From a different perspective, Kernberg (1975) argued that people hold both object-representations (i.e., internal images of important others) and self-representations (i.e., internal images of themselves). In healthy development, he argued, children internalize both positive and negative object and self-representations. In narcissistic development, children may internalize only positive object and self-representations, a process from which narcissism might emerge. At the same time, Kernberg argued, narcissistic children devalue negative object and self-representations (e.g., by projecting them onto others, leading to negative views of others). Because narcissistic children lack healthy object representations, they experience an internal void, a feeling of emptiness—which, so Kernberg held, they can compensate for by garnering praise and admiration from others. Moreover, much like Millon, Kernberg believed that future narcissists often occupy a central role within their family (e.g., they are only children, or considered by their parents to be particularly talented, special, or good-looking).

Taken together, Kohut proposed that narcissism represents arrested self-development, whereas Kernberg proposed that narcissism represents pathological self-development. They agreed, however, that narcissists' inflated self-views and strong need for external validation stem from dysfunctional socialization experiences.

Empirical Evidence

Both perspectives—social learning theory and psychoanalytic theory—have received preliminary empirical support, though mainly from research in adults. Retrospective, cross sectional, and prospective research suggests that narcissism is associated with parental overvaluation and the parenting practices that follow from it, such as permissiveness and indulgence. For example, retrospective studies show that adult narcissists have childhood recollections of their parents overvaluing them—putting them on a pedestal, having overly positive views of them, excessively praising them, and rarely criticizing them (Otway & Vignoles, 2006; but see Horton & Tritch, 2014). Adult narcissists also remember their parents being permissive (Ramsey, Watson, Biderman, & Reeves, 1996), overly indulgent (Capron, 2004), and rarely keeping track of their activities (Miller & Campbell, 2008). In addition, cross sectional research shows that older adolescents and young adults often perceive their parents as providing praise and tangible rewards (Mechanic & Barry, 2015), as warm, and (although less conclusively) as rarely monitoring them (Horton, Bleau, & Drwecki, 2006). Cross sectional research among 9-to-15-year-olds shows that narcissism is associated with both self- and parent-reported parental permissiveness (Barry et al., 2007). Finally, prospective research shows that some narcissistic traits (e.g., observer-rated traits of high aspirations and desire for autonomy) at age 23 are related to parent-reported permissive and indulgent parenting at age 3 (Cramer, 2011), suggesting that perhaps narcissism is rooted in early socialization experiences. Together, these studies provide preliminary evidence consistent with the social-learning perspective that holds that narcissism is cultivated by parental overvaluation and related parenting practices.

There is also preliminary evidence for predictions made by psychoanalytic theory. Retrospective and cross sectional research suggests that narcissism is associated with

parental lack of warmth, including coldness and unresponsiveness. For example, retrospective research indicates that adult narcissists have childhood recollections of their parents being cold, indifferent, and spiteful towards them (Otway & Vignoles, 2006). Other retrospective research indicates that adult narcissists, specifically those high in entitlement or grandiosity, have childhood recollections of their parents exerting harsh discipline, threatening with separation, and failing to provide a secure base (Cater, Zeigler-Hill, & Vonk, 2011). In addition, cross sectional research shows that adults with narcissistic traits, especially those with vulnerable narcissistic traits, perceive their parents as psychologically controlling (e.g., withdrawing their love when their children do not conform to their expectations; Horton et al., 2006; Miller & Campbell, 2008). Together, there is some evidence consistent with the notion that narcissism is influenced by parental lack of warmth and related parenting practices.

Thus, the available research suggests that multiple socialization experiences may be involved in cultivating narcissism. It has been suggested that "narcissistic traits can develop, curiously, when there are deviations from ideal rearing on either side: pampering or neglecting; expecting too much or too little" (Stone, 1993, p. 260). Either way, parents are ultimately insensitive and unresponsive to their child's needs and behaviors (Morf & Rhodewalt, 2001). These findings are in line with the concept of *equifinality*: Multiple developmental pathways (rather than a single pathway) may lead to a similar constellation of traits or disorder (Cicchetti & Rogosch, 1996). An important task for future prospective longitudinal research, from both a basic research and applied perspective, is to identify the multiple pathways that lead to narcissism. An improved understanding of the origins of narcissism will help explain the purpose of narcissists' self-regulation, which may partially arise from needs that were thwarted during childhood (Morf & Rhodewalt, 2001). In addition, an improved understanding of the origins of narcissism is needed to help practitioners devise developmentally tailored interventions to prevent or curtail narcissistic traits at a young age.

Millon and O. F. Kernberg proposed that narcissists often are only children. There is mixed support for this notion. Preliminary studies did not find evidence for birth order effects on narcissism (Curtis & Cowell, 1993; Eyring & Sobelman, 1996; Joubert, 1989; Narayan, 1990). Yet, these studies lacked sufficient sample size to detect birth order effects on personality, effects that are typically very small (for methodological considerations in birth order research, see Paulhus, 2008). Researchers have recently overcome this limitation by conducting two studies in large Chinese samples (N= 10,655 and 15,522; Cai, Kwam, & Sedikides, 2011). Both studies demonstrated a small yet robust link between only child status and narcissism (Cohen's d = .12 and .14, respectively, $p < .001$). These findings may not necessarily generalize to other cultures, however. Many Chinese families are subject to the one-child-per-family policy, implemented by the Chinese government in 1978 to control population size. It is possible that only-child status has different social and psychological consequences for children growing up in China than for children growing up in other countries.

Future research needs to further uncover the mechanisms that explain the potential link between birth order and narcissism, and a few questions seem of particular importance. Does only-child status actually foster narcissism in children, or are parents who are genetically more likely to have narcissistic children somehow more likely to have only one child? And if only-child status indeed fosters narcissism, is such influence mediated by parenting practices, such as increased overvaluation, indulgence, or permissiveness towards children with an only-child status?

Limitations of Previous Research

Previous research on the socialization of narcissism has been informative, and provided glimpses into the origins of narcissism. Yet it also suffered from methodological limitations. First, with some exceptions (e.g., Barry et al., 2007), previous research has mainly relied upon self-reports of experienced parenting. This might be problematic when studying narcissism, to the extent that narcissists' self-enhancing tendencies generalize to how they perceive or report on their parents' behavior towards them. Other-reported and observational measures are needed to index narcissists' socialization experiences. Second, previous research has mainly been cross sectional. Findings have been typically interpreted as showing that parenting practices affect children's narcissism, but the reverse pattern (i.e., children's narcissism affecting parenting practices) may of course be plausible as well. In fact, is it quite likely that narcissistic children's attempts to mold their social interactions (e.g., squeezing out admiration from others) affects the way their parents raise them. Longitudinal research is needed to study the transactions between children's narcissism and their socialization experiences, and to better understand temporal ordering. Third, previous research has been conducted mostly among college students, while the early developmental origins of narcissism probably lie in childhood. To uncover the origins of narcissism, research must investigate its development and socialization in childhood.

Temperament–Environment Interactions

One other limitation of previous research is that it did not take into account that some children, due to constitutional factors, might be more susceptible to socialization experiences than other children. Twin studies found that trait narcissism, measured in adults, is moderately heritable (Luo, Cai, Sedikides, & Song, 2014; Vernon, Villani, Vickers, & Harris, 2008), and that NPD is more heritable than any other personality disorder (Livesley, Jang, Jackson, & Vernon, 1993). Similarly, researchers have argued that the development of narcissism will at least be partially rooted in temperamental traits (Elliot & Thrash, 2001).

Temperament refers to early emerging, constitutionally based individual differences in how children react to their environment and how they control or regulate these reactions (Rothbart & Bates, 2006). From the earliest stages of development, temperament shapes and is shaped by children's experiences, thereby laying the foundation for personality (e.g., Rothbart & Bates, 2006). Crucial for understanding individual differences in narcissism are temperamental dimensions involved in the motivation of emotion and behavior. Research in children as well as adults has identified two fundamental motivational systems: *approach motivation*, which facilitates behavior toward desirable outcomes; and *avoidance motivation*, which facilitates behavior away from undesirable outcomes (Elliot & Thrash, 2002; note that different labels have been used for these motivational systems; see Rothbart, Ahadi, & Evans, 2000).

Approach Temperament

Approach temperament refers to a sensitivity to rewarding (e.g., positive, desirable) stimuli, accompanied by vigilance for, emotional reactivity to, and behavioral inclination toward such stimuli (Elliot & Thrash, 2002). Individuals high in approach temperament are sensitive to desirable stimuli, feel attracted to them, and react strongly to their presence or absence. Approach temperament appears to be based on brain systems previously labeled Behavioral Approach System, SEEKING system, or extraversion/surgency (for an overview, see Rothbart et al., 2000). Approach temperament can be observed from early development onward. Between 3 and 13 months of age, it is manifested by children smiling, laughing, vocalizing, and displaying motor activity (Rothbart, 1989), and it predicts actual behavioral approach (e.g., quickly reaching out for desirable objects, such as toys; Rothbart, 1988). Later in development, children high in approach temperament tend to approach desirable stimuli rapidly, are physically active, quickly feel at ease in new social settings, and prefer situations that involve intense stimuli (Rothbart et al., 2000). During adolescence, approach temperament can become evident in risk behavior, such as drug or alcohol use and risky sexual behavior (e.g., Zuckerman & Kuhlman, 2000). Although the manifestations of approach temperament change throughout development, individual differences in these manifestations are relatively stable over time (Rothbart & Bates, 2006).

Avoidance Temperament

Avoidance temperament refers to a sensitivity to punishing (e.g., negative, undesirable) stimuli, accompanied by vigilance for, emotional reactivity to, and behavioral inclination away from such stimuli (Elliot & Thrash, 2002). Individuals high in avoidance temperament are sensitive to undesirable stimuli, feel dispelled from them, and react strongly their presence or absence. Avoidance temperament appears to be based on brain systems previously labeled Behavioral Inhibition System or FEAR system (Rothbart et al., 2000). In the earliest months of life, infants high in avoidance temperament are prone to express fear and frustration and tend to inhibit their responses to novel and high-intensity stimuli (Rothbart, 1986, 1988). Later in development, avoidance temperament predisposes children to experience negative emotion (Rothbart et al., 2000). Although the manifestations of avoidance temperament change throughout development, individual differences in avoidance temperament are relatively stable (Rothbart & Bates, 2006). For example, children who are classified as inhibited at age 3 are more socially anxious during adolescence (Schwartz, Snidman, & Kagan, 1999) and more cautious at age 18 (Caspi & Silva, 1995).

Temperament and Narcissism

There are theoretical and empirical reasons to presume that narcissistic children are high in approach temperament. First, narcissists display many characteristics that are known to be associated with high approach temperament, including aggression (Bushman & Baumeister, 1998; Thomaes, Bushman, et al., 2008), impulsiveness, risk taking, extraversion (Paulhus, 2001), and dominance (Paulhus & Williams, 2002). Second, the early childhood precursors of narcissism are typical of high approach temperament. Prospective observational research indicates that children who later become narcissistic tend to be impulsive, physically active, and attention seeking during preschool years (Carlson & Gjerde, 2009). Third, much like individuals high in approach temperament, narcissists are highly sensitive to reward. Adult narcissists are at increased risk for gambling problems, are prone to making risky stock market investments, and are at increased risk to

using drugs (e.g., Stinson et al., 2008). Fourth, theories of narcissism emphasize that narcissists' pursuit of praise and admiration resembles a pattern of addiction (Baumeister & Vohs, 2001). Intriguingly, and in line with this idea, recent research found that people high in entitlement (a core dimension of narcissism) especially strongly desire to be praised by others (Bushman et al., 2011).

The link between narcissism and avoidance temperament is less straightforward. If anything, narcissists tend to show marked individual differences in avoidance temperament. For example, narcissistic children differ markedly in their tendency to experience negative affect, to dwell upon criticism and rejection, and to suffer from episodes of self-derogation (e.g., Thomaes et al., 2010, 2011; Nelemans et al., 2015). We propose that narcissists' differences in avoidance temperament may account for grandiose and vulnerable manifestations of narcissism (Foster & Trimm, 2008; Thomaes, Bushman, Orobio de Castro, & Stegge, 2009). Although this has not been investigated in children or adolescents, it is theoretically plausible that grandiose narcissism is rooted in high approach temperament and low avoidance temperament. In contrast, vulnerable narcissism may be rooted in both high approach temperament and high avoidance temperament. Thus, the level of avoidance temperament may be a key distinction between the two faces of narcissism (Foster & Trimm, 2008).

Integrative Model

Children vary in how much they are affected by environmental influences. Dual-risk models (Sameroff, 1983) and diathesis–stress models (Monroe & Simons, 1991) propose that some children, due to their vulnerable or susceptible personality makeup, are more strongly affected by environmental stressors than other children, thereby making them more prone to derailments of healthy social and emotional development. There is now ample evidence that temperament may determine children's susceptibility to socialization influences (for an overview, see Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van Ijzendoorn, 2011).

We propose a diathesis–stress model of the development of narcissism, which casts narcissism as an addiction to admiration from others. The model holds that dysfunctional socialization experiences (i.e., socialization stress) may activate a latent, biologically based vulnerability to become overly dependent on rewarding stimuli, including rewarding social stimuli such as praise and admiration (i.e., the diathesis; Thomaes, Brummelman, Reijntjes, et al., 2013; Thomaes, Bushman, Orobio de Castro, & Stegge, 2009). From early development onward, individuals high in approach temperament are biologically wired to be sensitive to rewarding stimuli. When these individuals experience little socialization stress, their diathesis may remain dormant. However, when they experience much socialization stress, they may develop addictive problems (e.g., Goeders, 2003). In the particular context of an upbringing characterized by overvaluation or coldness, children high in approach temperament may become overly dependent upon receiving validation from others to feel good about themselves, a dependency that is central to narcissism. That is, narcissism may originate from joint dysfunctional socialization experiences and high approach temperament—an amalgam that may make children overly dependent on (or addicted to) praise and admiration from others.

The parallel between narcissism and addiction may reach even further, and account for the processes involved in the maintenance of narcissism over time. Repeated drug use causes persistent changes in the brain underlying sensitization (i.e., the process that makes individuals hypersensitive to the motivational effects of the drug; Robinson & Berridge, 2008). This neural sensitization causes addicts to become relapse-prone whenever they encounter drug-related cues, even if they have been clean for years. Analogously, it is possible that narcissists become sensitized to admiration, and therefore have difficulty resisting its allure, even after a period of abstinence (e.g., when they have obtained little admiration from their classmates for weeks). Another process that maintains drug use is withdrawal: Quitting drugs causes addicts to experience withdrawal symptoms, including restlessness, anxiety, and depression. Taking drugs alleviates these painful feelings (Koob & Le Moal, 2005). Narcissists may likewise strive for admiration to alleviate lurking feelings of anxiety and depression that may arise when they fail to feel admired. Taken together, we putatively suggest that the addiction-related processes of sensitization and withdrawal may at least partially underlie the maintenance of narcissism.

We hope this chapter will encourage researchers to contribute to the study of the etiology and development of narcissism. Knowledge of when and why narcissism emerges is not only of basic interest; it will also pave the way for prevention and intervention efforts to reduce narcissistic maladjustment.

CLINICAL PERSPECTIVES ON NARCISSISM

Throughout this chapter, we have drawn on both social-personality and developmental research on trait narcissism, and on clinical observations and research on

narcissistic pathology. The study of trait and pathological narcissism has remained relatively separated thus far (Cain et al., 2008). This is unfortunate. An integrative, interdisciplinary approach is needed to increase our understanding of what exactly distinguishes normal and pathological narcissistic functioning at different stages of development. Moreover, an interdisciplinary approach would facilitate our understanding of the psychological and developmental processes by which normal self-development can go awry and lead to narcissistic pathology.

Thus, given the current state of the literature, it would be premature to try to provide a comprehensive account of pathological narcissistic development, its origins, and outcomes. Rather, in the following section, we will address a number of issues that are important to understanding narcissistic pathology and its treatment. First, we will address the issues of whether or not NPD can or should be diagnosed in youth, and how NPD is different from related forms of personality characteristics and disorders. Next, we will review clinical and basic research approaches to intervening with narcissism and its consequences.

Pros and Cons of Diagnosing Narcissistic Personality Disorder in Children and Adolescents

The *DSM-IV* (American Psychiatric Association, 2000) discourages clinicians from diagnosing NPD (as well as other personality disorders) in children and adolescents. At the same time, it leaves open the possibility of NPD diagnosis in youth by noting:

> Personality Disorder categories may be applied to children or adolescents in those relatively unusual instances in which the individual's particular maladaptive personality traits appear to be pervasive, persistent, and unlikely to be limited to a particular developmental stage or an episode of an Axis I disorder. . . . To diagnose a Personality Disorder in an individual under age 18 years, the features must have been present for at least 1 year. (P. 687)

Thus, although the *DSM* warns against diagnosis of NPD before adulthood, it ultimately leaves the decision on whether or not to apply such a diagnosis in individual cases up to the clinicians' professional expertise. Perhaps as a result of that ambiguity, clinicians use the NPD diagnosis relatively rarely to classify the problems of their young patients, with psychiatric population prevalence estimates ranging from 0 to 3% in samples of adolescents (Tromp, 2010; Westen, Shedler, Durrett, Glass, & Martens, 2003). Yet, in studies that have used structured interviews or other standardized assessment procedures to measure specific symptoms of personality pathology, greater proportions of youth appear to meet the criteria for NPD diagnosis, with both psychiatric and general population prevalence estimates ranging from 6 to 9% in samples of adolescents (with the highest prevalence estimates found in boys in their early adolescence; Bernstein et al., 1993; Eppright, Kashani, Robison, & Reid, 1993). These figures suggest that narcissistic pathology may be relatively prevalent among youth, yet clinicians only rarely diagnose it as such (Westen et al., 2003).

To be sure, most clinicians and researchers agree that NPD typically has its onset in late childhood or adolescence. Patients do not start to suffer from narcissistic pathology at their eighteenth birthday—they often grow up as individuals who deviate, to some extent, from the expectations of their culture, and experience impairment in important domains of functioning. Yet, there is disagreement on whether it is sensible, even in extreme cases, to actually assess and diagnose NPD in children and adolescents.

One important reason to diagnose children or adolescents with NPD, is that such a diagnosis may, in certain cases, facilitate adequate support and treatment. Accurate diagnosis might help youth to get appropriate, specific treatment for their NPD symptoms and the conditions sustaining those symptoms. Such treatment might help prevent individuals from developing more crystallized and hard-to-treat forms of narcissistic pathology later in life. Also, more prosaically, insurance companies may be more likely to cover treatment of narcissistic pathology among youth when formally diagnosed. Finally, diagnosis may sometimes help patients and their close others to be more acknowledging or accepting of their problems and be more committed to treatment. They may be less likely to trivialize the traits that cause their impairment as unimportant when these traits have a name. Thus, when patients have difficulty acknowledging their problems, which is not unusual among narcissistic individuals, this may be reason for clinicians to actually apply the NPD diagnosis.

Yet of course there is also good reason to be cautious with diagnosing children and adolescents with NPD. First, a personality disorder diagnosis connotes pervasive and long-term psychological maladjustment that is difficult to treat, while clinicians of young patients are typically unsure of how symptoms will develop over time, and how well their patients will respond to treatment. Similarly, thorough empirical knowledge of the stability of narcissistic pathology from childhood or adolescence into adulthood is lacking (though preliminary evidence has suggested that dimensionally measured narcissistic pathology may

show considerable stability from early adolescence into early adulthood; Crawford, Cohen, & Brook, 2001). Thus, clinicians should be wary of premature NPD diagnosis. Second, even in individual cases when NPD diagnosis is not premature, it entails a risk of stigmatization. Youth diagnosed with NPD may come to feel aberrant, weird, and chronically debilitated, or they may come to be seen in such a light by others. As detailed elsewhere (Hinshaw, this Volume), stigmatization can lead to feelings of shame or self-blame and social distance—factors that might exacerbate rather than alleviate patients' symptoms. In fact, because the very nature of narcissism involves a heightened sensitivity to shame and social disapproval, it is possible that stigmatization is even more damaging to narcissistic youth than to others.

What, then, should clinicians do when a young patient suffers from persistent narcissistic pathology to such an extent that these problems would meet the criteria for NPD diagnosis? We propose that they should weigh, for each individual patient, the potential benefits of such a diagnosis against the risk of stigmatization and potential other costs. NPD diagnosis is viable in individual cases when the benefits of appropriate treatment or disorder acknowledgement can reasonably be expected to outweigh the psychological burden that the NPD label might cause.

Associated Traits and Disorders and Differential Diagnosis

Narcissism entails a unique, empirically distinguishable pattern of personality functioning. Consistent with this reasoning, in a recent study (Westen, DeFife, Malone, & DiLallo, 2014), a factor analysis was conducted to identify naturally occurring personality groupings within a clinical sample of adolescents (13 to 18 years). The analysis yielded three higher-order factors (Internalizing, Externalizing, Borderline/Dysregulated), and 10 lower-level personality traits including narcissism (as part of the Externalizing spectrum). Subsequent validation analyses in an independent clinical sample of adolescents showed that narcissism was positively associated with observer-rated delinquent and aggressive behavior, but negatively associated with observer-rated withdrawal, anxiety, depression, and thought problems.

Yet, although narcissism has unique characteristics, it does share overlap with associated personality traits and mental disorders. Most prominent among them, in youth, are the traits of psychopathy and Machiavellianism, borderline personality disorder (BPD), and oppositional defiant disorder (ODD). In clinical settings, accurate diagnosis can be difficult, especially because narcissistic patients typically do not seek help for their core narcissistic traits but rather for the associated problems they experience (e.g., fear of negative evaluation, inability to sustain close relationships, difficulty to manage angry or aggressive impulses).

Psychopathy and Machiavellianism

The traits of narcissism, psychopathy, and Machiavellianism have collectively been labeled the Dark Triad of personality (Paulhus & Williams, 2002). The common core of the Dark Triad personality traits is a disagreeable interpersonal orientation, associated with a tendency toward self-promotion, superficial charm, and aggression (Barry et al, 2011; Paulhus & Williams, 2002). Despite this common core, narcissism is distinct from the other Dark Triad traits in a number of important ways.

Compared with psychopathy, narcissism is marked by different emotional predispositions. Youth holding psychopathic traits (especially those high in the callous-unemotional dimension of psychopathy), tend to be emotionally cold, shallow, and fearless. Youth holding narcissistic traits, by contrast, tend to experience emotional extremes (e.g., euphoria and pride interspersed with shame and humiliation), are highly emotionally reactive to both positive and negative events that are relevant to their self-views or public image (e.g., public successes or failures), and often actually express those emotions (Thomaes et al., 2011). One other main difference lies in the intentionality behind psychopathic and narcissistic youth's adversarial interpersonal behavior. Psychopathic youth are more likely to intentionally harm others, perhaps partially because harming others derives them pleasure or fulfillment. For narcissistic youth, harming others is not a goal in itself, but is collateral damage from their egocentric pursuit of individual goals, their attempts to turn the tables when they feel insulted by others, or their inconsiderate neglect of others' needs and concerns (Barry et al., 2011).

Machiavellianism may be even more closely associated with narcissism, yet an important distinction lies in the motives behind Machiavellianists' social behavior. Youth high in Machiavellianism typically pursue dominance and social power as a goal in itself (i.e., they strive to be on top of others), whereas narcissists pursue social power only as a means to build a desirable public image and get the positive attention that they need (i.e., they strive to be admired by others). Another important difference is that narcissists have overly positive, inflated views of themselves (e.g., they see themselves as more important and competent than others, even when they aren't), whereas Machiavellianists

have relatively realistic views of themselves (Paulhus & Williams, 2002).

Borderline Personality Disorder

NPD shares some overlap with other PDs, especially BPD. Differential diagnosis can be especially challenging in adolescence—a time when emotional instability and reactivity (characteristic of both NPD and BPD) is more normative than it is at other ages. NPD and BPD are similar in that they are both marked by emotional instability, overdependence upon others' attention, and difficulty with sustaining mutually satisfying interpersonal relationships. It may be especially difficult to distinguish more vulnerable forms of NPD, marked by high levels of interpersonal difficulty and distress, from BPD (Dickinson & Pincus, 2003). Narcissists are different, however, in the *kind* of attention that they need. Narcissists' primary social motive is to be admired, and so in their interactions they seek to be respected, applauded, or adored. The primary social motive of individuals with BPD is to not be abandoned, and so in their interactions they seek to be reassured of the closeness of their interpersonal bonds. One other difference is that narcissists engage less in interpersonal idealization and subsequent devaluation than do individuals with BPD, who tend to engage in black-and-white thinking about other people. In fact, narcissists rarely idealize others (with the possible exception of their adoration for certain heroes with whom they can identify or who serve as a self-enhancing role-model). Finally, compared with individuals with BPD, individuals with NPD tend to be less impulsive and self-destructive (e.g., they are less likely to injure themselves).

Oppositional Defiant Disorder

In late childhood and adolescence, NPD also shares some overlap with ODD. Differential diagnosis may be complicated because the features that both disorders have in common are the very features for which patients with these disorders tend to seek psychological help. That is, individuals with NPD and ODD may present with very similar problems when they enter treatment. In particular, both NPD and ODD are marked by hostile or resentful predispositions, a tendency to externalize blame for one's own mistakes or misbehaviors onto others, and an unwillingness to take up compliant or submissive social roles or to follow others' requests. Grandiose manifestations of NPD, marked by a dominant and hostile interpersonal orientation, may be especially difficult to distinguish from ODD. Narcissists are different, however, in that their hostile, vengeful predispositions are specifically triggered by situations in which their grandiose self-images are undermined, whereas individuals with ODD tend to be hostile and vengeful in response to a broader array of situations that involve frustration or authority conflict. Narcissists are also different in their craving for positive attention, which is not a typical feature of ODD. Finally, whereas ODD usually becomes evident before age 8, narcissism (or at least its core characteristics) typically emerges only after age 8, or even considerably later. The age at which problems have first emerged are important to consider when trying to tease NPD and ODD apart.

Intervening with Narcissism and Its Consequences: Clinical Approaches

How to intervene with narcissistic pathology in youth? Ideally, narcissism interventions would be based on a thorough empirical knowledge base of the etiology and development of narcissism, which would allow clinicians to target the factors critical to the causation and maintenance of narcissistic pathology. In addition, given timely identification, such knowledge would allow clinicians to start their interventions in those stages of development when narcissism and its underlying processes are most susceptible to change. Alas, we know relatively little of the factors that cause and maintain initial narcissistic development, or the developmental stages when narcissism is most malleable. Thus, up until today, clinicians face a choice of making do with the means available to them and directly targeting those conditions that impair the psychological adjustment of their narcissistic patients (rather than intervening with their causal or maintaining factors), or not to intervene at all. Understandably, most choose the first (e.g., Kernberg et al., 2000).

Typical clinical interventions are targeted at narcissistic youth's (1) limited skills to manage ego-threatening experiences, and (2) limited awareness or acknowledgment of the needs and concerns of other people. Clinicians face the challenge to carefully motivate narcissistic youth to engage in self-reflection, obtain self-insight, and strive for self-improvement, without activating the feelings of worthlessness or inferiority that are pervasively threatening to them. When narcissistic youth feel that their egos are threatened in treatment, their commitment to treatment might decrease (Beck, Freeman, & Davis, 2004). Another factor that may complicate treatment is that narcissists often lack a strong motivation to change. Narcissistic patients, particularly those with grandiose narcissistic problems, may be reluctant to acknowledge the inadequacies (that they themselves may consider signs of weakness)

that may cause or sustain their problems (e.g., Young, Klosko, & Weishaar, 2003).

Cognitive-Behavioral Intervention

Various techniques from cognitive-behavior therapy (CBT) programs can be adapted to the specific needs of narcissistic youth. Psychoeducation can be used to teach youths how fluctuations in their self-esteem are linked to how they feel and behave. Affect education can be used to help youths to be aware of and accurately identify how they feel in ego-relevant situations, and to use that awareness to guide their thought and behavior. In social skills training, narcissistic youths may learn alternative ways of reacting to ego threats besides rigidly externalizing blame or lashing out against others. Social skills training may also teach narcissistic youths to acknowledge other people's perspectives, and to wisely balance their own interests with those of others. Cognitive reframing techniques can be used to alter the interpretation of ego threats (e.g., by teaching youths that criticism or failure does not automatically imply that one is worthless), to make youths realize that they do not have to excel at everything to be able to hold a favorable public image, and more generally, to motivate them to become less invested with the pursuit of self-esteem. Yet purely cognitive techniques by themselves may be insufficient at motivating youths to become less preoccupied with building and buttressing self-esteem, especially because that preoccupation is strongly emotionally and motivationally driven. As such, narcissistic youths may benefit from the incorporation of interventions that address their emotions and motivations more directly, such as mindfulness interventions.

Mindfulness Intervention

Mindfulness interventions teach youths to adopt an open, nonjudgmental awareness of their thoughts and feelings in the present moment. Individuals differ in their natural predispositions to be mindful, but mindfulness skills can also be effectively cultivated, in youth as well as in adults (e.g., Burke, 2010). Rather than trying to alter thoughts and feelings, which is often the goal of cognitive techniques, mindfulness interventions seek to change the way people *deal* with their thoughts and feelings. Mindfulness is a promising technique for use with narcissistic patients, for several reasons. First, it helps youths to disengage from automatically occurring thoughts and feelings that can result in impulsive, maladaptive behavior (e.g., from the anger that leads to aggressive behavior, or from the shame that leads to defensive self-aggrandizement; Andersen et al., 2002). Second, it helps youths to become aware of the full breadth and intensity of their emotional experience, including their negative self-related emotional experience, in a way that promotes acceptance and reduces defensiveness (i.e., the tendency to repress feelings of shame and humiliation; Gilbert, 2007). Research has shown that mindfulness can be effective at overwriting previously learned stimulus-response associations, and may lead to the extinction of automatically triggered emotional reactions (Hölzel et al., 2011). Third, mindfulness training can be effective at quieting the ego—at making people less involved with creating and maintaining desirable self-images. Mindfulness teaches individuals to view their psychological experience as transient rather than static. Negative self-related thoughts and feelings become less threatening when they are seen as mere psychological events that dissipate after some time (Hölzel et al., 2011). Because many problems that narcissistic youth face are caused by impulsiveness, problematic emotion regulation, and the continuous pursuit of grandiose self-esteem, mindfulness interventions may be particularly well-suited to reduce narcissistic maladjustment.

Importantly, mindfulness interventions should not be confused with interventions that focus on raising self-esteem, such as by providing indiscriminate praise. Parents and teachers often target praise at those who seem to need it the most—children with low self-esteem. More specifically, they often praise children with low self-esteem for who they are as a person (e.g., You're great!) or in an inflated manner (e.g., You made an *incredibly* beautiful drawing!), in an attempt to raise these children's self-esteem. However, such praise inadvertently leads children with low self-esteem to avoid challenges and to feel ashamed in the face of failure (Brummelman, Thomaes, Orobio de Castro, et al., 2014; Brummelman, Thomaes, Overbeek, et al., 2014). Thus, although praise is often well-intended, person-directed and inflated praise can ironically backfire in the face of difficulty or failure (also see Kamins & Dweck, 1999). Moreover, although empirical evidence is lacking, some experts are concerned that interventions that focus on raising self-esteem might inadvertently cultivate inflated and narcissistic self-views in youth (Twenge, 2006). Mindfulness does not boost self-esteem, but fosters an accepting, self-compassionate stance that helps individuals tolerate their failures and inadequacies. Because narcissistic youth find it difficult to accept failure and imperfections, mindfulness techniques may provide a powerful tool to help them to become less vulnerable to ego threatening events.

Schema Therapy

Schema therapy is an integrative psychotherapeutic approach based on, among others, cognitive-behavioral, attachment, and emotion-focused traditions (Young et al., 2003), that may be well suited for use with narcissistic youth (Behary & Dieckmann, 2011; Kellogg & Young, 2006). One key assumption underlying schema therapy is that in response to childhood experiences in which basic needs were not met (e.g., due to parental overvaluation or lack of warmth), youth may develop maladaptive schemas—deeply entrenched, biased ways of thinking about oneself and one's interpersonal relationships—that impair healthy psychological adjustment (Young et al., 2003). These maladaptive schemas may come to form the root of a personality disorder. Narcissistic youth often hold schemas that, in schema-therapy terminology, are labeled entitlement (the schema that one is special, better than others, and entitled to privileges), unrelenting standards (the schema that one must continuously strive to excel), defectiveness/shame (the schema that one is flawed, inferior, and unlovable), and approval seeking (the schema that one needs recognition, applause, and admiration; Behary & Dieckmann, 2011; Young et al., 2003).

Schema interventions are aimed at changing patients' maladaptive schemas, primarily by helping patients to fulfil the needs that were thwarted in childhood. Initially, this happens within the confines of the therapeutic setting—for example, when parents of a narcissistic patient were cold or provided conditional love, the therapist emphatically seeks to create a therapeutic setting that is warm and unconditionally accepting. Emotion-focused techniques can be used to try to make painful childhood memories less upsetting. For example, imagery techniques allow patients to re-enact and restructure difficult childhood memories, while letter-writing techniques (that let patients write open, constructive letters to those who they feel have harmed them) allow patients to affirm their interpersonal needs. Cognitive techniques can be used to teach patients about their motives and feelings and their consequences (e.g., therapists may teach patients that their need for admiration compromises their ability to sustain close relationships), and to restructure harmful cognitions (e.g., therapists may use what-if techniques to explore with patients the worst things that would happen if they are not seen as perfect by others). In the final stage of schema interventions, patients are encouraged to practice what they have learned in the real world, outside of the therapeutic setting. For example, narcissistic patients who feel unable to sustain close relationships can be guided to form close relationships in which they pursue mutual affection rather than continuous admiration. Such positive real-world experiences may affirm patients' adaptive schemas, and thereby create an upward spiral of improvement. As such, these real-world experiences should help patients sustain initial therapeutic change.

Intervening with Narcissism and Its Consequences: A Basic Research Approach

Basic research in nonclinical samples has explored the psychological processes that can be altered to improve the functioning of individuals high in narcissistic traits (e.g., Finkel, Campbell, Buffardi, Kumashiro, & Rusbult, 2009; Thomaes, Bushman, Orobio de Castro, Cohen, et al., 2009). The goal of this research was not to provide ready-to-use intervention strategies. Rather, this research sought to illustrate how psychological processes can be influenced to decrease problematic narcissistic functioning, at least in the short term. As such, this basic research may inform clinical approaches to intervening with narcissism and its consequences.

This line of research has followed a rather straightforward but important set of principles that promises to be guiding for future work in this field. The first principle is to identity what psychological processes are involved in the causation or maintenance of narcissists' problematic functioning. Such knowledge should inform the design of well-targeted strategies to try to influence narcissistic maladjustment. The second principle is to experimentally manipulate the processes that cause or maintain narcissists' problematic functioning. These experimental procedures sometimes take the form of premature, explorative versions of intervention strategies as they may eventually be implemented in regular intervention.

Reducing Narcissistic Aggression

As an illustration, we detail a study that we conducted to try to reduce the aggressive behavior of youth high in narcissism (Thomaes, Bushman, Orobio de Castro, Cohen, et al., 2009). This study was based on the finding that narcissists, due to their vulnerable egos, often respond aggressively to ego-threatening experiences (e.g., Thomaes, Bushman, et al., 2008). We reasoned that, in theory, attempts that would succeed at reducing narcissists' sensitivity to ego threatening experiences should also reduce narcissists' inclination to behave aggressively. Social psychologists have explored experimental procedures to reduce the psychological impact of ego threatening experiences; the most prominent procedure is self-affirmation (or value affirmation; e.g., Cohen, Garcia, Apfel, & Master,

2006). Self-affirmation procedures allow people to reflect on their personally important values, such as self-defining skills or interests. Self-affirmation procedures reduce the impact of ego threat by making people realize that their worth as a person does not hinge upon one particular domain of functioning (Cohen et al., 2006).

In the study, adolescents first completed a measure of narcissistic traits (the Childhood Narcissism Scale), and then they were randomly assigned within their classrooms to either a self-affirmation or control condition. In the self-affirmation condition, they wrote about their most important values (e.g., being athletic, being creative, belonging to a social group, having good relationships with friends or family) and why these are important to them. In the control condition, they wrote about their least important values and why these may be important to others (for a detailed account of self-affirmation procedures, see Cohen et al., 2006). These exercises took about 15 minutes to complete. In the weeks following the self-affirmation manipulation, measures of aggressive behavior and experiences of ego threat were obtained. Specifically, aggression was measured using a peer nomination instrument that contained items for physical, direct verbal, and relational aggression. Experienced ego threat was measured by asking participants to rate how satisfied they were with themselves in the past week—lower ratings are reflective of higher levels of experienced ego threat.

The results showed that the self-affirmation manipulation reduced narcissistic aggression. In the control condition, the familiar pattern of results emerged with narcissists being more aggressive than others when they experienced high levels of ego threat. (This result is similar to what previous studies, such as Thomaes, Bushman, et al., 2008, have obtained in the laboratory.) Yet this familiar pattern of results was eliminated in the self-affirmation condition. Here, narcissists were no more aggressive than others, regardless of whether they had experienced high levels of ego threat. These results indicate that it is possible to reduce narcissistic aggression by making individuals less sensitive to ego threatening experiences. The results also indicate that seemingly minor manipulations, if they are targeted at the exact processes that cause or maintain narcissists' problems, can have sustained real-world effects.

Implications for Clinical Intervention

Basic research such as that described previously may have implications for clinical intervention. First, it illustrates that it is possible to reduce narcissists' problematic behaviors by implementing theory-based, well-targeted strategies to ameliorate the precise conditions and processes that normally drive these problematic behaviors. Second, basic research provides an empirical basis that may help clinicians to design interventions that target the factors that cause and maintain narcissists' problematic functioning.

That said, several important steps need to be taken to derive effective clinical intervention strategies based on the experimental procedures used in basic research. First, one challenge that clinicians face is to try to make intervention strategies effective for longer time periods. From a basic research perspective, the mere observation that certain experimental manipulations can cause improved functioning among narcissists is important by itself. From an applied perspective, it is more important that initial positive change in narcissists' functioning be sustained for a longer period of time. For example, in our study described above, the 15-minute self-affirmation exercise reduced narcissistic aggression for a period of a school week. A critical applied question is how the intervention effect can be sustained over time. One strategy might be to help patients incorporate effective exercises in their daily lives, such as by teaching them how to employ self-affirmation exercises in times of need.

Second, once potentially lasting intervention strategies have been devised, their effectiveness should be examined in applied or clinical settings. Thus far, research in this field has been conducted in laboratory or controlled field settings. These settings are ideal as a first step in the sequence of devising interventions because they allow for a relatively clean test of the presumed intervention effects. Yet, an important next step is to examine these intervention effects in less controlled applied or clinical settings. For example, researchers and practitioners might want to build on the Thomaes, Bushman, Orobio de Castro, Cohen, et al. (2009) study by incorporating self-affirmation procedures in their treatment of narcissistic individuals with aggressive behavior problems. In the most rigorous research design, patients would be randomly assigned to receive either treatment-as-usual or treatment-as-usual plus self-affirmation procedures, so that it could be examined what is gained by incorporating self-affirmation procedures in regular treatment. Another option might be to try to implement self-affirmation procedures in regularly employed conduct problem prevention or intervention programs in schools, and to examine what is gained in this way.

