blaming other people for negative events (e.g., personalizing bias, Penn, Sanna, & Roberts, 2008). Finally, a few studies have examined the role of hostile attributional style in depression and anxiety. Quiggle, Garber, Panak, and Dodge (1992) found that children with high levels of depressive symptoms showed a hostile attributional bias. Bell-Dolan (1995) found that anxious children identified hostile intent within nonhostile vignettes, whereas the control children did not. Because these were cross sectional studies, no conclusions can yet be made as to whether hostile attribution bias may also serve as a risk factor for these disorders.

Looming Maladaptive Style

The looming maladaptive style (Riskind, Williams, Gessner, Chrosniak, & Cortina, 2000) is based on a danger or threat schema and is traditionally associated with anxiety, and not depression. These danger or threat schemas are hypothesized to lead to the formulation of biased expectations about the temporal and spatial progression of potential threats, such that these threats are perceived as rapidly mounting, escalating, or approaching the individual (Riskind et al., 2000). As a result of this active and dynamic perception of threat, individuals interpret even mundane situations as being potentially dangerous, and therefore initiate cognitive processes to assess these situations.

Findings have shown that looming maladaptive style is concurrently associated with both clinical and subclinical anxiety disorders (Riskind et al., 2000). In addition,

looming maladaptive style is a prospective predictor of changes in anxiety symptoms overall (Williams, Shahar, Riskind, & Joiner, 2005) as well as changes in specific types of anxiety symptoms, such as OCD (Elwood, Riskind, & Olatunji, 2009; Riskind, Tzur, Williams, Mann, & Shahar, 2007), SAD (Brown & Stopa, 2008), generalized anxiety (Williams et al., 2005) and PTSD (Elwood, Williams, Olatunji, & Lohr, 2007).

Because looming maladaptive style is conceptualized to relate specifically to anxiety, no study has examined its role in other internalizing disorders (e.g., depression and BD), externalizing disorders (e.g., ADHD, aggression), or schizophrenia. However, the fact that looming maladaptive style is a way of identifying, interpreting, and categorizing information that is grounded in schemas suggests some conceptual relation to previously discussed schema theories (Beck, 1967;Young et al., 2003).

Repetitive Negative Thought

This section describes various forms of repetitive negative thought. The response style theory (Nolen-Hoeksema, 1991) defines repetitive negative thought, or rumination, as a type of self-focused attention that involves repetitively and passively focusing on negative events and symptoms of distress, as well as the causes and consequences of these events and symptoms (Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008). It is important to note that the defining feature of rumination is the *process* of perseverative thinking, and not necessarily the *content* of the thinking. More recently, theorists have determined two distinct components within the greater construct of rumination (Treynor, Gonzalez, & Nolen-Hoeksema, 2003). The first component, called *brooding*, involves negative and self-critical thinking about the self (Watkins, 2008). Brooding is considered to be a maladaptive component of rumination and is positively associated with negative mood (Rood, Roelofs, Bögels, Nolen-Hoeksema, & Schouten, 2009). *Reflective pondering*, on the other hand, represents contemplation of symptoms of distress and negative events to better engage in problem solving behaviors (Watkins, 2008). This is the adaptive component of rumination and is negatively associated with negative mood (Roelofs et al., 2009).

Rumination is associated with various forms of psychopathology, especially depression, anxiety, and aggression. There is a lack of studies that have explored rumination among individuals with ADHD and schizophrenia, however. It is important to note that the process of rumination is nearly identical across these disorders, however the *content* of ruminative thought demonstrates content-specificity (e.g., sadness in depression, anger in aggression). Similar to cognitive styles, repetitive negative thought activates regions of the brain associated with self-referential processing, such as the medial prefrontal cortex, anterior cingulate cortex, and amygdala. For instance, the medial prefrontal cortex showed greater activity for depressed participants compared with control participants during a rumination task (Cooney et al., 2010).

Depressive Rumination

There is a substantial body of literature linking rumination to depression. Cross sectionally, rumination is elevated in both currently and formerly depressed inpatients, which suggests that rumination is a stable trait factor (Watkins, 2008). Rumination is also concurrently associated with elevations in depressive symptoms among children, adolescents, college students, and adults (Abela & Hankin, 2008; Nolen-Hoeksema et al., 2008; Watkins, 2008). Furthermore, children, adolescents, and adults who engage in rumination when distressed demonstrate more severe and prolonged periods of depression and are more likely to develop depressive disorders (Abela & Hankin, 2011; Nolen-Hoeksema et al., 2008). For example, a recent meta-analysis (Aldao, Nolen-Hoeksema, & Schweizer, 2010) found large effect sizes for the relationship between rumination and depression. Longitudinally, rumination predicts increases in depressive symptoms (Hankin, 2008b; Rood, Roelofs, Bögels, & Alloy, 2010; Watkins, 2008) as well as the onset of a clinically significant depressive episode among never-depressed individuals (Abela & Hankin, 2011; Nolen-Hoeksema, Stice, Wade, & Bohon, 2007; Watkins, 2008) consistent with the risk factor model. In parsing out the specific effects of brooding and reflective pondering, researchers have found that brooding alone significantly predicts increases in depressive symptoms over time (Burwell & Shirk, 2007; Rood et al., 2010 for youth; Treynor et al., 2003 for adults). Reflective pondering, on the other hand, did not significantly predict changes in depression (Rood et al., 2010).

Findings in BD indicate that rumination is comparable to that seen in unipolar depression (Johnson, McKenzie, & McMurrich, 2008), or at a level that is intermediate between those with unipolar depression and healthy controls (Johnson et al., 2008; Thomas, Knowles, Tai, & Bentall, 2007). Rumination in BD is associated with greater depression, but not mania levels (Alloy et al., 2005). In addition, studies have found higher rumination levels among individuals at risk for BD (Johnson et al., 2008).

Studies of individuals with remitted BD have also found higher levels of rumination compared with healthy controls (Thomas et al., 2007), which provides additional support for the idea that rumination is a stable and enduring trait-like characteristic. Unfortunately, there is a relative dearth of longitudinal research on rumination in BD (Johnson et al., 2008), so it is unclear whether rumination represents a risk factor for BD.