Conclusion

Clinicians and researchers increasingly recognize narcissistic maladjustment in youth, and are making progress at

trying to prevent narcissism and its consequences. In this section, we covered some key issues related to the diagnosis and treatment of narcissistic maladjustment in youth. We hope this section will spur future research on narcissistic pathology in youth, research that should further ease the burden that narcissistic youth place on themselves and the people around them.

CONTROVERSIES

A number of controversies and unanswered questions surround the topic of narcissism in youth. Three will be discussed here. First, there has been a somewhat polarized debate on whether societal levels of narcissism have been increasing over the past decades, with some authors claiming that it has (perhaps even to epidemic proportions; Twenge & Foster, 2008), and others challenging this claim on methodological grounds. Second, experts have differed in their views of the extent to which narcissism is adaptive, with some emphasizing that it may be beneficial for youth to hold at least some level of narcissism (particularly its leadership/authority features), and others emphasizing the harmful consequences of narcissism to both individuals themselves and the people around them. Third, there have been different views on what's behind the narcissistic mask, with some experts believing that narcissism is essentially a cover-up for deep-seated feelings of insecurity and insufficiency, and others arguing that narcissists have nothing to hide and are actually convinced of their exceptional talents and superiority over others.

Narcissism and Generational Change

Western culture has become increasingly individualistic over the past decades, perhaps especially from the 1960s or 1970s onward (e.g., Fukuyama, 1999). It seems plausible to assume that this cultural change has translated into the personality traits, self-evaluations, and behavioral predispositions of the individuals who make up society. Indeed, there is evidence to suggest that college students in the United States have come to score higher on agentic traits such as independence and assertiveness from the 1970s to the 1990s, and have come to evaluate themselves more positively on agentic traits such as the drive to achieve and leadership ability from the 1960s to 2009 (Twenge, Campbell, & Gentile, 2012). Also, there is evidence that college students as well as younger adolescents and preadolescents have come to hold increasingly high levels of self-esteem from the 1980s to the 1990s, and further up until 2008 (Gentile, Twenge, & Campbell, 2010). These patterns of psychological change over generations beg the question of whether levels of narcissism have also increased with the rise in individualism.

Evidence for Increases in Youth Narcissism Over the Past Decades

Jean Twenge and her colleagues have conducted cross-temporal meta-analyses and used other sources of historic evidence to conclude that today's young people are considerably more narcissistic than previous generations of young people. These authors have used time-lagged meta-analytic techniques, and compared narcissism levels in samples of people (in particular college students) of the same age at different historic periods. This technique allows for comparisons in level of narcissism across generations.

For an initial study, a systematic literature search yielded a total of 85 independent samples of college students from the United States who completed the NPI at some point in time between 1982 and 2006 ($N > 16{,}000$, 60% female; Twenge, Konrath, Foster, Campbell, & Bushman, 2008). When weighted by sample size (effect sizes obtained in larger samples were treated as more influential), there was a strong positive association ($\beta = .53$, $p < .001$) between NPI scores and year of data collection, such that more recent generations of college students reported higher levels of narcissism. In fact, as the authors noted, almost two-thirds of the most recent college students in their sample would have scored above the mean narcissism score two decades earlier. They also noted that the increase in narcissism was steady over time (there were no indications that narcissism had risen more steeply in some periods than in others), and tended to be stronger for women than for men.

An updated version of the meta-analysis, which included studies up until 2009 and, more importantly, controlled for possible confounding by campus (the possibility that historic differences in level of narcissism were not actually driven by year of data collection, but by differences in campus populations sampled at different points in time), found further support for increased levels of narcissism among American college students (Twenge & Foster, 2010). Other evidence from the same group of authors was not directly relevant to the question of whether narcissism has increased over time, but did suggest that it has become more common for Americans to strive for uniqueness and to stand out from the rest rather than to fit in with the crowd—developments which might be consistent with a more general trend toward individualistic self-focus. For example, an analysis of the first names given to 325 million American babies born 1880 to 2007 found that common

names have become increasingly less popular between the 1950s and 2007, even when controlling for immigration rate (Twenge, Abebe, & Cambell, 2010). Also, analysis of the words used in popular song lyrics suggests a historic trend toward word use indicative of a more individualistic self-focus (as evidenced by the use of first-person singular pronouns such as I or my) and less communal group focus (as evidenced by the use of first-person plural pronouns such as we and our) from 1980 to 2007 (DeWall, Pond, Campbell, & Twenge, 2011).

Together, this line of evidence is consistent with the view that with the rise of individualism from the second half of the previous century, Western young people have become increasingly narcissistic over time.

Evidence Against Increases in Youth Narcissism Over the Past Decades

Other authors, and Kali Trzesniewski and Brent Donnellan in particular, have been critical of the view that levels of narcissism have been increasing over time. In fact, they have argued that the empirical evidence on presumed generational change in narcissism, and interpretations in the media and some popular scientific writings (such as that the Western world is currently suffering from a "narcissism epidemic"), are much ado about nothing (Donnellan, Trzesniewski, & Robins, 2009; Trzesniewski, Donnellan, & Robins, 2008a, 2008b).

These authors have analyzed data from samples of University of California students from 1982 to 2007 and found no evidence for meaningful increases in narcissism (Donnellan, et al., 2009; Trzesniewski et al., 2008a, 2008b). These authors raised three methodological criticisms of research on the narcissism epidemic. First, they argued that all findings that point toward generational increases in narcissism have been obtained in convenience samples of college students, and that it is problematic to make inferences based on convenience samples about entire birth cohorts or trends in the general population. For example, it is possible that findings on generational change in narcissism reflect no actual societal trend but merely a change in the kinds of individuals who attend college or participate in psychological research in different periods in time.

Second, Trzesniewski et al. (2008b) argued that examining potential changes in narcissism as an overall construct—as Twenge and her colleagues have mainly done—is less informative than examining potential changes in individual facets of narcissism. The seemingly straightforward conclusion that levels of narcissism among youth have been increasing over the past decades may not be very informative if that increase was driven entirely by increases in some facets of narcissism, but not in others. Importantly, then, Trzesniewski et al. (2008b) found evidence to suggest that the superiority and vanity facets of narcissism have been slightly decreasing among American college students between 1996 and 2007, whereas the self-sufficiency facet has been slightly increasing over the same time period. This is especially relevant, they argue, in light of evidence that the superiority and vanity facets of narcissism might be more psychologically maladaptive than the self-sufficiency facet. If so, they argue, it would be premature to conclude that possible increases in narcissism may bring about interpersonal and societal problems.

Third, Trzesniewski et al. argue that cohort differences in psychological traits, such as narcissism, are only meaningful to the extent that it is possible to explain *why* certain sociohistorical developments lead to those cohort differences. Twenge and her colleagues did provide such an explanation, and suggested that increases in narcissism may be rooted in individualistic trends in Western society. In particular, they thought that the self-esteem movement, which has led to a preponderance of educational programs and media campaigns emphasizing the importance of feeling good about oneself over real accomplishment, may have cultivated increases in narcissism among American youth. Yet, Trzesniewski et al. pointed out that there is no evidence that self-esteem programs lead children to hold narcissistic or inflated self-views, which might render the individualism hypothesis for increases in narcissism premature.

Conclusion

What is needed to be able to draw a concluding statement on generational change in narcissism are representative cohort studies that include a standard measure of narcissism. Such studies are not available to date. As it stands, there is evidence from multiple sources that provide evidence to suggest that secular societal trends exist, yet the magnitude and toxic nature of these trends for the general population of American youth (let alone for other youth) is unknown.

Narcissism and Psychological Health

How problematic is it for individuals to hold narcissistic traits? Narcissism has been typically thought of by theorists and researchers as a primarily maladaptive trait. Indeed, narcissism is linked to emotional extremity, self-esteem instability, fear of being negatively evaluated by others, reduced perspective taking skills and empathic concern, an adversarial interpersonal orientation, and the

predisposition to behave aggressively (i.e., traits that may primarily harm others, but may ultimately boomerang and harm narcissists' own psychological health as well). Yet, the issue of how (mal)adaptive narcissism is more complex than it might initially seem. To be sure, there is no debate about the maladaptive nature of NPD. There is debate, however, about the maladaptive nature of trait narcissism (illustratively, trait narcissism is sometimes labeled normal narcissism; e.g., Sedikides, Rudich, Gregg, Kumashiro, & Rusbult, 2004). For example, it might be difficult to reconcile conceptualizations of narcissism as a maladaptive trait with evidence that some members of society who are often seen as particularly successful, including corporate and political leaders, tend to be high on narcissistic traits (Campbell, Hoffman, & Marchisio, 2011; Watts et al., 2013). As Kets de Vries and Miller (1984, quoted in Campbell et al., 2011, p. 272) argued: "Narcissistic personalities . . . are frequently encountered in top management position. Indeed it is only to be expected that many narcissistic people, with their need for power, prestige, glamour, eventually end up seeking leadership positions. Their sense of drama, their ability to manipulate others, their knack for establishing quick, superficial relationships serve them as well."

And even if one is not in top management position, one may experience at least some benefits from such narcissistic traits as self-reliance, interpersonal charm, and the appearance of authority. It is conceivable that narcissistic individuals, youth as much as adults, benefit from narcissistic traits when trying to establish social relationships or when performing in competitive contexts. There are two perspectives on the potentially adaptive nature of narcissistic traits: the adaptive tipping point perspective and the adaptive facet perspective.

The Adaptive Tipping Point Perspective

It is sometimes thought that although extremely high levels of narcissism may not bode well for individuals (or the people around them), very low levels of narcissism may do neither. The argument is that individuals should be able to experience some level of grandiosity, to feel comfortable with some degree of positive attention, and not become overwhelmed by too much concern over others' well-being to be able to show optimal psychological adjustment. For example, youths who feel reasonably, but not overly, confident about how their competencies measure up to those of others may often be better off than youths who are more modest or submissive. According to this view, there might be an adaptive tipping point along the narcissism dimension at which individuals function particularly well, suggesting that narcissism may not be linearly but curvilinearly related to several important psychological and behavioral outcomes.

Although intuitively plausible, empirical evidence has not been kind to this possibility thus far. In our own research, we have failed to find curvilinear relationships between narcissism and important outcome variables, including aggressive behavior, mood reactivity, and symptoms of anxiety or depression. Others have found no empirical support for curvilinear effects of narcissism either (Barry et al., 2007). Future research needs to more comprehensively explore the adaptive tipping point perspective, but as is stands, it seems reasonable to assume that narcissism is linearly related to important outcomes of psychological (mal)adjustment.

The Adaptive Facet Perspective

Even if narcissism, as a single dimension, is related to indices of psychological maladjustment, it is possible that certain *facets* of narcissism are more adaptive than others. There is some empirical evidence consistent with this notion. Psychometric research on the NPI, the most commonly used measure of trait narcissism in adults, has shown that it is sometimes useful to distinguish between a number of narcissism facets—some of which are more adaptive (or at least less maladaptive) than others (Corry, Davis Merritt, Mrug, & Pamp, 2008; Raskin & Terry, 1988). For example, although the predisposition to show off and to see oneself as entitled to special privileges (a facet of narcissism labeled exhibitionism/entitlement) may bring little good to individuals, the predisposition to see oneself as a leader and to strive for authority (a facet of narcissism labeled leadership/authority) might be more adaptive, perhaps especially in societies that emphasize the importance of such traits (Corry et al., 2008).

Psychometric research on the NPI for Children (Barry & Ansel, 2011; Barry et al., 2007) has found that it is possible to distinguish between two facets that the developers of the scale labeled adaptive narcissism (i.e., comprising traits related to self-sufficiency and authority) and maladaptive narcissism (i.e., comprising traits related to exhibitionism, exploitativeness, and entitlement). As the labels suggest, the adaptive narcissism facet is associated with a self-assured, easy-going interpersonal orientation and the ability to be noticed by other people. The maladaptive narcissism facet has a darker side, and is associated with callous-unemotional and adversarial interpersonal traits including the predisposition to engage in aggressive and delinquent behavior (Barry et al., 2007; Barry & Wallace, 2010; Barry & Ansel, 2011). Yet, the mere fact that the

adaptive facet of narcissism has a number of adaptive correlates is important, but does not by itself prove its adaptive nature. Future research will need to provide a comprehensive picture of its positive and negative outcomes across multiple domains and multiple contexts. Finally, and perhaps most important, future research will need to show that adaptive narcissism actually is a facet that is inherent to narcissism, and does not merely reflect adaptive traits that happen to be associated with narcissism but are not inherent to it, such as one's perceived competence (Brown et al., 2009). In summary, although it is well possible that narcissism encompasses traits that are primarily adaptive, given the current state of empirical evidence it seems too early to draw final conclusions.

Narcissism and Masked Insecurity

One longstanding view has held that narcissists' grandiosity may function as a façade to conceal their deep-seated feelings of insecurity and insufficiency. According to this mask model of narcissism, narcissists exhibit grandiosity and act as if they feel superior to others in an attempt to hide inner self-loathing—a view that can be traced back to psychoanalytic writings, especially those of Kohut. At first blush, there is much to be said for this hypothesis. If narcissists would genuinely feel positive about themselves, then why would they experience the need to shout from the rooftops that they are exceptional, and why would they crave continuous validation from other people? And if narcissists would genuinely believe in their own superiority, then why would they be so sensitive to slight criticisms or failures? It seems plausible that narcissists search for continuous validation and avoid criticism or failure because deep down inside they actually feel insecure and inferior. What does the empirical evidence say?

Unfortunately, research on the mask model of narcissism that involves children or adolescents is lacking. Thus, the question of whether early manifestations of narcissism may function to blanket children's feelings of insecurity and insufficiency remains unanswered. Research involving adult participants does exist, and provides a rather complex picture. One line of research has relied on measures, such as the Implicit Association Test, that index implicit self-views (Greenwald & Farnham, 2000). In particular, this line of research has explored the possibility that narcissists may hold positive self-views on an explicit (or conscious) level, and more negative self-views on an implicit (or nonconscious) level, but has found inconsistent results (reviewed by Bosson et al., 2008). One particularly insightful study (Campbell, Bosson, Goheen, Lakey, & Kernis, 2007) found that narcissists hold positive explicit and implicit self-views on indices of agency (i.e., traits that reflect extraversion and competence, and function to distinguish oneself from others); but more neutral explicit and implicit self-views on indices of communion (i.e., traits that reflect agreeableness and affection, and function to connect oneself with others). Thus, there is no compelling evidence that narcissists harbor insecurities of which they are not aware. If anything, this research suggests that narcissistic adults hold *imbalanced* self-views, and evaluate themselves positively on agentic traits and less positively (but not negatively) on communal traits.

Yet, it is still possible that narcissists report more positive explicit self-views than they actually hold, perhaps to convince themselves or others of their grandiosity. This possibility was recently explored (Myers & Zeigler-Hill, 2012). Adult participants first completed measures of narcissism and self-esteem, and then reported their self-esteem again under conditions in which they were motivated to tell the truth using a bogus pipeline procedure. Participants were attached to bogus lie-detecting physiological equipment during the self-esteem assessment. Half of the participants were told that the equipment was switched on; the other half were told that the equipment was switched off. Narcissistic participants in the bogus pipeline condition reported lower levels of self-esteem than those in the control condition. In fact, narcissistic participants in the bogus pipeline condition reported lower self-esteem than nonnarcissistic participants did. By contrast, nonnarcissists reported equal levels of self-esteem in both conditions. Thus, these results indicate that although narcissists may not harbor negative self-views they are unaware of, they may deliberately provide somewhat inflated ratings of how they view themselves, and may actually hold more negative self-views than they typically report using standard assessment procedures. Future research will need to explore the mask model of narcissism in younger participants, especially in pre- and young adolescents, to examine the possibility that narcissistic traits emerge to defend against unwanted feelings of insecurity or insufficiency.

CONCLUSION AND FUTURE RESEARCH

The field of research on youth narcissism is young. It is only from the turn of this century, when the first youth measures of trait narcissism were developed (Barry et al., 2003; Frick et al., 2000), that researchers were able to study narcissistic personality functioning in children and adolescents in

a systematic, standardized way. And they did: As reviewed in this chapter, multiple groups of researchers across the world have started to examine the nature, causes, and consequences of youth narcissism.

What explains the strong increase of interest in youth narcissism as a research focus? One likely explanation is that developmental researchers increasingly realize that the classic adagio that favorable self-regard is the cornerstone of healthy psychological adjustment holds merit, but only tells part of the story. The category of youth holding favorable self-regard appears to be a mixed bag, with some youth (i.e., those who hold accurate, well-balanced positive self-views) faring better than others (i.e., those who hold inflated, defensive positive self-views). Although trait narcissism probably is not entirely maladaptive, it does provide researchers a key construct to learn more about the problematic traits and behavioral consequences that may be associated with youths' favorable self-regard. One other explanation is that there is increasing societal concern that youth in individualized, Western cultures might have become more entitled and self-centered over the past decades. Obviously, adults' concerns or complaints about today's youth are of all times, yet in this case empirical research suggests that there might be some reason for concern.

The field of research on youth narcissism has made impressive progress over the past years. It has shown that trait narcissism can be identified and measured reliably and validly in older children and adolescents (Barry et al., 2003; Thomaes, Stegge, et al., 2008). It has shown that narcissism is different from, and even largely unrelated to self-esteem—narcissists are not necessarily satisfied with themselves, but they passionately pursue grandiose self-views, and seek to create favorable images in the eyes of others. It has found that narcissism in youth, much like narcissism in adults, can have grandiose manifestations (as evident in grandiose and entitled self-views, and the sense of superiority) as well as more vulnerable manifestations (as evident in brittle and unstable self-views, and negative emotional reactivity). Perhaps most important, it has found that narcissism is relevant to multiple domains of psychological adjustment. Narcissism predisposes youth to behave aggressively, especially when faced with ego threatening experiences. Narcissism influences youth to pursue agentic rather than communal social goals, and to strive for interpersonal dominance rather than interpersonal closeness. Narcissism leads youth to be hypervigilant to the appraisals of others, and to experience intense negative mood following negative interpersonal appraisal. Finally, narcissism puts youth, and especially those with lower self-esteem, at risk to develop symptoms of anxiety and depression.

Notwithstanding scientific progress, there is still much to be learned. We propose six broad and important directions for future research on youth narcissism. First, research is needed to understand the etiology and development of narcissism. This research should examine multiple (e.g., social-learning, psychoanalytic) perspectives on the socialization of narcissism, and should be guided by the principles of equifinality (i.e., different developmental pathways may lead to similar outcomes) and multifinality (i.e., similar developmental pathways may lead to different outcomes; Cicchetti & Rogosch, 1996). From a developmental psychopathology approach, the ultimate goal for this research is to uncover the interplay between multiple constitutional (e.g., temperament) and social factors (e.g., parenting) that influence the emergence and course of narcissistic development. We have proposed a diathesis–stress model that describes one potential developmental pathway to narcissism: High levels of approach temperament may interact with dysfunctional parenting practices, such as parental overvaluation or lack of warmth, to jointly influence the emergence of narcissism. Similarly, we have suggested that individual differences in avoidance temperament may influence early manifestations of narcissism in its grandiose or more vulnerable forms. Also, we have proposed that narcissism typically develops as a derailment of normal self-development, and may not become manifest before age 8. These hypotheses need to be tested empirically. Related important questions are to what extent early emerging narcissistic traits are predictive of individual differences in narcissism later in life (to what extent are individuals high in narcissistic traits at some point in childhood or adolescence predestined to become narcissistic as adults?), and to what extent some developmental stages may show normative increases and decreases in narcissism (is adolescence indeed a period when narcissism reaches a developmental high?). In addition, more needs to be learned about resilience in the context of narcissistic development (Luthar, Cicchetti, & Becker, 2000; Masten, 2001): Why do some youth not develop narcissistic traits despite exposure to risk factors, such as parental overvaluation, or resume normal self-development after initial narcissistic development? An improved understanding of resilience will contribute to our knowledge of the origins and nature of narcissism and may help in designing effective, targeted intervention. The study of the etiology and development of narcissism deserves priority in the upcoming years.

Second, research is needed to understand more about what youth narcissism exactly entails. We see particular

merit in research on the addiction model of narcissism. Can narcissism be seen as an addiction to others' esteem (e.g., others' attention, praise, and admiration), as the model suggests? One way to answer this question is by testing whether narcissism shares hallmarks of addiction—including cravings, tolerance, and withdrawal. Such knowledge will not only yield fundamental insight into the nature of narcissism, but will also raise intriguing questions from developmental and clinical perspectives. From a developmental perspective, does narcissism share genetic predispositions, developmental trajectories, and developmental outcomes with more familiar addictions? And from a clinical perspective, does the treatment of narcissistic pathology benefit from incorporating strategies central to the treatment of drug addiction? Given that addictions are relatively resistant to change, should one aim to prevent narcissism before it develops into a full-blown addiction, rather than to treat it afterward (much like it is easier to prevent than to treat more familiar addictions)? Hence, by testing the parallel between narcissism and addiction, future research promises to yield important insights into the nature, development, and treatment of narcissism.

Third, an interdisciplinary, multiple levels of analysis approach is needed to develop an integrative understanding of the development of trait narcissism and narcissistic pathology. Should we think of the difference between trait narcissism and narcissistic pathology as dimensional, reflecting individual differences in intensity and pervasiveness of symptoms or in the extent to which symptoms interfere with adjustment? Or are there perhaps more qualitative differences between trait narcissism and narcissistic pathology? If so, how do such qualitative differences develop over time? A related set of questions concern the psychological processes that explain derailment of normal self-development into narcissistic pathology, and conversely, the psychological processes that maintain normal self-development and prevent youth from developing narcissistic pathology. As mentioned before, the fields of research on trait narcissism and narcissistic pathology in youth have remained largely separated thus far. Current conceptualizations of normal and pathological narcissistic personality functioning are diffuse and tell little about the fine line that runs between them. Accurate conceptualizations not only are relevant from a basic research perspective but also are necessary to inform discussions on dimensional versus categorical approaches to diagnosing narcissistic pathology (e.g., Miller & Campbell, 2008). A developmental psychopathology approach to narcissism, an approach which seeks to explain the processes underlying normal and abnormal development across the lifespan, and which examines psychopathological processes as deviations from normal development, provides a promising means to reduce the dualism in our understanding of trait narcissism and narcissistic pathology (Cicchetti & Toth, 2009; Sroufe, 1990).

Fourth, research is needed to inform developmentally tailored interventions to reduce the problematic manifestations or consequences of narcissism (regardless of whether these can be seen as reflecting pathology). Increased understanding of the psychological processes that explain problematic manifestations of narcissism is important to design novel intervention techniques. By testing the impact of theory-based procedures (such as self-affirmation procedures) on problematic narcissistic outcomes (such as narcissistic aggression) in controlled field settings, such basic research can lay the groundwork for narcissism interventions in less controlled clinical settings. A number of questions seem especially important. How can intervention techniques that are proven effective in laboratory or other controlled settings be adapted and implemented in clinical settings? How can intervention techniques that are proven effective on the group level, be tailored to fit the narcissistic problems that individual patients suffer from? Also, in what developmental phases are narcissists most likely to reap the benefits of intervention? Most basic research examines only the short-term impact of putative intervention techniques. Yet actual intervention obviously seeks to cause longer-term, or even self-sustaining reductions in narcissistic pathology. The overarching goal of intervention research would be to develop a knowledge base of intervention techniques that can be employed to treat specific manifestations or consequences of narcissism in developmental phases when change is most likely to occur. Once such well-targeted and developmentally sensitive intervention techniques have been tested in controlled field settings, they should be implemented in real-world contexts in collaborative efforts with practitioners and policy makers to benefit vulnerable youth and their families at a larger scale.

Fifth, research is needed to uncover the potential functions or benefits of trait narcissism. Researchers, clinicians, and laypeople alike have asked themselves whether narcissism is mainly a curse or a blessing. Obviously, there is no single answer to this question. Some narcissistic traits are more adaptive than others, and their adaptiveness may well differ between developmental phases and across contexts. Thus, relevant questions to be addressed are: Are certain narcissistic traits more adaptive than other

traits? Does the adaptiveness of these traits change over the course of development? For example, it seems plausible that it is functional for adolescents to adopt a narrow self-focus in the process of developing an autonomous identity, but that such a self-focus may be less functional for young adults when seeking to develop and maintain longstanding intimate relationships. And does the adaptiveness of narcissistic traits depend on social context? For example, a sense of entitlement might help children thrive in settings where resources are scarce (e.g., when they need to be able to assertively act in their self-interest), but might harm children's peer relationships in settings where resources are abundant. In summary, an important task for future research is to uncover when and why narcissism is a blessing or a curse.

Sixth, more research is needed on ethnic and cross-cultural differences in narcissism. The degree to which individuals feel part of a particular social group is an important aspect of their sense of self (Tajfel, 1981). Initial research on ethnic differences has suggested that, within the United States, Black adolescents tend be somewhat more narcissistic than are White adolescents, especially to the extent that they hold a strong sense of ethnic identity (Pickard, Barry, Wallace, & Zeigler-Hill, 2013). Future research should seek to understand the psychological processes by which youths' ethnic identity influences the development of narcissistic traits. This research may be guided by the principles of social identity theory (Tajfel, 2010), which suggests that the experience of being a minority group member may impact how individuals compare themselves to others (with minority members being more likely to engage in social comparisons within their own group), and how individuals attribute negative outcomes (with minority group members being more likely to make external rather than internal attributions); processes that might translate into ethnic differences in narcissism. Furthermore, in terms of cross-cultural research, it is often believed that narcissism should be higher in individualistic cultures than in nonindividualistic cultures. Although cross-cultural research on youth narcissism is lacking, one study involving mainly adults found that narcissism levels are higher in individualistic countries (United States, Canada, Western European countries) than in nonindividualistic countries (countries in Asia and the Middle East; Foster et al., 2003). Apart from cultural differences in individualism, differences in how strongly cultures emphasize honor (Leung & Cohen, 2011) might be relevant to narcissism as well. What is needed is systematic research on youth narcissism in representative samples of cultural groups across the world.

Coda

The study of youth narcissism has gained momentum over the past years. For a long time, the fields of developmental psychology and developmental psychopathology have been fascinated by the self. A new branch of this fascination now revolves around youth narcissism. We propose that the study of youth narcissism is important to these fields, in that it promises to yield a more accurate and comprehensive understanding of both normal and pathological self-development. By studying youth narcissism, researchers will be able to learn more about the multifaceted nature of the developing self. Moreover, they will be able to learn more about how healthy and less healthy forms of favorable self-regard develop, and how they can be distinguished from one another. The study of youth narcissism would benefit from an interdisciplinary approach to learn more about what narcissism essentially is, how it originates and develops, and how normal narcissistic traits should be distinguished from narcissistic pathology. We are looking forward to learning about the exciting new insights that will result from such a collaborative endeavor.

INTRODUCTION

This chapter provides an update on the mentalizing approach to borderline personality disorder (BPD), which was originally formulated in the 1980s but has developed considerably over the past few years. The recent evolution of thinking on mentalizing has in particular been influenced by new findings in developmental psychology and psychopathology, the neurosciences, and the continuing experiences with the different varieties of the empirically evaluated treatment modality that evolved from this approach, mentalization-based treatment (MBT).

Accordingly, we present here a multilevel approach to BPD from a mentalizing perspective, integrating findings from clinical and developmental psychology as well as from the biological processes involved in BPD, which range from genetic to neurobiological, neuroendocrine and neural. Further, we adopt a life span perspective, discussing the emergence of BPD from infancy to adolescence and (young) adulthood. Adolescence in particular has been neglected in earlier research; we argue here that this stage of life is pivotal to understanding the origins of BPD.

The chapter is structured as follows. First, we briefly discuss the nature, prevalence, and core features of BPD. Specifically, we argue that any theoretical approach needs to facilitate our understanding of these core features, and particularly the subjective experience of individuals suffering from this disorder. Second, we provide a summary of the mentalizing approach to BPD, with an emphasis on the impairments in several dimensions of mentalizing that we consider typical of individuals with BPD. Next, we present a developmental psychopathology model of BPD, locating the origins of the mentalizing impairments typical of BPD patients in attachment disruptions. This also includes a discussion of the importance of gene–environment transactions in BPD, and an outline of emerging research findings concerning the neurobiology of BPD and the neural circuits involved in impairments in several dimensions of mentalizing in these patients.

[1]Color version of Figure 17.1 is available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

We close this chapter with an outline of MBT for BPD, and we present a new view on the mechanisms of change in the treatment of BPD, and suggest that this mechanism may be the missing link that connects and is shared by all effective treatments of BPD.

WHAT IS BORDERLINE PERSONALITY DISORDER?

The definition of BPD has been revised with each edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) in the direction of increasing specificity, to arrive at the current criteria requiring five out of the following nine features: (1) a pattern of unstable intense relationships; (2) inappropriate, intense anger; (3) frantic efforts to avoid abandonment; (4) affective instability; (5) impulsive actions; (6) recurrent self-harm and suicidality; (7) chronic feelings of emptiness or boredom (dysphoria); (8) transient, stress-related paranoid thoughts; and (9) identity disturbance and severe dissociative symptoms (American Psychiatric Association, 2000).[2]

The group of patients captured by the *DSM* BPD criteria is extremely heterogeneous. The dismantling of this heterogeneity is a major task facing the field. Understanding and untangling borderline heterogeneity is necessary to enable us to describe the domains of the pathology that are likely to have different etiological roots, and to describe and appropriately refine treatments to fit the various domains of pathology currently nested under the wide borderline construct. It is most unlikely that the numerous available evidence-based treatments are equally applicable to all subtypes of BPD. To be able to make a nuanced set of recommendations about what works for whom, it may be helpful to understand the origins of the concept of borderline, as the current usage of the term tends to focus on a limited, albeit important, subgroup of individuals with borderline features. We have reviewed these classical theories elsewhere (Higgitt & Fonagy, 1992).

A Little Phenomenology

Borderline personality disorder defined as outlined previously is a severe condition with a lifetime prevalence estimated at possibly as much as 6% (Grant et al., 2008). BPD is often comorbid with mood disorders (Sjastad, Grawe, & Egeland, 2012), anxiety disorders (Friborg, Martinussen, Kaiser, Overgard, & Rosenvinge, 2013), bipolar disorder (Perugi et al., 2013), and schizotypal and narcissistic personality disorders (PDs) (Tomko, Trull, Wood, & Sher, 2014). It may be particularly common in outpatient (Korzekwa, Dell, Links, Thabane, & Webb, 2008) and forensic (Slade & Forrester, 2013) populations, where between one-quarter and one-third may be expected to meet criteria for the diagnosis.

There is increasing consensus that BPD, as defined in *DSM-IV*, consists of three related core features. First, according to Linehan's theory (Linehan, 1993) and recent research (Crowell, Beauchaine, & Linehan, 2009; Glenn & Klonsky, 2009), *emotional dysregulation* is thought to drive other BPD symptoms. Experimental studies have indeed confirmed that patients with a BPD diagnosis are less willing to experience distress to pursue goal-directed behavior (Gratz, Rosenthal, Tull, Lejuez, & Gunderson, 2006; Salsman & Linehan, 2012), have significantly prolonged anger reactions (Jacob et al., 2008), show a reduced inhibition of negative emotional material (Domes et al., 2006; Gratz, Breetz, & Tull, 2010), manifest abnormalities in processing unpleasant emotional stimuli (Baer, Peters, Eisenlohr-Moul, Geiger, & Sauer, 2012; Hazlett et al., 2007), and are more likely to behave impulsively when in a negative mood (Chapman, Leung, & Lynch, 2008). Over any specific time period they are likely to experience dramatic shifts in mood states, manifest greater intraindividual variability in affect valence and intensity (Reich, Zanarini, & Fitzmaurice, 2012; Santangelo, Bohus, & Ebner-Priemer, 2012), and undergo heart rate increases not associated with metabolic activity (Reisch, Ebner-Priemer, Tschacher, Bohus, & Linehan, 2008; Trull et al., 2008). BPD patients also report more complex emotions, and experience greater problems in identifying specific emotions associated with higher levels of distress (Bornovalova, Matusiewicz, & Rojas, 2011; Ebner-Priemer et al., 2008; Preissler, Dziobek, Ritter, Heekeren, & Roepke, 2010), although this may be the effect rather than the cause of emotional hyperreactivity (Domes, Schulze, & Herpertz, 2009). Taking these pieces of evidence together, it is generally assumed that an anomalous reciprocal relationship between brain mechanisms underpinning the subjective experience of emotion (i.e., limbic structures) and mechanisms responsible for their regulation (i.e., anterior brain regions) brings about an aberrant processing of negative emotionality in patients with BPD (Maurex et al., 2010; Ruocco, Amirthavasagam, Choi-Kain, & McMain, 2013). However, it should be noted that some studies report no

[2] *DSM-5* has not changed the definition of any personality disorder diagnoses from those in *DSM-IV* because of opposition to the particular combination of trait measures and clinical methods suggested (Shedler et al., 2011), although a new model informed by the draft recommendations is included as part of Section III of *DSM-5*.

differences in emotional response to affect-eliciting stimuli in BPD patients (Herpertz, Dietrich, et al., 2001; Herpertz, Kunert, Schwenger, & Sass, 1999; Herpertz et al., 2000; Suvak et al., 2012), which, as we shall see, reflects the complexities involved in examining emotional dysregulation in BPD outside a genuine social context.

Second, BPD is characterized by *impulsivity*, the most disquieting aspect of which is suicidality. Three-quarters of BPD patients attempt suicide at least once (Black, Blum, Pfohl, & Hale, 2004). While outpatient treatment appears at least in some studies to decrease suicide attempts, medication visits appear to increase them (Soloff & Fabio, 2008). Affective instability, particularly negative mood amplitude and the intensity of negative mood (Links, Eynan, Heisel, & Nisenbaum, 2008), has been associated with an increased likelihood of impulsivity (Gratz et al., 2010). A diagnosis of major depressive disorder (MDD), substance use disorder (SUD), posttraumatic stress disorder (PTSD), the presence of self-harm, adult sexual assault, having a caregiver who has completed suicide, affective instability, and more severe dissociation have each been shown to increase suicidal behavior (Wedig, Frankenburg, Bradford Reich, Fitzmaurice, & Zanarini, 2013; Wedig et al., 2012). A curious aspect of the impulsivity literature in BPD is that while self-report measures point to high levels of impulsivity (e.g., Domes et al., 2006; Grootens et al., 2008), behavioral measures such as the go/no-go task (e.g., Jacob et al., 2010; Lampe et al., 2007) less readily demonstrate inhibition problems in laboratory settings. It is possible that the impulsivity observed in self-report is more closely related to an incapacity to inhibit mental states (cognitive inhibition), and it is unruly mental states that go on to generate problem behaviors. Suicide risk has been associated with poor social adjustment and the absence of supporting family, work, and social relationships (Soloff & Fabio, 2008; Soloff, Feske, & Fabio, 2008; Wedig et al., 2013; Wedig et al., 2012).

Indeed, *social dysfunction* is typically seen as the third factor in the core triad of BPD symptom clusters, and specific dysfunctions within and across interpersonal domains have been invoked to account for the origins and maintenance of BPD (e.g., Gunderson, 2011; Hill et al., 2008; Soeteman, Verheul, & Busschbach, 2008; Tomko et al., 2014). For example, patients with BPD experience heightened social problem-solving difficulties compared with other clinical groups (Dixon-Gordon, Chapman, Lovasz, & Walters, 2011; Maurex et al., 2010; Thoma, Friedmann, & Suchan, 2013) and report high levels of disturbances in romantic relationships (e.g., Bhatia, Davila, Eubanks-Carter, & Burckell, 2013; Clifton, Pilkonis, & McCarty, 2007; Hill et al., 2011). While certain social problem-solving deficits may be linked to impulsivity (McMurran & Wilmington, 2007), they could equally be secondary to an autobiographical memory deficit (Maurex et al., 2010). Social problem solving is also likely to be directly connected to dysfunctional attachment processes, which, as evidence we will discuss further below shows, have long been considered to characterize this group (Agrawal, Gunderson, Holmes, & Lyons-Ruth, 2004; Barone, Fossati, & Guiducci, 2011; Fonagy et al., 1996; Gunderson, 1996; Levy, 2005; Levy, Meehan, Weber, Reynoso, & Clarkin, 2005; Minzenberg, Poole, & Vinogradov, 2006a; Patrick, Hobson, Castle, Howard, & Maughan, 1994; Rosenstein & Horowitz, 1996; Steele & Siever, 2010; Stovall-McClough & Cloitre, 2003). In one study of a sample of patients with BPD (Fonagy et al., 1996), which controlled for conditions that commonly co-occur with BPD, a unique association between BPD and preoccupied attachment was reported (75% of PD patients meeting criteria for BPD fell into the rarely used adult attachment scoring subgroup of fearfully preoccupied with respect to trauma), even after controlling for comorbid Axis I and II disorders. Numerous studies have reported that individuals with BPD appear to anxiously expect, readily perceive, and intensely react to social rejection (Ayduk et al., 2008; Berenson, Downey, Rafaeli, Coifman, & Paquin, 2011; Renneberg et al., 2012). We, along with many others, have highlighted a characteristic pattern in borderline patients of fearful attachment (attachment anxiety and relational avoidance), painful intolerance of aloneness, a marked hypersensitivity to social situations, alertness to a hostile response from others, and greatly reduced positive memories of dyadic interactions (e.g., Berenson et al., 2011; Bhatia et al., 2013; Chapman, Walters, & Dixon Gordon, 2014; Critchfield, Levy, Clarkin, & Kernberg, 2008; Dixon-Gordon, Gratz, Breetz, & Tull, 2013; Frick et al., 2012; Gratz et al., 2010; Gunderson & Lyons-Ruth, 2008; Miano, Fertuck, Arntz, & Stanley, 2013; Preissler et al., 2010; Staebler, Helbing, Rosenbach, & Renneberg, 2011). Similarly, Beck, Freeman, and Davis (2004) proposed that the prototypical pattern of alternately clinging and pushing people away is underpinned by a feeling of helplessness in the absence of constant support of others, combined with a profound mistrust of others. Lack of trust also predicts suicide (Bhar, Brown, & Beck, 2008; Ozkan & Altindag, 2005) and could be related to the rejection sensitivity trait that frequently prompts dissociation and self-injurious behavior triggered by aversive interpersonal events (Gratz et al., 2006; Gunderson, 2007; Zanarini, Laudate, Frankenburg, Wedig, & Fitzmaurice, 2013). Rejection sensitivity, in turn,

may be mediated by lack of affect regulation capacity (Dixon-Gordon et al., 2013), which serves to exaggerate the experience of social rejection.

The interrelatedness of these primary deficits once again highlights the need for a developmental psychopathology model that maps the interactions between, and the developmentally changing prominence of, a range of genetically programmed or environmentally triggered influences on individual function.

Further, in our opinion, three features of BPD that refer to disturbances in social relatedness continue to be underemphasized but are essential to a comprehensive developmental understanding of BPD, as well as a full appreciation of the subjective experience of patients with the disorder, and are central in the MBT approach to BPD:

1. First, *dissociative comorbidity* is more frequently reported by patients with BPD than other groups (Barnow et al., 2012; Ross, 2007; Zanarini, Frankenburg, Jager-Hyman, Reich, & Fitzmaurice, 2008). It appears to be a response to increased stress (Stiglmayr et al., 2008); to be associated with emotional neglect (Sar, Akyuz, Kugu, Ozturk, & Ertem-Vehid, 2006); to moderate emotional responsivity (Barnow et al., 2012); to be linked to suicidal ideation (Klonsky, 2008); and to reduce the likelihood of effective psychosocial treatment (Kleindienst et al., 2011).

2. Second, a *disturbed sense of identity*, or "failure to establish stable and integrated representations of self and others" (Livesley, 2003, p. 19), is frequently described as characteristic of BPD (e.g., Blatt & Auerbach, 1988; Bradley & Westen, 2005; Jorgensen, 2010; Kernberg, 1975, 1984). Rooted in a dysfunction or deficit of a sense of agency or self-directedness, this characteristic has been identified in empirical clinical studies (e.g., Adler, Chin, Kolisetty, & Oltmanns, 2012; Barnow, Ruge, Spitzer, & Freyberger, 2005; Bender & Skodol, 2007; Jorgensen et al., 2012).

3. Third is the experience of intense *inner pain* that is out of keeping with the significance of the event. This may indeed be a core feature of BPD (Zanarini & Frankenburg, 2007), and is frequently associated with disturbed relationships (Gunderson & Lyons-Ruth, 2008) and childhood abuse and neglect (Holm & Severinsson, 2008; Hopwood & Zanarini, 2012). It is commonly prompted by social situations that involve rejection, abandonment, or isolation (e.g., Briand-Malenfant, Lecours, & Deschenaux, 2012; Hopwood, Thomas, & Zanarini, 2012; Stiglmayr et al., 2008); it involves intense or toxic shame (Gratz et al., 2010; Levy, Edell, & McGlashan, 2007; Rusch et al., 2007), and can prompt dissociation (Philipsen et al., 2004) and self-harm (Coid, 1993; Wedig et al., 2013; Zanarini, Laudate, Frankenburg, Reich, & Fitzmaurice, 2011; Zanarini et al., 2013). A number of clinicians have described the phenomenological intensity of this experience, but Gunderson and Lyons-Ruth (2008) drew attention to the interpersonal hypersensitive phenotype and made it a central part of any account of BPD; certainly, recovery is associated with improvements in this respect (Reed, Fitzmaurice, & Zanarini, 2012).

KEY IDEAS IN THE MENTALIZATION-BASED APPROACH TO BPD

The mentalizing approach aims to provide a comprehensive theoretical account of the phenomenology and origins of BPD from a developmental psychopathology perspective. This is congruent with increasing interest, over recent years, in the emergence of BPD (Arens et al., 2013; Bornovalova, Hicks, Iacono, & McGue, 2013; Chanen & McCutcheon, 2013; Stepp, Olino, Klein, Seeley, & Lewinsohn, 2013), particularly as there is increasing evidence to suggest that the disorder may have roots in early development (Goodman, Patel, Oakes, Matho, & Triebwasser, 2013; Lopez-Castroman et al., 2013; Perroud et al., 2013; Siever, 2008).

Here we first briefly summarize the key assumptions of the mentalizing approach to BPD; each of these assumptions will subsequently be discussed in detail (see Allen, Fonagy, & Bateman, 2008; Fonagy & Luyten, 2009; Fonagy, Luyten, & Strathearn, 2011).

Developmental Perspective

A developmental perspective is at the heart of the mentalizing approach to BPD. The mentalization model was first outlined in the context of a large empirical study in which security of infant attachment with parents proved to be strongly predicted not only by the parents' security of attachment during pregnancy (Fonagy, Steele, Steele, Moran, & Higgitt, 1991) but also even more by the parents' capacity to understand their childhood relationships with their own parents in terms of states of mind (Fonagy et al., 1991).

This study paved the way for a systematic program of research demonstrating that the capacity to mentalize, which emerges in the context of early attachment relationships, is a key determinant of self-organization and affect regulation. The concept of mentalization postulates that one's understanding of others depends on whether

one's own mental states were adequately understood by caring, attentive, nonthreatening adults. Problems in affect regulation, attentional control, and self-control stemming from dysfunctional attachment relationships (Agrawal et al., 2004; Lyons-Ruth, Yellin, Melnick, & Atwood, 2005; Sroufe, Egeland, Carlson, & Collins, 2005) are thus thought to be mediated through a failure to develop a robust mentalizing capacity (Bateman & Fonagy, 2010). From this perspective, mental disorders in general can be seen as the mind misinterpreting its own experience of itself, and therefore of others (Bateman & Fonagy, 2010).

Mentalizing thus refers to the understanding of both the self and others in terms of thoughts, feelings, wishes, and desires. This capacity is not a constitutional given but does seem to be a capacity that is in part prewired (Kovacs, Teglas, & Endress, 2010). It might be useful to understand it as being, just like language, based on an evolutionarily protected, nonconscious, reflexive appreciation of others' intentions, emotions, and perspectives (Seyfarth & Cheney, 2013), which is subject to modulation by social environments. Verbal competence may be guaranteed by our genes, but the quality of an individual's command of a language is down to the exigencies of geographical and social origin influencing developmental achievements over the early years of life. The development of mentalizing is thus similarly thought to depend on the quality of the social learning environment, the child's family relationships, and, in particular, early attachments, as the latter reflect the extent to which the child's subjective experiences were adequately mirrored by a trusted other. The attachment figure's ability to respond with contingent and marked affective displays of their own experience in response to the infant's subjective experience makes possible the child's development of coherent second-order representations of these subjective experiences. As we will discuss in more detail below, we are thus not adopting a naive environmentalist perspective on BPD. Rather, the interaction between genetic predisposition and early and later influences on the development of the capacity to mentalize is thought to be crucially important in the development of BPD.

Mentalizing and the Development of Self-Regulation and Control

Specifically, we believe that the quality of affect mirroring by attachment figures plays a major role in the development of affect-regulatory processes and self-control (including attention mechanisms and effortful control) as well as the capacity for mentalizing in the individual. Mentalizing is seen as a fundamentally bidirectional or transactional social process (Fonagy & Target, 1997): it is thought to develop in the context of interactions with others, and its quality in relation to understanding others is assumed to be influenced by how well those around us mentalize. This experience of how other people mentalize is internalized, enabling us to enhance our own capacity for empathizing and to better engage in interactive social processes; conversely, poor mentalizing begets poor mentalizing.

The Multidimensional Nature of Mentalizing

The quality of mentalizing may be conceptualized as the achievement of a balance between the two extremes of four dimensions, each with their own relatively distinct underlying neural circuits (Fonagy & Luyten, 2009). These four dimensions are (1) cognitive versus affective mentalizing; (2) mentalizing based on external versus internal features of self and others; (3) automatic versus controlled mentalizing; and (4) mentalizing with regard to self versus others.

Automatic mentalizing describes fast, parallel, reflexive processes that require little consciousness or effort, while *controlled* mentalizing involves more conscious, deliberate, serial reflective processes. The focus of mentalizing can be the *self* (including one's embodied experiences) or *others*, and mentalizing can involve inferences based on the *external* features of others (e.g., their facial expressions) or assumptions about *internal* features—that is, one's own mind or that of others. Finally, full mentalizing involves the integration of both *cognitive* knowledge (i.e., agent-attitude propositions) and *affective* input (i.e., affective-state propositions; see later in this chapter for a fuller description). From this perspective, different types of psychopathology can be distinguished on the basis of different combinations of impairments along these four dimensions (which we can refer to as different *mentalizing profiles*; see Figure 17.1 for an example of the mentalizing profile in BPD).

The Context/Relationship-Specific Nature of Mentalizing

The capacity to mentalize has both trait and state aspects that may vary in quality in relation to emotional arousal and the interpersonal context (e.g., mentalizing levels may differ considerably when reflecting on the relationship with one's mother vs. one's father, for instance, or when reflecting offline on these relationships versus online in the course of real-life interactions).

Typically, with heightened psychological arousal, the capacity for controlled mentalizing is increasingly lost, and automatic and often unreflective mentalizing starts

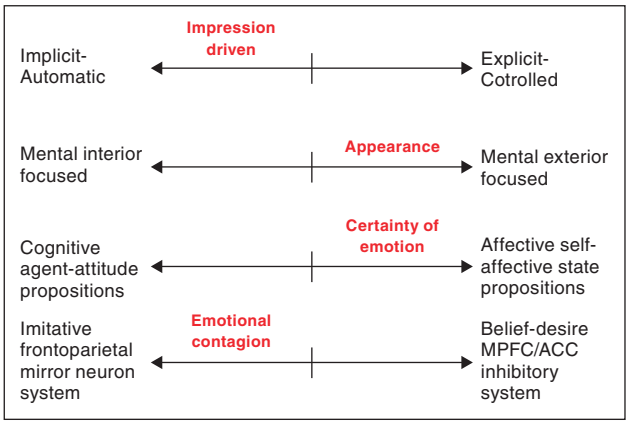

Figure 17.1 Mentalizing profile of the prototypical BPD patient. See footnote 1.

to dominate (Figure 17.2). Attachment hyperactivating and deactivating strategies play a key role in explaining the relationships among stress/arousal and mentalizing in different arousal/interpersonal contexts.

The Reemergence of Nonmentalizing Modes

The capacity for mentalizing and the associated capacities for affect representation, affect regulation, and attentional control normally obscure forms of experiencing subjectivity that developmentally antedate the capacity for full mentalizing. These modes of experiencing the self and others tend to reemerge whenever we lose the ability to mentalize, as typically happens in individuals with BPD, particularly in high arousal contexts:

In the *psychic equivalence mode*, thoughts and feelings become too real, and there are no conceivable alternative perspectives. There is a suspension of doubt, and the individual increasingly believes that his or her own perspective is the only one possible.

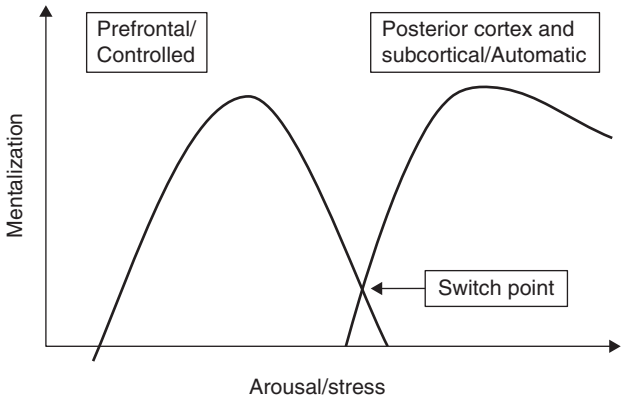

Figure 17.2 A biobehavioral switch model of the relationship between stress and controlled versus automatic mentalization.

Second, in the *teleological mode* there is only a recognition of real, observable goal-directed behavior and objectively discernible events that may potentially constrain these goals. Hence, the individual can recognize the existence and potential role of mental states, but this recognition is limited to very concrete, observable goals.

Third, in the *pretend mode* thoughts and feelings become severed from reality (which we term hypermentalizing or pseudomentalizing); in the extreme, this may lead to feelings of derealization and dissociation.

These three prementalizing modes are particularly important as they are often accompanied by a pressure to externalize unmentalized aspects of the self (so-called *alien-self parts*), which may be expressed in attempts to dominate the mind of others, self-harm, or other types of behavior that in the teleological mode are expected to relieve tension and arousal, a feature typical of BPD (Fonagy & Target, 2000).

Mentalizing and Pathology of the Self

Impairments in mentalizing are thought to play an important role in the emergence of various psychiatric disorders that involve pathology of the self (Sharp, Fonagy, & Goodyer, 2008) and thus are not limited to BPD (Bateman & Fonagy, 2004; Fonagy et al., 2010). Indeed, mentalizing impairments can be thought of as a transdiagnostic vulnerability factor that is implicated in a wide variety of disorders, ranging from antisocial PD (Bateman, Bolton, & Fonagy, 2013; Bateman & Fonagy, 2008b; McGauley, Yakeley, Williams, & Bateman, 2011) to eating disorders (Cate, Khademi, Judd, & Miller, 2013; Rothschild-Yakar, Levy-Shiff, Fridman-Balaban, Gur, & Stein, 2010; Skårderud, 2007a, 2007b), PTSD (Allen et al., 2008), depression (Luyten, Fonagy, Lemma, & Target, 2012), and functional somatic disorders (Luyten, van Houdenhove, Lemma, Target, & Fonagy, 2012).

In subsequent sections, we discuss these assumptions in more detail, focusing on BPD. Yet, inevitably, in accordance with the developmental psychopathology approach, this will also lead us to discuss overlap between BPD and related disorders that share important developmental trajectories with BPD.

ATTACHMENT, MENTALIZING, AND BPD

As noted, the mentalizing approach to BPD is fundamentally developmental. Its focus is on attachment disruptions and related impairments in mentalizing or the capacity to

develop second-order representations (representations of representations). Yet we are quite aware that this focus may lead to a theory that is overdetermined. We seek to situate these ideas, therefore, within a broader developmental approach that emphasizes the elements of interaction and diathesis–stress that are implicated in the emergence of BPD. In this section, we elaborate on how the most current thinking on mentalizing is informed by and theoretically congruent with this increasingly nuanced and complex picture of the developmental processes in BPD and the emerging evidence for gene–environment transactions.

The developmental theory we advance has several subhypotheses. First, we assume that early (especially emotional) neglect in particular, but a disrupted early social environment in general, is common in BPD, and we assume that it can undermine the ability of some individuals to develop full mentalizing capacities. Second, we assume that, particularly in these individuals, subsequent adversity or trauma could further disrupt mentalizing, in part as an adaptive maneuver on the part of the child to limit exposure to a brutalizing psychosocial environment, and in part because of the high level of arousal generated by attachment hyperactivating and disorganized attachment strategies that serve to disrupt less well practiced and less robustly established higher cognitive capacities. Third, mentalizing is a multidimensional capacity, and thus different subtypes of BPD patients are characterized by specific impairments in these capacities.

Several predictions follow from these views. In BPD patients we expect to see higher levels of insecure attachment strategies and attachment disorganization in particular, an association with high levels of early (emotional) neglect and later trauma, and a complex pattern of sociocognitive (or mentalizing) deficits moderated by (1) the nature of the task; (2) the emotional and, in particular, the attachment demands the task places on the individual; and (3) the nature of the attachment history of the individual. We review evidence for each of these assumptions in the following sections.

Disordered Attachment in BPD

BPD and Attachment Disorganization

The mentalizing approach to BPD is strongly rooted within contemporary attachment theory. There are at least two strands of research supporting the link between BPD and attachment issues. The first strand has provided direct evidence for such a link by showing that BPD is associated with increased levels of insecure attachment styles, by using both interview-based assessments of attachment such as the Adult Attachment Interview (AAI), and self-report measures. The second strand relates to attachment trauma (Allen, 2013). These views are congruent with general biopsychosocial models of BPD (Oldham, 2009), assuming that adverse childhood experiences and genetic factors interact to create a unique combination of biological factors (neurobiological structures and dysfunctions) and psychosocial factors (personality traits, personality functioning) that underpin BPD pathology (affective and behavioral dysregulation and disturbed relatedness).

Within the empirically derived taxonomy of PD diagnoses, based on over 1,200 clinician ratings of the Shedler–Westen Assessment Procedure (SWAP-II, an assessment tool for personality classification), the borderline-dysregulated spectrum emerges as a coherent prototype characterized as fearful of rejection, abandonment, and isolation, and becoming attached quickly and intensely (Westen, Shedler, Bradley, & DeFife, 2012). We suggested some time ago (Fonagy & Higgitt, 1990; Fonagy, Target, & Gergely, 2000) that the hyperactivation of the attachment system may be a core aspect of BPD. In forming an attachment bond, children, when exposed to threat and experiencing fear and distress that activates the attachment system, are biologically predisposed to proximity seeking. Under optimal circumstances of caregiver sensitivity and responsiveness, a down-regulation of emotion and deactivation of the attachment system takes place, and a lasting bond is formed to the individual who was attentive to the child's need (Bowlby, 1969, 1973). However, where early relationships are disrupted, for reasons of biology, circumstance, or a combination of the two, the proximity seeking that is set in motion by the activation of attachment is expected to lead to further adverse emotional experience. This negative experience generates the emotional response of fear and distress that has evolved to trigger the attachment system, which then inevitably stimulates further proximity seeking in the increasingly forlorn hope of achieving down-regulation (Main, 2000). Within this model there is considerable room for individual differences to emerge; these differences are affected by genetic predisposition (Fearon, Shmueli-Goetz, Viding, Fonagy, & Plomin, 2013) and formative psychosocial experience (e.g., Fraley, Roisman, Booth-LaForce, Owen, & Holland, 2013; Repetti, Taylor, & Seeman, 2002).

There is a rich body of empirical data now available to support these speculations about the relationship between attachment and BPD. For example, one large investigation with over 1,400 participants compared competing multivariate models of adult attachment patterns, impulsivity, and trait negative affect as these related to borderline

features (Scott, Levy, & Pincus, 2009). The relationship between attachment anxiety and BPD features was most effectively modeled when seen as generating negative affectivity and impulsivity. This provided a better fit than the alternative model of impulsivity or negative affectivity generating attachment anxiety. The suggestion from this study is that impulsivity and negative affect can lead to BPD when these occur in the context of high levels of attachment anxiety.

Agrawal et al. (2004) reviewed 13 empirical studies of adult attachment styles of individuals with BPD, all showing an association between BPD and insecure attachment. These findings have been subsequently confirmed in comparisons with other PD groups (Aaronson, Bender, Skodol, & Gunderson, 2006; Barone et al., 2011; Fossati et al., 2005; Meyer, Ajchenbrenner, & Bowles, 2005; Scott, Kim, et al., 2013). Congruent with our assumptions, cross sectional investigations show those with borderline features to have preoccupied (reflecting attachment hyperactivating strategies), disorganized, and unresolved patterns of attachment (Levy, Beeney, & Temes, 2011). Yet, these studies are not particularly compelling because the symptomatology (and phenomenology) of BPD maps directly on to a pattern of preoccupied and disorganized attachment. If the desperate pursuit of comfort and reassurance is part of the definition of the disorder, it is hardly surprising that attachment patterns describing this behavior are found with greater frequency within this group. On the other hand, attachment formulations have undoubtedly influenced (diagnostic) descriptions of BPD and offer a presumed explanation of the psychological and neurobiological mechanisms underlying descriptive features of BPD. Nevertheless, we need to beware of allowing descriptions to masquerade as explanations. This imperative makes longitudinal developmental studies particularly valuable: unfortunately, only a handful of studies looking at early attachment and BPD as the outcome are available to date (Carlson, Egeland, & Sroufe, 2009; Lyons-Ruth, 2008), and most studies cover adolescent development only. For example, it has been found that adolescent behaviors that indicate impulsivity and deficits in self-regulation are predicted by a pattern of preoccupied attachment from age 13, through age 15, and up to age 17 (Kobak, Zajac, & Smith, 2009).

A further cross sectional study reported by Choi-Kain, Fitzmaurice, Zanarini, Laverdiere, and Gunderson (2009) was able to differentiate patients with mood disorder from those with BPD in terms of attachment style. While both MDD and BPD patients showed greater preoccupation and fearfulness than community controls (although BPD patients were more severely affected for both traits), only patients with BPD simultaneously showed preoccupation and fearfulness. This study confirms what a number of attachment theorists have suggested: that the key marker of BPD is a lack of any functional regulation strategy to reduce attachment distress (Fonagy & Bateman, 2008; Main, 2000).

Genetic Effects in BPD and Attachment

To use cross sectional data on the disorganization of attachment as an indirect indication of putative early environmental influences on BPD is further misguided in the light of evidence concerning the limited stability of attachment classification across development (e.g., Fraley, 2002) and emerging evidence on the genetic determinants of both attachment classification in adolescence and BPD. In our view, attachment theory, as conceived by John Bowlby, is a thoroughgoing biological model that is often mistakenly coupled to a naive environmentalist position. It would also be mistaken to assume that the mentalizing approach is yet another psychodynamic parent-blaming approach.

In fact, strong emerging evidence concerning the genetic determinants of BPD is fully consistent with an attachment theory perspective, and evidence is now overwhelming in relation to the genetic determination of BPD. Recent years have seen the publication of several reports confirming the familial nature of BPD (White, Gunderson, Zanarini, & Hudson, 2003; Zanarini, Barison, Frankenburg, Reich, & Hudson, 2009). Classical twin studies place heritability estimates of BPD at around 40–50% (Bornovalova, Hicks, Iacono, & McGue, 2009; Distel et al., 2008; Kendler et al., 2008; Torgersen et al., 2000). Adding siblings, spouses, and parents of twins to generate more complex behavioral–genetic models makes the genetic evidence even more persuasive (Torgersen et al., 2008). Molecular studies have, however, so far failed to identify a compelling anomaly associated with BPD (Leichsenring, Leibing, Kruse, New, & Leweke, 2011). Nor have molecular genetic studies of attachment been unequivocally successful. Several candidate gene studies have reported associations or gene–environment interactions in relation to attachment security in infancy, primarily involving polymorphisms in the dopamine D4 receptor gene, the serotonin transporter gene, and the oxytocin receptor gene (Barry, Kochanska, & Philibert, 2008; Chen, Barth, Johnson, Gotlib, & Johnson, 2011; Gervai et al., 2005; Gervai et al., 2007; Lakatos et al., 2000; Spangler, Johann, Ronai, & Zimmermann, 2009). None of these candidate gene associations has been consistently replicated, however, and the most recent paper on

the subject, which combined two relatively large cohorts, found no evidence of reliable single-gene associations or gene–environment interactions (Fraley et al., 2013; Luijk et al., 2011), although the stability of attachment security may have molecular genetic markers (Raby, Cicchetti, Carlson, Egeland, & Collins, 2013).

In contrast, behavioral–genetic studies of attachment are providing novel insights into the possibility of gene–environment interactions. Studies of early attachment have consistently yielded negative results in regard to the heritability of attachment classifications in infancy and toddlerhood. Where behavioral–genetic studies have found evidence of shared environmental effects on development in other domains, they have tended to involve younger samples (infants and preschoolers); this suggests that shared environmental effects may be relatively restricted to infancy and toddlerhood and may not always be stable beyond these early years (Plomin, DeFries, Knopik, & Neiderhiser, 2013). A recent study of attachment in adolescence has shown a powerful genetic component (Fearon et al., 2013). This is consistent with the common observation that genetic influences on a number of psychosocial traits begin to show their effects at later developmental phases. It is possible that the child's genes could come to influence attachment only in later development because they increasingly influence parental attitudes and caregiving behavior (gene–environment correlation; see Price & Jaffee, 2008). Particularly in relation to attachment, it seems that we may assume that there is considerable selective advantage in interpersonal styles being exclusively responsive to caregiver behavioral characteristics at the age of greatest parental dependence. Into adolescence, attachment styles may then become increasingly influenced by genetic predisposition as the individual has greater opportunities to impose his or her genetic makeup on the quality of an emerging attachment relationship.

However, to discount entirely the significance of early attachment experiences in the emergence of BPD on the basis of genetic data would fly in the face of other substantial and rapidly accumulating evidence. Genetic studies are also seriously hampered by methodological issues in the assessment of attachment across the life span (Roisman et al., 2007). Further, the powerful association between social inequality and the prevalence of health and social problems makes an incontrovertible case for the role of social determinants in developmental psychopathology. Wilkinson and Pickett (2009), for example, provided ample evidence that countries with the highest levels of income inequality also manifest higher levels of the kind of mental health and social problems we normally associate with the borderline syndrome (e.g., drug and alcohol addiction, teenage births). In fact, on the basis of studies that use interview-based estimates of population prevalence of BPD, we can make a reasonable prediction of BPD prevalence from the ratio of the average income of the richest 20% to that of the poorest 20% of the population. We make this point not simply to underscore the importance of social determination, but also to sound a note of caution. Across roughly the first three-quarters of the twentieth century, the unequal distribution of income in terms of the proportion of wealth held by the top 1% of the society generally decreased in most Western countries (from over 20% to under 10%), having reached a historic peak of inequality in the late nineteenth century. However, the United States experienced a dramatic reversal of this trend in the 1980s and the first decade of this century, and the figure now hovers at between 20 and 25%. A similar pattern is evident in the United Kingdom, although the figure remains under 20%. Even more traditionally egalitarian countries, such as Sweden, appear to be following suit. If the relationship between a lack of apparent social concern and BPD prevalence is causal, we may well anticipate a dramatic increase in prevalence; this may indeed be already indicated by some figures (Grant et al., 2008).

Gene–Environment Interactions

Increasingly, authors have therefore been considering interactional models, which incorporate biological vulnerability with psychosocial risks such as early neglect and abuse, and pinning their hopes on emergent studies of gene–environment interactions (e.g., Wagner, Baskaya, Dahmen, Lieb, & Tadic, 2010; Wagner, Baskaya, Lieb, Dahmen, & Tadic, 2009). Modern psychodynamic views could usefully revisit classical psychoanalysis (e.g., Freud, 1896/1962, 1905/1953; Freud & Breuer, 1893/1962), which saw genetic factors in combination with adverse childhood experiences as the cause of both biological (neurobiological structures and dysfunctions) and psychosocial (neuroticism, interpersonal and self-structure deficits) anomalies. Joel Paris (2011), among others, has identified the urgent need to consider biological and environmental factors together in studies of the emergence of PD.

As noted, a BPD gene has not been identified so far, but researchers are perhaps gradually approaching the identification of an endophenotype for the disorder. For example, impulsive aggression and suicidal behavior have been linked to the tryptophan hydroxylase (TPH) gene, and patients with BPD have a higher frequency of two of eight polymorphisms in one of the two known isoforms of the TPH gene (Ni, Chan, Chan, McMain, & Kennedy, 2009).

Impulsive aggression is also associated with reduced serotonergic responsiveness and the inefficient (short or s) allele of 5-HTTLPR, which has been more commonly identified in patients with BPD (Ni et al., 2006) in some but not all reports (e.g., Pascual et al., 2008). There are interesting suggestions that the s allele marks a vulnerability to stressful life events (Caspi et al., 2003) on the one hand, and the positive influence of maternal sensitivity on the other (Barry et al., 2008). Accumulating evidence supports the view that the s allele, in combination with secure attachment, increases agreeable yet autonomous social behavior in adolescents (Zimmermann, Mohr, & Spangler, 2009). The same polymorphism in combination with insecure parenting predicts poor self-regulation (Kochanska, Philibert, & Barry, 2009) and impulsiveness in response to threats to autonomy (Zimmermann et al., 2009). The challenging suggestion is that the inefficient s allele may be retained in the gene pool because in favorable circumstances it enhances social sensitivity, potentially making a child both more and less prosocial depending on the emotional environment.[3]

There may be further epigenetic evidence of the complexity of gene–environment interactions. A recent study hinted at the role of environmental influence in the penetration of the 5-HTTLPR polymorphism. It seems that, in line with the environmental vulnerability of those with the s allele, attachment disorganization (indicated by unresolved loss and trauma scores) is elevated for those with the s allele only in cases with lower levels of methylation (van IJzendoorn, Caspers, Bakermans-Kranenburg, Beach, & Philibert, 2010). This literature promises to yield further exciting developments, and there may indeed be genetically determined serotonergic anomalies that underpin the kind of aggressive impulsive symptoms that Kernberg (1967) placed at the center of his psychoanalytic theoretical model. The molecular nature of this association remains unclear at this time, but the adequate consideration of triggering psychosocial relational environment factors seems key to a proper understanding of the biological narrative (Wagner et al., 2010).

The role of environmental factors appears to be cumulative. In a twin study of over 5,000 twins and almost 1,300 siblings, Distel et al. (2011) showed that the unique environmental variance identified by the behavioral–genetic model increases linearly with the number of traumatic life events to which an individual is exposed (from 54% with no events to 64% with six events), while neither additive genetic variance nor dominant genetic variance changes. The proportion of variance accounted for by the genetic contribution declines linearly with exposure to social adversity, and decreases from 46% to 36% when those exposed to no traumatic life events are contrasted with those who report six or more of such events (Distel et al., 2010).

Biological vulnerability to environmental events was also illustrated by Belsky et al. (2012). A family history of psychopathology was studied in a nationally representative birth cohort of over 1,100 families with twins. When the children were 12 years old they were assessed using a self-report measure of BPD. In the presence of a family history of psychopathology, 47% of those in whom maltreatment was observed were in the extreme group (they topped the 95th percentile). By contrast, maltreatment in the absence of a family history of psychopathology was found in only 7% of the subjects in the BPD category. The same indication of a diathesis–stress interaction was found for maternal negativity and a dimensional measure of BPD. Maltreatment was only weakly associated with BPD symptoms overall. When genetic vulnerability (operationalized as *any* family history of psychological illness) was used as a moderator, maltreatment became a highly significant predictor of membership of the BPD group. The relative risk of BPD was only about twofold for those with an experience of maltreatment who carried no genetic risk via a family history of mental disorder. However, among those with a family history of psychiatric illness (taken to indicate a genetic vulnerability), experience of early maltreatment increased the risk of membership of the BPD group by a factor of 13. Further, maternal negative expressed emotion about the child, recorded when the child was 5 years of age, was twice as strongly associated with borderline personality characteristics among those with genetic vulnerability/family history as among those without.

This limited set of observations could be seen as confirming the evolutionary-neurodevelopmental theory on differential susceptibility to the environment (Belsky & Fearon, 2008; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011), which suggests that children vary in how they respond to the psychosocial environmental context. Some (low-susceptibility) children are expected to do similarly well irrespective of the environmental context. Other children are assumed to have a genetically

[3]It may be interesting to note that collectivistic nations (e.g., Korea and China) that particularly value interdependence appear to have a higher prevalence of s allele carriers and social susceptibility genes more generally than nations where individualism is more highly valued (Chiao & Blizinsky, 2010), providing evidence for so-called gene–culture coevolution (Luyten & Blatt, 2013).

transmitted susceptibility to environmental influence and are consequently more susceptible to abusive childhoods. For this phenotype to remain in the gene pool we must assume that (1) these children benefit more from favorable circumstances and (2) they find ways to adapt to malevolence and adversity and respond to threat by reducing the experience of pain, even if, compared with less susceptible individuals, they appear to be engaging in behaviors that are maladaptive (e.g., self-harming, risk-taking).

Two separate UK longitudinal cohort studies bring together risk factors of maltreatment, bullying, and BPD (Shakoor et al., 2012; Wolke, Winsper, & Hall, 2012). The E-Risk study, an environmental risk longitudinal twin study of over 2,200 children and families, demonstrated lower mentalizing capacities, as assessed with a theory of mind (ToM) task, in individuals who showed clear indications of emergent BPD in early adolescence (Belsky et al., 2012). ToM performance also predicted more general interpersonal difficulties, particularly becoming a victim, being a bully, or, most unequivocally, being a bully–victim (i.e., a bully who has a history of being a victim) (Shakoor et al., 2012). A longitudinal study on a separate sample, the Avon Longitudinal Study of Parents and Children, found that the risk of BPD symptoms increased with increased risk of bully–victimization (Wolke, Winsper, et al., 2012). Both these findings underscore that, as well as focusing on parent–child relationships, the nature of peer relationships as mediating factors should be included in biopsychosocial models of BPD, in the light of the anomalous capacity for social cognition (Sansone, Lam, & Wiederman, 2010; Wolke, Schreier, Zanarini, & Winsper, 2012). The extent to which this pathway may run parallel to or may be independent from maltreatment in mid-childhood is unclear. In the E-risk study, ToM deficit predicted bully–victim status when maltreatment was controlled for. In the Avon study, bully–victimization rather than maladaptive parenting mediated the relationship between childhood dysregulation and BPD symptoms. It is possible that bully–victimization leads to an exacerbation of dysfunctional social cognition such as hypermentalization. A likely explanation may be that some of the key etiological effects of parenting, perhaps with the exception of the most severe forms of persistent brutalizing of children, are primarily felt in early childhood (Winsper, Zanarini, & Wolke, 2012) through initiating a cascade of events (Bornstein et al., 2006).

When it comes to the transgenerational transmission of BPD, a significant aspect of the gene–environment model is the parent–child interaction in families where mothers have a diagnosis of BPD. Negative parent–child relationships are more likely where children manifest high emotional reactivity, and such relationships are likely, in turn, to exacerbate internalizing and externalizing symptoms (Feinberg, Button, Neiderhiser, Reiss, & Hetherington, 2007). By contrast, there is indirect evidence that warm, accepting parenting can moderate some of the outcomes of genetic and physiological vulnerabilities (Eley et al., 2004). There is also evidence that points to genetic factors protecting from even adverse social environments (e.g., Kaufman et al., 2006).

There are preliminary data from a number of small-sample studies (Crandell, Patrick, & Hobson, 2003; Hobson, Patrick, Crandell, Garcia-Perez, & Lee, 2005; Newman, Stevenson, Bergman, & Boyce, 2007) that maternal BPD can impact on infant affect as well as capacities for self-regulation. Hobson et al. (2005) reported high levels of infant attachment disorganization in 12-month-old infants of mothers with BPD. Stepp, Whalen, Pilkonis, Hipwell, and Levine (2012) have summarized the literature on parenting behaviors of mothers with BPD, highlighting insensitive forms of communication (including frightening statements and actions, intrusion, and unwarranted criticism), role confusion, and high levels of reported distress. The literature, however, is not consistent. In a relatively large-scale investigation of 200 mothers, Conroy, Marks, Schacht, Davies, and Moran (2010) found no effect of Cluster B PD status on maternal involvement and maternal sensitivity. The interactions were short, however, and 2 months following childbirth may not be an ideal time for identifying pathological outcomes.

Implications for a Developmental Understanding of BPD

The main implications of a bidirectional model of environmental (including attachment issues) and genetic/biological factors in BPD are far-reaching, although such a bidirectional model is by no means new in accounts of BPD (Crowell et al., 2005; Fonagy, 1998; Gunderson & Lyons-Ruth, 2008; Paris, 2005; Zanarini & Frankenburg, 2007). From a mentalizing perspective, it is inconceivable that a proper understanding of borderline pathology can be arrived at without thought being given to the nature of early object relationships. For a start, an immediate implication of a genetic model of BPD is that the parents of these individuals would be likely to manifest BPD traits or even frank BPD, which would profoundly impact on their caregiving. The implication therefore goes beyond mere gene–environment correlations (Plomin & McGuffin, 2003) and suggests quite specific developmental paths for social inheritance. For example, children of mothers with BPD show deficits in emotion regulation and distorted self–other representations, as well as later problems in

psychosocial functioning (Hobson et al., 2005; Hobson et al., 2009).

Given the difficulties these patients have in affective communication and relatedness in their moment-to-moment interactions with others, it would be surprising if their children were spared the impact of these shortcomings, which directly interfere with the caregiving function (Bowlby, 1988; Sroufe et al., 2005). Young children of mothers with BPD often manifest disorganized attachment (Hobson et al., 2005), which is associated with disrupted affective communication and fearful and disoriented responses from the mother (Hobson et al., 2009). A fearful pattern of attachment persists in these children until adolescence; they show an inability to make close friends or to feel socially accepted (Herr, Hammen, & Brennan, 2008). In mid-childhood, the children of mothers with BPD show increased fear of abandonment, fantasy-proneness and role reversal when completing story stems (Macfie & Swan, 2009). Macfie (2009) reported that a girl aged 5, whose mother had BPD, completed a story about a birthday party using family dolls, a table, and a cake thus: "The girl tells how the family open presents and eat cake. She then adds: *And then Mom takes off her clothes and gets drunk*" (p. 69).

The social environment of infancy thus can still be thought of as critical because the infant acquires a sense of self through interactions with the object (Fairbairn, 1952a, 1952b). Early attachment experiences therefore should be robust predictors of BPD pathology in later life, not so much because of the attachment experiences themselves, but because it is in the context of these attachment relationships that the infant comes to understand his or her own emotional states, acquires the capacity for affect regulation, and discovers him/herself as a psychological entity through marked mirroring interactions (Fonagy, Gergely, Jurist, & Target, 2002; Fonagy, Gergely, & Target, 2007a).

The evidence linking harsh treatment in early life with later BPD goes beyond patient recollections; it has been largely confirmed by numerous prospective studies (Carlson et al., 2009; Crawford, Cohen, Chen, Anglin, & Ehrensaft, 2009; Johnson, Cohen, Chen, Kasen, & Brook, 2006). Microanalytic studies of parent–infant interaction have contributed to our understanding of the way the child's genetic predisposition may compound the effects of suboptimal parenting environment to increase the risk of attachment disorganization (Beebe et al., 2010) and BPD symptoms (Lyons-Ruth & Jacobvitz, 2008). In Lyons-Ruth's longitudinal study (Lyons-Ruth, 2008), disrupted maternal communication and maltreatment were found to be independent predictors of BPD symptoms at age 18. An unusual longitudinal study by Crawford et al. (2009) examined the trajectory of BPD symptoms over time, and found deprivation of early parenting influence (early separation) to be predictive of BPD symptoms in adolescence and early adulthood, and a slower developmental decline of symptom severity over this period. Importantly, temperament (presumably genetically determined) was a partial mediator between early development and later BPD symptoms. We can speculate that individuals with a difficult temperament are, on the whole, somewhat more likely to be abandoned by parents who are themselves more impulsive and less able to feel emotional commitment toward the child (gene–environment correlation, as described earlier in this chapter). It is also likely that this type of environmental deprivation will cause these individuals to miss out on the self-organizing influence of early parenting; they will additionally be more likely to experience negative parenting events in a more exaggerated manner, turning on themselves in relation to deprivation, blaming themselves for the separation, and ending up feeling unworthy of love and attention.

The same bidirectional process is brought into relief by a carefully conducted longitudinal study of the emergence of borderline symptoms in young adulthood. Carlson and colleagues (2009) reported significant, but weak, correlations between borderline symptoms at 28 years of age and indicators of a suboptimal early environment (maltreatment, maternal hostility, attachment disorganization, and family stress in the first 3–4 years of life). These culminated in a range of social-cognitive anomalies—attentional disturbance, emotional instability, and relational disturbance—that were evident by 12 years of age. A path-analytic approach offered strong evidence that disturbances in self-representation in early adolescence mediated the link between disorganization of early attachment relationships and PD. A narrative projective task administered at age 12 yielded more intrusive violence related to the self, more unresolved feelings of guilt and fear, and more self-associated bizarre imagery in individuals who showed borderline symptoms 16 years later. Early adversity was strongly associated with these anomalies. A combined indicator of early adversity predicted such effects both directly and indirectly via the disorganization of the attachment system. Anticipating our discussion of findings concerning impairments in mentalizing in BPD discussed later in this chapter, Carlson and colleagues conclude that "representations and related mentalizing processes are viewed as carriers of experience that link early attachment to later psychopathology" (p. 1,328).