Anxious Rumination and Worry

Anxious rumination has found support as a form of rumination that is distinct from depressive rumination (Rector, Antony, Laposa, Kocovski, & Swinson, 2008). A recent meta-analysis demonstrated medium to large effect sizes for the relationship between anxious rumination and anxiety among clinical and community samples of adults, as well as children, with different strengths applying to different anxiety disorders (Aldao et al., 2010). For anxiety disorders that feature repetitive thoughts related to personal concerns, such as SAD, GAD, OCD, and PTSD, these effect sizes were particularly large. In particular, GAD and OCD, which are characterized by not only persistent and repetitive thought, but also lack of cognitive control, demonstrated rumination scores that were comparable to those of mood disorders (Aldao et al., 2010). Conversely, panic disorder exhibited the smallest association with rumination. This is not surprising, given that some of the more defining features of panic disorder include physical arousal, rather than repetitive thoughts.

A line of research has explored a specific type of repetitive thought, known as post-event processing, in social anxiety. Individuals with social anxiety maintain a negative mental representation of themselves in social situations based upon how they believe they appear to others (Rapee & Heimberg, 1997). Following a social interaction, socially anxious individuals immediately conduct a postmortem of the event, recalling not only the mental representation of the self in that particular social situation but also memories of the self in other social situations. Because socially anxious individuals perceive the social situation as more negative than it actually was, they believe that the interaction reflected another social failure, thus preserving their beliefs of their own social inadequacy and thus perpetuating their social phobia (Clark & Wells, 1995). Both clinical and nonclinical socially anxious individuals reported higher levels of post-event processing compared with nonsocially anxious individuals (Brozovich & Heimberg, 2008). Findings indicate that socially anxious individuals engage in more post-event processing following a social interaction or speech task in the lab (Abbott & Rapee, 2004; Mellings & Alden, 2000; Perini, Abbott, & Rapee, 2006; Rachman, Grüter-Andrew, & Shafran, 2000). Finally, nonanxious college students who were instructed to ruminate following a similar lab-based socially evaluative task maintained their levels of state anxiety (Wong & Moulds, 2009).

Another line of research has examined the role of rumination in PTSD, as trauma-related rumination features prominently in this type of anxiety disorder (Elwood, Hahn, et al., 2009). More specifically, trauma-related rumination may involve thinking about the causes and consequences of the trauma, which prevents focusing on the events of the trauma itself (Elwood, Hahn, et al., 2009). Cross sectional studies have found associations between rumination and PTSD for several types of trauma, including physical and sexual assault, motor vehicle accidents, and disasters (Elwood, Hahn, et al., 2009). Prospective longitudinal analysis has shown that rumination shortly following a traumatic event predicts changes in PTSD symptoms over time (Elwood, Hahn, et al., 2009). It is important to note that the relation between rumination and PTSD is also present in children and adolescents (Ehlers, Mayou, & Bryant, 2003).

Similar to rumination, worry is another form of self-focused perseverative thought for negative events that provoke fear and anxiety due to perceived lack of control and uncertainty (Nolen-Hoeksema et al., 2008). Worry is an attempt at problem solving, such that individuals who worry try to anticipate all potential future outcomes, especially those that are negative and also highly unlikely. When these negative outcomes do not occur, fear is reduced and the worry is reinforced. Despite the substantial conceptual overlap with rumination, worry can be differentiated from rumination according to several factors. First, worry is focused on future threats, or on past events that have implications for future threats (Nolen-Hoeksema et al., 2008). Rumination, on the other hand, is related solely to past events. In addition, individuals who worry anticipate future outcomes to avoid present negative affect and cognitions. In contrast, rumination is actively focused on current negative affect and cognitions (Nolen-Hoeksema et al., 2008).

Anger Rumination

Anger rumination, which involves perseverative thought on angry affect and planning future aggressive acts, is associated with anger (Pedersen et al., 2011), as well as verbal (Anestis, Anestis, Selby, & Joiner, 2009), relational (Peled & Moretti, 2009), and physical aggression (Bushman,

Bonacci, Pedersen, Vasquez, & Miller, 2005; Bushman, 2002). Findings have indicated that both state and trait rumination are linked to aggression (Borders & Giancola, 2011). Whereas anger rumination is positively associated with anger and aggression, sadness rumination has been found to be a negative predictor of aggression (Peled & Moretti, 2009). It is hypothesized that sadness rumination involves a passive form of repetitive thought that is focused on the self, which leads to withdrawal behaviors. In contrast, anger rumination is a more action-oriented type of thought that is focused on others, which facilitates aggressive behavior and retaliation toward the offender (Peled & Moretti, 2009).

Cognitive Emotion Regulation Strategies

Cognitive emotion regulation strategies are cognitive responses to stressors that are used to mitigate emotional distress or modify the type of emotional experience (Aldao et al., 2010). Additionally, cognitive emotion regulation strategies can also be used to target the stressor itself. Unlike the maladaptive cognitive products reviewed to this point, distraction and reappraisal are two *adaptive* cognitive strategies that are shown to decrease negative emotional experience.

The medial prefrontal cortex has also been implicated in reappraisal and distraction, as this brain region is involved in appraising emotional stimuli in relation to the self and the environmental context (McRae et al., 2010). Lateral regions of the prefrontal cortex, which are closely related to cognitive control, are also recruited during these regulation strategies. Researchers have posited that activation of these regions may reflect the use of verbal working memory to generate and maintain the necessary cognitions to mitigate emotional distress (McRae et al., 2010). This hypothesis provides one potential connection between cognitive processing (e.g., working memory, EF) and products (e.g., reappraisal).