BPD and Childhood Adversity

The role of developmental trauma in BPD in general has been a significant focus of research and further amplifies our considerations concerning the importance of attachment disruptions in relation to BPD.

Among individuals with PDs, rates of childhood trauma are high (73% report abuse, of which 34% is sexual abuse, and 82% report neglect; Ball & Links, 2009). Compared with nonclinical adults, PD patients are four times as likely to have suffered early trauma (Johnson, Cohen, Brown, Smailes, & Bernstein, 1999). Childhood physical abuse increases the risk for adult antisocial, borderline, dependent, depressive, passive-aggressive, and schizoid PDs (McGauley et al., 2011). BPD is more consistently associated with childhood maltreatment than are other PD diagnoses (Baird, Veague, & Rabbitt, 2005; Battle et al., 2004; Buchheim et al., 2008; Fonagy & Bateman, 2008; Fonagy, Target, Gergely, Allen, & Bateman, 2003; Johnson et al., 1999; Teicher, Andersen, Polcari, Anderson, & Navalta, 2002).

A particularly impressive study following up several hundred abused and neglected children and matched controls into adulthood reported a 2.5-fold increase in the prevalence of BPD associated with abuse and neglect (Widom, Czaja, & Paris, 2009). In this prospective investigation of children who were identified as maltreated by child protection services, early neglect appeared to be the most potent risk factor for both genders, whereas physical abuse represented a risk only for males. Of course, not all those with a history of abuse go on to develop BPD; Widom et al. (2009) found that only 14.9% of those who had been abused met criteria for BPD. Conversely, there is a substantial proportion of individuals with confirmed BPD who do not report abuse in childhood, with rates varying between 8% (Kingdon et al., 2010) and 70% (Afifi et al., 2011) depending on the population sampled. Sexual abuse, which has been highlighted by retrospective studies as a potentially causative factor in BPD, appeared not to increase the risk of BPD for either gender. In general, findings highlight the pernicious impact of early neglect. In our opinion, this is important to underline, as early neglect critically deprives children of the opportunity to use interpersonal interactions with the caregiver to acquire knowledge and control over their subjective worlds—that is, to acquire the capacity for mentalizing.

In our view, at the present state of knowledge, the existence of an association between adversity and BPD is less in question than the nature of the potential mediating variables linking maltreatment (and neglect in particular) to BPD. In what is perhaps the most thoughtful review of this literature so far, Ball and Links (2009) attempted to use Hill's epidemiologic criteria for *causality* (relationship strength, temporality, dose response, specificity, consistency, epidemiologic and biologic plausibility, and analogy) to determine the status of the association between childhood trauma and BPD. As Ball and Links note, several systematic reviews offer strong evidence for an association between child abuse and psychosis (e.g., Read & Bentall, 2012), bipolar disorder (e.g., Daruy-Filho, Brietzke, Lafer, & Grassi-Oliveira, 2011), and depression (e.g., Nanni, Uher, & Danese, 2012). Despite lack of evidence for specificity (i.e., some individuals experience BPD in the absence of trauma, while many experience trauma without developing BPD), Ball and Links (2009) nevertheless conclude that a causal relationship between trauma and BPD is likely. In their review of pathways to BPD, Chanen and Kaess (2012) similarly conclude that studies of both clinically and nationally representative samples confirm that a range of cumulative aversive events contributes to the development of BPD.

However, frank abuse cited by BPD patients occurs mostly in adolescence (e.g., Pietrek, Elbert, Weierstall, Muller, & Rockstroh, 2013). In drawing up a mentalizing, developmental model of BPD in relation to childhood adversity, we suggest that two processes unfold, which have a cumulative effect. First, we assume that the development of mentalizing depends on the social co-construction of internal states between child and parents. Following on from this, we hypothesize that early neglect and an early emotional environment incompatible with the normal acquisition of understanding oneself and others creates vulnerability for BPD. Second, we further hypothesize that subsequent brutality in an attachment context can disrupt mentalization as part of an adaptive adjustment to adversity when a child—whose early experiences of neglect have left them less resilient to deal with trauma—is in a state of helplessness in relation to those individuals (Fonagy, Steele, Steele, Higgitt, & Target, 1994; Stein, Fonagy, Ferguson, & Wisman, 2000). In summary, we propose (Fonagy & Luyten, 2009) that early emotional neglect in particular, rather than physical or sexual abuse as such, predisposes an individual to developing BPD by limiting his or her opportunity to acquire mentalization and leaving the capacity to mentalize vulnerable to disruption under the influence of later stress.

We further assume (and will review evidence related to this below) that childhood environments that are

emotionally abusive, or in which the discussion and validation of mental states are absent, lead to the generation of coping strategies that favor rapid intuitive (as opposed to more deliberative reflective), emotion-focused (as opposed to cognition-focused) mentalizing—particularly in individuals primed to rapidly identify risk by an experience of early neglect. This intuitive state is dominated by mental-state attributions based on external observable cues (as opposed to the inference of internal states, which may be unreliable in a maltreating environment). In addition, such individuals may need to develop a strategy of being highly sensitive to and readily influenced by (mirroring) mental states in others (at the cost of achieving a clear differentiation of self and others' mental states; Fonagy, 2000; Fonagy & Luyten, 2009; Luyten, Fonagy, Lowyck, & Vermote, 2012). We wish to emphasize that while this approach may appear to suggest a deficit theory, our emphasis is upon adaptation. The specific configuration of mentalizing capacities characterizing individuals with BPD may be conceived of as that most likely to favor survival under conditions of significant adversity (Frankenhuis, Panchanathan, & Clark Barrett, 2013). Our model is fully compatible with Linehan's (1993) original biosocial theory of the development of BPD and its later elaboration (Crowell et al., 2009), which highlights that an invalidating childhood environment can serve to undermine the understanding, regulation, and toleration of affect states, leading the child to adapt by displaying more extreme emotions to achieve a contingent response from carers (the so-called intermittent reinforcement of extreme emotional outbursts).

There is indeed some evidence to support these assumptions, although most reviews of childhood trauma in BPD (Ball & Links, 2009; Chanen & Kaess, 2012) combine reviews of abuse with neglect. Yet, in view of the specific predictions we make in relation to neglect, a separate consideration of the neglect and emotional abuse literature is appropriate here. In contrast to the relatively incontestable ways physical and sexual abuse can be objectively defined, neglect and emotional maltreatment are harder to pinpoint (Kempke et al., 2013). Glaser (2002) defines emotional abuse and neglect as (1) being emotionally unavailable or unresponsive to the child, (2) placing negative attributions and misattributions upon the child, (3) engaging in developmentally inappropriate or inconsistent interactions with the child, (4) failing to recognize the child's boundaries and individuality, for example, using the child for the fulfillment of the parent's own psychological needs, and (5) failing to promote the child's social adaptation.

In a systematic literature review, Crombie and Fonagy (2015) identified 298 studies relevant to BPD and trauma that were reported between 1980 and 2012. Of these, 202 could be excluded because they failed to measure BPD or trauma systematically. Of the 99 remaining studies (three were added following hand searching), 60 were excluded because they measured only physical or sexual abuse, did not involve a clinical population, or had no systematic measure of childhood trauma. The final 39 studies reported on 33 independent samples, mostly using the Structured Clinical Interview for *DSM-IV-TR* Axis II Personality Disorders (SCID-II) as a diagnostic instrument and a combination of self-report and interview-based measures of trauma. There were eight cohort, 18 cross sectional, and 13 case–control studies, each with specific methodological limitations. Cross sectional studies invariably raise questions concerning the validity of the retrospectively measured trauma, which may be undermined and confounded by concurrent symptomatology (Widom et al., 2009). Indeed, there are a range of methodological concerns specific to BPD that may make one suspect the veracity of BPD patients' reports of childhood experience, including misinterpretation, exaggeration, or even fabrication of caregiver behavior (Zanarini et al., 2000), negative bias toward traumatic events and parental failings (Huang et al., 2012; Machizawa-Summers, 2007), and reporting maltreatment as a means of actively seeking sympathy (Battle et al., 2004). However, such designs can be of great use in estimating the prevalence of disorders and causal factors (Mann, 2003). There is also indirect support for the validity of retrospective data from studies where family members were asked to verify patients' self-reports of trauma histories (Laporte & Guttman, 2001; Laporte, Paris, Guttman, & Russell, 2011).

Prospective cohort studies overcome reporting bias, but have their own weaknesses. By definition, their sampling frame will be arbitrary or driven by the theoretical considerations dominant at the time of study design. They are likely to capture only a selection of those who will develop BPD, raising questions not only of statistical power, but also of the representativeness of the sample (Cohen, Crawford, Johnson, & Kasen, 2005). More pertinent in the context of neglect is the inevitable limitation of prospective studies to use time-bound (historical) definitions of risk. Awareness of emotional neglect and abuse, as defined by Glaser (2002), is relatively recent and may have been missed in many earlier investigations (Cawson, Wattam, Brooker, & Kelly, 2000). Eleven studies (Driessen et al., 2000; Giesen-Bloo & Arntz, 2005; Horesh, Ratner,

Laor, & Toren, 2008; Lange, Kracht, Herholz, Sachsse, & Irle, 2005; Laporte & Guttman, 2001; Laporte et al., 2011; Lobbestael & Arntz, 2010; Lobbestael, Arntz, & Sieswerda, 2005; Sieswerda, Arntz, Mertens, & Vertommen, 2007; Weniger, Lange, Sachsse, & Irle, 2009; Wingenfeld et al., 2011) comparing emotional abuse and neglect in healthy controls and BPD patients reported higher levels in the patient groups, with two studies (Lange et al., 2005; Weniger et al., 2009) reporting a specific effect for neglect. Fourteen studies identified in the review compared neglect and emotional abuse in groups of patients with Axis I disorders and BPD (Battle et al., 2004; Bellino et al., 2005; Bornovalova, Levy, Gratz, & Lejuez, 2010; Giesen-Bloo & Arntz, 2005; Gratz, Tull, Baruch, Bornovalova, & Lejuez, 2008; Horesh et al., 2008; Huang et al., 2012; Joyce et al., 2003, 2006; Kingdon et al., 2010; Laporte & Guttman, 2001; Machizawa-Summers, 2007; Sieswerda et al., 2007; Wingenfeld et al., 2011). Two studies focusing on emotional neglect and abuse (Machizawa-Summers, 2007; Sieswerda et al., 2007) reported large odds ratios compared with non-PD Axis I disorders. Huang et al. (2012) found that the differences were significant for both mothers and fathers, and four of the six studies making specific comparisons with MDD found BPD groups to have experienced significantly higher levels of abuse and neglect (Battle et al., 2004; Bellino et al., 2005; Joyce et al., 2003, 2006). Only two studies (Horesh et al., 2008; Wingenfeld et al., 2011) reported no difference. These studies suggest that patients with BPD may experience more neglect or abuse than control patients with Axis I disorders.

Crombie and Fonagy also discuss 11 studies (Battle et al., 2004; Giesen-Bloo & Arntz, 2005; Goodman et al., 2003; Huang et al., 2012; Joyce et al., 2003, 2006; Lobbestael & Arntz, 2010; Lobbestael et al., 2005; Sieswerda et al., 2007; Zanarini et al., 2000; Zhang, Chow, Wang, Dai, & Xiao, 2012) that compared neglect and emotional abuse among groups with Axis II diagnoses. The large majority of these studies found BPD diagnosis to be specifically linked to emotional neglect or abuse. In a study reported by Zhang et al. (2012), emotional neglect was found to be a significant predictor of any PD diagnosis. However, rates of emotional neglect appear similar for antisocial PD and BPD (Battle et al., 2004; Lobbestael & Arntz, 2010; Lobbestael et al., 2005). Taking these studies together, it seems reasonable to conclude that individuals with BPD are more likely to report experiencing emotional neglect and abuse than those with most other PDs.

Further evidence of this association comes from studies correlating BPD symptoms or traits with self-rated emotional abuse and neglect (Afifi et al., 2011; Bierer et al., 2003; Bradley, Jenei, & Westen, 2005; Gratz, Latzman, Tull, Reynolds, & Lejuez, 2011; Specht, Chapman, & Cellucci, 2009). Of course, emotional abuse may be predictive of other types of PD (e.g., Afifi et al., 2011), but for BPD the association can be found at an early age (Gratz et al., 2011; Joyce et al., 2003, 2006; Zanarini, Frankenburg, Hennen, Reich, & Silk, 2006). Tyrka, Wyche, Kelly, Price, and Carpenter (2009) contrasted abused and nonabused PD patients and found higher levels of BPD among those with histories of emotional neglect and abuse.

Importantly, results obtained from longitudinal cohort studies confirm that emotional neglect and abuse predict the emergence of BPD symptoms in later life. In a follow-up of adults who were inpatients in adolescence, Helgelend and Torgerson (2004) reported that instability and emotional abuse were higher among those later presenting with BPD. Several publications from the Children in the Community (CIC) study (Johnson et al., 2001; Johnson, Smailes, Cohen, Brown, & Bernstein, 2000) have reported that supervision neglect combined with verbal abuse is a significant predictor of BPD symptoms. In a more recent report on the same cohort, Crawford et al. (2009) reported that those experiencing early separation have a slower rate of decline of BPD symptoms from adolescence. In one of the best-controlled studies to date, Widom et al. (2009) reported BPD to be significantly more likely to be present in adults who had legal records of childhood emotional neglect. Finally, in a small-scale study, Carlson et al. (2009) found a combination of early maltreatment, attachment disorganization, and general disturbance of the parent–child relationship to be a significant predictor of BPD symptoms in adulthood.

It is difficult to disentangle the impact of neglect and emotional abuse from that of physical or sexual abuse, as these types of early adversity often co-occur. For instance, 13 of the studies identified in Crombie and Fonagy's (2015) review also reported elevated levels of physical and sexual maltreatment. This is not surprising, given that sexual and physical abuse are more likely to occur in households characterized by emotional neglect. However, the particular heft of neglect and emotional abuse in the BPD profile is underscored in the studies that failed to find a significant difference in BPD prevalence in relation to sexual abuse (Bellino et al., 2005; Bierer et al., 2003; Laporte et al., 2011; Widom et al., 2009; Zanarini et al., 2000) or physical abuse (Battle et al., 2004; Widom et al., 2009 [in male patients only]; Wingenfeld et al., 2011), yet yielded significantly higher BPD prevalence in association with emotional neglect and abuse. In three studies (Gratz et al., 2008; Machizawa-Summers, 2007; Zhang et al., 2012),

emotional neglect and abuse were significant predictors of BPD symptoms over and above all other types of abuse. In the study of Specht et al. (2009), lack of emotional support was shown to be the only significant predictor of BPD symptoms.

In conclusion, generally high-quality studies across a range of designs and measurement methodologies converge in showing, both prospectively and retrospectively, that emotional neglect and abuse predict BPD symptoms and diagnosis in line with or in excess of the impact that can be observed to be associated with physical and sexual abuse. The risk associated with emotional neglect and abuse is at least comparable with that of physical and sexual maltreatment (see, e.g., Tyrka et al., 2009). In line with our views, we feel this observation to be critically important because we expect that even in the absence of dramatic maltreatment, the individual's competence to represent mental states may be undermined by the absence of contingent responding to their subjective experience, resulting in increased vulnerability for BPD.

Disruptions of the Caregiving Environment and the Development of Mentalizing

Many studies support the suggestion that secure children are better than insecure children at mentalization tasks (see, e.g., de Rosnay & Harris, 2002). The first of these findings, reported from the London Parent–Child Project (Fonagy, Steele, Steele, & Holder, 1997), found that 82% of children who were secure with their mother in the Strange Situation test passed Harris's Belief-Desire Reasoning Task at 5.5 years, compared with 50% of those who were avoidant and 33% of the small number who were preoccupied. As we will show in more detail below, findings along these lines are not always consistent (see, e.g., Meins et al., 2002), but it generally seems that secure attachment and mentalization are subject to similar social influences.

Before reviewing the relevant research, it is, first of all, necessary to identify what it is about emotional abuse and neglect that may leave the child with this increased vulnerability to BPD. We (Fonagy & Luyten, 2009) have stressed the importance of secure attachment in providing a context in which the child is allowed to develop the ability to mentalize and regulate his or her own emotions. Clearly, in an environment that is invalidating and emotionally abusive, an insecure and disorganized attachment pattern is likely to develop (Fonagy, 2000; Fonagy & Luyten, 2009). We contend that it is the absence of this safe base from which to learn the capacity to mentalize and self-regulate that can create a greater vulnerability for developing BPD later in life. In this section we examine the relationship between the emotional environment, the obstruction of acquisition of general mentalizing abilities, and the emergence of BPD. More specific mentalizing impairments in relation to BPD will be discussed further on.

Emotional dysregulation (Gratz et al., 2008), schema modes (particularly disconnection/rejection and impaired limits) (Specht et al., 2009), and distorted self-representation in middle childhood (Carlson et al., 2009) have all been shown to mediate the relationship between childhood abuse and BPD. However, these studies used a composite score of maltreatment rather than looking more specifically at particular aspects of emotional abuse and/or neglect. Rogosch and Cicchetti (2005) found that attentional networks and processes did not mediate the precursors to BPD in abused children. The formation of schemas and the representation of the self, often conspicuously impoverished in individuals with BPD, are themselves mediated by selective disruption of social cognition (Carlson et al., 2009). These studies point to the importance of these key psychological processes in mediating the impact that the experience of trauma in childhood has on the development of BPD symptoms in later life. More work is needed in this area, but the available research suggests that the key psychological processes that make the impact of trauma on personality development so harmful and enduring relate to the emergence of the concept of self and identity.

Significantly, Widom et al. (2009) found that the impact of child abuse and neglect (all types) became nonsignificant in a regression model when other family and lifestyle characteristics were included (e.g., parental substance use, employment, education level, and Axis I disorders); these authors concluded that maltreatment may represent a marker for family dysfunction, and that it is this family dysfunction that may actually be more significant in leading to a greater risk of BPD. This is also congruent with the notion that abuse and neglect are typically part of a broader context characteristic of risky families and environments (Repetti et al., 2002) or pathogenic relational environments (Cicchetti & Toth, 2005). A number of family-related factors—all likely to undermine the acquisition of mentalizing—were reported to be significant predictors of BPD: these included parental psychopathology (Afifi et al., 2011; Helgeland & Torgersen, 2004; Widom et al., 2009; Zanarini et al., 2006), witnessing domestic violence in childhood (Afifi et al., 2011; Zanarini et al., 2006), and parental imprisonment and suicide attempts (Afifi et al., 2011). As noted, early neglect seems to be particularly pernicious in predicting strong associations with BPD symptoms in both men and women (Carlson et al., 2009; Crawford et al., 2009; Johnson, Cohen, Chen,

et al., 2006; Johnson, McGue, & Iacono, 2009; Widom et al., 2009).

However, more detailed prospective studies of caregiver–child interactions are needed to further investigate these assumptions. Existing studies in this context (Carlson et al., 2009; Lyons-Ruth, 2008) do suggest that parenting behavior is implicated in the development of BPD, but also show that anomalous development is often predicted by quite subtle anomalies of caregiver–child interaction. Yet, the demanding coding methods used in these studies create challenges for replication, particularly for population-representative studies. With increasing interest in the diagnosis, a number of ongoing and planned birth cohort studies and other longitudinal studies include BPD as an outcome. The measures of environmental influence in these studies often remain fairly broad, however, and able to detect only the crudest indicators of suboptimal childhood experience. Nevertheless, growing up in an environment of insecure and unpredictable attachment relationships may be expected to disrupt the acquisition of robust mentalization.

Maltreatment thus not only disorganizes the attachment system (see Cyr, Euser, Bakermans-Kranenburg, & Van IJzendoorn, 2010 for a comprehensive review), there is also evidence to suggest that it may disrupt mentalization. An accumulating body of evidence indicates that childhood maltreatment can have a negative impact on several aspects of social-cognitive competencies in individuals who are not yet explicitly diagnosed with a mental disorder (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003; Pears & Fisher, 2005; Smith & Walden, 1999). Young maltreated children display impairments with regard to several indices of mentalizing: (1) they engage in less symbolic and less child-initiated dyadic play (Alessandri, 1991; Valentino, Cicchetti, Toth, & Rogosch, 2011); (2) they sometimes fail to show empathy when witnessing distress in other children (Klimes-Dougan & Kistner, 1990); (3) they have poor affect regulation, which contributes to later psychopathology and peer rejection (Kim & Cicchetti, 2010; Maughan & Cicchetti, 2002; Robinson et al., 2009); importantly, (4) they make fewer references to their internal states (Shipman & Zeman, 1999); and (5) they struggle to understand emotional expressions, particularly facial expressions (During & McMahon, 1991), even when verbal IQ is controlled for (Camras et al., 1990; Shenk, Putnam, & Noll, 2013). These latter findings are probably a consequence of altered functioning of neural systems associated with the processing of facial emotion (Curtis & Cicchetti, 2011; McCrory et al., 2013). Specifically, maltreated children tend to misattribute anger (Camras, Sachs-Alter, & Ribordy, 1996) and show elevated event-related potentials in response to angry faces (Cicchetti & Curtis, 2005). Findings concerning significant developmental delay in the emotional understanding of maltreated young children are quite consistent (Pears & Fisher, 2005), if somewhat reduced, when IQ and socioeconomic status are controlled for (Smith & Walden, 1999).[4] Understanding sad and angry emotions at age 6 predicts social competence and social isolation at age 8 (Rogosch, Cicchetti, & Aber, 1995). There have also been reports of delayed ToM understanding in maltreated children (Cicchetti et al., 2003; Pears & Fisher, 2005), and studies suggest that the capacity to parse complex and emotionally charged representations of the parent and of the self may even deteriorate with development (Toth, Cicchetti, Macfie, Maughan, & VanMeenen, 2000). Stein, Fonagy, Wheat, Kipp, and Gerber (2004), testing a heterogeneous sample, showed that mentalizing, as measured by the AAI Reflective Functioning (RF) Scale, fully accounted for the relationship between childhood maltreatment and impairment in adult romantic relationships. Similarly, Taubner and Curth (2013) showed the RF Scale to fully mediate the relationship between experiences of abuse and aggressive behavior in 97 adolescents aged between 15 and 18 years. Chiesa and Fonagy (2014), in a study of 234 individuals drawn from a clinical PD group ($n = 112$) and one demographically matched nonpsychiatric group ($n = 122$) using a shared battery of measures, which included the SCID-II, the Symptom Checklist-90-R and the AAI (used to assess RF levels), found RF to be a mediator between childhood adversity, PD, and symptom distress. A comprehensive systematic review (Macintosh, 2013) identified five studies (Bouchard et al., 2008; Fonagy & Bateman, 2006b; Fossati et al., 2009; Fossati, Feeney, Maffei, & Borroni, 2011; Stein & Allen, 2007) providing support for the assumption that mentalizing mediates the relationship between attachment or adversity and adult functioning. However, more research is clearly needed in this area.

We will review the evidence for impairments in different aspects of mentalizing in detail. It is sufficient here to say, however, that evidence that directly connects maltreatment, trauma, and mentalizing capacities in BPD patients is also still relatively limited. Yet, importantly, BPD patients have been found to exhibit high levels of alexithymia (i.e., impairments in mentalizing with regard to the self) and have difficulty in describing their affect in

[4]The appropriateness of controlling for IQ is not entirely clear given that IQ itself will also reflect social and emotional deprivation (see, e.g., Crandell & Hobson, 1999).

social situations (New et al., 2012), both of which have been related to trauma. In samples where the majority of patients report early trauma, patients manifest amygdala hyperreactivity in response to social stimuli combined with blunted subjective appraisal of these stimuli (Hazlett et al., 2012; Minzenberg, Fan, New, Tang, & Siever, 2007). Ghiassi et al. (2010) reported more impaired cognitive ToM performance on the Happe Cartoon Picture Story Task in BPD patients with lower self-reported parental care during childhood, frequent maternal punishments, and lengthy periods of separation. PTSD intrusions and sexual trauma have been shown to be negatively related to performance on the Movie for the Assessment of Social Cognition (MASC; Preissler et al., 2010). Furthermore, 58% of patients in this study reported sexual assault by a known assailant, which was associated with further impairment in mental state attributions. Only around half of these patients had a comorbid diagnosis of PTSD, suggesting that trauma, rather than PTSD, was responsible for the impairment in mentalizing. Dyck et al. (2009) provided tentative data that traumatized patients with BPD were most likely to show dysfunctional emotion recognition. Dziobek et al. (2011) showed that there was less activation in the superior temporal sulcus and superior temporal gyrus (STS/STG)—brain areas involved in mentalizing (see below)—in BPD patients with increased levels of intrusive traumatic memories.

Indirect support was also provided by a longitudinal study of 1,100 twins in the United Kingdom, showing that extreme scores on borderline symptoms in early adolescence were predicted by poor ToM scores at age 5, independently of IQ, and by early behavioral and affective indicators of mental health problems specifically in families characterized by a history of mental ill health (Belsky et al., 2012).

Considered in relation to attachment, mentalizing deficits associated with childhood maltreatment may be a form of decoupling, inhibition, or even a phobic reaction to mentalizing: (1) adversity may undermine cognitive development in general (Cicchetti, Rogosch, & Toth, 2000; Crandell & Hobson, 1999; Stacks, Beeghly, Partridge, & Dexter, 2011); (2) mentalizing problems may reflect arousal problems associated with exposure to chronic stress (see Cicchetti & Walker, 2001); and (3) the child may avoid mentalizing to avoid perceiving the abuser's hostile and malevolent thoughts and feelings about him or her (e.g., Fonagy, 1991; Goodman, Quas, & Ogle, 2010). These are all potential problems that will have a significant negative impact on a child's psychological, emotional, social, and educational development.

Maltreatment can contribute to an acquired partial mind-blindness by compromising open, reflective communication between parent and child. Maltreatment may undermine the benefit derived from learning about the links between internal states and actions in attachment relationships (e.g., the child may be told that he or she deserves, wants, or even enjoys the abuse to which he or she is being subjected). This is more likely to be harmful if the maltreatment is being perpetrated by a family member. Even in cases when maltreatment is taking place outside the home, the parents' ignorance of it may invalidate the child's communications with the parents about his or her feelings. In such a situation the child finds that reflective discourse does not correspond to his or her feelings, a consistent misunderstanding that could reduce the child's ability to understand and mentalize verbal explanations of other people's actions. In such circumstances, the child is likely to struggle to detect the mental states behind actions, and will tend to see these actions as inevitable rather than intended.

Taken together, these speculations clearly imply that the foundations of subjective selfhood will be less robustly established in those who have experienced early neglect. Such individuals will find it more difficult to learn about how subjective experiences inevitably vary between people. As we have seen, in some longitudinal investigations, low parental affection or nurturing in early childhood appears to be more strongly associated with elevated risk for borderline, antisocial, paranoid, and schizotypal PDs than physical or sexual abuse in adolescence (Afifi et al., 2011; Gao, Raine, Chan, Venables, & Mednick, 2010; Hengartner, Ajdacic-Gross, Rodgers, Muller, & Rossler, 2013; Johnson, Cohen, Kasen, Ehrensaft, & Crawford, 2006; Powers, Thomas, Ressler, & Bradley, 2011; Tyrka et al., 2009; Widom et al., 2009), pointing to the importance of neglect, low parental involvement, and emotional maltreatment. But this is just part of the picture.

There is an emerging view that apparent impairment of cognition as a consequence of early adversity could be more appropriately seen as a tendency favored by natural selection for development to optimize the child's adaptation to his or her social context, even given the challenges posed by the social context (Blair & Raver, 2012; Frankenhuis & Panchanathan, 2011). The anomalies of mentalization associated with adversity reviewed above can as readily be considered to be an atypical specialization as an impairment (Frankenhuis et al., 2013). We have previously suggested that there is likely to be a considerable cost to children contemplating the mental state of adults who hold malevolent and hostile intentions toward

them; in such circumstances it may be preferable to forgo reflective considerations, particularly of the cognitions of others (Fonagy, 1991). This speculation is consistent with an evolutionary-developmental view that suggests that we have to study the likely impact for survival and the costs and benefits (to children) of developing particular mental capacities in particular social contexts (Belsky, 2012; Ellis et al., 2012). Here, we want to emphasize the idea of a common final pathway: all these types of adversity seem to cause impairments in mentalizing that may bring benefit to the child under some social conditions, but in normal adult contexts tend to render the individual more vulnerable—even in the face of social adversity in adulthood. The precise nature of these impairments largely depends on the way individuals initially attempt to deal with experiences, which becomes increasingly generalized: they tend to use either predominantly attachment hyperactivating strategies, predominantly attachment deactivating strategies, or, in more severe cases, attachment disorganization, a combination of hyperactivating and deactivating strategies. Studies reviewed earlier show that the first and third strategies are most often used by BPD patients, and that attachment deactivating strategies are used not only in the context of disorganized attachment but also by most BPD patients in certain interpersonally challenging circumstances. In the next section, we review these strategies and their influence on mentalizing in more detail.

SECONDARY ATTACHMENT STRATEGIES, MENTALIZING, AND THE NEUROBIOLOGY OF BPD

Neurobiology of Stress, Attachment, and Mentalizing

Having summarized the emergence of mentalizing impairments in the course of development, we are in a better position to understand the specific mentalizing impairments of BPD patients. Beyond a general impact of attachment disruptions on mentalizing, secondary attachment strategies have a more specific influence on mentalizing in BPD and may explain individual differences in the expression of BPD and specific mentalizing profiles, in accordance with the evidence reviewed earlier in this chapter that BPD is markedly heterogeneous with respect to attachment status and mentalizing impairments. We argue that recent neuroscientific findings may further help us understand the intrinsic relationships among attachment experiences, mentalizing, and affect regulation.

Earlier formulations (e.g., Fonagy & Bateman, 2006b; Fonagy & Target, 2006) proposed that, at extreme levels, the activation of the attachment system is associated with a deactivation of mentalizing along with other emotion-induced cognitive dysfunction (e.g., Krause-Utz et al., 2012). Following the model outlined by Arnsten and colleagues (Arnsten, Mathew, Ubriani, Taylor, & Li, 1999) and Mayes (2000, 2006), we now suggest that with increased arousal there is a switch from cortical to subcortical systems, from controlled to automatic mentalizing, and, subsequently, to nonmentalizing modes (see Figure 17.2), with first evidence showing that activation in the neural network underpinning mental state decoding is reduced as a result of exposure to attachment-related stress (Nolte et al., 2013).

Two points are critical for understanding impairments in mentalizing in this context. First, owing to the neurochemical switch associated with escalating levels of emotional stress, patterns of brain functioning can shift from flexibility to automaticity: that is, from relatively slow executive functions mediated by the prefrontal cortex (PFC) to faster habitual behaviors mediated by posterior cortical (e.g., parietal) and subcortical (e.g., amygdala, hippocampus, and striatum) structures. At the same time, mentalizing seems to disappear as self-protective physical reactions (i.e., fight–flight–freeze) begin to dominate behavior. This has the presumed evolutionary value of promoting immediate adaptive responses to danger. In situations of interpersonal stress, however, where complex cognitive-emotional functioning (i.e., mentalizing) may be helpful, the loss of mentalizing may be a significant inconvenience, to say the least. Thus, the degree of arousal generated by interpersonal situations is critical. More generally, there will be situational variations when social stress triggers the threshold for switching from executive (mentalizing) to automatic (fight–flight–freeze) responding. We also assume, following Arnsten et al. (1999), Mayes (2000), and Nolte et al. (2013), that the threshold for switching can be lowered as a result of exposure to early stress and trauma of the type that has been documented for BPD patients, as described earlier in this chapter.

Second, both situational and more stable within-person variations play a role in the switch from more controlled to automatic mentalizing. This may also be a domain in which genetic as well as developmental influences make themselves felt. In particular, research suggests that in BPD, stress regulation, mediated by the hypothalamic–pituitary–adrenal (HPA) axis, is disturbed (Jogems-Kosterman, de Knijff, Kusters, & van Hoof, 2007; Nater et al., 2010; Scott, Levy, & Granger, 2013; Wingenfeld, Spitzer, Rullkotter, & Lowe, 2010). Functional magnetic resonance imaging (fMRI) studies of BPD patients in which the background

level of stress and/or attachment system activation was manipulated (e.g., Minzenberg et al., 2007) confirm the abnormal pattern of frontal deactivation and associated hyperresponsiveness of the limbic system in a range of contexts, using situational induced stress (Kraus et al., 2010) and in studies of the moderating influence of trait arousal (Holtmann et al., 2013; see reviews by Mier et al., 2013; Salavert et al., 2011). For example, Silbersweig et al. (2007) reported that under conditions of negative emotion and behavioral inhibition, BPD patients showed relatively decreased ventromedial PFC (vmPFC) activity, including medial orbitofrontal and subgenual anterior cingulate cortex (ACC), and increased amygdalar–ventral striatal activity correlating with decreased constraint. Further, findings with implications for the function of the HPA axis have confirmed that BPD patients with an explicit trauma history show a reduction in pituitary size (Garner et al., 2007), elevated levels of corticotropin-releasing hormone in cerebrospinal fluid (Lee, Geracioti, Kasckow, & Coccaro, 2005), dysfunctions of cortisol responsivity (Jogems-Kosterman et al., 2007; Minzenberg, Grossman, et al., 2006; Walter et al., 2008), and disturbed dexamethasone suppression test responses (Wingenfeld et al., 2007).

Although these studies require further replication in view of several methodological limitations, including small sample sizes, disparate experimental paradigms, and considerable heterogeneity in sample selection (e.g., comorbidity with depression, childhood abuse, PTSD and coping styles; Fertuck et al., 2006; Kahl et al., 2006), research to date has provided considerable evidence that the activation and deactivation of the attachment system is closely linked to arousal and stress regulation (Heinrichs & Domes, 2008; Lieberman, 2007; Mayes, 2006). Studies on rodent models and neuroimaging studies have shown that the activation of the attachment system underpinning both caregiving and partner preference is associated with the activation of two related systems that have consistently been shown to play an important role in promoting and maintaining attachment behavior: (1) the dopaminergic reward-processing system (Champagne et al., 2004; Strathearn, Li, Fonagy, & Montague, 2008); and (2) the oxytocinergic system (Levine, Zagoory-Sharon, Feldman, & Weller, 2007; Prossin, Love, Koeppe, Zubieta, & Silk, 2010). The functioning of the oxytocinergic system provides an obvious account for the replicated association between attachment security and the developmental acquisition of mentalizing competencies (Heinrichs, von Dawans, & Domes, 2009). Vasopressin may play an analogous role, perhaps especially in males (Atzil, Hendler, Zagoory-Sharon, Winetraub, & Feldman, 2012; Caldwell, Lee, Macbeth, & Young, 2008; Gouin et al., 2012; Young & Hammock, 2007). Oxytocin facilitates empathic facial recognition and in-group trust (Bakermans-Kranenburg & van IJzendoorn, 2013), it increases perceived salience of social cues (Shamay-Tsoory et al., 2009), and it improves empathic accuracy in less socially proficient individuals (Bartz et al., 2010), including improving altruistic behavior in individuals with relatively higher right frontal activity (Huffmeijer, Alink, Tops, Bakermans-Kranenburg, & van IJzendoorn, 2012) (the emotional empathic approach recruits mainly left frontal areas). By enhancing activity in the insula and inferior frontal gyrus, it improves understanding of others' emotions, and it reduces anxiety by decreasing amygdalar activity, facilitating contingent responses of help and compassion (Bakermans-Kranenburg & van IJzendoorn, 2013).

Yet the effects of oxytocin are influenced by situational and interindividual differences (Bartz, Zaki, Bolger, & Ochsner, 2011). Research suggests that attachment history moderates the effects of oxytocin as well as the setting of the switch that turns the mentalizing system from planned, controlled, and organized cognition to automatic processing with narrowed, poorly sustained attention, and increased vigilance for attachment disruptions such as rejection and abandonment (Cullen et al., 2011; Kamphausen et al., 2013). For example, Gillath, Bunge, Shaver, Wendelken, and Mikulincer (2005) reported an fMRI study of women with high and low scores on attachment anxiety and avoidance who were asked to either think about or stop thinking about various relationship scenarios. When thinking about negative scenarios, women with high levels of attachment anxiety showed more activation in the hippocampus (a brain region associated with memory retrieval), anterior temporal pole, and dorsal ACC (dACC) (emotion-related regions), and less activation in the orbitofrontal cortex. It seems that in contemplating negative scenarios, individuals with an anxious attachment style may under-recruit areas of the brain associated with emotion regulation, and show enhanced retrieval of negative memories. In a prospective study, Strathearn and colleagues (Strathearn, Fonagy, Amico, & Montague, 2009; Strathearn et al., 2008) examined whether differences in the attachment security of 30 first-time mothers, assessed using the AAI before the birth of their child, were related to brain reward and peripheral oxytocin responses to infant cues. Approximately 10 months after the birth of the child, mothers viewed images of either their own infant's smiling and crying face or smiling/crying faces of other infants, while being fMRI scanned. Securely attached mothers showed greater activation of brain reward regions,

including the ventral striatum, and the oxytocin-associated hypothalamus/pituitary region. The mothers' peripheral oxytocin response during infant contact was also significantly higher in securely attached mothers, and the size of change from baseline oxytocin levels was positively correlated with brain activation in response to the mothers' own infants in both regions. Important differences based on attachment history emerged when the mothers viewed their infants' crying faces: securely attached mothers continued to show greater activation in reward-processing regions, while insecure/dismissing mothers showed deactivation of the reward system and insular activation, congruent with findings described earlier. Activation of the insula may be associated with feelings of unfairness, pain, and disgust (see review by Montague & Lohrenz, 2007). Mothers with insecure/dismissing attachment histories appeared less able to down-regulate the sad feelings evoked in them by their infant's crying faces, possibly because they felt overwhelmed by sad memories of their own past. These findings suggest that for securely attached mothers, infant cues (whether positive or negative in affect) may act as an important affective signal of incentive salience (Berridge, 2007), reinforcing and motivating responsive maternal care. However, insecurely attached mothers may experience a negative subjective reaction that would make them reflect (mirror) their infant's sadness without being able to create a symbolic/mentalizing distance between their infant's state of mind and their own.[5]

The finding of reduced reward activation in mothers with insecure/dismissing attachment is also consistent with a study of responses to smiling adult faces and positive task feedback (Enzi et al., 2013; Vrticka, Andersson, Grandjean, Sander, & Vuilleumier, 2008). This study reported a negative correlation between dismissing attachment scores and activation of the ventral striatum. This is congruent with the typical distant and detached relational style of avoidant individuals, and their tendency to deny the importance of attachment relationships. In both studies, challenges to the attachment system yielded greater ventral striatal activation in securely attached individuals, while in avoidant/dismissing individuals it was associated with a relative down-regulation of reward-related activity.

[5]The phenomenon of insecure mothers experiencing and therefore perhaps mirroring their infant directly, rather than in a marked (nearly, but clearly not, the same) manner, may be one of the mechanisms behind the intergenerational transmission of patterns of attachment (van IJzendoorn & Bakermans-Kranenburg, 1997).

Consistent with the above claims about the complementary activation of the attachment and mentalizing systems, in the study of Vrticka et al. (2008), avoidant attachment was positively correlated with activation in the medial PFC (mPFC) and the ventral ACC—areas that have been implicated in controlled social cognition and mentalization, social rejection, and emotion suppression. Moreover, Vrticka et al. (2008) reported that secure attachment was positively correlated with activation of the ventral striatum in response to positive reinforcement, but negatively related to activation of the amygdala in response to negative reinforcement (Hazlett et al., 2012). This is in line with our previous suggestions that secure attachment requires the simultaneous (and paradoxical) activation of components that are normally reciprocally activated—mentalizing and reward salience-associated regions of the brain (Fonagy & Bateman, 2006b). These observations are also congruent with the assumption that secure attachment consists of a combination of low anxiety and low avoidance.

Importantly, these findings also suggest that we can expect to see differences in the quality of mentalizing depending on the quality of the relationship within which this aspect of interpersonal cognition is observed (Allen et al., 2008). This is congruent with the view that internal working models of attachment relationships may be to a large extent relationship-specific (Fraley, 2007; Overall, Fletcher, & Friesen, 2003), as evidenced by substantial within-person variation in internal working models of attachment (e.g., father vs. mother; see, e.g., Fraley, 2007; Pierce & Lydon, 2001). Similarly, mentalizing capacities are not invariant across different relationships. This assumption is also borne out by findings that general and relationship-specific mentalization, although overlapping, can be distinguished (Happé & Frith, 1996; Humfress, O'Connor, Slaughter, Target, & Fonagy, 2002; O'Connor & Hirsch, 2001). Further, key aspects of mentalizing, such as feelings of trust and fairness, are relationship-specific (Bugental & Johnston, 2000; Fiddick & Cummins, 2007). Perhaps the best evidence for the relationship-specific nature of mentalizing comes from studies on parental mentalizing (for a review, see Sharp & Fonagy, 2008), showing distinct features of mentalizing with regard to one's infant (Luyten, Mayes, Nijssens, & Fonagy, 2015; Rutherford, Goldberg, Luyten, Bridgett, & Mayes, 2013; Slade, 2005), and from studies suggesting interactions among therapist levels of mentalizing and mentalizing capacities in patients (Diamond, Stovall-McClough, Clarkin, & Levy, 2003; Diamond & Yeomans, 2008; Prunetti et al., 2008; Vermote et al., 2009).

Secondary Attachment Strategies and Mentalizing

On the basis of these and other findings, we thus propose that a combination of characteristics strongly associated with attachment history is likely to determine whether an individual switches in a particular context from more controlled, reflective to automatic mentalization (Figure 17.2; see Fonagy & Luyten, 2009; Luyten, Fonagy, Lowyck, et al., 2012, for a detailed discussion).

Studies reviewed suggest that *anxious-preoccupied attachment strategies*, which are, as noted, characteristic of many BPD patients, are associated with simultaneously lowered thresholds for attachment system activation and controlled mentalizing deactivation. Thus, more automatic, subcortical systems, including the amygdala, have a low threshold for responding to stress in BPD patients. This could offer a comprehensive explanation for one of the central dynamic features of BPD patients, that is, their tendency to form attachments easily and quickly, often resulting in many disappointments. This pattern would be due to their low threshold for activation of the attachment system and their low threshold for deactivation of neural systems associated with controlled social cognition, including systems involved in judging the trustworthiness of others (Fonagy & Bateman, 2006b). The vicious interpersonal cycles that are so characteristic of many BPD patients can thus be understood in terms of excitatory feedback loops leading to increased vigilance for stress-related cues in anxious attachment, particularly attachment characterized by high anxiety and high avoidance (Mikulincer & Shaver, 2007). These cycles are also related to BPD patients' hypervigilance concerning emotional states in others and their failure to deactivate their tendency to emotionally resonate with these states, which in turn feeds into their lack of self–other differentiation, setting up a likely sequence of further failures in understanding their own internal world, that of others, and the relationship between the two.

We assume that the arousal of the attachment system, beyond more general interpersonal stress-induced arousal, brings with it a general loss of mentalizing. Any trauma arouses the attachment system (in seeking for protection), and attachment trauma may do so chronically. In the situation where a child is seeking proximity to a traumatizing attachment figure as a consequence of trauma, he or she may, naturally, be further traumatized. The prolonged activation of the attachment system may be an additional problem, as the arousal of attachment may have specific inhibitory consequences for mentalizing over and above that which might be expected as a consequence of increased emotional arousal. It is therefore possible that in BPD the inhibition of mentalizing may not just be accounted for by trauma-related rapid triggering of the fight–flight system, but, more specifically, the hyperactivation of the attachment system characteristic of BPD may be a consequence of maltreatment specifically in an attachment context. Attachment theorists, in particular Mary Main and Erik Hesse, have suggested that maltreatment leads to disorganization of the child's attachment to the caregiver because of the irresolvable internal conflict created by the need for reassurance from the very person who also (perhaps by association, if the caregiver is not themselves the maltreater) generates an experience of lack of safety (Hesse & Main, 2000). Activation of the attachment system by the threat of maltreatment is followed by proximity seeking, which drives the child closer to an experience of threat, leading to further activation of the attachment system (Hesse, 2008). This conflict leaves the child with an overwhelming sense of helplessness and hopelessness and leads to what has been considered a hyperactivation of the attachment system. There is no resolution of the anxiety; looking for reassurance and protection generates more fear through the (mental) proximity of the maltreating figure. The ready triggering of the attachment system in BPD may be a residue of trauma history and manifests as both the rapidly accelerated tempo of intimacy in interpersonal relations and vulnerability to the temporary loss of mentalizing.

In contrast, in individuals with *secure attachment*, activation of the attachment system predictably involves a relaxation of normal strategies of interpersonal caution. There is good evidence that intense activation of the neurobehavioral system underpinning attachment is associated with deactivation of the arousal and affect-regulation systems (Fonagy & Luyten, 2009; Luyten, Fonagy, Lowyck, et al., 2012), as well as the deactivation of neurocognitive systems likely to generate interpersonal suspicion, that is, those systems and brain regions involved in social cognition or mentalizing, including the lateral PFC (LPFC), mPFC, lateral parietal cortex (LPAC), medial parietal cortex (MPAC), medial temporal lobe (MTL), and rostral ACC (rACC; Bartels & Zeki, 2000, 2004; Lieberman, 2007; Nolte et al., 2013; Satpute & Lieberman, 2006; Van Overwalle, 2009). For example, with increased intimacy, regions of the brain associated with reflective mentalizing will be deactivated. This is congruent with expressions in many languages that associate love with various forms of sensory handicaps, particularly blindness.

Moreover, as noted, the neuropeptides oxytocin and vasopressin play key roles in two aspects of creating attachment relationships: (1) by activating the reward/attachment system; and (2) by deactivating neurobehavioral systems that are involved in mediating social avoidance (Bartels & Zeki, 2004). For instance, oxytocin and vasopressin have been shown to inhibit aversion of both female and male rodents to infant pups, as well as promoting a number of affiliative behaviors, including caregiving behavior (Heinrichs et al., 2009; Insel & Young, 2001). Oxytocin also reduces behavioral and neuroendocrine responses to social stress, and seems to enable animals to overcome their natural avoidance of proximity and to inhibit defensive behavior, thereby facilitating approach behavior (Simeon et al., 2011). Vasopressin has primarily been implicated in male-typical social behaviors, including aggression and pair-bond formation, and mediates anxiogenic effects (Heinrichs & Domes, 2008). Thus, in the context of secure attachment, the activation of the attachment system will generate increased experience of reward, increased sensitivity to social cues, and decreased social avoidance, but also the potential for the reward to override lack of trust. This complex set of associations with social behavior may help to account for the puzzling combination of facilitative and inhibitory associations between attachment history and social cognition. For instance, in two separate imaging studies, Bartels and Zeki (2000, 2004) reported that the activation of areas mediating maternal and/or romantic attachments appeared simultaneously to suppress brain activity in several regions mediating different aspects of cognitive control, including those associated with making social judgments and mentalizing. The medial prefrontal, inferior parietal and medial temporal cortices, mainly in the right hemisphere, as well as the posterior cingulate cortex, may be part of the specialized neurocircuitry for attention and long-term memory (Cabeza & Nyberg, 2000), perhaps specifically responsible for integrating emotion and cognition (e.g., emotional encoding of episodic memories; Maddock, 1999) and subserving mood-mediated inhibition or enhancement of cognitive processing (Mayberg et al., 1999). The second set of brain areas observed to be deactivated by the activation of attachment concerns included the temporal poles, temporoparietal junction (TPJ), amygdala, and mPFC—areas consistently linked to explicit and internally focused mentalizing, including judgments of social trustworthiness, moral judgments, ToM tasks, and attention to one's own emotions.

BPD patients also tend to use *attachment deactivating strategies* in some contexts in an attempt to deal with increasing levels of arousal and affect dysregulation. Attachment deactivating strategies have been shown to keep the neural systems involved in controlled mentalization online for longer, including systems involved in judging the trustworthiness of other individuals (i.e., the pull mechanism associated with attachment; Vrticka et al., 2008). Yet, whereas securely attached individuals are able to keep the controlled mentalizing system online even in the context of increased stress, meaning that the attachment system is less likely to be triggered, the deactivating strategy of dismissive individuals is likely to fail. If securely attached individuals are those who are able to retain a relatively high activation of prefrontal areas in the presence of activation of the dopaminergic mesolimbic pathways (the attachment and reward system), then differences in mentalization between securely attached individuals and those individuals who primarily rely on attachment deactivating strategies may become apparent only under increasing stress; this seems consistent with the findings of experimental studies (Mikulincer & Shaver, 2007).

By contrast, a low threshold for the stress-induced activation of the attachment system may translate as a low threshold for overriding of distrust. In addition, we hypothesize that, if all other factors are constant, the greater an individual's use of hyperactivating strategies, the lower will be their threshold for the activation of automatic mentalizing, and thus the stronger the relationship between stress and a switch to automatic mentalizing will be (Figure 17.2; Fonagy & Luyten, 2009; Luyten, Fonagy, Lowyck, et al., 2012). Moreover, we predict that greater use of hyperactivating strategies will also be associated with an increased time to recovery of mentalizing, while secure attachment (and perhaps deactivating) strategies might be associated with relatively rapid recovery of the capacity for mentalizing (Mikulincer & Shaver, 2007), but these predictions largely remain to be investigated.

However, this model would explain why mentalizing deficits in BPD are more likely to be observed in experimental settings that trigger the attachment system, such as in studies collecting AAI narratives (e.g., Fonagy et al., 1996; Levinson & Fonagy, 2004), and also why BPD patients who mix deactivating and hyperactivating strategies, as is characteristic of *disorganized attachment*, show a tendency for both hypermentalization and failure of mentalizing. On the one hand, because attachment deactivating strategies are typically associated with minimizing and avoiding affective content, BPD patients often have a tendency for hypermentalization, that is, continuing attempts to mentalize, but without integrating cognition and affect. On the

other hand, as the use of hyperactivating strategies is associated with a decoupling of controlled mentalization, this leads to failure of mentalizing as a result of over-reliance on models of social cognition that antedate full mentalizing (Bateman & Fonagy, 2006b). Similar conclusions have been drawn from an fMRI study in BPD patients in which Thematic Apperception Test cards elicited hyperactivation of the ACC and mPFC, suggesting an overly sensitive switch between emotionally salient and neutral information processing (Schnell, Dietrich, Schnitker, Daumann, & Herpertz, 2007).

Finally, it is important to note that BPD is in some ways at the opposite end of the spectrum from *interpersonal resilience* (Gunderson & Lyons-Ruth, 2008; Higgitt & Fonagy, 1992). Understanding the association between resilience and mentalizing also provides helpful insight into BPD (Fonagy & Target, 1997). Studies suggest that the ability to continue to mentalize even when under considerable stress leads to so-called broaden and build (Fredrickson, 2001) cycles of attachment security, which reinforce feelings of secure attachment, personal agency, and affect regulation (build) and lead one to be pulled into different and more adaptive environments (broaden) (Mikulincer & Shaver, 2007). Congruent with these assumptions, studies on resilience have shown that positive attachment experiences are related to resilience in part through relationship recruiting, that is, the capacity of resilient individuals to become attached to caring others (Hauser, Allen, & Golden, 2006). Hence, high levels of mentalizing and the associated use of security-based attachment strategies when faced with stress are good candidates to explain the effect of relationship recruiting and resilience in the face of stress. In contrast, attachment hyperactivation and deactivation strategies have been shown to limit the ability to broaden and build in the face of stress. Moreover, they have also been shown to inhibit other behavioral systems that are involved in resilience, such as exploration, affiliation, and caregiving (Insel & Young, 2001; Mikulincer & Shaver, 2007; Neumann, 2008). This may also partially explain these individuals' difficulties in entering lasting relationships (including relationships with mental health care professionals) and the intergenerational transmission of borderline pathology.

To summarize, we may thus envisage three types of association between aspects of social cognition and attachment. These are created by (1) attachment relationships based upon intense romantic or maternal love; (2) attachment relationships based upon threat/fear; and (3) secure and predictable attachment relationships. Although any given attachment relationship may have features of each of these three types, they are important to distinguish, as the relationship between attachment activation and mentalizing may differ considerably depending on which feature is activated within an attachment relationship. First, mediated by dopaminergic structures of the reward system in the presence of oxytocin and vasopressin, the love-related activation of the attachment system can inhibit the neural systems that underpin the generation of negative affect. Second, threat-related activation of the attachment system (e.g., triggered by perceived threat, loss, or harm) may also evoke intense arousal and overwhelming negative affect, bringing about an activation of posterior cortical and subcortical areas and switching off frontal cortical activity, including mentalizing (Arnsten et al., 1999; Arnsten, 1998; Mayes, 2000). Third, meanwhile, a secure and predictable attachment relationship may be most effective in *preempting* threat, which possibly reduces the need for frequent activation of the attachment system.

The Multiple Vectors of Mentalizing

We are now in a better position to understand the often seemingly conflicting evidence on mentalizing in BPD, with enhanced capacities for accurate identification often matched by inferior performance in other settings. This lack of consistency has been well documented and suggested to be linked to characteristics of the interaction situation (Dinsdale & Crespi, 2013). In our view, the main reasons for these conflicting findings are that mentalizing is a multidimensional capacity, and BPD patients are characterized by specific impairments in mentalizing capacity, while other aspects of mentalizing are not impaired or are even more highly developed than in nonclinical controls. The literature on social cognition in BPD (e.g., Ripoll, Snyder, Steele, & Siever, 2013; Roepke, Vater, Preissler, Heekeren, & Dziobek, 2012; Thoma et al., 2013) is difficult to interpret without contemplating the disorder as characterized by what we have termed a specific *mentalizing profile*, and thus results of studies on social cognition in BPD depend on the participants' engagement in the task, the level of arousal the experiment evokes, and the individuals' dominant attachment strategy primed by the context of the study or experiment. Further, as mentalizing is a multicomponent capacity made up of a normally finely balanced set of complementary competencies or vectors, inadequate mentalizing can, paradoxically, manifest as superior mentalizing because dysfunction in one pole of a vector will cause the other pole to manifest in the absence

of normal moderation if the task used to assess mentalizing calls for only one of the two poles of paired competencies.

Over the years, we have come to distinguish four vectors of mentalizing: (1) cognitive–affective; (2) internal–external; (3) automatic–controlled; and (4) self–other. Here, we review research concerning impairments in these different vectors of mentalizing in BPD and the typical mentalizing profile associated with BPD (Figure 17.1). In each section, we discuss relevant research (see also Table 17.1 for a summary).

Cognitive Versus Affective Mentalizing

The most commonly made developmental and neuroscientific distinction in relation to mentalizing is between *cognitive* and *affective* content. One pertinent formalization of this distinction was suggested by Baron-Cohen and colleagues (Baron-Cohen, Golan, Chakrabarti, & Belmonte, 2008), who identified two independent processing systems that might normally be charged with parsing these categories of content: (1) the ToM mechanism (TOMM), which mediates agent-attitude proposition representations (or M-representations) such as "Mother – believes Johnny – took the cookies"; and (2) the empathizing system (TESS), which uses self-affective state proposition representations (or E-representations) such as "I am sorry – you feel hurt – by what I said." The latter are labeled self-affective state propositions because TESS is constrained always to create representations where emotion in the other is consistent with the self-affective state. Thus, it will not create "I am pleased that you are in pain" because it has to be a state that the self can generate in relation to the presumed state in the other (a constraint that may not be present in psychopaths; Blair, 2008). A phrase such as "I am pleased that you are in pain" feels wrong at many levels because the attribution of affect originates from self-experience and, as one would not feel pleased to be in pain, attributing pleasure in this connection sounds almost ungrammatical (unless one has antisocial tendencies).

In relation to affect, propositions are appropriately grounded in self-state; conversely, in relation to cognition, the assumption that just because I *assume* something to be the case, it must *be* the case is inappropriate. The logic of agent-attitude propositions separates physical reality from belief by allowing a belief to be true while at the same time being incompatible with the reality to which it links (e.g., "I believe you had bagels for breakfast" may be a true statement in relation to one's beliefs—that is, it is what I believe—but is incompatible with your having had fruit salad for breakfast, rather than bagels).

Emotion understanding and belief-desire reasoning normally interact, and only in combination do they generate genuine social understanding in what we have termed *mentalized affectivity* or the feeling of feeling (Fonagy et al., 2002; Jurist, 2005). Full mentalizing involves the integration of both *cognitive* knowledge (dominated by agent-attitude propositions) and *affective* knowledge (dominated by inferences drawn from one's own feelings, i.e., self-affective state propositions).

Agent-attitude propositions are probably subserved by several areas within the PFC, particularly cortical midline structures, while self-affective state propositions appear to be more likely to be processed by a more automatic, embodied, and lateralized system including parts of the vmPFC (Sabbagh, 2004; Shamay-Tsoory, 2009; Shamay-Tsoory & Aharon-Peretz, 2007; Shamay-Tsoory, Aharon-Peretz, & Levkovitz, 2007). The latter structure may be particularly important as TESS and TOMM representations come to be integrated, but it is currently not known how these two systems might function together to generate what we experience as empathy. Thus, ToM, from the neurobiological perspective, seems to recruit two independent (but interacting) systems, based on a neuroanatomical distinction within the mPFC. Cognitive ToM, which primarily concerns the processing of information about others' beliefs, is supported by dorsomedial PFC (dmPFC) activity. Affective ToM, which is an emotional form of mentalizing, cognitively inferring others' emotions, entails vmPFC activity. It should be noted that while this obviously overlaps with an emotion-focused empathy system, it is not the same as actually *feeling* the other's feeling (i.e., emotional empathy). Affective ToM is closer to being able to *imagine* affect (Gweon, Dodell-Feder, Bedny, & Saxe, 2012; Shamay-Tsoory, 2011).

Deficit in Understanding Beliefs. We may expect a young person to find difficulty in developing a strong capacity for processing the belief states of others if the behavior of their parent(s) is unpredictable (see, e.g., Helgeland & Torgersen, 2004). An early study by Arntz and Veen (2001) reported less complexity in BPD patients' character descriptions after watching a series of emotional and nonemotional film sequences. Veen and Arntz (2000) used short video clips from commercial movies and found that BPD patients made more extreme evaluations than controls with Cluster C PD diagnoses, but only when the themes concerned topics likely to generate emotional arousal in the patients. In a more recent study (Arntz & ten Haaf, 2012) involving evaluation of telephone discussions, BPD patients displayed more extreme evaluations compared with Cluster C

TABLE 17.1 Mentalizing Strengths and Impairments in BPD Across the Four Vectors

	BPD < comparison	BPD = comparison	BPD > comparison	
Cognitive (agent-attitude propositions)	Self-reported cognitive empathy reported lower (Harari, Shamay-Tsoory, Ravid, & Levkovitz, 2010; Ritter et al., 2011) Understanding Faux Pas test: show impaired cognitive understanding (Harari et al., 2010) Multifaceted Empathy Test: show cognitive empathy deficits, with less activation in the STS/STG regions in an fMRI study (Dziobek et al., 2008)	Happe Strange Stories Test: show no marked deficit in cognitive mentalizing (Arntz, Bernstein, Oorschot, & Schobre, 2009)	Heightened sensitivity to emotional cues (Lynch et al., 2006), especially in case of anger and fear (Domes et al., 2009; Wagner & Linehan, 1999) Superiority in attributing mental states on the basis of emotional cues (Franzen et al., 2011)	**Affective (self-affective state propositions)**
Mental interior (internally) focused	Deficits in making mental state judgments of others based on mental interiors, such as social exchange tasks (King-Casas et al., 2008; Unoka, Seres, Aspan, Bodi, & Keri, 2009) Studies of resting-state disconnectivity suggest abnormal default mode network (which has internal mentalizing as its function) connectivity in BPD (Saxe, 2006; Wolf et al., 2011)	Equal performance in Reading the Mind in the Eyes Test (Preissler et al., 2010; other studies have found BPD superiority in this area, see next column)	Stronger activation of visual processing when viewing negatively valenced pictures (Koenigsberg, Siever, et al., 2009) Hypersensitive to facial expressions (Domes et al., 2006; Lynch et al., 2006) Higher sensitivity to nonverbal communication (Frank & Hoffman, 1986; Ladisich & Feil, 1988) Better at Reading the Mind in the Eyes Test (Fertuck et al., 2009), or at least as good as clinically normal subjects (Preissler et al., 2010; Schilling et al., 2012) More likely to view characters/behaviors as negative or aggressive (Barnow et al., 2009); to have an impaired view of neutral faces in the context of anger or disgust (Daros, Zakzanis, & Ruocco, 2013); and to react with hostility to neutral social interactions (Domes et al., 2008)	**External cue focused**
Conscious, deliberate, reflective	Dramatically reduced reflective mentalizing ability in the context of attachment relationships (Fischer-Kern et al., 2010; Fonagy et al., 1996; Gullestad, Johansen, Hoglend, Karterud, & Wilberg, 2013) Poorer results in the MASC test (Preissler et al., 2010; Ritter et al., 2011; Sharp et al., 2011)	Able to perform experimental mentalizing tasks relatively well under low arousal (Arntz et al., 2009)	Superiority in inferring others' intentions (Ladisich & Feil, 1988) Better at perceiving and responding to small social cues relating to fairness (Franzen et al., 2011) Self-report tests: BPD patients more able to predict others' self-ratings (Ladisich & Feil, 1988)	**Implicit, automatic, nonconscious, immediate**
Relies on explicit mental state attributions to other, (inhibits shared representation); relies on mental state attribution system in empathy tasks	Severe impairment in ability to differentiate self from other (Barnow et al., 2005; Bender & Skodol, 2007; Blatt & Auerbach, 1988; Fuchs, 2007) Mental state attribution system, which relies on symbolic, abstract processing of others' mental states, is impaired (Fonagy & Luyten, 2009; Ripoll et al., 2013) Decreased activity in superior temporal sulcus during deliberate empathic processing (Dziobek et al., 2011; Mier et al., 2013) Decreased activation of medial prefrontal cortex during regulation of aggression (New et al., 2009) Hyperactivation of the medial prefrontal cortex in response to rejection (Ruocco, Medaglia, Tinker, et al., 2010)		Greater susceptibility to emotional contagion, overwhelmed by others' affect (Fonagy & Luyten, 2009; Ripoll et al., 2013) Hyperreactive response to both positive and negative emotional stimuli in the amygdala (Hazlett et al., 2012; Minzenberg et al., 2007), and when attempting to regulate responses to negative cues (Koenigsberg, Fan, et al., 2009) Anterior insula more aroused in affective empathy tasks (Dziobek et al., 2011) Higher conflation of bodily experiences (Allen et al., 2008) Difficulty in decoupling their representations of others from self-representations (Bender & Skodol, 2007)	**Relies on shared self-other representations; reliance on shared representation system in empathy tasks**

patients; Arntz and colleagues label this *multidimensional dichotomous thinking*.

The Happe Strange Stories Test revealed no marked deficit in cognitive mentalizing (Arntz et al., 2009), and another version of this higher order ToM test also showed no difference in performance on the part of BPD patients (Ghiassi et al., 2010). Yet, in this latter study, performance was associated with lower quality parental care (maternal punishment and lengthy separation) during childhood, supporting our hypothesis concerning the negative impact of an adverse early environment on the development of mentalizing. Moreover, on the Understanding Faux Pas test, in which the participant is asked to detect a social faux pas in each story they are presented with, BPD patients were shown to have impaired cognitive understanding but intact affective appreciation (Harari et al., 2010).

On self-reported empathy based on the Interpersonal Reactive Index, BPD patients have been reported to score significantly lower on cognitive empathy (Dziobek et al., 2011; Guttman & Laporte, 2000; Harari et al., 2010; New et al., 2012; Ritter et al., 2011). The more recently developed Multifaceted Empathy Test (MET) (Dziobek et al., 2008) also showed BPD patients to have cognitive empathy deficits associated (in an fMRI study) with less activation than controls in the STS/STG regions. Notably, this reduction was associated with the increased likelihood of intrusive traumatic memories. The MET consists of photographs depicting people in emotionally charged situations and is intended to produce strong emotional reactions in the subject. Thus, the test assesses cognitive empathy but under an emotional charge.

Heightened Sensitivity Toward Emotional Experience. Several studies have shown that patients with BPD respond with heightened sensitivity toward any kind of emotional cue (Lynch et al., 2006); this is particularly marked in the case of anger (Domes et al., 2009) and fear (Wagner & Linehan, 1999). There is accumulating evidence that, in the presence of emotional cues, patients with BPD may outperform nonclinical controls in attributing mental states to interaction partners (Franzen et al., 2011).

The literature on emotional intelligence in BPD is split. Some studies (Gardner, Qualter, & Tremblay, 2010; Hertel, Schutz, & Lammers, 2009) show reduced emotional intelligence. By contrast, Beblo et al. (2010) found no difference, and Park et al. (1992) claimed evidence of enhanced emotional intelligence. As the construct of emotional intelligence itself links poorly to mentalization, it may be best simply to set aside these ambiguous findings. Interestingly, increasing the cognitive load—in other words, not allowing the emotional processing to have priority over outputs and increasing the complexity of the task—removes the advantage of BPD patients and even creates apparent impairment (Dyck et al., 2009; Minzenberg, Poole, & Vinogradov, 2006b). We would argue that the impact of cognitive load on performance indicates a cognitive deficit that serves to abolish the emotional processing advantage normally experienced by BPD patients in the absence of such a load.

One hypothesis to account for emotional hyperactivity assumes a combination of amygdala overactivation and orbitofrontal cortex and PFC regulatory deficits (Domes et al., 2009). Self-reported measures of emotional empathy are sometimes (Ritter et al., 2011) but by no means always (Dziobek et al., 2011; Harari et al., 2010) shown to be lower in BPD patients. While this may seem contrary to the argument we propose here of heightened sensitivity to emotion in the absence of a cognitive counterbalance, it seems to us to be counterintuitive to expect patients with BPD to have accurate introspective capacity in relation to their functioning in the absence of adequate deliberate reflective competence, and we question, along with others (see also Dziobek et al., 2011), the validity of these self-ratings.

Mentalizing Based on Internal Versus External Features of Self and Others

The heightened sensitivity to emotional experiences in BPD seems to be intrinsically related to an increased sensitivity to external features of self and others as a source of knowledge about mental states. The focus of attention for making imaginative inferences about both our own and others' states of mind can be internal or external and, accordingly, different neural networks appear to be involved (Lieberman, 2007). The focus in mentalizing can be on one's *self* (including one's embodied experiences, i.e., embodied mentalizing) or on *others*, but ideally a balance is struck between the two. In creating mental models of mental states we can focus on *external* reactions of others (e.g., their facial expressions) or make indirect inferences based on more complex computations about their *internal* processes—that is, what they might be feeling or thinking in a given situation given what we know about their past behavior and the situation at hand.

A focus on mental interiors means directly considering thoughts, feelings, and experiences, and is accompanied by the activation of a medial frontoparietal network (Satpute & Lieberman, 2006). Converging functional imaging evidence supports the notion that the default mode network (DMN) is specifically related to self-referential activity and is only minimally involved in the processing of external stimuli (Buckner, Andrews-Hanna, & Schacter, 2008). The

DMN is a resting-state network assumed to have as one of its functions internal mentalizing detached from external stimuli (Smith et al., 2009). Focusing mentalization on exteriors—on physical and visible features or actions of one's own or another's actions—appears to recruit a more lateral frontotemporoparietal network. As the mental interior may be thought of as a second-order representation of the exterior (Fonagy et al., 2007a), the internal/external distinction applies as much to self- as to other-related mentalizing.

Problems in Internal Cue-Focused Mental State Understanding. Studies clearly suggest that BPD patients primarily show deficits in making mental state judgments when these call for a direct focus on mental interiors. For example, when King-Casas et al. (2008) asked BPD patients to engage in a neuroeconomic social exchange task, they found that these patients had difficulty in anticipating the likely impact of their actions on a partner player they had not met before. In particular, they were poor at coaxing their partner (i.e., generating a good feeling in the partner about the collaboration). These findings were replicated by Unoka, Seres, Aspan, Bodi, and Keri (2009), who showed that BPD patients transferred smaller amounts of money when playing the role of investor in a multiple-round trust game. More recently, studies of resting-state disconnectivity in BPD (Wolf et al., 2011) suggest that patients with BPD have abnormal DMN connectivity, particularly in the left frontopolar cortex (FPC) and insula; the former in particular is linked to the processing of intentional thoughts, self-referential information, and interpersonal interactions (Saxe, 2006). The FPC has been shown to exhibit abnormal levels of activation during the experience of social exclusion (Ruocco, Medaglia, Ayaz, & Chute, 2010). However, the task-independent resting-state connectivity anomaly suggests that internally directed attention in BPD patients has diminished importance. The same study revealed a correlation between increased resting-state connectivity of the insula (which has been related to the perception and monitoring of somatosensory and affective internal states) and symptoms of dissociation (Lanius et al., 2005). Taken together, the findings confirm an absence of balance and connection between internal and external experience in BPD patients.

Superiority in External Cue-Focused Mental State Understanding? Processing mental states from external cues is likely to be phylogenetically older as well as less controlled and reflective. Increased vigilance in relation to external indicators of negative attitudes may be highly adaptive in social situations of childhood, where early recognition of these indicators could help the child to avoid and even preempt threat, rejection, or brutal attack, as discussed earlier in this chapter.

We assume that, when *not* moderated by context-activated cues related to the observed person's internal state, individuals with BPD may be more accurate in mental state understanding than non-BPD controls based on external features. Koenigsberg et al. (2009) noted a stronger activation of visual processing in borderline patients, relative to healthy controls, during the processing of negatively valenced emotional pictures, which was associated with stronger amygdala activation. The weight of evidence suggests that mentalizing tasks that focus attention on external features cause fewer problems for these patients, and BPD patients have actually been found to be hypersensitive to facial expressions (e.g., Domes et al., 2008; Lynch et al., 2006; Schulze, Domes, Koppen, & Herpertz, 2013; but see Matzke, Herpertz, Berger, Fleischer, & Domes, 2014; Mier et al., 2013).

An elegant test of judging mental states by external cues is the widely used Reading the Mind in the Eyes Test (Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001). Studies have shown the performance of BPD patients to be either better than normal (Fertuck et al., 2009; Frick et al., 2012; Scott, Levy, Adams, & Stevenson, 2011 for negative emotions) or the same as healthy controls (Preissler et al., 2010; Schilling et al., 2012). Fertuck et al.'s findings echo demonstrations showing exceptional sensitivity to nonverbal (external) cues on the part of BPD patients (Frank & Hoffman, 1986; Ladisich & Feil, 1988). Further, as noted, substantial trauma may be an important moderator here: trauma has been related to hypervigilance to emotional states, but lower levels of accuracy in mental state attribution (Fertuck et al., 2009; Roepke et al., 2012).

In the *absence* of a contextual counterpoint of putative internal states, tiny behavioral cues, coupled with a general negative stance (fueled by current and past negatively valenced interpersonal interactions), are likely to lead BPD patients to identify indications of negative intentions in the actions and demeanor of others who are, in fact, neutral. As an example of this, Barnow et al. (2009) presented short silent video clips of individuals simply entering a room and sitting down. BPD patients saw the characters more negatively and as more aggressive than both MDD patients and healthy controls. If impairment of facial affect recognition is reported, it is evident primarily for neutral faces when anger or disgust is encountered (Daros et al., 2013). BPD patients also give more hostile evaluations of normal social interactions (Domes et al., 2008).

Implicit–Automatic Versus Explicit–Controlled Mentalizing

From the mentalizing perspective, BPD is characterized by an overreliance on automatic or implicit mentalizing. *Automatic* mentalizing refers to fast, parallel, reflexive processes that require little consciousness or effort, whereas *controlled* or explicit mentalizing involves more conscious, deliberate, and serial reflective processes. While different situations might call for more immediate nonreflective or more contemplative deliberate mentalizing, the overemphasis of either intuition or contemplation would clearly reflect poor-quality mentalizing in most circumstances (Frith & Frith, 2012; Lieberman, 2007; Nosek, Hawkins, & Frazier, 2011; Payne & Gawronski, 2010; Satpute & Lieberman, 2006; Uddin, Iacoboni, Lange, & Keenan, 2007).

Explicit mentalizing is typically interpreted, conscious, verbal, and reflective. It is a serial and slow process that requires attention, intention, awareness, and effort. By contrast, automatic or implicit mentalizing is perceived, nonconscious, nonverbal, and unreflective. It presumes parallel (and therefore much faster) processing, is reflexive, and requires little effort, focused attention, or intention (Satpute & Lieberman, 2006). Developmentally, nonverbally determined implicit mentalizing appears to be robust early in the second year of life (Baillargeon, Scott, & He, 2010) or perhaps earlier (Kovacs et al., 2010), while verbal recognition of another's perspective is reliable only in the fourth year (Carpendale & Lewis, 2006) or even later, perhaps after age 8 (Gweon et al., 2012). Different brain areas may be recruited for automatic and controlled mentalizing (Keysers & Gazzola, 2006, 2007). Automatic social cognition involves the amygdala, basal ganglia, vmPFC, lateral temporal cortex (LTC), and dACC—in general phylogenetically older brain circuits that rely heavily on sensory information. By contrast, controlled mentalizing recruits the LPFC, mPFC, LPAC, MPAC, MTL, and rACC, which are phylogenetically newer brain circuits involved in the processing of linguistic and symbolic material.

Deficit in Conscious, Deliberate, Reflective Mentalizing. Mentalizing in real time under realistic contextual demands requires the capacity to consciously and deliberately reflect on and make accurate attributions about the emotions, thoughts, and intentions of others, and to display an accurate and balanced appreciation of a social situation. Such a capacity has been repeatedly demonstrated to be suboptimal in BPD patients. In what was perhaps the first demonstration of the failure of reflective mentalizing in BPD, Fonagy et al. (1996) showed a dramatically reduced ability of BPD patients to reflect on their own and others' mental states in the context of attachment relationships; this deficit in RF has been shown to be reversible by psychotherapy (Levy et al., 2006). The findings on RF have been replicated by two relatively large studies (Fischer-Kern et al., 2010; Gullestad et al., 2013). A number of studies have shown BPD patients to be impaired on the MASC, which is currently probably the most valid and reliable measure of this aspect of mentalizing (Preissler et al., 2010; Ritter et al., 2011; Sharp et al., 2011). The MASC is a video-based test of mentalizing requiring participants to recognize the mental state of characters as they interact in an everyday life group scenario involving relationships. The misinterpretation of interpersonal situations because of limited reflective capacity may generate extreme and inappropriate emotions in social interactions (Dziobek et al., 2011), particularly in combination with an overemphasis on externally oriented social cognition.

Increased arousal could further disrupt the possibility of effective higher order cognitive function. Arousal has indeed been shown to increase automatic mentalizing and inhibit neural systems associated with controlled mentalizing (Lieberman, 2007; Mayes, 2006). As discussed earlier, BPD patients tend to have a lower threshold for the activation of these fight–flight arousal systems (Jogems-Kosterman et al., 2007), although this association may be more complex than it appears (Kahl et al., 2006). Abnormal stress regulation and the developmental and neurological separation of these two systems may explain how emotional arousal in BPD might on the one hand cause the loss of explicit mentalizing, but on the other hand allow for particularly accurate implicit attunement to the states of mind of individuals around them (i.e., externally based mentalizing). By the same token, individuals with BPD may be able to perform experimental mentalizing tasks relatively well under low arousal (Arntz et al., 2009), but they cannot explain the states of mind they experience under high arousal, and show confusion about such mental states because they are dominated by reflexive assumptions about the internal states of others. Unfortunately, psychotherapists of many orientations often attempt to provide mentalistic understandings for issues that trigger intense emotional reactions (e.g., challenging interpersonal situations, issues of shame, guilt, feelings of inadequacy) at a time when the patient's capacity for effective explicit mentalizing is practically inaccessible (Fonagy & Bateman, 2006a).

Superior Intuition and the Borderline Empathy Paradox. Contrary to the assumption of a general social-cognitive deficit in BPD, clinical observations (Carter & Rinsley, 1977; Krohn, 1974) had already drawn attention to an interpersonal hypersensitivity in this group of patients. This was confirmed by investigations using sensitivity to nonverbal communication cues as criteria (Frank & Hoffman, 1986). Dinsdale and Crespi (2013) reviewed 28 studies of empathic functioning in BPD in an attempt to resolve the so-called empathy paradox. They report that in about half the studies, mentalizing—assessed in terms of levels of empathy—is enhanced in BPD. They particularly note the superiority of BPD patients in tasks that call for inference of others' intentions (as in Ladisich & Feil, 1988), or perceiving and responding strategically to small social cues indicating fairness (Franzen et al., 2011). In an ingenious study, Ladisich and Feil (1988) assessed the perception of other people's feelings and personality by comparing individuals' self-ratings with personality ratings made by others (BPD patients, non-BPD patients, and psychiatrist expert raters). The ratings made by BPD patients matched self-ratings better than those of non-BPD patients, indicating higher empathy among the BPD patients, although they did not quite manage to outperform the expert raters. The experience of borderline empathy is familiar to most clinicians suddenly struck by a remarkably insightful comment by their BPD patient.