Distraction

Distraction is a form of emotion regulation that involves engaging in thoughts or behaviors to divert one's attention away from negative mood and instead toward more positive stimuli (Nolen-Hoeksema et al., 2008). Distraction can involve a change in internal focus, such as invoking pleasant thoughts or memories, or it can involve a change in external focus, such as engaging in a favorite hobby (Gross & Thompson, 2007). Distraction can be further divided according to two domains of strategies: active and passive. Active strategies require effort to attend to and engage in positive or neutral information that is unrelated to the negative stimulus (Webb, Miles, & Sheeran, 2012). For example, in a laboratory experiment, participants might be given explicit instructions to distract themselves by thinking about something that is unrelated to the negative emotional stimulus. Passive strategies, on the other hand, do not involve explicit instructions to distract, but still involve engagement in emotionally neutral or positive materials or tasks that are unrelated to the negative emotional stimulus (Webb, Miles et al., 2012). In utilizing distraction as an emotion regulation strategy to replace negative mood with a more neutral or positive mood, an individual avoids the potential for the negative mood to bias self-reflection or cognitive problem solving strategies (Nolen-Hoeksema, 1991).

Overall, findings indicate that distraction may serve as an important strategy for mitigating negative mood, however, studies examining the relationship between distraction and specific disorders are lacking. Meta-analytic findings suggest that distraction contributes to relatively large shifts in affect ($d = 0.46$; Augustine & Hemenover, 2009). A more recent review by Webb and colleages (2012) examined studies with nonclinical samples that employed experimental manipulation of emotion regulations strategies, such as distraction, and found variable effect sizes depending on the type of instructions that were provided. For instance, active distraction strategies demonstrated larger effect sizes ($d = 0.47$ when participants were asked to focus on positive material; $d = 0.38$ when asked to focus on neutral material) than passive distraction strategies ($d = 0.18$ when focusing on positive material; $d = 0.23$ when focusing on neutral material). The fact that these studies utilized experimental manipulation provides evidence that distraction may act as a causal protective factor that buffers against negative emotional experience.

A small body of research has explored the relationships between distraction and specific emotional disorders. A number of cross sectional studies with adults have found that distraction confers benefits for dysphoric individuals (e.g., Chang, 2004; Lam, Smith, Checkley, Rijsdijk, & Sham, 2003; Lyubomirsky & Nolen-Hoeksema, 1993); however other studies have not found this relationship (e.g., Just & Alloy, 1997; Nolen-Hoeksema & Morrow, 1993). Longitudinal studies with youth (e.g., Abela, Aydin, & Auerbach, 2006; Ziegert & Kistner, 2002) and adults (e.g., Huffziger & Kuehner, 2009) have found some support for the finding that distraction predicts decreases in depressive symptoms over time, but others have not been able to support these findings (e.g., Abela, Brozina, & Haigh, 2002; Abela, Vanderbilt, & Rochon, 2004).

Some studies have also examined remitted depressed patients (e.g., Huffziger & Kuehner, 2009; Joormann, Siemer, & Gotlib, 2007; Singer & Dobson, 2007). Overall, these studies have found that experimentally induced distraction strategies were as effective as other strategies, such as mindfulness, at improving mood. In addition, Huffziger and Kuehner (2009) found that a greater tendency to engage in distraction was associated with less negative mood and more positive mood across all experimental groups. Moreover, Huffziger, Reinhard, and Kuehner (2009) also found that distraction in formerly depressed inpatients predicted fewer depressive symptoms over time.

There is a lack of research on the association between distraction and other types of disorders. One study by Ehring, Fuchs, and Kläsener (2009) conducted an experimental manipulation of distraction among individuals with PTSD and found that distraction led to decreases in negative mood and also a decrease in the frequency and distress of intrusive memories. A few studies have examined the relationship between distraction and anger. Ray, Wilhelm, and Gross (2008) and Denson, Moulds, and Grisham (2012) examined a nonclinical undergraduate sample and found that distraction significantly reduced anger. Moreover, Bushman et al. (2005) and Rusting and Nolen-Hoeksema (1998) found that distraction was not only associated with reports of decreased anger, but also better problem solving abilities. These experimental manipulation strategies lend further support to the causal role of distraction in reducing the impact of negative affect in various forms of psychopathology.

Cognitive Reappraisal

Cognitive reappraisal refers to the ability to change how one thinks about a situation or about one's capacity to manage the demands of a situation to alter its emotional significance (Gross & Thompson, 2007). Reappraisal can act upon different aspects of the situation (Webb, Miles, et al., 2012). One could reinterpret the cause or context of the situation that is evoking the emotion. For instance, Hajcak and Nieuwenhuis (2006) instructed participants to "Come up with a less negative interpretation of the picture content (e.g., a bloody crime scene could be seen as the place where a murder investigation was finally solved)" (p. 292). One could adopt a more objective or third-person perspective.

As with distraction, reappraisal may also serve as an important strategy for mitigating negative mood; however, studies examining the relationship between reappraisal and specific disorders is still in its infancy. Meta-analytic findings for experimental manipulation of emotion regulation strategies, such as reappraisal, have found a small-to-medium sized effect of reappraisal on emotional responding ($d = 0.36$; Webb, Miles, et al., 2012). These researchers further examined this effect by considering the target of the reappraisal strategy. Reappraising the cause or context of the situation had a small-to-medium effect on emotional response ($d = 0.45$), distancing oneself or taking a third person perspective had a small-to-medium size effect ($d = 0.36$), and reappraising the resulting emotional response had a small effect ($d = 0.23$).

Although a substantial body of literature has examined the relationship between reappraisal and various types of affect (e.g., general negative affect, sadness, anger) fewer studies have considered how reappraisal may relate to the more extreme and severe forms of affect that are implicated in psychopathology. A meta-analysis of reappraisal found that self-reported reappraisal was negatively associated with psychopathological symptoms overall ($d = -0.28$; Aldao et al., 2010). In the case of depression, specifically, trait reappraisal is associated with lower symptom levels (Gross & John, 2003) and fewer depressive episodes (Garnefski, Kraaij, & Spinhoven, 2001; Garnefski & Kraaij, 2006; Kraaij, Pruymboom, & Garnefski, 2002).