Mentalizing with Regard to Self Versus Others

Finally, what about mentalizing about the self versus others in BPD? Social-cognitive theories of BPD focus primarily on deficits in social cognition with regard to others. Yet neuroscience studies suggest surprising parallels between the developmental and brain processes underpinning how the self and others are understood in mental state terms (Lieberman, 2007; Uddin et al., 2007). From a mentalizing perspective, given the dialectic nature of the emergence of the capacity to mentalize, such an intimate connection is to be expected. This is also in line with theories suggesting that in BPD the capacity to differentiate between the self and the other is severely impaired (e.g., Barnow et al., 2005; Bender & Skodol, 2007; Blatt & Auerbach, 1988; Fuchs, 2007; Kernberg, 1975, 1984). We have argued that such identity diffusion is created by an absence of a sense of agency, which reflects a more general failure of mentalization—the continuity of our sense of self is normally ensured via our sense of a connection between intentional mental states and actions (Bolton & Hill, 1996; Fonagy, 1991).

The common brain circuitry used in mentalizing self and other may explain the difficulty of the normally developing child to acquire a sense of selfhood and may, perhaps more importantly, also explain BPD patients' struggle to free themselves from the undue influence of others' mental states. The neuroimaging literature suggests that two distinct neural networks are used in self-knowing and knowing others (Lieberman, 2007; Uddin et al., 2007), and BPD patients may show a marked imbalance between these two systems (Fonagy & Luyten, 2009). Ripoll et al. (2013) suggested distinguishing these two systems as follows: the *shared representation* (SR) system, in which empathic processing relies on shared representations of others' mental states; and the *mental state attribution* (MSA) system, which relies more on symbolic and abstract processing. This distinction overlaps with those suggested by Shamay-Tsoory (2011) and others (Dimaggio, Lysaker, Carcione, Nicolo, & Semerari, 2008; Lieberman, 2007; Lombardo, Barnes, Wheelwright, & Baron-Cohen, 2007; Uddin et al., 2007).

The SR system entails a visceral recognition of the experience of others without high-level cognitive processing, based on a similarity of neural activation while experiencing and observing others experiencing states of mind (Lombardo et al., 2010). It is assumed to be a more body-based, frontoparietal mirror-neuron system that is involved in understanding the multimodal embodied self (e.g., face and body recognition) and understanding others through motor-simulation mechanisms (Gallese, Keysers, & Rizzolatti, 2004; Rizzolatti & Craighero, 2004; Van Overwalle & Baetens, 2009). This suggests that a fundamental process allowing us to appreciate the actions and emotions of others involves the activation of the mirror neuron system for actions and the activation of visceromotor centers for the understanding of affect (Lombardo et al., 2010). This is thought to be one of the key evolutionary mechanisms underpinning social empathy—knowing from the inside, as it were, how another feels. Hence, this is an implicit, automatic system, providing physical other-to-self and self-to-other mapping, allowing the immediate understanding (but also misunderstanding, as we shall see) of self and others. SR processing is present from infancy and phylogenetically dates back to rodents. Neuroanatomically, it engages the inferior frontal gyrus, inferior parietal lobule (both of these zones are rich in mirror neurons; Bernhardt & Singer, 2012; Van Overwalle & Baetens, 2009), anterior insula, and ACC (both of which are involved in observed and felt pain). Seyfarth and Cheney (2013) argue that trust, empathy,

and sensitivity to others' emotional states develops out of a largely unconscious mimicking tendency, which we share with primates and which plays a key role in affiliative behavior (van Baaren, Holland, Kawakami, & van Knippenberg, 2004). Seyfarth and Cheney provide primate data to suggest that this subconscious, reflexive appreciation of others' intentions and experience has substantial selection advantages and potentially forms the basis of complex forms of mentalizing because natural selection favored individuals who were motivated to empathize with others. Neurochemically, it is linked to oxytocinergic functioning (Hurlemann et al., 2010). The SR system provides for motor empathy, underpins shared pain, and explains emotional contagion, as well as rudimentary recognition of intention and emotional states (Shamay-Tsoory, 2011).

While SR processing dominates early development (Decety & Michalska, 2010), because automatic mirroring inevitably generates distress in response to others' distress, a further neural development is needed to supplement it, based on a cortical midline system consisting of the vmPFC and dmPFC, the TPJ and the medial temporal pole (Lieberman, 2007; Uddin et al., 2007). This system is less bodily based, and processes information about the self and others in more abstract and symbolic ways (Frith & Frith, 2006; Uddin et al., 2007). The system also appears to be mainly shaped across development by interpersonal relationships, is phylogenetically initially found in primates, emerges fully in adolescence, and is neurochemically strongly linked to dopaminergic functioning (Lackner, Bowman, & Sabbagh, 2010). Behaviorally, this explicit MSA network underpins perspective taking and both cognitive ToM (involving the dmPFC) and affective ToM (underpinned by the activity of the vmPFC). It is important to note that cognitive inference of affect is an act of imagination that is not the same as feeling another's feelings, which SR processing entails (Gweon et al., 2012).

The SR and MSA systems may be mutually inhibitory (Brass & Haggard, 2008; Brass, Ruby, & Spengler, 2009; Brass, Schmitt, Spengler, & Gergely, 2007), which in our opinion further elucidates typical features of BPD. Neuroimaging studies indicate that the neural regions most often recruited in the inhibition of imitative behavior are those involved in explicit mental state attributions. If, as we have suggested, the MSA-based system is impaired in BPD, these individuals may experience an excessive and developmentally inappropriate activation of the SR system, leaving them with difficulties in decoupling their representation of another person's experience from their self-representations (Fonagy & Luyten, 2009; Ripoll et al., 2013), which leads to an overemphasis on others' feelings and emotions (emotional contagion) and, in turn, to confusion about the self (identity diffusion and feelings of inner emptiness), as well as an undue emphasis on externally oriented mentalizing ("jumping to conclusions") that is difficult to modulate.

Deficit in the MSA System. Decreased activity has been noted in the STS of patients with BPD during deliberate empathic processing (Dziobek et al., 2011; Mier et al., 2013). Decreased activation of the mPFC was noted during the regulation of provoked aggression (New et al., 2009), which may indicate an inadequate perspective-taking stance on the part of these patients. Similarly, a task calling for the use of psychological distancing from affective stimuli failed to demonstrate higher activation in the posterior cingulate cortex for BPD patients (Koenigsberg, Fan, et al., 2009). Dysfunction may also be indicated by hyperactivation (hypermentalizing) of the mPFC in response to an experience of rejection (Ruocco, Medaglia, Tinker, et al., 2010), an important finding, as BPD has been associated both with hypomentalizing and hypermentalizing, particularly in the context of tasks involving complex interpersonal relationships (Sharp et al., 2011).

Inappropriate Activation of the SR System. Amygdala hyperreactivity has been shown in individuals with BPD in response to both positive and negative stimuli (Hazlett et al., 2012; Mier et al., 2013; Minzenberg et al., 2007), as well as in attempts by patients to regulate their response to negative social cues (Koenigsberg, Fan, et al., 2009). Ripoll et al. (2013) cite unpublished data suggesting a lack of habituation indicated by amygdala activity associated with limitations in subjective perception of social support. The anterior insula has also been shown to be hyperreactive during affective empathy tasks. Dziobek et al. (2011) reported that during emotional empathy the right mid-insula was more strongly activated in individuals with BPD than in nonclinical controls. This anatomical region is associated with bodily arousal (Simmons et al., 2013), suggesting that an emotional empathy task engages BPD patients more than controls. In support of this speculation, a positive association between right mid-insula activation and skin conductance was shown for this patient group. One interpretation of the finding reported by King-Casas et al. (2008) is that BPD patients' mistrustful reactions to fair offers in a multi-round social exchange task were due to insula hyperreactivity.

A more complex account may be necessary to explain the fairly consistent finding that patients with BPD appear to be less responsive in terms of facial cues than nonclinical controls. For example, Herpertz et al. (2001) found

that male criminal offenders with BPD showed less facial response to emotionally arousing stimuli than normal controls. Similar observations were made by Renneberg et al. (2012) for female BPD patients watching films with both positive and negative emotional valence. Lobbestael and Arntz (2010) showed abuse-related films to BPD patients and also found reduced facial response. Finally, in a carefully conducted investigation, Staebler et al. (2011) found that BPD patients reacted with more mixed emotions in a social exclusion paradigm, but not with greater expressed affect, as may be expected. At first glance, these findings of reduced emotional expression appear to contradict the claim of overactive SR processing. However, the masking of expression on the part of these patients may be a learned response to an internally exaggerated response (see above), which, these patients have learned, is required of them to maintain adequate social interactions. The observed dissociation between internal experience (as receiver of social signals) and external expression (as sender of signals) might be a further expression of a disturbed relationship between emotional processing mechanisms (Roepke et al., 2012). Only further research including multiple measures of (physiological) arousal can shed further light on these findings, particularly as dissociations between stress channels have often been noted, suggesting marked impairments in stress regulation (Luyten, Van Houdenhove, Lemma, Target, & Fonagy, 2013).

The sharing of structures to reflect on the self and others not only implies a model for acquisition but also highlights the potential for conflating the embodied simulation of another person's experience with one's own experience. As mentioned already, despite some contrasting findings, such conflations of bodily experience often appear to occur in BPD (Allen et al., 2008). Developmentally, we tend to assume a state of egocentrism in children—that they are limited to interpreting the world from their own point of view (Piaget & Inhelder, 1948/1956). However, motor neuron findings suggest the opposite: that infants have to develop the capacity to learn what is "me" as distinguished from states of mind assumed to be shared by others. So how does the child learn to differentiate self from others?

Work by Marcel Brass and colleagues has offered a suggestion about how these two apparently independent systems that process representations of self and other may interact to create an experience of "not-me" and therefore, by extension, an experience of "me" (Brass, Derrfuss, Forstmann, & von Cramon, 2005; Brass & Haggard, 2008; Brass et al., 2007). The theoretical claim that self and other representations are shared and are the default mode of the motor system is, as we have seen, reasonably well supported. People have a tendency to mirror actions automatically. This causes interference with voluntary actions when the observed action of another is incongruent with the intended act. Studies have shown that observing an action has a powerful influence on movement execution: being shown an image of a congruent action results in the subject initiating the movement themselves more quickly, while observing an image of an incongruent action interferes with execution of the movement (e.g., Kilner, Paulignan, & Blakemore, 2003; Ramsey, Cumming, Eastough, & Edwards, 2010). For example, if participants are asked to lift their middle finger while observing the experimenter lift his or her index finger at the same time, their reaction times will be extended. Interference from incongruent observed actions appears to be particularly powerful when the observed action is seen as intentional (Bouquet, Shipley, Capa, & Marshall, 2011; Liepelt, Cramon, & Brass, 2008) and when the intent is perceived—even without the movement being performed (Liepelt et al., 2009).

Neuroimaging studies indicate that the neural regions that are most often recruited in the inhibition of such imitative behavior are the anterior frontomedial cortex (aFMC) and the TPJ area (Brass et al., 2005; Derrfuss, Brass, Neumann, & von Cramon, 2005)—in other words, the cortical areas that are also related to mentalizing, self-referential processing, and self-agency. The TPJ is involved in perspective-taking (e.g., Aichhorn, Perner, Kronbichler, Staffen, & Ladurner, 2006; Ruby & Decety, 2003), sense of agency (e.g., Decety & Grezes, 2006; Kuhn, Brass, & Haggard, 2013; Spengler, von Cramon, & Brass, 2009; Sperduti, Delaveau, Fossati, & Nadel, 2011), and mentalizing (Frith & Frith, 2006). The aFMC is involved in mentalizing (Fonagy & Luyten, 2010; Frith & Frith, 2006; Gilbert et al., 2007) and self-referential processing (Northoff et al., 2006). In fact, work by Brass's group suggests that there is a functional relationship between the extent to which an individual can inhibit imitative behavior and his or her capacity for belief-desire reasoning (Brass et al., 2007, 2009). Thus, it appears that the inhibition of imitative behavior involves cortical areas that are also related to mentalizing, self-referential processing, and determining self-agency.

In summary, knowing oneself and knowing others are two capacities clearly connected both developmentally and in terms of the brain structures subserving these processes. This applies to both symbolic and automatic ways of knowing. Congruent with the mentalizing approach, this overlap—in terms of both ontogeny and neural circuits—points to the interpersonal origins of the self, which

experiences itself and other selves as motivated by mental states (Cicchetti & Toth, 2009; Hobson, 2002; Rochat, 2009). This also sheds further light, in our opinion, on the strong impact of experiences of separation and rejection in BPD patients. These experiences become more understandable if we assume that the real or symbolic disappearance of the attachment figure is experienced as catastrophic because the individual feels exposed to a direct and unmediated experience of vulnerability to others' reactions, necessarily fragmented and impossible to differentiate from phenomenological self-experience. In such a nonmentalizing mode, the self is experienced in a psychic equivalence mode: the other and the self are experienced as being the same. The self can emerge only when it is able to know that it is *not* the other person. This leads us to a discussion of similar nonmentalizing modes of experiencing subjectivity; what happens when the capacity for (controlled) mentalizing is lost?

Reemergence of Nonmentalizing Modes in BPD

The capacity for mentalizing and the associated capacities for affect representation, affect regulation, and attentional control normally obscure forms of experiencing subjectivity that developmentally antedate the capacity for full mentalizing. These nonmentalizing modes allow us to better understand some intriguing features of BPD phenomenology and the aforementioned findings concerning BPD and the dimensions of mentalizing:

1. In the *psychic equivalence mode*, thoughts and feelings become too real and internal experience acquires the compelling power of external reality. There is a suspension of the experience of doubt, and individuals increasingly believe that their own perspective is the only one possible. This state reflects the domination of the propositional logic of emotion states (where reality is defined by self-experience) over the propositional logic of cognition (where agent-attitude propositions permit knowledge that belief is independent of reality; Baron-Cohen et al., 2008).
2. In the *teleological mode*, there is a focus on observable goal-directed behavior and objectively discernible events that may potentially constrain these goals. The individual cannot accept anything other than a modification in the realm of the physical as a true index of the intentions of the other. This reflects an extreme exterior focus in the mentalizing profile and a momentary loss of controlled, reflective, deliberate mentalizing.
3. In the *pretend mode*, thoughts and feelings become severed from reality (resulting in hypermentalizing or pseudomentalizing[6]), which, in the extreme, may lead to feelings of derealization and dissociation. As noted, these features of BPD are—in our opinion quite inappropriately given their prevalence and role (Luyten, Fonagy, Lowyck, et al., 2012; Sharp et al., 2011)—neglected in research and theoretical conceptualizations of this condition. Ideas form no bridge between inner and outer reality; the mental world is no longer fully coupled with external reality. This reflects explicit mentalizing being overridden by implicit mentalizing, such that there is excessive internal focus unchecked by references to external indicators, poor belief-desire reasoning, and vulnerability to fusion with others' identity and a tendency to become lost in the complexity of the world of beliefs and desires with which physical reality is only loosely coupled. The common consequence is hypermentalizing, where groundless inferences are made about mental states, sometimes reminiscent of confabulation. Hypermentalizing can arise because the failure to mentalize generates challenging interpersonal encounters that in turn produce stress, drawing the individual away from appropriately considering the social context. This creates schematic rudimentary models of belief states that are inappropriately enriched by poorly grounded inferences about mental states, generating further interpersonal difficulties and stress. These limitations of mentalizing generate increasingly desperate attempts to make sense of what may be occurring in the interpersonal domain.

As we mentioned earlier, the prementalizing modes are often accompanied by a pressure to externalize unmentalized alien-self parts. We assume that these discontinuities in self-experience (when the person feels aspects of their self-experience to be of themselves or their own, yet also to be alien to their self-experience) generate a sense of incongruence, which is dealt with through externalizing (or projection)—behaving toward others as though the others own the unmentalized self-experiences and on occasions being successful in generating these experiences in them (Fonagy & Target, 2000).

[6]These are related tendencies to overproduce putative beliefs and desires in relation to others and to do so without reference to available contextual information, leading to the generation of excessively detailed images of internal states that do not correspond to what is genuinely experienced as real.

ADOLESCENCE AND THE EMERGENCE OF BPD

We have thus far covered the early origins of BPD, which are most likely rooted in interactions between genetic endowment and environmental factors, but this does not explain the full picture of BPD and its origins. One important and often neglected developmental phase remains to be discussed. This neglect is indeed remarkable for several reasons. First, although most major mental disorders, including BPD, first develop in adolescence, BPD pathology in adolescence is still underdiagnosed (Laurenssen, Hutsebaut, Feenstra, Van Busschbach, & Luyten, 2013). Second, we have seen that genetic factors may come to play an important role in determining attachment in adolescence (Fearon et al., 2013). Third, adolescence is also characterized by marked changes in cognitive function and these considerably influence mentalizing capacities. Specifically, adolescence is associated with dramatic changes in social cognition: it marks the beginning of the capacity to hold in mind multiple dimensions of a concept, enabling the ability to plan and to think about the implications of one's actions; cognitive control and executive functioning are greatly increased; and self-awareness, self-consciousness, and self-reflective capacities become a central focus of adolescents' self-experience (Steinberg, 2005). Recent studies of the development of mentalizing in adolescents, for instance, have shown that the capacity of young people to adopt others' perspectives improves substantially between 12.5 and 16.5 years, yet even at age 17 it is less than adults are capable of (Dumontheil, Apperly, & Blakemore, 2010).

The mentalizing approach to adolescence essentially proposes that those adolescents who have adequate capacity for mentalizing (and linked capacities of effortful control and attention) make considerable progress in their capacity to make sense of their own mind and the complexities of relationships during this developmental stage, leading to relatively stable, and essentially positive, feelings of identity (including sexual identity) and autonomy, and the capacity to enter into stable, differentiated interpersonal relationships (Blatt & Luyten, 2009; Fonagy & Luyten, 2011). Hence, adolescence may be associated with marked changes in attachment, which may partially result from genetic factors, changes in mentalizing capacities leading the adolescent to be pulled into different (interpersonal) environments, and interactions among these factors. This is not a linear process, however, and both research and clinical practice suggest that this process, even in normal development, is essentially characterized by (1) much trial and error and (2) hypomentalizing–hypermentalizing cycles, features that are typical of the typical storm and stress of adolescence.

These assumptions are supported by findings concerning brain development in adolescence, showing (1) increased numbers of brain connections (synaptogenesis), followed by synaptic pruning, which creates more efficient brain networks; and (2) axonal myelination, increasing the efficiency of neural transmission (Blakemore, 2008, 2010; Giedd, 2004). During adolescence, the PFC, which, as noted, plays a key role in mentalizing and self-regulation, undergoes pronounced structural reorganization, with brain grey matter (indicative of new synaptic connections being made) increasing in this region up to the onset of puberty. Importantly, it then shows a rapid decrease in density, which continues throughout adolescence into early adulthood, suggesting an increasing efficiency of processing through the pruning of unused connections. Further, the changes in the superior temporal cortex, including the second major center for representing mental states, the STS, are more protracted and do not follow the pattern in the PFC of a sharp inverted U-curve; rather, grey matter in the STS steadily *declines* during adolescence and well into adulthood, reaching maturity relatively late. At the same time, improved connectivity between nerve cells is indicated by an increase in cortical white matter density from puberty, throughout adolescence, and into adulthood. Thus, early adolescence is characterized by a decrease in mentalizing capacities followed by gradual improvement throughout later phases, underpinned by neurobiological changes in the brain systems implicated in mentalizing.

In our view, this fine tuning of cortical regions involved in mentalizing underpins the dramatically changed sense of identity (self) and relationships (others) with the emergence of pubertal sexuality. Greater sensitivity to emotional states, a greater centrality of self-conscious emotions (e.g., shame, embarrassment, guilt, pride), and greater emphasis on sexuality and aggression, in particular, puts mentalizing under considerable pressure by increasing arousal; this is further reinforced by peer pressure and the challenge to de-identify with attachment figures, involving the challenge to redefine the balance between autonomy and relatedness (Blatt & Luyten, 2009). Mentalizing, thus, is biased in adolescence because of an imbalance between neural circuits subserving mentalizing and a functionally more mature limbic region. Greater self-consciousness and the resulting increased social awareness also render adolescents more aware of the importance of succeeding in social situations

and the social costs of failure. Hence, imbalances in brain development might underlie both increased sensitivity to rejection in adolescence (Davey, Yucel, & Allen, 2008) and the inability to manage the implications of this increased awareness, expressed via hypermentalizing in an attempt to make sense of these experiences, alternating with hypomentalizing as a defensive strategy to avoid thinking about the painfulness of these experiences. A similar model may be suggested in relation to the development of executive functions (Hare et al., 2008), whereby the gradual development of prefrontal cognitive control mechanisms enables increased connectivity between prefrontal and limbic regions.

Whereas adolescence thus involves considerable challenges for adolescents with normal developmental histories, adolescents with a history of poor mentalizing are at even greater risk when faced with the typical social challenges that adolescence brings. Exaggerated experience of affect and limited capacities for affect regulation because of impairments in effortful and attentional control and mentalizing seriously impair the capacity to make sense of developmental changes in one's own mind, and in one's own mind in relation to others' minds. At the extremes, this may lead to feelings of identity diffusion and extreme hypomentalizing–hypermentalizing cycles, so typical of BPD patients. In our opinion, continuing attempts to make sense of one's own mind in relation to changing demands of others (e.g., parents, teachers, peers), leading to extreme pretend mode functioning (expressed in hypermentalizing), are a core feature of adolescents who are vulnerable for BPD. This assumption is congruent with studies reporting higher levels of both identity diffusion (Goth et al., 2012; Jung, Pick, Schluter-Muller, Schmeck, & Goth, 2013; Kassin, De Castro, Arango, & Goth, 2013; Westen, Shedler, Durrett, Glass, & Martens, 2003) and hypermentalizing (Sharp et al., 2011) in adolescents with (borderline) PD features.

These features seem to be intrinsically related to problems with increased self-consciousness and particularly shame, one of the most painful self-conscious emotions (Luyten, Fontaine, & Corveleyn, 2002). Indeed, a shame-prone self-concept has been related to BPD (Rusch et al., 2007), and a recent study suggests that a shame-prone self-concept was uniquely related to borderline personality features, and identity problems in particular, in middle childhood and adolescence (Hawes, Helyer, Herlianto, & Willing, 2013). These findings are congruent with our emphasis on a disturbed sense of identity and strong feelings of inner pain (Zanarini & Frankenburg, 2007) and toxic shame (Gratz et al., 2010; Levy et al., 2007; Rusch et al., 2007) as core features of BPD. Moreover, developmentally, these features are linked with marked interpersonal hypersensitivity (Gunderson & Lyons-Ruth, 2008) in adolescence. Rejection hurts, as is also evidenced by shared neural mechanisms of physical and psychological pain (Eisenberger, Lieberman, & Williams, 2003), and it seems that BPD patients have developed a heightened sensitivity to experiences of rejection, and thus inner pain, because of their inability to make sense of the pain associated with repeated feelings of shame and rejection. In many BPD patients, this vicious cycle seems to be increased by experiences of childhood abuse and neglect (Holm & Severinsson, 2008; Hopwood & Zanarini, 2012), which have also been shown to dysregulate pain-processing mechanisms (Luyten et al., 2013). Further, increased sensitivity to pain, which is also expressed in marked comorbidity between BPD and pain disorders (McWilliams & Higgins, 2013), coexists with blunting of pain sensations in BPD patients, probably as a consequence of repeated self-harm (Magerl, Burkart, Fernandez, Schmidt, & Treede, 2012; Pavony & Lenzenweger, 2014), providing further evidence for dysregulation of pain processing mechanisms in BPD. Moreover, findings of a blunted pain response are congruent with the earlier reported paradoxical finding of impaired expression of emotions but hyperreactivity to mental states in BPD patients.

Further, sexuality and aggression create additional challenges in adolescence, as psychoanalysts have long noted (Blos, 1962; Laufer & Laufer, 1984). Sexual excitement represents a special challenge to mentalizing, as the expression of infantile sexual feelings is among those rare infant emotion expressions that—at least to a certain extent—remain unmirrored even by the most sensitive of attachment figures (Fonagy, 2008). The hormone-driven emergence of psychosexuality in adolescence subsequently creates internal psychophysical experiences for the young person for which there is no adequate second-order representation, making action and enactment the preferred route for the expression of subjective experiences that are always, to a certain extent, alien to the self. This tendency to act out these alien-self parts (i.e., unmirrored experiences) in an attempt to come to grips with sexual urges is all the more problematic for adolescents vulnerable to BPD, given their problems with mentalizing, particularly for those adolescents with a history of sexual abuse. Risky sexual behaviors in BPD starting in adolescence have been well documented (Harned, Pantalone, Ward-Ciesielski, Lynch, & Linehan, 2011; Tull, Gratz, & Weiss, 2011), but what is important in our view is that these behaviors often tend to repeat victim–perpetrator cycles as expressed in

high rates of repeated sexual revictimization (Sansone, Chu, & Wiederman, 2011). Many of these adolescents have grown up in families with little mind-mindedness, and thus they often seem to completely lack the ability to make sense of their own mind and the minds of others, which, as noted above, renders them prone to acting out subjective experiences that cannot be mentalized, leading to impulsive behavior (e.g., externalizing symptoms, sexual promiscuity, self-harm). Alcohol or drugs might be used in an attempt to cope with these painful experiences of inner emptiness, pain, and confusion, and might function as a substitute for attachment relationships. These assumptions are supported by studies suggesting high rates of both risky sexual behavior and drug use in BPD patients (Harned et al., 2011; Tull et al., 2011). As noted, from a neurobiological perspective, attachment and addiction seem to be underpinned by the same neurobiology (Insel & Young, 2001).

In adolescents with a history of trauma, and sexual trauma and/or physical abuse in particular, feelings of sexuality and aggression are likely to pose a tremendous challenge, as, when confronted with these alien-self parts, such adolescents might feel a constant pressure to externalize these feelings, either by becoming involved in relationships in which they are abused or are the abuser, or by self-harm in an attempt to eradicate the feelings, or by a combination of these. Dissociation may also ensue in an attempt to get rid of intrusive memories and extensive rumination when in a pretend mode because it "drives them crazy." Moreover, in those who have abusive experiences, the close intertwining of sexuality and aggression puts their mentalizing abilities under increasing pressure. In these adolescents, feelings of love often lead, in a psychic equivalence mode, to the expectation that they will be abused, while conversely, the only way some of these adolescents may relate to others is by dominating and abusing them. Hence, feelings of love and desire may be easily confused with, and change into, primitive feelings of envy, jealousy, and rage, as emphasized in traditional (Klein, 1975) and more contemporary (Yeomans & Diamond, 2010) object-relational accounts of BPD.

Although the evidence in this area is less clear, destructive aggression (including envy and jealousy) may thus similarly be related to experiences of being unmirrored by early attachment figures. These experiences therefore remain without an internalized representation that the adolescent could use as a handle for regulation and control. In fact, a more general failure of representing changed body-states may characterize these adolescents. This may also explain the high comorbidity between BPD and functional somatic disorders (Luyten, van Houdenhove, et al., 2012) and eating disorders (Skårderud & Fonagy, 2012), as these disorders seem to reflect a failure of the mentalization of the ordinary events and experiences of life and a consequent representation of these in terms of bodily states. Particularly in eating disorders, major (bodily) changes seem to challenge mentalizing abilities, as these changes, together with other sociocultural expectations typical of this developmental phase (particularly for girls), herald the beginning of a major redefinition of the self, and of the self in relation to others. Although still speculative, these assumptions are supported by studies suggesting low levels of embodied mentalizing in patients with functional somatic disorders (Luyten, van Houdenhove, et al., 2012) as well as in those with eating disorders (Redondo, Luyten, & Estevez, 2015).

These considerations help us to understand not only the emergence of BPD in adolescence, but also its high comorbidity—particularly in adolescence—with externalizing problems (e.g., aggressive outbursts, risky sexual behavior), feelings of depression, eating disorder problems, substance abuse, and functional somatic complaints. They may also help us to understand the intricate relationship between a disturbed sense of identity and the profound interpersonal problems that characterize BPD, as they are both related to impairments in mentalizing (Luyten & Blatt, 2013), that is, the inability to make sense of the self in relation to others (and to make sense of others in relation to the self), leading to feelings of inner pain, emptiness, toxic shame, and, in the extreme, to dissociative experiences.

IMPLICATIONS FOR INTERVENTION

The MBT Approach

General Approach

Mentalization-based treatment (MBT) was initially developed in the 1990s for the treatment of adults with BPD, although it is now being applied to a range of disorders across the life span (see Bateman & Fonagy, 2012 for a representative set of therapeutic applications). The MBT approach is closely informed by our developmental perspective on the development of the social-cognitive functions—affect regulation; attentional control; the management of the dual arousal system involved in maintaining a balance between the mental functions undertaken by the anterior and posterior portions of the brain; and the capacity to mentalize—that are so necessary for healthy

interpersonal relations. Because these social functions develop in the context of early caregiver relationships, as well as genetic vulnerabilities, they are shaped by the individual's attachment experiences and, in particular, are vulnerable to the experiences of attachment trauma connected with childhood adversity. MBT, therefore, is rooted in attachment theory. It places mentalizing, within the attachment context, at the center of the therapeutic process. It is a therapy primarily defined not by a clustering of specific and related techniques but more by the *process that is stimulated in therapy*. At its core, MBT works through establishing an enduring attachment relationship with the patient while continuously stimulating a mentalizing process in the patient. Its aim is to develop a therapeutic process in which the mind of the patient becomes the focus of treatment. The objective is for patients to find out more about how they think and feel about themselves and others, how those thoughts and feelings influence their behavior, and how distortions in understanding themselves and others lead to maladaptive actions, albeit actions intended to maintain stability and manage incomprehensible feelings (more detail on the MBT model can be found in Allen et al., 2008; Bateman & Fonagy, 2006a; Bateman & Fonagy, 2010).

The Aims of MBT and the Dimensions of Mentalizing

If we refer to the four dimensions of mentalizing described earlier in this chapter, we can see how these theoretical and neurologically based conceptualizations give shape to the practice of the MBT therapist on the ground.

The Automatic–Controlled Dimension. Mentalizing in BPD often tends to be unhelpfully automatic or implicit. It can often be perceived as quite simplistic, nonconscious, nonverbal and unreflective. The processing involved is rapid, requiring little attention or focus. The MBT therapist aims to slow down the patient's thinking, and move them to a more reflective, explicit form of mentalizing that requires more conscious, verbal attention. BPD patients are particularly likely to fall back on this automatic reliance on affective, nonreflective mentalizing at moments of intense emotional arousal (e.g., challenging interpersonal situations, feelings of shame, guilt, anger or inadequacy). Therefore, encouraging the patient to shift toward more reflective controlled form of interpersonal thinking at such moments is a critical challenge for both MBT therapist and patient.

The External–Internal Dimension. Patients with BPD tend to interpret the mental states of others on the basis of exterior cues—physical and visible features such as gestures or actions, or indeed, their own actions. The therapist, then, attempts to move the patient's focus on to mental interiors: the thoughts, feelings, history and experiences that might offer further insight into how someone behaves. This attempt at counterbalancing impression based on appearance with inference involves not only slowing patients down and encouraging them to recognize the assumptions they have made, but also to start to consider the subtleties and complexities of people's subjective experiences.

The Affective–Cognitive Dimension. Patients with BPD often over-rely upon the propositional logic of emotion in assessing subjective states, and indiscriminately apply the very particular logic of emotion to wider thoughts and beliefs. When this emotional logic is extended to cognitions in this way, the patient makes assumptions of psychic equivalence (i.e., "I am thinking this way, and thus this must be the way you are thinking too"). In such a situation, the approach of the MBT therapist would be to help the patient step back from this collapsing of appearance and reality, and draw attention to the patient's vulnerability to excessive and unreasonable certainty on the basis of relatively flimsy cues. The MBT approach works on broaching the disconnection between cognitive and emotional experience. The patient with BPD will frequently experience moments where he or she is overwhelmed by affect; the response of the MBT therapist at such times should be to help the patient integrate this intense sense of affective knowledge or awareness (whether about the self or others) with more reflective and cognitive knowledge. On the other hand, when the patient is functioning in pretend mode, he or she may display apparent cognitive understanding of mental states, but be disconnected from their emotional significance. In both cases the imbalance is indicated by the absence of doubt that cognition about emotion or belief brings to the foreground. For example, a patient might describe an overwhelming feeling of being bad inside, which may, when more carefully represented, become a more specific sadness about failures, which can then helpfully be considered while the patient is experiencing this bad feeling.

The Self–Other Dimension. The limitations of cognitive, reflective modes of understanding give excessive weight to the influence of mental states sensed in others, leaving the individual vulnerable to emotional contagion and suggestibility through others' subjective experience. This temporary disappearance of the self–other boundary is addressed by MBT through the systematic emphasis of the

absent pole of the self–other construct. When a patient starts to talk about his or her own state in a nonmentalizing way, a strategy employed in MBT practice is for the therapist to shift the patient's attention to the mental state of others. Conversely, when the patient becomes intensely concerned with someone else's mental state, the patient should be encouraged to consider how this preoccupation is affecting his or her own functioning. Working to shift the patient's thoughts and feelings between the self and the other in a consistent, flexibly responsive way that counters the patient's preoccupations is a core element of the MBT therapist's practice. It is a process that, critically, requires the therapist to recognize the patient's proneness to psychic equivalence and to consistently seek to create an awareness of the differentiation between the self and others.

Focus of MBT

In working across the four mentalizing dimensions, the basic and consistent aim of MBT is to reestablish mentalizing when it is lost, or rather to work to maintain a balanced form of mentalizing. MBT is not a therapy that claims to seek structural or personality change in the patient with BPD, or to alter their cognitions or schemas. Rather, the emphasis is on improving the patient's capacity for mentalization and to make his or her mentalizing capacities (or skills, to use the frame of dialectical behavior therapy) more stable and robust so that the patient is more able to manage affect and think about problems, particularly within interpersonal relationships. Throughout the treatment, MBT therapists are expected to focus on the patient's subjective sense of self; this requires the therapist to identify and work with the patient's mentalizing capacities at any moment, and to be able represent internal states in themselves and in their patient as these are likely to be experienced by the patient at that moment. To think of this process concretely, therapists do not interpret the patient's state of mind; rather, seeing themselves as sitting side by side with the patient, they endeavor to describe their sense of how the patient is seeing the world and, using this as the platform for further exploration, elaborate this view and its implications, gently presenting alternative perspectives once they feel confident that the patient senses that they can see the world through the patient's eyes.

This careful attention to the BPD patient's current mental state, while activating an attachment relationship through the therapist's presence in the patient's life as a significant (potentially caregiving) figure, serves to enhance the patient's mentalizing capacities, hopefully without generating the iatrogenic effects that can arise from the activation of a disorganized attachment system. To avoid the negative effects so often experienced in conventional psychodynamic treatment of BPD, the MBT approach avoids situations where patients are expected to talk about mental states that they cannot link to subjectively felt reality and instructs the therapist to moderate the affective tone of interventions to maintain a constant distance—not too arousing but arousing enough.

The Inquisitive Stance and Interventions in MBT

The MBT model involves (1) a deemphasis of deep unconscious interpretations in favor of conscious or near-conscious content; (2) a modification of therapeutic aim, especially with severely disturbed patients, from insight to recovery of mentalizing (i.e., achieving representational coherence and integration); (3) careful avoidance of descriptions of complex mental states (e.g., conflict, ambivalence, unconscious) that are incomprehensible to a person whose mentalizing is vulnerable; and (4) avoidance of extensive discussion of past trauma, except in the context of reflecting on current perceptions of the mental states of maltreating figures and changes in mental state from being a victim in the past versus one's experiences now.

To maximize the impact on the patient's ability to think about thoughts and feelings in relationship contexts, especially in the early phases of treatment, the therapist is most helpful when interventions (1) are simple and easy to understand; (2) are affect focused; (3) actively engage the patient; (4) focus on the patient's mind rather than on his or her behavior; (5) relate to a current event or activity, whatever the patient's currently felt mental reality (in working memory); and (6) make use of the therapist's mind as a model (by therapists disclosing their own anticipated reaction in response to the event being discussed, i.e., talking to the patient about how the therapist anticipates that he or she might react in that situation). This requires the therapist to flexibly adjust the complexity and emotional intensity of interventions in response to the intensity of the patient's emotional arousal. As we have noted, the MBT therapist needs to be vigilantly aware of the patient's current mentalizing capacity and how it fluctuates.

Pseudomentalizing and other fillers to replace genuine thought about thought are explicitly identified by the therapist, and the lack of practical success associated with them should be clearly highlighted. Often, the MBT therapist is required to step in to interrupt discourse that is clearly in the pretend mode, which is the most likely stance taken by an individual predisposed to hypermentalizing (Sharp et al., 2011). Only through interrupting pseudomentalizing can patients learn about how they think and feel about themselves and others, how that shapes their responses to

others, and how errors in understanding self and others may lead to inappropriate actions. Put simply, unlike other insight-oriented therapies, in MBT it is not for the therapist to tell patients about how they feel, what they think, how they should behave, or what the underlying reasons may be, conscious or unconscious, for their difficulties. Rather, the therapist uses and models the *inquisitive stance*, an interpersonal stance that fundamentally entails that the therapist does not know the mental states of the patient, but is interested to find out what the patient thinks and feels, and shows openness to being wrong (demonstrating humility) and to be positively surprised by the patient's states of mind.

From a practical standpoint, an effective mentalization-based intervention may unfold along the following lines: (1) the therapist identifies a break in mentalizing (described earlier in this chapter as psychic equivalence, pretend, or teleological modes of thought); (2) the patient and therapist rewind to the moment before the break in subjective continuity; (3) the current emotional context for the break in the session is explored by identifying the momentary affective state between the patient and therapist; (4) the therapist explicitly identifies and claims responsibility for their own contribution to the break in mentalizing; and (5) the therapist seeks to help the patient to understand the mental states implicit in the current state of the patient–therapist relationship at that moment (to mentalize the relationship).

Key to the MBT approach is the therapist's mentalizing stance (or inquisitive stance), which serves to highlight their own interest in how mental states underpin behavior, describing their own understanding and inferences (while acknowledging the opaqueness of mental states), and demonstrating how such information can help the patient to make sense of their experiences. The therapist's mentalizing therapeutic stance should include (1) humility deriving from a sense of not knowing; (2) whenever possible, taking time to identify differences in perspectives; (3) legitimizing and accepting different perspectives; (4) active questioning of the patient in relation to their experience, asking for detailed descriptions of experience ("what" questions) rather than explanations ("why" questions); and (5) eschewing the need to understand what makes no sense (i.e., saying explicitly that something is unclear). An important component of this stance, as noted, is for the therapist to monitor and own up to their own mistakes, to take their share of the responsibility for a temporary failure of communication between therapist and patient. This not only tends to lower arousal, thus increasing the likelihood of adequate mentalizing, but also offers invaluable opportunities to explore how mistakes can arise out of mistaken assumptions about opaque mental states and how misunderstanding can lead to massively aversive experiences.