Reappraisal manipulations in a laboratory setting have also been demonstrated as an effective strategy for reducing anxiety in college undergraduates (Hofmann, Heering, Sawyer, & Asnaani, 2009) and for decreasing negative emotion in children and adolescents diagnosed with GAD, separation anxiety, and SAD (Carthy, Horesh, Apter, Edge, & Gross, 2010). Reappraisal was also associated with lesser total PTSD severity among military service veterans diagnosed with PTSD (Boden, Bonn-Miller, Kashdan, Alvarez, & Gross, 2012). Conversely, less frequent use of cognitive reappraisal was associated with higher levels of PTSD symptom severity (Eftekhari, Zoellner, & Vigil, 2009; Ehring & Quack, 2010).

A moderate reduction in anger was shown for treatment programs that utilized cognitive restructuring, a correlate of reappraisal (DiGiuseppe & Tafrate, 2003). Ray et al. (2008) and Denson et al. (2012) examined a nonclinical undergraduate sample and found that reappraisal of an anger-eliciting event significantly reduced anger. Among outpatient participants with schizophrenia and schizoaffective disorder, those who were instructed to reappraise reported experiencing less sadness and general negative affect (Perry & Henry, 2012). However, there may be no trait differences in tendency to reappraise, as individuals with schizophrenia did not differ from control participants in their use of reappraisal strategies (Badcock, 2010; Henry, Rendell, Green, McDonald, & O'Donnell, 2008).

As with distraction, experimental manipulation of reappraisal, as well as treatment interventions that employ reappraisal, this type of cognitive emotion regulation strategy may be causally related to emotional distress and psychopathology.

Gender, Cultural, and Ethnic Differences and Considerations

A preponderance of studies examining demographic differences in cognitive products have focused largely on gender, as rates of internalizing psychopathology are markedly higher in females, whereas externalizing psychopathology is more prevalent in males (Zahn-Waxler, Crick, Shirtcliff, & Woods, 2006). Studies of gender differences in negative inferential styles, for instance, have found that females report more negative inferential styles than males, which might explain the fact that females are more likely to develop depression in adolescence than males (Hankin & Abramson, 2002; Mezulis, Abramson, Hyde, & Hankin, 2004). In addition, studies have found that negative attributional style was only associated with elevations in depressive symptoms at high levels of negative life events for males (e.g., Hankin, Abramson, & Siler, 2001; Stone, Gibb, & Coles, 2009). Among females, however, negative attributional style was associated with depressive symptom elevation even at low levels of negative events. Therefore, a negative inferential style may both mediate and moderate gender differences in depression. There is a relative lack of studies examining gender differences for other types of cognitive styles. A few studies have found that males exhibit more dysfunctional attitudes compared with females (Haeffel et al., 2003; Hankin, 2009). In addition, some studies have identified gender differences in hostile attribution biases, such that boys demonstrate hostile attribution bias for instrumental provocation situations and girls exhibiting this bias for relational provocation (Crick & Dodge, 1994; Crick et al., 2002).

There are also notable gender differences in repetitive negative thought, such that females report higher levels of depressive rumination compared with men (Hankin, 2008b; Susan Nolen-Hoeksema, 2012; Rood et al., 2010), whereas males may engage in more anger rumination compared with women (e.g., Rusting & Nolen-Hoeksema, 1998). As with negative inferential style, it has been suggested that the gender difference in depressive rumination, in particular, partially accounts for the gender difference in depression rates among females and males (Hankin, Wetter, & Cheely, 2008; Hankin, 2009; Watkins, 2008). However, some studies, especially with children and early adolescents, have not found sex differences in rumination (Abela, Brozina, & Haigh, 2002; Abela, McGirr, & Skitch, 2007; Abela & Hankin, 2011; Abela, Vanderbilt, & Rochon, 2004). This underscores the point that consistent sex differences in response styles, such as rumination, may not develop until early to middle adolescence (Hankin et al., 2008; Watkins, 2008).

There is also some evidence for gender differences in cognitive emotion regulation strategies. According to a review by Nolen-Hoeksema (2012), women were more likely than men to report using reappraisal and distraction. Some researchers (e.g., Barrett, Lane, Sechrest, & Schwartz, 2000) have posited that men may engage in more automatic, subconscious emotion regulation, and as a result may not report the use of conscious, language-based strategies, such as reappraisal or distraction. In line with this finding, a neuroimaging study by McRae and colleagues (2008) suggests that men may indeed engage in reappraisal; however results indicate that they do so more automatically and with less mental effort compared with women.

Compared with research on gender differences in cognitive products, relatively few studies have explored cultural and ethnic differences in these constructs. There is evidence showing that predictive associations are maintained across different cultural and ethnic groups. For example, interactions between negative cognitive styles (e.g., inferential style and dysfunctional attitudes) and stressful life events predict depressive symptoms in youth samples of rural and urban regions of China (Abela et al., 2011) as well as youth in Spain (Calvete, Villardón, & Estévez, 2008), the same as found in the United States. Furthermore, early maladaptive schemas are risk factors for the development of depression (Calvete, Orue, & Hankin, 2012), anxiety (Cámara & Calvete, 2011), and aggression (Calvete, 2008) in Spanish youth. While predictive associations seem to be similar across cultural groups, there is also evidence for mean level differences in cognitive influences. For example, the positivity bias (i.e., stronger positive relative to negative attributional style) is higher among individuals from Western, individualistic cultures relative to East Asian, collectivistic cultures (Mezulis et al., 2004). Additional research that directly compares these constructs across cultures will help to elucidate potential cultural and ethnic differences.

DISCUSSION

Summary: Empirical Status of Cognitive Products and Processes in the Development of Psychopathology

There are several main points to emphasize based upon our review of the literature. First, it is clear that the preponderance of evidence shows that cognitive products and

processes are associated, at least concurrently, with many prevalent psychopathologies in children, adolescents, and adults (Table 8.8). At this point and with the current state of knowledge, the field generally does not need more cross sectional, case control designs comparing a group with one specific disorder to healthy controls (especially adults, as much of the literature, particularly with cognitive processes, has used almost exclusive adult samples). The cross sectional case-control design only addresses the question of whether there is a difference in cognitive risk between groups, and that question has been satisfactorily answered in the affirmative, at least for disorders, cognition, and age groups reviewed herein. There is value for cross sectional work in new areas (e.g., preschool psychopathology). At a minimum, future research examining the cognitive products and processes reviewed here should utilize longitudinal designs to better disambiguate which of several logical conceptual models (e.g., cause, consequence, correlate; see earlier for expanded discussion) best characterizes how these cognitive influences relate to developmental trajectories of psychopathology (onset, maintenance, desistance) over the life-course.

Second, there is need for research using carefully selected age-relevant samples that are thoughtfully chosen to investigate developmentally oriented questions. As just noted, most of the process studies have used adult samples, yet such research cannot easily address developmentally sensitive questions relevant for understanding onset, course, and trajectory of disorders because many disorders have child or adolescent onsets and then exhibit a chronic pattern, especially in adulthood. As such, exclusive use of adult samples, which likely comprises an unknown admixture of some new onsets alongside mostly recurrences (and it would be important to assess and investigate whether these are first recurrences or multiple), does not significantly advance knowledge on the role of cognitive influences in developmental trajectories of psychopathology. On the other hand, very few studies have examined cognitive influences with preschool-age children; developmentally sensitive and age-appropriate measures of cognitive products and processes can be used to examine associations with prevalent preschool psychopathologies (Egger & Angold, 2006). While our review shows that cognitive products, in particular, and likely cognitive processes, are associated with common psychopathologies in children and adolescents to an equal magnitude as found in adults, often the ages of samples in these studies employed relatively wide age ranges (e.g., 9–18 year olds) that may not carefully match developmental questions. Future research would benefit from using tighter age ranges that are thoughtfully connected to developmentally sensitive questions.

Last, there likely exist meaningful developmental patterns in how cognitive risks operate over time to influence the development of psychopathology, yet it is not entirely clear how various developmental factors (e.g., biological, cognitive, and emotional development; changes in social contexts—peers, parents) affect this process. The extant data, as reviewed earlier, suggest that cognitive products and processes may broadly apply as risks to multiple common psychopathologies across the life span, including children, early adolescents, adolescents, and adults. Yet at the same time, it is likely that much change occurs with respect to these cognitive risks throughout childhood and adolescence. In particular, it is likely that accumulating environmental experience (e.g., stressful life events) and known changes in cognitive, emotional, and biological influences across development contribute to (1) the emergence, and developmental origins, of these cognitive influences and when they function to confer risk to development of psychopathologies; (2) greater stabilization of cognitive influences into more enduring, trait-like risks over time; and (3) enhanced interrelatedness and consolidation among the different cognitive products and processes. In sum, there is still a need for research examining cognitive products and processes in the development of psychopathology across the life span. In the sections that follow, we discuss developmentally relevant areas for advancing knowledge of cognitive risks to psychopathology.

Developmental Considerations

Cognitive risks to the development of psychopathology, by definition and theory, are believed to reflect stable individual differences, certainly by adulthood. However, the age when cognitive products and processes emerge as stable risks for psychopathology, and the extent to which they represent trait-like risk processes over the life span, especially in childhood and adolescence, remains largely unknown. Addressing these questions is essential for both basic developmental clinical scientific knowledge and for informing translational applications. Understanding when and how cognitive products and processes emerge as stable risks to various psychopathologies can potentially inform when to implement optimal, developmentally sensitive interventions and provide etiologically valuable clues to better understand the established developmental epidemiological patterns (e.g., first onset, maintenance, recurrence, desistance) in various prevalent psychopathologies.

Moreover, and as we discuss in greater detail later, it may be that different underlying *mechanisms* lead to various psychopathologies at different developmental periods.

TABLE 8.8 Summary of Findings

	Executive function	Attention	Memory	Cognitive styles	Repetitive negative thought	Cognitive emotion regulation strategies
Depression	• Broad impairment across all aspects of EF	• Mixed evidence for impaired sustained attention • Little research on selective attention, but appears intact • Little research on divided attention, but may be impaired • Biased attention toward negative stimuli	• Impaired episodic memory • Impaired autobiographical memory • Little research on semantic memory, but appears to be intact	• Negative inferential style, dysfunctional attitudes, and early maladaptive schemas (e.g., disconnection/ rejection, impaired autonomy, other-directedness) linked to symptoms and episodes of depression; mixed evidence for remitted depression • Very little evidence for link to hostile attribution bias • No evidence for looming maladaptive style	• Depressive rumination, especially brooding linked to symptoms and episodes of depression	• Distraction and reappraisal linked to lower levels of negative affect • Mixed findings linking distraction and reappraisal to dysphoria and depressive symptoms
Bipolar disorder	• Broad impairment across all aspects of EF	• Impaired sustained attention • Little research on selective attention • Little research on divided attention, but may be impaired • Little research on biased attention, but may be bias toward negative and manic stimuli	• Impaired episodic memory • Intact semantic memory • Little research on autobiographical memory, but may be impaired	• Negative inferential style linked to depression and mania • Positive inferential style linked to mania • Early maladaptive schema (e.g., impaired limits) linked to BD • No evidence for hostile attribution bias or looming maladaptive style	• Small body of evidence linking depressive rumination to depression in BD	
Anxiety	• Impairments across most aspects of EF for OCD and PTSD • Little research on other anxiety disorders	• Little research on sustained or selective attention • Little research on divided attention, but may be impaired • Biased attention toward negative stimuli	• Impaired episodic memory in OCD and PTSD • Impaired autobiographical memory in PTSD • Little research on other anxiety disorders	• Some evidence for link between negative inferential style and comorbid depression and anxiety, but not anxiety alone (PTSD is an exception) • Early maladaptive schemas (e.g., impaired autonomy) linked to anxiety • Strong link to looming maladaptive style	• Anxious rumination linked primarily to SAD, GAD, OCD, PTSD • Support for postevent processing, a type of anxious rumination, in SAD • Little evidence for link to PD	• Little evidence linking distraction to decreases in negative mood in PTSD, only • Reappraisal linked to deceases in anxiety