In this context, it is important to be aware that the therapist is constantly at risk of losing their capacity to mentalize in the face of a nonmentalizing patient. Consequently, we consider therapists' occasional enactments as an acceptable concomitant of the therapeutic alliance, something that simply has to be acknowledged. As with other instances of breaks in mentalizing, such incidents require that the process is rewound and the incident explored. Hence, in this collaborative patient–therapist relationship the two partners have a joint responsibility to understand enactments.

Effectiveness of MBT

The evidence base for the effectiveness of the mentalization-based therapeutic approach for BPD patients has been tested in different randomized control trials (RCTs). In an RCT of MBT for BPD in a partial hospital setting (Bateman & Fonagy, 1999, 2001), significant and enduring changes in mood states and interpersonal functioning were associated with an 18-month program. Outcome measures included frequency of suicide attempts and acts of self-harm, number and duration of inpatient admissions, service utilization, and self-report measures of depression, anxiety, general symptom distress, interpersonal function, and social adjustment. The benefits, relative to treatment as usual (TAU), were large (with a number needed to treat of approximately 2), and were observed to increase during the follow-up period of 18 months. Analysis of participants' healthcare utilization suggested that day hospital treatment for BPD was no more expensive than general psychiatric care and showed considerable cost savings after treatment (Bateman & Fonagy, 2003). A follow-up study of BPD patients 5 years after all treatment was completed and 8 years after initial entry into treatment, comparing patients treated with MBT versus those receiving TAU, has found that those receiving MBT remain better than the TAU group. Superior levels of improvement were shown on levels of suicidality (23% in the MBT group vs. 74% in TAU group), diagnostic status (13% vs. 87%), service use (2 years vs. 3.5 years), and other measurements such as use of medication, global function, and vocational status (Bateman & Fonagy, 2008a).

Two well-controlled single-blind trials of outpatient MBT have been conducted with adults with BPD (Bateman & Fonagy, 2009) and adolescents presenting to clinical services with self-harm, the vast majority of whom met BPD criteria (Rossouw & Fonagy, 2012). In

both trials MBT was found to be superior to TAU in reducing self-harm, including suicidality, and depression. Importantly, in the Bateman and Fonagy trial, the control group received a manualized, highly efficacious treatment, structured clinical management, but MBT was superior, particularly in the long run (Bateman & Fonagy, 2009). Further, improvements generated by MBT in adolescents appear to have been mediated by improved levels of mentalization, reduced attachment avoidance, and assuagement in emergent BPD features: patients in the MBT group showed a recovery rate of 44% compared with 17% in the TAU group (Rossouw & Fonagy, 2012).

Three more recent studies provide further support for MBT in patients with BPD. An RCT from Denmark investigated the efficacy of MBT versus a less intensive, manualized supportive group therapy, both delivered in combination with psychoeducation and medication, in patients diagnosed with BPD (Jorgensen et al., 2013). Patients were randomly allocated to MBT ($n = 58$) or the specialist combined treatment ($n = 27$). Both the combined MBT treatment and the less intensive supportive therapy brought about significant improvements on a range of psychological and interpersonal measures (e.g., general functioning, depression, and social functioning) as well as the number of diagnostic criteria met for BPD; effect sizes were large ($d = 0.5$–2.1). The combined MBT therapy was superior to the less intensive supportive group therapy only on therapist-rated Global Assessment of Functioning. No follow-up or cost-effectiveness data are available from this study. Furthermore, the same therapists conducted both treatments (and thus there was a high risk for spillover effects between the two treatments), and incomplete data was a significant limitation.

A naturalistic study by Bales et al. (2012) in the Netherlands investigated the effectiveness of an 18-month, manualized program of MBT in 45 patients diagnosed with severe BPD. There was a high prevalence of comorbidity of Axis I and Axis II disorders. Results showed significant positive change in symptom distress, social and interpersonal functioning, and personality pathology and functioning; effect sizes were moderate to large ($d = 0.7$–1.7). Also, these authors showed that care consumption (additional treatments and psychiatric inpatient admissions) decreased significantly during and after treatment. The lack of a control group in this study limits the ability to draw conclusions about the efficacy of the MBT intervention. A multisite randomized trial by the same group comparing intensive outpatient and partial hospitalization-based MBT for patients with BPD is currently under way.

Finally, a recent naturalistic trial studied the feasibility and effectiveness of inpatient MBT for adolescents with borderline symptoms in 11 female adolescents aged 14–18 years (Laurenssen et al., 2014). Results showed significant decreases in symptoms and improvements in personality functioning and quality of life 12 months after the start of treatment, with effect sizes between $d = .58$ and 1.46, indicating medium to large effects. Further, 91% of the adolescents showed reliable change on the Brief Symptom Inventory, and 18% moved to the functional range on this measure.

Attachment, Mentalizing, and Epistemic Trust

MBT is not the only effective therapy for BPD, and a key fact associated with the disorder is that numerous coherent approaches to treatment appear to produce significant improvement (Stoffers et al., 2012). At least nine different forms of therapy have been trialed in at least 20 randomized trials with waitlist or TAU comparisons and three large head-to-head comparison studies. Although there is clearly more evidence for dialectical behavior therapy than any other therapy (Kliem, Kroger, & Kosfelder, 2010), its superiority to other methods is not apparent from head-to-head comparison studies (Clarkin, Levy, Lenzenweger, & Kernberg, 2007; McMain et al., 2009) and some effectiveness trials (Feigenbaum et al., 2012). We propose that while the mentalizing approach may be only one of the effective approaches to treatment, the theoretical understanding of BPD outlined in this chapter may provide helpful insights as to why such a wide range of technical approaches appears to produce evident improvements in the condition.

Notwithstanding incommensurate techniques, all the effective treatments seem to be characterized by three features: *consistency*, *coherence*, and *continuity*. The common factor explaining effectiveness could be linked to the constraint of these three Cs. Here, we present a recent extension of the mentalizing approach that may shed more light on putative mechanisms of change in the treatment of BPD patients.

How Do We Learn From Experience?

We now have considerable evidence that the caregiver's capacity to mentalize predicts secure attachment in the child. Studies looking at different ways caregiver mentalizing is operationalized—including prenatal reflective function (Fonagy et al., 1991), child-specific reflective function (Slade, Grienenberger, Bernbach, Levy, & Locker, 2005), mind-related comments (Meins, Fernyhough,

Fradley, & Tuckey, 2001; Meins et al., 2002), and a diverse range of other measures (Aber, Slade, Berger, Bresgi, & Kaplan, 1985; Koren-Karie, Oppenheim, Dolev, Sher, & Etzion-Carasso, 2002; Oppenheim, Koren-Karie, & Sagi, 2001; Solomon & George, 1999)—have found that each of these aspects of mentalizing capacity predicts attachment security in the child. Furthermore, the caregiver's capacity to mentalize can offer protection from risk factors in the caregiver that are associated with generating attachment insecurity, such as the transmission of maternal trauma and disruptive maternal behaviors. We also now know that the benefits of caregiver mentalizing extend beyond attachment outcomes: it is associated with higher performance in children's social cognition tasks (Laranjo, Bernier, Meins, & Carlson, 2010; Meins et al., 2002), as well as general social cognitive development (Meins et al., 2003). By contrast, social environments characterized by adversity in child development (e.g., neglect, abuse) impair the development of cognition (Ayoub et al., 2009; Fernald, Weber, Galasso, & Ratsifandrihamanana, 2011; Goodman et al., 2010; Rieder & Cicchetti, 1989).

The impact of the quality of a caregiver's mentalizing behavior has, then, been extensively analyzed and assessed. The related question is: how does the child learn from their caregiver's behavior? This is an issue that has powerful ramifications for our understanding of human social development, as well as—more pertinently for our purposes here—our understanding of how BPD emerges, and how therapeutic interventions with this disorder might work. We argue elsewhere (Fonagy, Luyten, & Allison, in press), on the basis of pioneering work by Dan Sperber (Sperber et al., 2010; Wilson & Sperber, 2012) and accumulating evidence (e.g., Corriveau et al., 2009), that secure attachment experiences pave the way not only for the acquisition of mentalizing but also potentially more generally for the formation of *epistemic trust* (defined as an individual's willingness to consider communication conveying new knowledge from someone as trustworthy, generalizable and relevant to the self).

Natural Pedagogy and Epistemic Trust

Csibra and Gergely's (2009) theory of natural pedagogy (ToNP) may offer a compelling model to explain the way attachment history could create distinct types of epistemic states. The ToNP posits a human-specific, cue-driven social cognitive adaptation of mutual design dedicated to ensuring the most effective and efficient transfer of culturally relevant knowledge. Csibra and Gergely argue that human communication is the evolutionary product of the requirement to transmit cognitively opaque cultural knowledge: generic knowledge that is robust to interference, is kind-generalizable, and becomes experienced as shared in the sense that it immediately generates an expectation that others belonging to one's social group also possess this knowledge. They use an idea first discussed by Bertrand Russell (1940), but extensively used by Sperber and Wilson (1995), suggesting that certain signals are employed by an agent and prepare the addressee for the intent of the agent to communicate. This communicational cue may also serve the function of counteracting natural epistemic vigilance (the self-protective suspicion toward potentially damaging, deceptive, or inaccurate information). Russell pointed to a process of *ostentiation* (signaling of communicative intent) that takes place as part of communication. *Ostensive cues,* it is claimed by the ToNP model, generate a particular attentional state where natural disbelief is momentarily suspended and the addressee feels that the subsequent communication conveys pieces of knowledge that will contain information specifically relevant to them, which should be remembered and encoded with knowledge generally relevant to social situations involving the self with others. Such information can be about an object, or about the other's views and attitudes about the object—or indeed the beliefs communicated by the other about the self—that is to be regarded as generalizable and relevant across situations. The information can be laid down and used as part of procedural and semantic memory, not uniquely or primarily episodic memory. The distinction between these memory systems is of course well established in neuroscience (Squire, 2004).

In a securely attached child, the caregiver is felt to be a reliable source of knowledge, as the predictors of secure attachment relationships are in essence also ostensive communication cues. The consistent emotional responses of a sensitive caregiver are clearly enacted to the child via the caregiver's ostensive cues, which include eye contact, turn-taking contingent reactivity, and the use of a special tone of voice, all of which appear to trigger a special mode of learning in the infant. The marked nature of mirroring[7] of the infant's emotional expression by the caregiver, which underpins the development of emotion understanding, can be seen as ostensive in nature, signaling the relevance of the caregiver's display to the infant's accumulating knowledge base about their own subjective experience (Fonagy et al., 2007a).

[7]Marked mirroring of the infant by the caregiver refers to the use of exaggerated facial displays and the voice to reflect how the infant is feeling back to the infant, but in a play-acting manner.

The biological predisposition of the caregiver to respond contingently to the infant's (at first automatic) expressive displays creates the foundation for the infant to acquire further knowledge from that individual. During marked mirroring interactions (Fonagy et al., 2002; Gergely & Watson, 1996), the attachment figure will mark his or her referential emotion displays in a manifestative manner to signal the generalizability of knowledge and effectively instruct the infant about the infant's subjective experience: "look at me" (marked display/ostensive cue), "this is what you are feeling" (culturally transmitted self-knowledge) (Fonagy, Gergely, & Target, 2007b). In other words, marking by the caregiver, which is part of good enough mirroring, serves as an ostensive cue to the infant that the concurrent mirrored affect signals are relevant and generalizable. Human infants display a species-specific sensitivity in relation to certain nonverbal ostensive behavioral signals (Csibra & Gergely, 2006, 2009, 2011). They attend preferentially to such signals and the impact of these signals on their behavior is readily apparent.

In brief, ostensive cues trigger epistemic trust and simultaneously engender secure parent–child attachment (Fonagy et al., 2007b). They set aside the biological protection provided by epistemic vigilance. They open a channel of information exchange designed by evolution to transmit and assist in receiving knowledge about the social and personally relevant world, going beyond the specific experience, all the while remembering the information and encoding it with the authority but not the person of the communicator. Ostensive cues signal that we must go beyond the specific physical experience and acquire information that is relevant across a range of settings. Epistemic trust is there to ensure that we can safely change our position, and it triggers the opening of an evolutionarily protected *epistemic superhighway* that signals readiness for knowledge acquisition.

There are several fascinating developmental experiments summarized by Csibra and Gergely (2009), which give powerful support to the ToNP. They offer compelling evidence from infancy for the power of this dialogic learning process. In one simple demonstration, 6-month-old infants were shown to follow an agent's gaze shift selectively to an object only if it had been preceded either by eye contact with the infant or by infant-directed speech (Senju & Csibra, 2008). Shared attention with an agent is triggered by the infant experiencing the agent's interest. The interest triggers the infant's expectation (epistemic trust) that there may be something relevant for the infant to learn.

A second study employing an automated eye-tracker used an infant-induced contingent reactivity paradigm (Deligianni, Senju, Gergely, & Csibra, 2011). During the familiarization phase, 8-month-old infants observed a display where five unfamiliar animated objects (looking more like jugs or kettles than anything else) were displayed. Four of these, in the four corners of the display, moved unpredictably. The object at the center acted differently in two conditions. In the interactive condition, whenever the infant's gaze wandered toward the object, it would respond to the infant's gaze with movements and sound. In the control condition, the central object would move a comparable amount but this would be independent of the infant's gaze. In the test phase, only three objects were present. The central object in this phase turned toward either the left or the right object. It should be noted that although none of the five jug-like objects had eyes, they had a clear, unequivocal front signaled by a pointed "hat" and an elongated "nose" (somewhat reminiscent of a kettle with an upturned beak). The 8-month-olds in the interactive condition detected the contingent activity of the central object and looked at the object it turned toward (i.e., followed its "gaze") far more. In the noncontingent control condition, the infants did not look for longer, more frequently, or more promptly at the object that the central object turned toward. It seems that the contingent reactivity of this nonhuman and somewhat bizarre object was sufficient to influence the infant's orientation. The study is important in showing that it is the experience of response-induced contingencies that creates epistemic trust and elicits a joint attention response.

From all that we know about the nature of attachment, it is evident that secure attachment is driven by sensitive responsivity contingent upon an infant's reaction (Belsky & Fearon, 2008; Marvin & Britner, 2008). In other words, secure attachment is created by a system that is capable of simultaneously generating a sense of epistemic trust. In a longitudinal study of attachment, 147 children assessed for attachment in infancy were tested twice for epistemic trust at the ages of 50 and 61 months (Corriveau et al., 2009). In this study, the child's mother and a stranger made conflicting claims to a child concerning (1) the name of a novel object; (2) the name of a hybrid animal made up of 50% of each of two animals (e.g., an image made up of 50% rabbit and 50% squirrel; the mother might call it a squirrel, while the stranger says it is a rabbit); and (3) the name of a hybrid animal made up of 75% of one animal and 25% of another. In the last case it was always the mother who made the improbable claim (e.g., that a picture made up of 75% bird and 25% fish was a fish), while the stranger gave the more likely answer (in this example, bird). The simple question was who the child

would spontaneously turn to for information and believe, and whether this behavior was moderated by the history of attachment security. The nature of a child's attachment relationship turned out powerfully to condition the child's trust in the information imparted by the attachment figure (mother) and others (strangers) as informants. Children who were securely attached in infancy displayed a flexible strategy, showing a preference toward accepting claims made by their mother when appropriate. Insecure-avoidant children appeared to withhold trust in their mother, preferring to attend to information from the stranger, while insecure-resistant children withheld trust in the stranger even when their mother made improbable claims. Children with insecure-disorganized histories evidenced what we may call *epistemic hypervigilance*; they appeared to regard both sources of information with suspicion.

Security of attachment, rooted in a history of feeling recognized, appears to increase the likelihood of trust in the source of communication when it is reasonably credible. Yet a secure attachment history also generates confidence in one's own experience and belief and empowers one's (i.e., the child's) judgment. A history of attachment avoidance may generate epistemic mistrust, while anxious attachment creates epistemic uncertainty through overreliance on the views of the attachment figure. Disorganized attachment, rooted in a history of chronic misattunement, unsurprisingly can create mistrust of both the attachment figure and strangers as a source of information. It is the unresolvable question of "whom can I trust?" that might contribute to epistemic hypervigilance in a child with a history of disorganized attachment. The child with a history of attachment disorganization mistrusts information from both attachment figures and strangers, and even mistrusts their own experience. While an insecure attachment history may preclude complete confidence in one's subjective experience, an organized strategy biases either toward or away from the attachment figure. But if neither can be trusted an interminable epistemic search may ensue, associated with disorganized attachment. The child seeks others to confirm or deny his or her own understanding, which he or she has little faith in, but, not being able to trust the information received from others, is left in a state of continued uncertainty. Ultimately, this generates a state of interminable searching for the validation of experience, coupled with the chronic lack of trust that we have termed epistemic hypervigilance.

We suggest that while attachment may be a key mechanism for the mediation of epistemic trust, it is secondary to an underlying biological process preserved by evolution. We have seen that stimuli such as the bizarre kettle-shaped object in the study described previously are capable of at least momentarily triggering the same category of response as human beings. In other words, secure attachment is not likely to be a *necessary* condition for generating epistemic trust but it may be *sufficient*, and the most *pervasive* in early childhood because it is a highly evolutionarily effective indicator of trustworthiness. Given that the human infant needs to overcome the self-preservative barrier created by natural epistemic vigilance and open their mind to acquiring the millions of bits of culturally relevant information on which their survival will ultimately depend, it would have been foolhardy for nature (evolution) not to gift us with a mechanism of deferential knowledge transmission that would create a kind of epistemic superhighway between learner and teacher, based normally on a shared genetic inheritance (Hamilton, 1964).

Attachment, Mentalizing, and Epistemic Trust

Looked at from a distance, micro-analytic (e.g., Beebe et al., 2010) and more global (e.g., DeWolf & van IJzendoorn, 1997; Isabella, Belsky, & von Eye, 1989; Kiser, Bates, Maslin, & Bayles, 1986; Mills-Koonce et al., 2007) ratings of sensitive caregiving can be seen as in essence recognizing the child's agentive self. It is this recognition that we believe offers the cognitive advantage to secure attachment, which has been fairly consistently noted, although not, to our knowledge, commonly studied (e.g., Crandell & Hobson, 1999; Jacobsen & Hofmann, 1997; Moss, Rousseau, Parent, St.-Laurent, & Saintong, 1998) and contributes to the cognitive disadvantage of developmental adversity we considered above (Ayoub et al., 2009; Fernald et al., 2011; Goodman et al., 2010; Rieder & Cicchetti, 1989). We believe that attachment establishes, through the down-regulation of affect triggered by proximity-seeking in the distressed infant, not only a lasting bond; it also opens a channel for information to be used for the transfer of knowledge between the generations.

Attachment insecurity is likely to be associated with a greater likelihood of cognitive closure, a lower tolerance for ambiguity, and a more pronounced tendency for dogmatic thinking (Mikulincer, 1997). Saving intellectual effort and adopting stereotypes is also more likely in individuals whose attachment is insecure (Mikulincer, 1997). The same predisposition to knowledge inflexibility is revealed by the tendency of insecure individuals to make judgments on the basis of early information and to pay insufficient heed to subsequent data even if it is incompatible with the configuration first created (Green-Hennessy & Reis, 1998; Mikulincer, 1997). Insecure individuals, who fear the loss of attachment figures, also anxiously hold on to their initial

constructions. Kruglanski (Kruglanski, 1989; Kruglanski & Webster, 1996; Pierro & Kruglanski, 2008) proposed the concept of *epistemic freezing*, characterized by a tendency to defend existing knowledge structures, even when they are incorrect or misleading (see also Fiske & Taylor, 1991). Returning to the earlier theme of seeing adversity as a cause not of deficit but rather of superior adaptation to challenging environments (Frankenhuis et al., 2013), we may see such a defensive strategy as adaptive if an individual's self-esteem is vulnerable. Cognitive closure, dogmatism, and conservatism may simply be strategies to create a bulwark to safeguard an inadequately individuated self (Bowlby, 1980). By contrast, the greater confidence of secure individuals that they will be able to recover from dysregulation also enables them to be less defensive in relation to opening their minds to information that may challenge their assumptions.

Mikulincer (1997) suggested that insecure individuals were more readily threatened by information that challenged their knowledge structures because of the vulnerability of their sense of self, and vulnerability in particular to being emotionally overwhelmed. If emotional dysregulation is experienced as a real and imminent threat, they may opt for knowledge stability, as it temporarily serves to down-regulate arousal. Such individuals are less likely to revise their knowledge in the face of information that challenges their assumptions (Green-Hennessy & Reis, 1998; Green & Campbell, 2000; Mikulincer, 1997; Mikulincer & Arad, 1999), as if they not only had less confidence in the robustness of their bond to their attachment figure, but also feared the loss of epistemic trust. In sum, we assume that the epistemic superhighway provided to us by evolution for us to learn from experience is partially closed to those whose attachment to their caregiver is insecure.

Vulnerability for BPD is associated with conditions in which there is a marked absence of respect for the recipient of communications as an active agent. To summarize, (1) as we have shown already, insecure attachment is associated with BPD; (2) insecure and frequently mindless, abusive child–caregiver interactions antedate BPD (e.g., Pietrek et al., 2013); and, perhaps most pertinent, (3) anomalies of early caregiver–infant communication predict not only attachment disorganization but, in some carefully conducted longitudinal studies (e.g., Lyons-Ruth, Bureau, Holmes, Easterbrooks, & Brooks, 2013), the likely emergence of personality pathology.

Detailed inquiry into these high-risk anomalies of parent–infant communication could be seen as part of caregiving interactions that may involve the misuse of ostensive cueing. By *misuse of ostensive cueing* we mean using cues to lead the infant to anticipate personally relevant, generalizable knowledge through a kind of pseudosensitivity followed by the transmission of disruptive and even destructive knowledge. Careful examination of the manual for the coding system Disconnected and Extremely Insensitive Parenting[8] (Out et al., 2009; predicting disorganized attachment) reveals a multitude of examples of this pattern. Some of these are: anomalous movements and postures; simultaneous contradictions in vocalizations; suddenly stilling and freezing the posture, or startling in response to the child's behavior; sudden voice alterations; sudden and inexplicable shifts of mood; and fear in relation to aspects of the environment that have no intrinsically frightening aspect. Future research will need to establish whether such anomalous or misused ostensive cues on the part of caregivers, in the context of imparting mirroring information about the child's experience, are particularly associated with the emergence of BPD.

The special significance of emotional neglect and abuse to BPD (as discussed earlier in this chapter) also fits well with ideas linking this disorder to chronic epistemic mistrust. We feel that it is less likely to be the frank brutality of abuse that undermines epistemic trust (although of course it can do) and that neglect and emotional abuse will play a larger role. Taking the perspective of epistemic trust as the mediator of culture and its key underlying engine for progression, we have to see the destruction of trust in social knowledge as a key mechanism in pathological personality development.

Developmental adversity, perhaps most deeply attachment trauma (Allen, 2012, 2013), may trigger a profound destruction of trust. There may be other reasons, but, once lost, the absence of epistemic trust generates an apparent rigidity. The rigidity is in the eyes of the communicator, who, in accordance with the principles of theoretical rationality, expects the recipient to modify their behavior on the basis of the information they have received and apparently understood. But, in the absence of trust, the capacity for change is absent. The information presented is not used to update the individual's social understanding.

[8]The DIP coding system assesses disconnected and extremely insensitive parental behavior. Items from Main and Hesse's (1998) coding instrument, titled "Frightening, Frightened, Dissociated, Sexualized and Disorganized Parental Behavior: A Coding System for Parent–Infant Interactions" are included, as well as items from the system by Bronfman, Parsons, and Lyons-Ruth (1999), titled "Atypical Maternal Behavior Instrument for Assessment and Classification (AMBIANCE)."

In terms of the ToNP (Csibra & Gergely, 2009) the person has (temporarily) lost the capacity for learning. From a therapist's standpoint, he or she has become hard to reach and interpersonally inaccessible.

Implications for the Conceptualization and Treatment of BPD

An individual in a state of epistemic mistrust (or, at an extreme, epistemic petrification) cannot change. A basic route for acquiring culturally relevant knowledge is functioning in only a limited way. The individual cannot change because they cannot accept that the information they receive is relevant to them or usefully generalizable to other social contexts. It is received episodically and remembered within autobiographical recall as simply something that happened, but it is not incorporated into the procedural and semantic systems that govern an individual's behavior across social situations as an element of their participation in the great evolutionary process of transgenerational cultural transmission.

To put it bluntly, we are suggesting that BPD is not a disorder of personality except by some old definitions whereby the term *personality* was used synonymously with *slow-changing*. In fact, BPD (and most, if not all, PDs) describes a state of social inaccessibility. It can be conceived of as a temporary state of incompatibility with a grand evolutionary design of intracultural communication in which we all play a part. It describes a state of isolation from communication from one's partner, one's therapist, one's teacher—all generated by intense and chronic epistemic mistrust.

At its simplest, epistemic mistrust is *not believing what one is told*. To put it more accurately, the person may avow a belief but beyond that is unable to use new information to alter existing schemata of procedural or semantic knowledge in relation to the world as it concerns the self or the other. Epistemic mistrust can be the consequence of high levels of epistemic vigilance (Sperber et al., 2010). It may arise from overinterpretation of the communicator's motives, rather than a more obvious closure to the communicator. For example, we know that emergent BPD is associated with hypermentalization (Sharp et al., 2011, 2013). If the recipient of a communication assumes that the communicator's intentions in communicating are other than those declared, the communication and the communicator's belief will not be treated deferentially and will not be used to update the reservoir of culturally transmitted knowledge. The communication may therefore affect behavior in relation to that particular individual but will not generalize across settings. The recipient of the communication appears to the communicator to be *rigid*.

Of course, the misattribution of intent and treating someone's communicative intent as fundamentally malevolent is part of a schizotypal and paranoid stance that is commonly comorbid with other PD diagnoses (e.g., Pulay et al., 2009; Watson & Sinha, 1998). In some individuals, perhaps for reasons of biological predisposition to hypermentalizing or adverse learning experiences, or both, the primary avenue for modifying stable beliefs about the world has been closed, causing significant disruptions particularly in social situations requiring flexibility and a capacity for learning (e.g., vocational functioning; McGurk et al., 2013). Attachment insecurity antedated by less contingent responsiveness on the part of the attachment figure perhaps leaves behind it a more limited eagerness to modify existing knowledge structures. According to the attachment–epistemic trust hypothesis as outlined above, attachment categories can be conceptualized as manifestations of how a child attributes trust toward possible informers.

Building on the ToNP, BPD could be seen as a consequence of a catastrophic breakdown of epistemic trust, a consequence of a series of failures of communication. By way of either adversity (neglect and abuse), a genetic predisposition to hypermentalize, or a combination of the two, a fundamental lack of trust in communication has built up, which has left the individual with severe mentalizing impairments; at moments of interpersonal pressure they cannot reliably relate to other people's minds as safe, predictable, or even imaginable, and they cannot, at such moments of intense affect, regulate or interpret their own thoughts or emotional processes. It is this epistemic hypervigilance that works to give BPD its qualities of rigidity, or being hard to reach, and storminess of affect. It is, therefore, unsurprising that in the context of such failures of communication, the subjective experience of BPD involves such intensely painful isolation. These difficulties in communication can also generate intense feelings of frustration on the part of therapists seeking to work with patients with BPD. It is now to the question of how therapy can serve to reach patients with BPD that we will turn.

Mechanisms of Change in BPD

As we have seen, a number of therapies appear to be effective for BPD. In other words, for treatments to work, they require a clear theoretical frame and a coherent, well-defined model of reliably delivered treatment. But

beyond this, a wide variety of therapeutic models can (and does) claim to be efficacious. Enumerating generic factors common to such therapies, such as positive regard or validation—which could equally characterize less effective generic supportive techniques—will by itself provide neither an adequate treatment nor an adequate explanation of what makes therapies work. There is a call for a single model of treatment mechanism that is able to accommodate the need for specificity and at the same time offer a parsimonious model explaining the working of the wide range of therapies that are effective in facilitating recovery from this condition. On the basis of the preceding section, we argue that three sets of processes, which we will label *communication systems*, underpin the mechanism of change in BPD. Here we will briefly discuss their nature and how these three systems relate to each other cumulatively to make change possible.

Communication System 1: The Teaching and Learning of Content

As noted, all evidence-based treatments of BPD provide a coherent, consistent, and continuous framework enabling the patient to examine, in a safe and low-arousal context, the issues that are deemed to be central according to the particular theoretical approach (e.g., early schemas, invalidating experiences, object relations, and current attachment experiences). All evidence-based psychotherapies provide skills or knowledge that assist the patient, whether this is part of acquiring strategies to deal with emotional dysregulation or restructuring interpersonal relationship schemata from the past or in the present as part of imparting such content. All evidence-based therapies deliver to the patient a model of mind, of disorder, and a hypothetical process of change that are convincing and accurate enough to enable the patient to feel recognized as an agent. The model contains sufficient information of personal relevance for the patient to experience feeling markedly mirrored or understood. These implicit or explicit explanations are, in essence, ostensive cues; they signal to the patient the relevance of the information that is conveyed by triggering personal recognition in the patient. This process is important because it leads the patient to reduce his or her epistemic hypervigilance as he or she increasingly sees the model's relevance to his or her own state of mind. Thus, acquiring new skills which had been lacking and new (useful) information about oneself has a nonspecific effect of creating openness that eases the learning of the specific content conveyed within the model. Feeling the truth of evidence-based content creates a virtuous cycle, increasing epistemic openness, which in turn allows the patient to take in further information that naturally also serves to reassure and validate. This process of teaching and learning between therapist and patient—of showing the relevance of the wisdom, or model—is facilitated by the experience of feeling mentalized by the felt truth of the content being communicated. The fact that there are so many different therapies, using so many different theoretical models that have been found to have some beneficial effect, indicates that the significance of communication system 1 lies perhaps not in the essential truth of the wisdom of the specific approach, to which the patient is increasingly open in the course of their treatment, but in the fact that it causes the patient to give some weight to a piece of communication from the social world—which brings us to system 2.

Communication System 2: The Re-Emergence of Social Learning

Where communication system 1 concerns the content of *what* is learned in treatment, communication system 2 is concerned with the process of *how* this learning became possible. In the process of effectively passing on knowledge, the therapist creates ways of recognizing the agentiveness of the person, which serve as ostensive cues and convey that he or she is seeking to understand the patient's perspective, which in turn enables the patient to hear and to listen. In effect, the therapist is modeling how he or she engages in mentalizing in relation to the patient. By creating an open and trustworthy social situation, a better understanding of the beliefs, wishes, and desires underpinning the actions of others and of the self is made possible. This in turn allows for a more trusting, less paranoid interpersonal relationship in the consulting room. Ideally, the patient's feeling of having been sensitively responded to opens a second virtuous cycle in interpersonal communication in which mentalizing is regenerated.

The mentalizing of patients, that is, acting in accordance with the patient's perspective, may be a common factor across psychotherapies not because patients need to learn about their minds or to learn about those of others. Rather, mentalizing may be a generic way of establishing increased levels of epistemic trust and therefore achieving change in mental function. The patients' capacity to mentalize improves, we would maintain, in all therapies. This will increase self-control, reduce the experience of mental pain, and improve the ability to think in the content of intense attachment relationships. This has been a key part of our understanding of the mechanisms of change since

the inception of the MBT model (Fonagy & Bateman, 2006b). The patient's subjectivity being understood is vital to this process. It is also vital to a further function of therapy, which we wish to recognize separately, namely: the reopening up of his or her wish to learn about the world, including the social world.

Communication System 3: Learning Beyond Therapy

We hypothesize that feeling understood opens a key biological route to information transmission and the possibility of taking in knowledge that is felt to be personally relevant and generalizable; this is what brings about change in previously rigidly held beliefs. In essence, the experience of feeling thought about enables us to learn new things about our social world.

The therapeutic situation teaches about sources of knowledge. It provides a clear social illustration of trust, making the therapist a *deferential* (Wilson & Sperber, 2012) source of knowledge with the capacity to undo previously rigidly held beliefs about the self, about others, and to dissolve the patient's experience of epistemic isolation, which is embodied in the rigidity of their subjective experience. A third virtuous cycle is initiated. Improved understanding of social situations through improved mentalizing leads to better understanding of important others in the patient's life, which in turn creates the potential for a person to notice a sensitive response and feel understood. Reopening the potential to feel sensitively responded to may in itself initiate more trusting (less paranoid) interpersonal relationships, and thus open the patient up to new understandings of specific social situations as they arise.

We posit that, as the patient's state of epistemic hypervigilance relaxes, his or her capacity for trust increases and he or she discovers new ways of learning about others. This brings with it an increase in the patient's willingness to modify cognitive structures for interpreting the behavior of others. Social experiences that may have been positive, but were in the past discounted as a result of the patient's hypervigilance, now have the potential to have a positive impact. This is the third communication system, which is now available after communication system 2 opened the way to change through enhanced mentalizing. As patients experience social interactions in a more benign way and see the social situation they are in more accurately (e.g., not seeing an experience of temporary social disappointment as an outright rejection), they update their knowledge of both themselves and others.

It is the recovery of the capacity for social information exchange that is at the heart of psychotherapies. They impart an ability to modify or benefit from benign social intentions, and to update knowledge about the self and others in social situations. The improved sense of epistemic trust enables learning from social experience; in this way the third virtuous cycle is maintained beyond therapy.

As therapists we often assume that the process in the consulting room is the primary driver of change. Yet our experience tells us that change is also brought about by what happens beyond therapy, by how a person uses their social environment. Empirical evidence from session-by-session monitoring of change suggests that the therapeutic alliance in the previous session foretells change in the next (Falkenstrom, Granstrom, & Holmqvist, 2013; Tasca & Lampard, 2012). This suggests that change occurs in between sessions but as a consequence of changed attitudes to learning engendered by the therapy. The implication is that the extent of benefit a patient derives from treatment may depend on what is accessible to the patient in his or her particular social world. We predict that psychotherapy for BPD is much more likely to succeed if the individual's social environment at the time of treatment is, by and large, benign.

This admittedly speculative model offers a way of integrating the specific and nonspecific factors in psychotherapy. Specific factors associated with therapies that work create experiences of truth, which in turn encourage a person to learn more. In this process, via a nonspecific channel, the patient's capacity to mentalize is fostered. Both these systems would be expected to lead to symptomatic improvement. Improved mentalizing as well as reduced symptomatology improves the experience of social relationships. It is likely that these new experiences, rather than just what happens in therapy, serve to erode the epistemic hypervigilance that has prevented benign social interactions from changing an individual's experience of themselves and of the social world.

CONCLUSIONS

This chapter has provided a review of the most current thinking within the mentalizing model of the development and treatment of BPD. It is a psychodynamic developmental psychopathology model, which incorporates the latest research findings that have implications for our more complete understanding of BPD at different levels, ranging from psychological to sociocultural and biological/genetic factors. Moreover, we have adopted a life-span approach to BPD; in particular, we have attempted to place a greater emphasis on adolescence and BPD, in keeping with our developmental approach, and our interest in the emergence

of BPD traits as the individual develops and bumps in different ways against their emotional, socioeconomic and genetic environments.

Mentalizing theory initially developed—and has continued to evolve—in the context of clinical practice. This intimacy between theoretical understanding of the phenomenology of BPD and treatment principles runs throughout our thinking on mentalizing, and across the chapter we have sought to explain the latest elaborations of mentalizing theory in conjunction with the empirical research that has shaped and underpins it, and then to describe how these theoretical iterations inform the practice and stance adopted by MBT therapists. We have also further developed the idea of mentalizing, via the concept of epistemic trust, to make a more general proposition about what might make therapeutic interventions for BPD work. In keeping with our conviction that the greatest rigor in both theory and practice is achieved when these two lines run in tight parallel, this proposition serves both a theoretical and a clinical purpose. We have sought to make a theoretical contribution to thinking on how an understanding of, and deficiencies of understanding in, interpersonal relations may be transmitted from caregiver to infant. But also, more pragmatically, we have sought to untangle what processes are shared by more successful evidence-based practices. Mentalizing, we argue, remains a taut and steady thread through the chaos of the multiple therapeutic interventions that currently exist.

As our knowledge derived from the various areas in developmental psychopathology increases the mentalizing model will no doubt continue to develop, leading to a better understanding of BPD and, we hope, to the development of more effective intervention strategies.

INTRODUCTION

Alcohol is the world's most common drug of use and abuse. In the form of wine and champagne, it is the drug with which we mark occasions of special joy; in the form of beer, it is the drug of our leisure time activity, and in the United States, in the form of spirits, it is the drug with which we celebrate the transition to adulthood. It is the drug of power and social bonding, and the drug of courtship, and it is also the drug we use to celebrate and remember the death of those close to us. At the same time, when alcohol is used heavily, it contributes to both spousal and nonfamilial violence, child abuse, downward social mobility, unprotected sex, both fatal and nonfatal traffic accidents, fetal alcohol syndrome, and a host of other negative outcomes. Of all the drugs of abuse, it has been rated as the most harmful when considering the joint criteria of harm to others and harm to self (Figure 18.1; Nutt, King, & Phillips, 2010). In short, even in the damage it does, it is closely tied to the fabric of society.

Preparation of this chapter was supported by grants from the National Institute on Alcohol Abuse and Alcoholism (R01 AA07065, R01 AA12217) and the National Institute on Drug Abuse (R01 DA027261) to RAZ and MMH and K01 DA025868 to BMH. We are also indebted to Mary Palnau for her considerable help in putting this chapter together.

[1]Color versions of Figures 18.1, 18.2, 18.10 and 18.12 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

Repeated adverse consequences to self and others that are associated with heavy and compulsive use, that continue despite their obvious personal cost, move the behavior into a different category of experience. Although this behavior is extraordinarily damaging, it does not meet the formal criteria for addiction. The latter involves behavior that is compulsive (i.e., it is experienced as outside the individual's conscious control), and we need to turn to models focused on the genetics and neurophysiology of the behavior to understand the underlying mechanisms driving the process. However, both of these syndromes meet the formal criteria for *DSM-5* alcohol use disorder (American Psychiatric Association, 2013). This issue of heterogeneity of disorder, involves multiple levels of system all the way from the societal to the molecular to be accurately characterized and along the way requires examining relationships across levels of analysis. Because of this complexity the science has tended to be fractionated, and within-level scientific explanations have often been staked out as claims that their domain of explanation encompasses the core elements of the disorder, even though this advocacy tends to be poorly informed about process at other levels of analysis. Although there is no way this chapter can address all of this complexity in great depth, it is driven by the principle that single level explanations are inadequate because they ignore multiple sources of information indicating that the processes are multilevel. The current state of scientific work is sufficiently advanced for us to provide brief summaries of work at most of these levels. Our approach is developmental, in a field where there is still considerable unevenness in recognition of the importance of a life course perspective. In the sections that follow we summarize recent changes in the diagnostic criteria for AUD and briefly summarize the epidemiology of use and disorder, provide a conceptual framework for the matrix of elements needed to specify the mechanistic structure for risk/disorder, briefly summarize earlier efforts to characterize the full matrix, and then provide a heuristic model that will handle the interplay of genes, brain, behavior, context, and development. We then provide two sections on variation in risk and course of disorder. We approach this developmentally. First we review alcohol nonspecific risks (i.e., risks that lead to alcohol use and abuse/disorder but do not pertain to alcohol and as well are risk for behaviors that are not alcohol related, such as

antisocial behavior, depression). We then discuss the development and course of alcohol-specific risk. Following, we review the neurobiological literature on risk development, including the genetics of use, abuse and disorder, as well as recent work on gene–environment (GxE) relationships. This is followed by a section that describes the brain systems and structures involved in creating risk for alcohol problems and disorder; also included is a brief discussion of the role of environment and genetics in the development of neural risk. The final section of the chapter describes some major next-step challenges for the field to address.