Schizophrenia	• Broad impairment across all aspects of EF	• Impaired sustained attention • Visual selective attention appears largely intact (overall response slowing only). Auditory selective attention may be impaired • Little research on divided attention, but may be impaired • Little research on biased attention, but may be bias toward disorder-specific stimuli (e.g., paranoia words)	• Impaired episodic memory • Impaired semantic memory • Impaired autobiographical memory	• Persecutory delusions associated with attributions of negative events to external personal causes as well as hostile attribution bias • Some evidence showing link to concern about self-efficacy and performance • No evidence for looming maladaptive style	• No evidence for rumination in schizophrenia	• No evidence for distraction or reappraisal in schizophrenia
ADHD/ externalizing	• Broad impairment across all aspects of EF	• Impaired sustained attention • Selective attention appears largely intact (overall response slowing only) • Little research on divided attention, but may be impaired • Little research on biased attention	• Impaired verbal episodic memory, but nonverbal episodic memory appears to be intact • May be small impairments in semantic memory • Little research on autobiographical memory	• Some evidence for negative inferential style in ADHD, includes a controllability dimension • Early maladaptive schemas (e.g., entitlement/grandiosity) linked to aggression • Hostile attribution bias linked to aggression and ADHD • No evidence for looming maladaptive style	• Anger rumination linked to aggression	• Distraction and reappraisal linked to decreases in angry mood

In particular, two logical hypotheses are important to consider. First, it may be that the mechanisms fundamentally implicated in products and processes only emerge and work to contribute to development of psychopathologies shortly before these disorders typically onset. Alternatively, the various cognitive influences may exist and function as risks earlier, but remain latent until activated (e.g., by stressors, for those cognitive influences postulated to operate per a vulnerability-stress model). In other words, a critical, but relatively uninvestigated question, is *why* various cognitive risks predict developmental patterns of psychopathology (e.g., first onsets) and *when* these phenomena are most likely to occur. The ensuing discussion focuses on theoretical possibilities and some key empirical evidence regarding developmental influences, specifically emergence and origins, then stabilization, and finally the structure and eventual consolidation, of cognitive influences.

Emergence of Cognitive Products

Historically, since the original theorizing on cognitive theories of psychopathology, there has been considerable speculation, and some empirical research, regarding which developmental stage and age period best characterize when cognitive products emerge as potent risks for the development of psychopathology (e.g., Gibb & Coles, 2005; Hankin et al., 2009; Rutter, 1987). For example, from the perspective of Beck's cognitive theory, it is hypothesized that schema are not consolidated until adolescence or even early adulthood because it has been postulated that repeated learning experiences need to reinforce the schemas to be actively operating and lead to symptoms (e.g., Hammen & Zupan, 1984). Also earlier theorizing for the hopelessness theory (Abramson et al., 1989) postulated that a depressogenic attributional style only emerges during the transition from childhood to adolescence when children acquire the ability to engage in abstract reasoning and formal operational thought (e.g., Nolen-Hoeksema, Girgus, & Seligman, 1992).

In seeking to explain mechanisms that may underlie potential developmental changes in cognitive products based on these early conceptual speculations, researchers have drawn from a wide variety of findings in the cognitive development literature—particularly those pertaining to middle childhood. For example, during middle childhood, children start to develop a more stable and less concrete sense of self (Rholes, Blackwell, Jordan, & Walters, 1980). Their self-views become increasingly differentiated as they shift their focus from concrete, behavioral characteristics in early childhood to relatively more personality trait-like characteristics in middle childhood to more abstract psychological constructs during adolescence (e.g., Harter, 1990). During this developmental period, children also become less here-and-now oriented (Shirk, 1988) and more likely to integrate past experience into working knowledge in a manner that informs interpretations and predictions (Rholes et al., 1980). Whereas very young children have a rudimentary understanding of causality (e.g., Oakes, 1994), middle childhood is when children use stable personality traits increasingly to explain their behavior (e.g., Corrigan, 1995).

Some early empirical research examined the hypothesis that cognitive products (mostly a negative attributional style, as the most theorized and researched) emerge during the transition from middle childhood to early adolescence, based on the view that it is necessary that concrete operations be present for negative attributions to be made about explaining the cause of negative events. Results from two studies in particular provide the most compelling support for this early hypothesis based on necessary cognitive developmental maturity requirements in late childhood (Nolen-Hoeksema et al., 1992; Turner & Cole, 1994); these studies suggest that a depressogenic attributional style interacted with negative events to predict higher levels of depressive symptoms in later childhood/early adolescence, but not earlier in childhood. However, these early studies tended to focus relatively narrowly on only one particular cognitive risk (e.g., negative attributional style) and tended to investigate age of emergence with psychometrically poor measures, which obviously affect ensuing conclusions. Since these initial investigations, more recent studies using more reliable and developmentally sensitive measures have shown that cognitive products, such as a negative attributional style, predict increases in depressive symptoms much earlier (e.g., by age 6, Conley et al., 2001; age 8, Abela, 2001) than previously thought and than what was originally theoretically expected based on cognitive maturity hypotheses.

Presently, the developmental period and age by which cognitive products emerge is not clearly established. Our review indicates that a negative cognitive style predicts depressive symptoms as early as age 6 (Conley et al., 2001), dysfunctional attitudes by age 6 (Abela & Skitch, 2007) in offspring of depressed mothers, and rumination by age 6 (Abela, Hankin, Sheshko, Fishman, & Stolow, 2012) in offspring of depressed mothers; age 8 in normative sample, (Lopez, Felton, Driscoll, & Kistner, 2012). However, these findings should be interpreted tentatively because there have been insufficient studies that have focused on the

earliest ages by which these cognitive products predict various psychopathological outcomes, and the earliest prediction may vary depending on the form of psychopathology examined (e.g., separation anxiety symptoms with earlier modal age of onset versus depression or PTSD). Also, developmentally sensitive and reliable measures are needed to rigorously examine emergence of these risks in earlier ages (e.g., preschoolers). Last, there is a paucity of theory to suggest when and why particular cognitive products would emerge as contributing factors conferring risk to different psychopathologies. (Note, there is some theory and evidence regarding developmental origins and precursors of these cognitive products, and such work, reviewed later, has relevance for understanding the emergence of these risks.)

Developmental theory and research on origins and emergence for hostile attributional bias has been less controversial. According to developmental literature, hostile attribution bias serves as the default attributional style in prevocational situations and is present very early in life (Dodge, 2006). Hostile attributions follow from a simple assumption that an act that brings about a negative outcome for the self must logically originate from an actor with a negative intent (Dodge, 2006). This rigid association between negative outcome and negative intent becomes more flexible as a result of cognitive development that begins at about age three or four. It is during this time that young children acquire the capacity to understand that others' mental states are different from our own, and they can make correct inferences about the content of the mental states (e.g., intentions and beliefs) of others (Couture, Penn, & Roberts, 2006).

These inferences serve an adaptive purpose by allowing individuals to predict and explain others' behavior in a social context (Lee, Farrow, Spence, & Woodruff, 2004). In the specific case of negative outcomes, identification and interpretation of social cues that signal that the actor may have acted without intent or with a benign intent, instead of malevolently, is a particularly important (Dodge, 2006), albeit more complicated, formal operation. Early adolescence is another key developmental period that facilitates the ability to infer lack of intent or benign intent, as this stage of cognitive development is characterized by the ability to generate alternatives and consider hypothetical possibilities (Dodge, 2006). Over time, the ability to interpret ambiguous social cues as nonintentional facilitates the development of a stable pattern of inferring benign intent, especially in ambiguous situations. Therefore, a hostile attribution bias evolves from an individual not acquiring a benign attributional style and instead continuing to match intent with outcome (Dodge, 2006).

Emergence of Cognitive Processes

While much is known about typical (and to some extent abnormal) development of cognitive processes, little is known about when cognitive processes emerge as risks for the development of psychopathology. Unlike cognitive products, which as discussed above are hypothesized to emerge only after particular stages of development, in typically developing children cognitive processes develop continuously throughout childhood, and in some cases into early adulthood. EF has a particularly protracted developmental course, following the protracted development of prefrontal cortex. Some early developmental milestones are reached during the preschool years (e.g., the ability to switch between two simple tasks rather than perseverating on the first task (Munakata, Chatham, & Snyder, 2012a). Throughout early and middle childhood, there is continued quantitative (e.g., ability to switch between tasks more efficiently), and qualitative (e.g., shift from reactive to proactive control strategies) development (Munakata et al., 2012a). Unlike some other cognitive abilities, which are relatively mature by the end of middle childhood, EF continues to develop through adolescence and even into early adulthood (e.g., Huizinga, Dolan, & van der Molen, 2006), and then declines in older adulthood (e.g., Buckner, 2004).

In contrast to EF, attention and memory processes develop relatively early, though they continue to develop throughout childhood. Infants already have the ability to selectively attend to particular stimuli in some circumstances (Atkinson & Braddick, 2012). Selective, divided, and sustained attention abilities continue to develop through middle childhood when they generally reach adult levels (e.g., Waszak, Li, & Hommel, 2010), although some development may continue in adolescence (e.g., McAvinue et al., 2012). As with attention, even infants have impressive memory abilities (Bauer, 2007), although the ability to retrieve specific episodic memories continues to improve through middle childhood (e.g., see Ghetti & Bunge, 2012 for review), and semantic memories continue to accrue throughout the life span. Like EF, age-related declines in memory are common (Buckner, 2004).

Given these normal patterns of development, there are several logical possibilities as to when these cognitive processes might emerge as psychopathology risks. First, deficits in these processes might be present from early in development and serve as risks throughout the life span.

This pattern is consistent with the evidence in ADHD, which is associated with poor EF from preschool to adulthood. There has been little research with young children in other areas, but many cognitive deficits are similarly associated with multiple forms of psychopathology in childhood, adolescence, and adulthood, suggesting that cognitive process risks may be relatively stable across the life span. Second, cognitive deficits could be present from early in development, but only become associated with psychopathology in the presence of other risk factors or developmental vulnerability periods for psychopathology. Detecting this pattern requires long-term prospective longitudinal studies beginning in early childhood. Finally, cognitive deficits could emerge later in development, either because of neurodevelopmental abnormalities or neurodegenerative processes, as discussed later.

Developmental Origins of Cognitive Risks. In addition to knowing when cognitive influences emerge as salient predictors of psychopathology, an important and related question concerns the developmental origins of these cognitive risks. While many precursors have been postulated and examined, here we consider some of the more consistently conceptualized and examined factors, including negative parenting and social modeling, negative life events including abuse and trauma, and genetics.

Parenting. A prominent hypothesis is that cognitive products and processes may arise from maladaptive parenting practices. Based on a cognitive-developmental framework, parenting behaviors convey information to the child which may be internalized and subsequently contribute to the construction of beliefs and related processes (Bruce et al., 2006). Positive aspects of parenting (e.g., high levels of warmth, acceptance, autonomy promotion, consistency, and positive reinforcement) would be expected to contribute to the development of positive self-beliefs, whereas negative forms of parenting (e.g., high levels of criticism, rejection, control, and inconsistency) likely contribute to the formation of negative self-views and related processes (e.g., Beck, 1967; Young, 1999).

Several cross sectional studies support the association between maladaptive parenting practices and cognitive products. For example, regarding Beck's cognitive theory, high levels of parental criticism, indifference, and control and low levels of parental acceptance and care are associated with dysfunctional attitudes and cognitive distortions in youth (e.g., Bruce et al., 2006; Garber & Flynn, 2001; Liu, 2003) as well as a negative self-concept (e.g., Bruce et al., 2006; Liu, 2003). Similarly, high levels of parental criticism and control and low levels of parental care and acceptance correlate with a depressogenic attributional style in youth (e.g., Bruce et al., 2006; Garber & Flynn, 2001). While comparatively less research has extended this line of inquiry into developmental origins of cognitive processes, one study demonstrated that coded observations of negative parenting styles (authoritarian) and behaviors (criticism, negative affect) were associated with youths' attentional biases to negative emotion, especially angry faces, in two independent samples (Gulley, Oppenheimer, & Hankin, 2013).

The few prospective studies to examine parental influences as precursors to development of cognitive products have been supportive. Maternal reports of high rejection and restrictiveness, when children were age five, prospectively predicted youths' self-criticism at age twelve (Koestner, Zuroff, & Powers, 1991). Also, observations of maternal feedback to child failure as well as temperament (from infancy to age 11, (Mezulis, Hyde, & Abramson, 2006); and from age 11 to 15, (Mezulis, Funasaki, & Hyde, 2011) along with maternal cognitive style (from age 11 to 15; Mezulis et al., 2011) predicted development of youths' cognitive style. Last, maternal encouragement of emotion expression in daughters predicted higher rumination levels from age 11 to 15 (Cox, Mezulis, & Hyde, 2010).

What mechanisms might explain this relation between negative parenting and youths' cognitive risks? Mostly, social modeling processes have been evaluated. Evidence for this proposed process is mixed. More consistent evidence has accumulated for one variation of the modeling hypothesis, in which children model feedback communicated to them by their parents about events in the children's own lives rather than modeling their parents' own negative cognitions (e.g., Garber & Flynn, 2001; Mezulis et al., 2011, 2006). Less evidence exists for the modeling variant that children learn and adopt negative cognitions by observing their parents' own negative styles concerning their parents' own behavior. One study showed that children's attributional styles correlated with those of their mothers, but not their fathers (Seligman et al., 1984), whereas others have failed to replicate these findings (e.g., Garber & Flynn, 2001).

Negative Life Events. Second, certain types of negative life events, including (1) repeated exposure to stressors in multiple and interacting domains (e.g., family conflict, divorce, poverty) and (2) traumatic events and maltreatment, may contribute as salient precursors in the development of cognitive products and processes. Accumulation of chronic exposure to negative events can lead to formation of negative cognitions that become deeply

ingrained in self-structures (e.g., Rose & Abramson, 1992). Prospective research has supported this hypothesis with children's experience of negative events (Garber & Flynn, 1998) as well as various facets of family disturbance (i.e., divorce, abandonment, parental death, interparental conflict; Rudolph, Kurlakowsky, & Conley, 2001). With respect to trauma and maltreatment, experience of these more adverse negative environments has been shown to associate with cognitive products in adults (e.g., Gibb et al., 2001; Hankin, 2005) and children (e.g., Dodge, Pettit, Bates, & Valente, 1995; Gibb et al., 2006) as well as various attentional (e.g., Pollak & Tolley-Schell, 2003) and memory (Parsons & Ressler, 2013) processes.

These robust associations between traumatic events and cognitive risks may occur for at least two reasons. First, after trauma exposure, youth attempt to understand the causes, meaning, and consequences of such events; especially when such events are chronic (recurrent across time) and pervasive (recurrent across situations), it is more likely that the child will develop stable, enduring cognitive beliefs to explain the maltreatment and to better predict and control future adverse events (Rose & Abramson, 1992). Formation of negative cognitive products may be particularly likely when the child is emotionally maltreated, as the abuser is directly providing the child with negative information (e.g., you're stupid, lazy) that can directly become cognitive products (e.g., attributions, dysfunctional attitudes, early maladaptive schemas). Second, Pollak's theory of experience-dependent affective learning (2003) proposes that children are biologically prepared for emotion, and the formation of such systems depends, at least to a certain extent, upon salient environment inputs. Abusive experiences are associated with threatening, inconsistent, or excessive emotional signals, which in turn contribute to enhanced threat detection and attentional allocation to predictive environmental and emotion cues (e.g., parents' angry face can probabilistically portend greater likelihood of physical abuse). What started as an initially adaptive learning process to detect threat to keep the child safe can extend into the formation of biased processing of social and emotional information across many contexts that are no longer objectively threatening (e.g., Pollak, Vardi, Bechner, & Curtin, 2005), and in turn, contribute to psychopathologies (Gulley et al., 2013; Shackman, Shackman, & Pollak, 2007).

Genetic and Biological Influences. Genetic, as well as other neural and biological influences, may serve as developmental precursors to the emergence of cognitive risks. First, significant associations have been observed between molecular genetics and cognitive products (e.g., rumination; Beevers, Wells, & McGeary, 2009; Hilt, Sander, Nolen-Hoeksema, & Simen, 2007) and processes (e.g., attention bias to negative emotion; Gibb et al., 2013). Similarly, behavioral genetic research has demonstrated that cognitive risks, such as a negative attributional style (Lau, Rijsdijk, & Eley, 2006), are moderately heritable. Furthermore, there is also evidence that some deficits in EF, memory and attention may be a particular form of genetic risk factor: endophenotypes (Gottesman & Gould, 2003). To be considered an endophenotype, a characteristic must be (1) associated with illness in the population, (2) heritable, (3) primarily state-independent (manifest even when illness symptoms are not present), (4) cosegregate with illness within families, and (5) be present in unaffected family members at a greater rate than in the general population. Criteria 1 and 2 are met for most cognitive processes across most disorders, since cognitive deficits are associated with mental illness as discussed in the literature review, and cognitive processes are largely heritable (Friedman et al., 2008). Moreover, there is evidence for criterion 3 in many cases—for example, cognitive deficits are present in individuals with MDD in remission and euthymic BD. Finally, criteria 4 and 5 are also met in many cases, with evidence that unaffected family members of individuals with schizophrenia, BD, OCD, and PTSD have cognitive function which is more impaired than the general population but less impaired than their affected family members. While these data showing associations between genetic factors and cognitive risks are consistent with a developmental origins hypothesis, the cascade of mechanisms connecting initial genetic risk (e.g., polymorphic variation in particular candidate genes) to later individual differences in cognitive products and processes are unknown and in need of theoretical and empirical investigation.