EPIDEMIOLOGY

Redefining the Alcohol Use Disorder Diagnostic Criteria

In 1980, with the advent of the third edition of the *Diagnostic and Statistical Manual*, the persistent and damaging problems of alcohol use and abuse were no longer classified as alcoholism. The term alcohol use disorder (AUD)—encompassing both abuse and dependence—was substituted, as more descriptive, precise, and differentiating of the clinical syndrome. In 2013, after using this two stage categorization system for three editions of the DSM, with the advent of the fifth edition of the *Diagnostic and Statistical Manual*, the criterion set for AUD was changed again in a major way. The revision involved collapsing the former abuse and dependence categorizations into a single substance use disorder diagnosis which for alcohol symptomatology meant that there would be only one AUD diagnosis. In the earlier system, alcohol dependence was meant to capture physiological dependence on alcohol and related behaviors, that is, experiencing tolerance and withdrawal symptoms as well as a compulsive need to consume alcohol despite physical and mental health problems and interference in meeting major life responsibilities (e.g., family, work). Alcohol abuse was meant to index less severe drinking problems that increased risk for harm (e.g., drunk driving) or led to problems in social functioning (e.g., lost friends or job due to drinking), but not physiological dependence. The conceptual framework was that abuse was an early manifestation of the disorder that could progress to its more severe and addictive form, dependence, but not necessarily.

There were several problems with this conception. One was that there was not a clear distinction in severity, so that some abuse symptoms were less prevalent and/or more severe than some dependence symptoms. In addition, item response theory models supported a dimensional or continuum model of alcohol use problems covering abuse and dependence, and total number of symptoms—rather than whether symptoms were abuse or dependence—was the best predictor of disability indicators (Borges et al., 2010; Saha, Chou, & Grant, 2006). Also, abuse was not a clear prodromal condition for dependence; that is, many people meant criteria for dependence without having abuse (Hasin & Grant, 2004). Another issue was that only one symptom was necessary for abuse, such as hazardous use. Legal problems due to drinking—such as drunk driving only once—would meet this criterion, yet of themselves these behaviors were not sufficient to be regarded as disorder. Inclusion of criteria such as this ended up yielding extremely high lifetime prevalence rates. There were also problems with the alcohol dependence specifiers, which sometimes resulted in diagnostic orphans, that is, people with two symptoms of dependence but none of abuse, who would not qualify for any diagnosis. The revised diagnostic criterion set is an attempt to simplify this system by combining the abuse and dependence categories, and utilize mild, moderate, and severe specifiers for severity. Last, a new symptom that assesses craving was added. Though there was much debate as to the incremental contribution of adding an addiction symptom, there was sufficient consensus of its utility for enough drugs of abuse (although not necessarily alcohol) to incorporate it as one of the substance use disorder criteria.

Epidemiologic Data

Since epidemiological data on the new *DSM-5* criterion set are not yet available, we discuss findings using the *DSM-IV* criteria for alcohol abuse and dependence. Table 18.1 provides the 12-month and lifetime prevalence rates (percentages) for *DSM-IV* alcohol abuse and dependence, based on the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC; Hasin, Stinson, Ogburn, & Grant, 2007). NESARC was conducted in 2001–2002 and included 43,093 respondents age 18 to over 65. To give a broader perspective on the alcohol problem, we also present rates for illicit drug abuse and dependence (Compton, Thomas, Stinson, & Grant, 2007). A number of points about these prevalence rates are of importance.

1. Alcohol abuse and dependence are the most common of the substance use disorders.
2. Among men, 4 in 10 adults have at some point in their lives met either abuse or dependence criteria.
3. Gender differences are significant, and are of the order of 2:1 for abuse, and 2.5:1 for dependence.

TABLE 18.1 Lifetime and 12-Month Prevalence of *DSM-IV* Substance Use Disorders

Disorder	Total lifetime	12 month	Male lifetime	12 month	Female lifetime	12 month
Alcohol abuse without dependence	17.8	4.7	24.6	6.9	11.5	2.6
Alcohol dependence	12.5	3.8	17.4	5.4	8.0	2.3
Alcohol abuse/ dependence combined	30.3	8.5	42.0	12.4	19.5	4.9
Other drug abuse without dependence	7.7	1.4	10/6	2.0	0.4	
Other drug dependence	2.6	0.6	3.3	0.9	2.0	0.4
Other drug abuse/ dependence combined	10.3	2.0	13.8	2.8	7.1	1.2

Sources: Data from D. S. Hasin, F. S. Stinson, E. Ogburn, & B. F. Grant, Prevalence, correlates, disability, and comorbidity of comorbidity of *DSM-IV* alcohol abuse and dependence in the United States, *Archives of General Psychiatry, 64*, 830–842, 2007, and from W. M. Compton, Y. F. Thomas, F. S. Stinson, & B. F. Grant, Prevalence, correlates, disability, and comorbidity of *DSM-IV* drug abuse and dependence in the United States: Results from the national epidemiologic survey on alcohol and related conditions, *Archives of General Psychiatry, 64*, 566–576, 2007.

4. Abuse without dependence represents over 50 percent of the life course problem, and the current (12 month prevalence) problem. Or, to put these figures in a slightly different perspective, over 50 percent of the lifetime national problem is of subclinical proportions, but involves socially and personally significant misbehavior (e.g., compromised driving, risky sex, date rape, job absenteeism, neglect of household responsibilities).
5. Other drug disorders are substantially less of an issue than alcohol use disorders, with a ratio of 12-month alcohol to drug use disorder of over 4:1 (Figure 18.1).
6. Other drug disorders are to a large degree superimposed upon alcohol use disorders, given that only a small minority of 12-month drug use disorders occur without a concomitant alcohol diagnosis.
7. The greater visibility of other drug disorders is likely because the disorders are more dramatic, hence socially compelling, because they appear to be more of a threat to the social order (e.g., because of their links with crime, as well as out of the belief that they may be less responsive to treatment), and because the social costs involved in interdiction and treatment are proportionately much larger. The lay view, as well, is that the disorders occur in isolation, which heightens the differentiation between the different types of drug involvement.

As already noted but not shown in the table, AUD is the nation's most prevalent disorder, with 30.3 percent of the adult population reporting symptomatology that qualifies for an abuse or dependence diagnosis at some point in their lives (Hasin et al., 2007). Thus, the set of problems encompassed by this disorder is an extraordinarily large one.

A major point of this chapter is that the adult disorder does not emerge full blown in adulthood, but rather develops over time in a process for which childhood precursors are identifiable. To hone in on the early harbingers of this process, Figure 18.2 presents national data on past-month use, binge (≥5 drinks per occasion), and heavy use (≥5 drinks per occasion on ≥5 of the past 30 days) from the National Survey on Drug Use and Health (Substance Abuse and Mental Health Services Administration, 2006). These data illustrate the sharp age-related increases in alcohol use and problem use as well as an estimate of the scope of early problem involvement. For example, among 15-year olds, 20% have engaged in recent alcohol use, 10% have engaged in a recent binge, and 2.5% are engaging in heavy drinking. To recast these figures, given that drinking for adolescents is heavily confined to weekends, this high-end group of 10% of 15-year-olds is reporting drinking at adult heavy drinking levels, and a fourth of that group is indicating that they are drinking at adult heavy drinking rates at most available opportunities. Using the new *DSM-5* criteria, and assuming any additional trouble related to the drinking (a not unreasonable assumption at this age), behavior sufficient to achieve a diagnosis of disorder has already been achieved by that group.

At the same time, it would be a mistake to presume that everyone with early signs of problem use will go on to develop adult disorder. The adolescent developmental literature has been clear that early alcohol use as well as alcohol problems need to be regarded as one component part of a deviance syndrome. The syndrome emerges in adolescence and is adolescent-specific in the sense that the majority of individuals with such problems do not go on to develop adult disorder, although some may reach diagnosable levels during their adolescent years (Blane, 1979; Donovan & Jessor, l985). Conversely, the problem prevalence figures, especially for those still in grade school, suggest that some etiologic factors have already been in place by the time middle school is started. Despite the ready availability of these incidence data, which drive the point home, this is not yet a widely known fact. Here and there one can find accounts in the clinical literature of the last generation, (e.g., Mitchell, Hong, & Corman, l979) which call attention to the occurrence of very early and severe child alcohol use. The effort to account for such beginnings

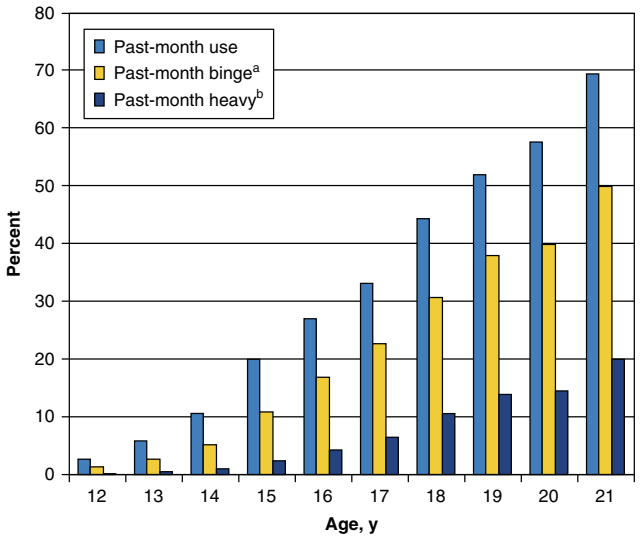

Figure 18.2 Past 30-day alcohol use (any, binge, or heavy) according to age. *Notes:* [a]Binge drinking was defined as ≥5 drinks per occasion; [b]heavy drinking was defined as ≥5 drinks per occasion on ≥5 days of the past 30 days. See footnote 1. Sources: Data from Substance Abuse and Mental Health Services Administration data from the 2005 National Survey on Drug Use and Health (SAMHSA, 2006). Figure reprinted from: A. S. Masten, V. B. Faden, R. A. Zucker, & L. P. Spear, Underage drinking: A developmental framework, *Pediatrics, 121,* S235–S251, 2008. doi: 10.1542/peds.2007–2243A PMID: 18381492

leads us to cast an etiologic net considerably earlier than adolescence. We do so later in the chapter, when dealing with the evidence about variations in risk and course of the disorder. However, this issue of differences in course, and a related set of questions about how many different variations there may be, what their determinants are, how best to describe and understand them, has become a major set of questions for the field because it encompasses issues of phenotypic heterogeneity as well as definitional issues about what the true nature of AUD might be. We also return to that set of questions later.

THE DEVELOPMENTAL PROGRESSION OF USE AND DISORDER: A MULTILEVEL MATRIX

Although it may seem a trivial point that one cannot have alcohol problems without the presence of alcohol, it is not trivial that such presence is regulated by societal norms about appropriate contexts of use, and the availability of the drug within society. At the same time, alcohol is not just a social object; it is also a drug, and understanding the pharmacodynamic and neurodynamic matrix of its action upon the human organism is also essential to understanding how the symptomatology of AUD comes to be. To chart the manner in which these causal structures interact requires model building that crosses multiple levels of analysis and multiple disciplines, operating over social, individual, and biological time (Cacioppo, Berntson, Sheridan, & McClintock, 2000). This perspective is inherent to a developmental psychopathological framework but it is not one regularly embraced by substance abuse researchers. To capture such a multilevel structure, a developmental systems framework (Cicchetti & Dawson, 2002) is essential as a means to organize these diverse levels.

The complexity of this multilevel network of systems makes it difficult to characterize as a unitary structure, but a few examples exist in the literature, including Sing and colleagues' elegant depiction of the developmental genetic architecture of complex diseases (e.g., Sing, Haviland, & Reilly, 1996) (see Figure 18.3) and at the opposite end of the biopsychosocial spectrum, Zucker's (2006) elaboration on Elder and Caspi's (1990) multigenerational linkage of individual, family, and historical events across three generations (see Figure 18.4). Although they are each incomplete, they convey a palpable sense of the multiple layers of system that operate a given point in time, that in turn change as time passes; they also convey how unspecified, and ultimately inaccurate, models are that purport to convey the mechanistic structure of addictive process but only operate within one or two of these systems (Cicchetti & Dawson, 2002). Perhaps the greatest challenge in these graphic representations is how to depict environment. The traditional view is that this is the simplest system of variation because its direction of influence is external to systems operating within the organism. It is often described only within the social domain, but it also encompasses the influences of social era and historical events (e.g., cataclysms, war) and to that extent surrounds all other mechanistic structures. Environment also operates internally, by way of variation in the neurohormonal, musculoskeletal, and organ systems, whose outputs are not all wired through brain (Maren, Phan, & Liberzon, 2013); to that extent, it is a system of influences that acts both externally upon the organism, and also internally, albeit in different ways.

Figures 18.5 and 18.6 provide a heuristic model of this multilayered system; it is laid out in this detail to allow specification both of targets of influence and also of timing of impact. As described here, it encompasses eight levels of analysis, involving genes, brain response/reactivity systems, the level of intermediate alcohol nonspecific phenotype (encompassing personality/temperament and behavior), environmental influences, depicted here as a unitary system, but capable of being disaggregated if the specificity of the variable network requires it (e.g., proximal social environment vs. interoceptive environment,

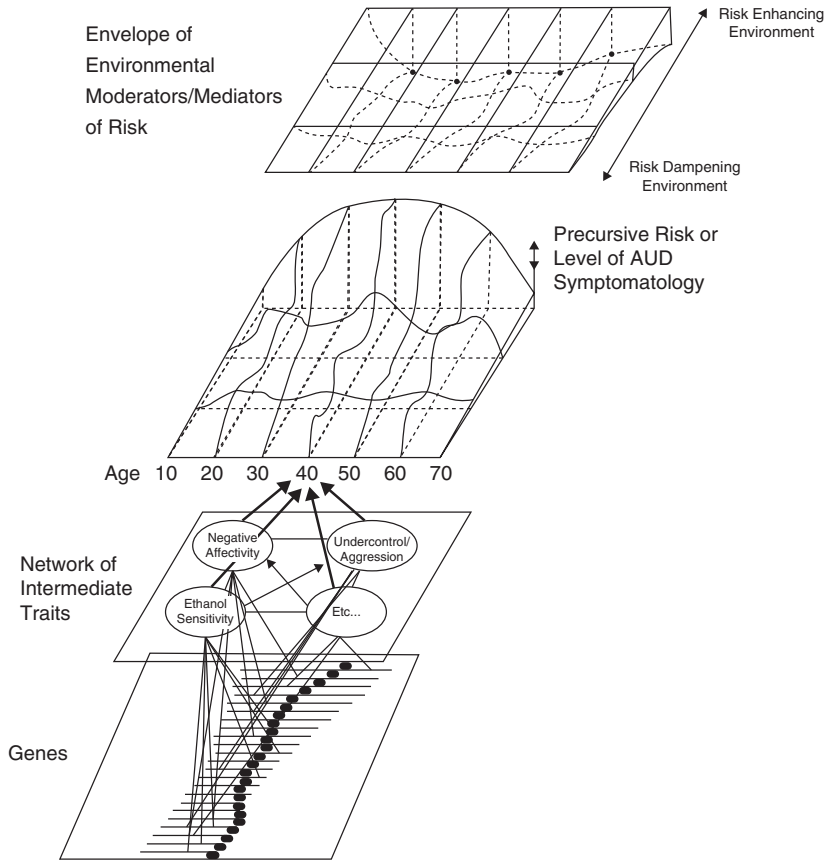

Figure 18.3 Probability of alcoholism (risk) over the life course: the envelope of risk expression as a function of genes, intermediate traits, environment, and life stage.

vs. distal (neighborhood, culture) environment, and time (both developmental and historical). Figure 18.5 diagrams the cross-sectional version of this multiply layered matrix, and Figure 18.6 is a crude depiction of the flow over time and across systems. The utility of this scheme is that it articulates the mechanistic scaffolding of a domain by charting the evidence for cross-level and cross-time connections, and it also identifies the connections that are currently unexamined. At the end of this chapter, we illustrate the utility of this matrix in characterizing multilevel gene–brain–behavior–environment relationships over the course of development.

VARIATIONS IN RISK AND COURSE OF DISORDER: ALCOHOL-NONSPECIFIC RISK, BEHAVIORAL DISINHIBITION, AND A HIERARCHICAL MODEL OF GENERAL AND SPECIFIC RISK FOR ALCOHOLISM

Not all of the casual structure for AUD is attributable to alcohol-specific processes. In fact, one of the historically most important findings of the past generation has been the repeated documentation of a link between an early and persistent pattern of antisocial behavior and earlier initiation of substance use and early onset substance use disorders (Donovan & Jessor, 1985). Earlier, we provided an overview of the work on problem behavior theory that emphasized the social psychological matrix for these differences. A parallel line of reasoning, driven strongly by a seminal paper by Tarter and colleagues (Tarter, Alterman, & Edwards, 1984), proposed that individual differences in temperament, ostensibly genetically mediated and relating to activity level, low attention span, and behavioral dysregulation are an essential early link in the chain of risk for alcohol use and problems in later childhood and adolescence. This temperamental substrate, coupled with an environmental structure that facilitates and even presses for the development of these initially neutral temperament attributes, is hypothesized to culminate in a behavioral adaption involving antisocial personality on the one hand, and a deviant peer network as a facilitating context on the other (Tarter et al., 1999; Zucker, Fitzgerald & Moses,

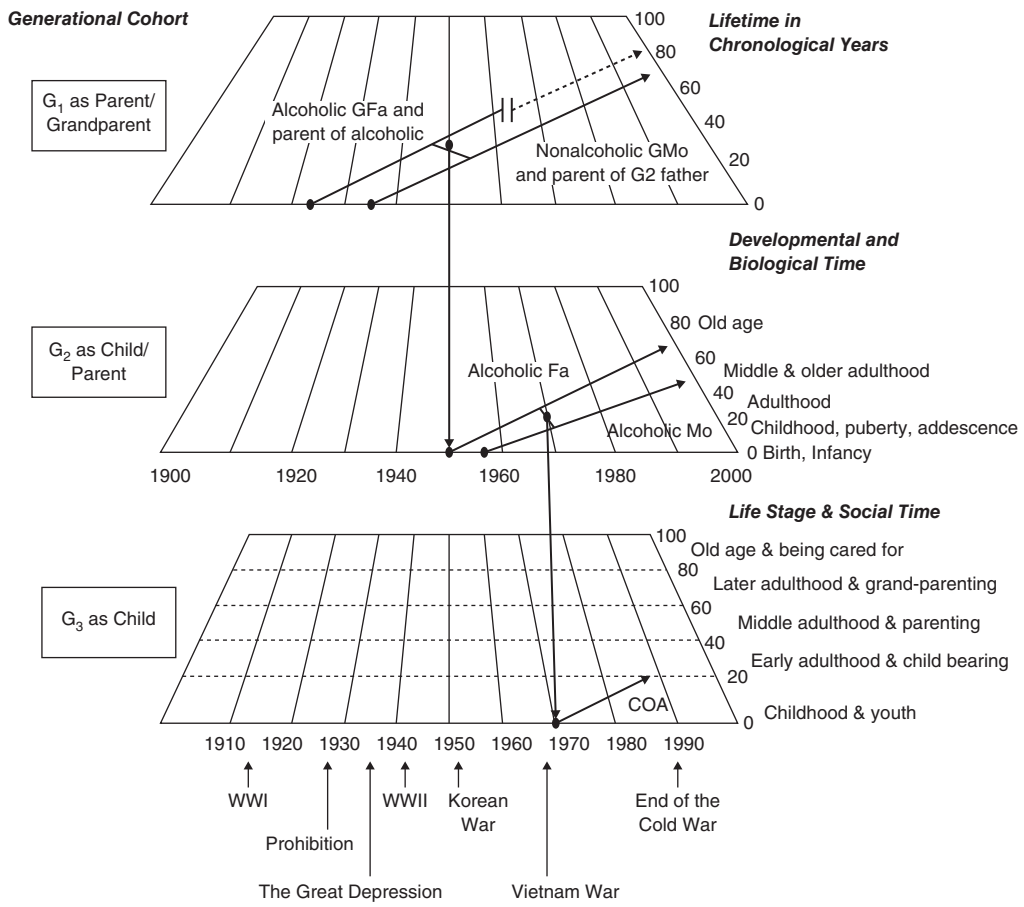

Figure 18.4 The multigenerational linkage of life-course trajectories in individual/developmental time, life-stage time, family time, and historical time: an example.

1995). These attributes are hypothesized to drive both initial alcohol use and the transition into early problem use.

Iacono, Malone, and McGue (2008) provided an updated summary of this line of research that conceptualized early onset substance use disorders as sharing common etiological influences with each other and other disorders, traits, behaviors, and neurological endophenotypes associated with behavioral disinhibition. Behavioral disinhibition was conceptualized as an inherited trait construct defined by an inability to inhibit socially undesirable or restricted actions. The phenotypic or observable manifestations of the behavioral disinhibition liability are typically referred to as externalizing behaviors, which include antisocial behavior, disinhibited personality traits, and substance use problems. The utility of the behavioral disinhibition model is that it helps to account for the high rates of co-occurrence among the various externalizing phenotypes. The model posits that a highly heritable behavioral disinhibition liability serves as a common diathesis, while environmental and disorder-specific influences (e.g., access to certain substances and not others, genetic sensitivity to certain addictive compounds) shape the final phenotypic expression of the general liability. This model then is ecumenical as it accounts for the high co-occurrence among externalizing phenotypes but also for why individuals develop some disorders and not others. Figure 18.7 depicts the Iacono et al. (2008) model of behavioral disinhibition and early-onset substance use disorders. The figure integrates the behavioral disinhibition liability, externalizing phenotypes, and environmental risk within a developmental context. A strength of the model is the hierarchical organization of general and specific risk factors, as well as its illustration of how the phenotypic expression of the behavioral disinhibition liability evolves over the course of development.

In childhood, behavioral disinhibition is evidenced by a collection of temperament traits—sometimes referred to as a difficult temperament (Tarter et al., 1985)—associated with undercontrolled behavior such as impulsivity, aggressiveness, hyperactivity, low frustration tolerance, lack of

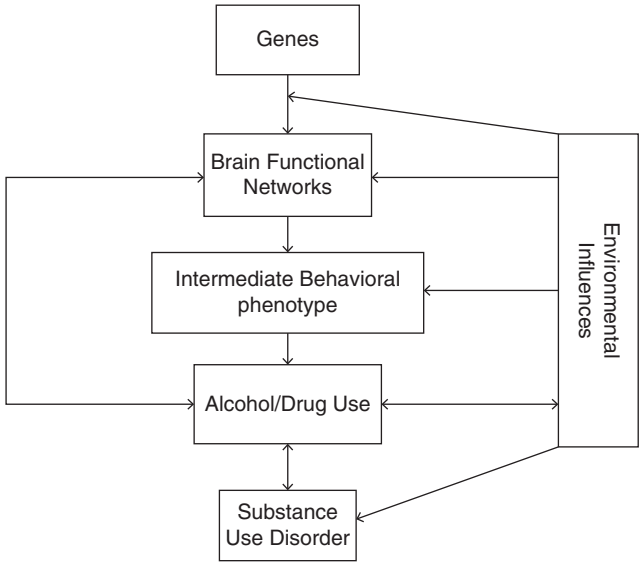

Figure 18.5 Cross-level/multidomain mechanistic structure of risk for alcohol use and AUD.

persistence, and inattention. Even in preschool aged children, these temperament traits have been associated with a greater familial loading for AUD, in particular, alcohol use problems of greater severity, duration, and comorbidity with antisocial behavior (Zucker, Ellis, Bingham, & Fitzgerald, 1996). Additionally, long-term prospective studies of both community and high-risk (e.g., children of alcoholics) samples have now verified that several of these trait markers of behavioral disinhibition that are present in preadolescence predict alcohol and other substance use problems in adolescence and young adulthood (Caspi et al., 1996; Cloninger et al., 1988; Dick et al., 2013; Hawkins et al., 1992; Hicks et al., 2014; Mayzer, Puttler, Wong, Fitzgerald & Zucker, 2002). The rate at which children mature and gain greater inhibitory control is also associated with risk for AUD, as those that are slower to do so are more likely to initiate alcohol and illicit drug use in adolescence (Wong et al., 2006). Further, as boys and girls transition into middle and later childhood, behavioral disinhibition takes the form of childhood disruptive behavior disorders including attention deficit hyperactivity disorder, conduct disorder, and oppositional defiant disorder. Consistent with the notion of a common liability, these disorders exhibit high rates of comorbidity, and are all associated with elevated risk for AUD and other substance use disorders in adolescence and adulthood (Iacono et al., 2008).

Continuing on the theme of nonspecific risk associated with behavioral disinhibition, the emergence of several problem behaviors in middle adolescence serves as an intermediate outcome linking externalizing behaviors in childhood to the eventual emergence of substance use disorders in adulthood (Jessor & Jessor, 1977). Such norm violating behaviors in adolescence include smoking, drinking alcoholic beverages, illicit drug use, delinquency, and precocious sexual behavior. Though the rate of these

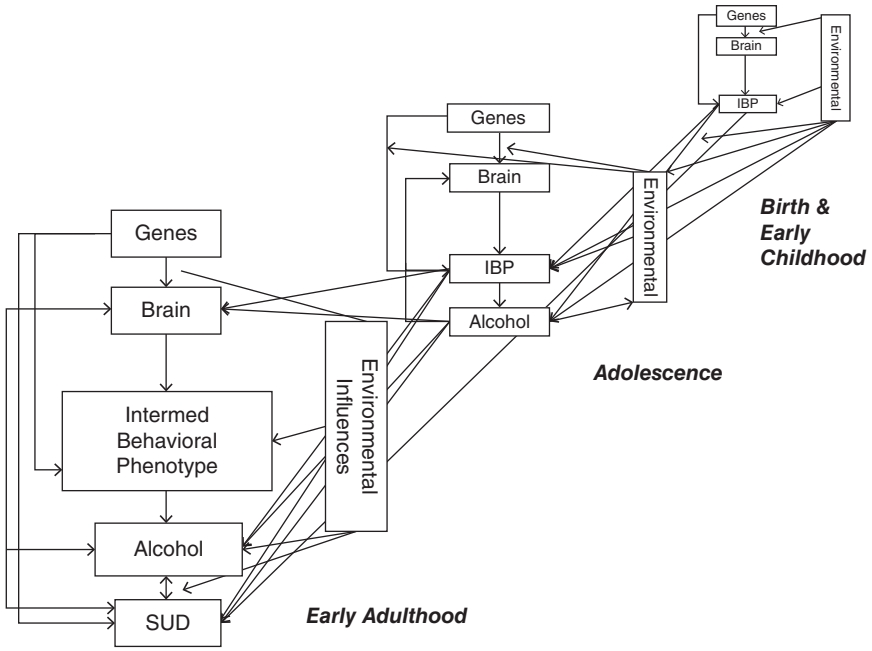

Figure 18.6 Multilevel mechanistic structure in developmental perspective.

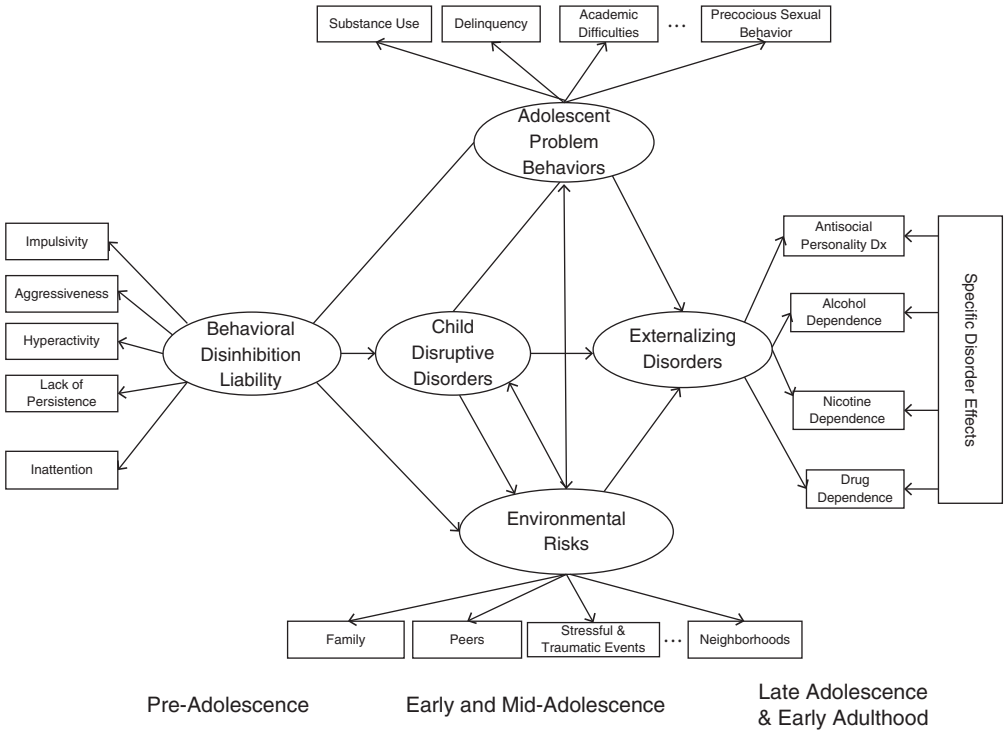

Figure 18.7 Model of behavioral disinhibition and early-onset substance use disorders. Note: the figure depicts the interplay among heritable individual differences characteristics and environmental influences on the development of three substance use disorders and antisocial personality disorder. Ellipses are latent variables that represent generalized risk factors. The variables in the boxes are conceptualized to represent specific and observable manifestations of these generalized risk factors. Specific genetic and environmental effects represented by the box at the far right work to differentiate the adult disorder from one another. Dots between the boxes are meant to indicate that other risk factors in addition to those depicted in the figure contribute to the development of substance use disorders. *Source:* Figure adapted from W. G. Iacono, S. M. Malone, & M. McGue, Behavioral disinhibition and the development of early-onset addiction: Common and specific influences, *Annual Review of Clinical Psychology, 4*, 12.1–12.24, 2008.

behaviors increases dramatically over the course of the teenage years, their early emergence—typically defined as prior to age 15—is associated with a substantial increase in the rate of AUD in adulthood. For example, Grant and Dawson (1997) found that initiation of alcohol use prior to age 15 was associated with a four-fold increase in risk for a lifetime AUD relative to persons who initiated alcohol use at age 20 or later. Rather than a causal factor per se, however, the evidence seems to favor a nonspecific mechanism of risk, with these problem behaviors being age appropriate markers of disinhibition. Focusing on an early initiation of alcohol use, McGue, Iacona, Legrand, Malone, and Elkins (2001) found that age of first drink predicted not only AUD but also nicotine dependence, illicit drug dependence, and antisocial personality disorder in adulthood, and was associated with an undercontrolled temperament, disruptive behavior disorders, and academic difficulties in preadolescence. McGue and Iacono (2005) went on to demonstrate that delinquency and initiation of alcohol, nicotine, illicit drug use, and sexual intercourse prior to age 15 all predicted not only AUD but also nicotine dependence, illicit drug dependence, and antisocial personality disorder at age 20. These findings were again consistent with the notion that adolescent problem behaviors represent an intermediate outcome along the behavioral disinhibition pathway to adult externalizing disorders.

The culmination of the behavioral disinhibition pathway is the emergence of full-blown substance use disorders and antisocial personality disorder in late adolescence and young adulthood. Consistent with the high co-occurrence among the different externalizing phenotypes present at earlier developmental stages, these disorders also exhibit high rates of comorbidity. Similar to models of childhood psychopathology (Achenbach, 1991), this externalizing factor is typically juxtaposed to a latent internalizing factor that accounts for the comorbidity among unipolar mood and anxiety disorders (Krueger & Markon, 2006). The behavioral disinhibition liability is often conceptualized as being a primary contributor to the comorbidity among the adult externalizing disorders. Interestingly, however,

the importance of this general liability in accounting for risk in the individual disorders seems to peak in late adolescence and then decline throughout adolescence (Vrieze, Hicks, Iacono, & McGue, 2012). People tend to be nonspecific in their substance use and abuse in adolescence, but tend to become more specialized in their drug use as they transition from young to middle adulthood. As such, disorder-specific factors become more important in the maintenance of addictions over time. These findings emphasize the hierarchical and ecumenical nature of the model. That is, behavioral disinhibition is not meant to account for every case of AUD; rather, the common disinhibition liability provides an organizing framework that incorporates both nonspecific risk that contributes to several correlated outcomes, that along with disorder-specific risk factors shapes the final phenotypic expression of substance use problems.

Environmental Risk: General and Specific

Environmental influences are also a key part of the behavioral disinhibition model and play a crucial role in development of AUD and other externalizing disorders (Hawkins et al., 1992). Similar to the hierarchical structure of externalizing symptoms, environmental risk can also be organized into influences associated with externalizing disorders in general, and environmental influences that have more specific effects for a given disorder (Bailey, Hill, Meacham, Young, & Hawkins, 2011). In fact, most of the environmental risk factors associated with AUD are associated with risk for externalizing disorders in general. For example, prenatal exposure to alcohol and drugs is associated with increased rates of conduct problems and alcohol and illicit drug use problems in adolescence (Baer et al., 2003). Childhood physical and sexual abuse is also associated with increased psychopathology in general including substance use disorders (Kendler et al., 2000). Several aspects of the family environment are also risk factors for conduct problems, antisocial behavior, and substance use problems including poor parent–child relationship quality, harsh and inconsistent discipline, and lack of parental monitoring (Granic & Patterson, 2006; Masten et al., 2008). Disinhibited children often experience difficulties in academic contexts related to both achievement and discipline, problems that tend to emerge early and persist through adolescence (Hawkins et al., 1992). Characteristics of a child's peer group are also strongly associated with antisocial behavior and substance use problems. Disinhibited children are often rejected by prosocial peers, and so tend to become isolated and depressed. As a consequence, disinhibited children tend to associate with each other, forming deviant peers groups that reinforce a culture of norm violation, potentiating individual risk factors (Dishion & Owen, 2002). A child's broader ecology such as aspects of their neighborhoods like poverty, residential instability, and crime rates are also nonspecific risk factors for antisocial behavior and substance use problems (Buu et al., 2009).

It is important to note that exposure to these different risk factors is not independent, that is, exposure to one risk factor increases the likelihood of exposure to another (Appleyard et al., 2005; Hicks et al., 2009). Further, exposure is disproportionately spread across the population such that a small number of people experience an especially high density of risk exposures. Additionally, the mechanism by which environmental variables increase risk for AUD and other externalizing disorders appears to be cumulative. That is, multiple rather than single exposures over time tend to be the norm, with the number of risk factors rather than the specific form of risk being the most important factor in the development of antisocial behavior and later substance use problems.

These contextual influences tend to carry over into adulthood. That is, as adults, formally disinhibited children tend to select into environments that help to maintain a pattern of maladaptive alcohol use (Masten et al., 2008). For example, persons whose AUD persists past young adulthood tend to maintain peer groups with norms for both frequent drinking and heavy drinking. Also, relative to the intimate partners of people whose AUD symptoms desist and drinking habits normalize by young adulthood (age 30), the intimidate partners of people who exhibit chronic alcohol use problems typically drink larger quantities and have more tolerate attitudes toward substance use (Hicks, Iacono, & McGue, 2010). Also, people with persistent AUD tend to remain in or migrate into disadvantaged neighborhoods as defined by high rates of crime, poverty, and residential instability (Buu et al., 2007). Transactional processes then between persons and situations contribute to the stability of the broader risk structure that helps to maintain AUD over the long term.

In addition to the nonspecific effects of many environmental variables, there are also a number of risk factors that are specific to AUD and other substance use disorders. The drinking patterns of parents and older siblings provide both norms regarding appropriateness of drinking as well as potential points of access, especially for underaged children. Bailey et al. (2011) found that the family drinking environment predicted AUD specific variance (i.e., independent of externalizing) after accounting for measures of

the general family environment. More generally, the social environment (context) plays a role in cueing (triggering craving), and in providing greater or lesser availability of the drug. Alcohol involvement within a heavy using social context is a significant element precursive to establishment of disrupted reward process, as well as influencing the probability that remission will or will not take place among recovering individuals. The epidemiologic literature provides some well-known examples of these effects. For one, the wetness or dryness of the society (Skog, l985) changes the threshold within which alcoholism will appear (Reich, Cloninger, Van Eeerdewegh, Rice & Mullaney, l988); a wetter society increases the rate of AUD in its population, and a drier one decreases it. Another longer term effect is that a lower level of genetic susceptibility is more likely to be expressed in higher as compared to lower consumption societies since drinking rates will be higher in the higher consumption environment. Under those circumstances, even persons with the lower susceptibility will be more likely to move into diagnosis because they are more likely to drink heavily due to greater environmental cueing (also see Rose, Kaprio, Winter, Koskenvuo, & Viken, 1999 for another example of such interactions).

Change in rates of heavy use as a function of change in legal age of access to alcohol is still another such example. Thus, drinking and driving accidents and loss of life during the 18 to 20 period noticeably decreased as a result of legislation moving the legal age to 21 (Wagenaar & Toomey 2002). The spread of effect beyond age 21 gives some sense of the long lasting impact of the change. Lower drinking rates were also found in the subsequent 21–25-year-old age period (O'Malley & Wagenaar, l991). More recent work has also shown lasting differences in drinking outcomes for those living in the era before the age 21 limit was in effect as compared to those living in the years thereafter, who were exposed to the legislation. Even when in their 40s and 50s, the nonexposed group had higher rates of both alcohol use disorder and other substance use disorder (Norberg, Bierut, & Grucza, 2009). Ultimately our models of process need to incorporate these cohort exposure variations as well.

Is There an Internalizing Pathway to AUD?

In addition to behavioral disinhibition, internalizing distress is hypothesized to be another precursor to AUD (Hussong et al., 2011). In the adult literature, internalizing typically refers to diagnostic symptoms of unipolar depression and anxiety disorders along with personality traits such as neuroticism and negative emotionality. In early childhood, this liability is expressed as a cluster of traits that includes lack of approach and exploratory behavior, passivity, flat affect, discomfort with novelty, shyness/social fearfulness, and anxiety when separated from caregivers (Capsi et al., 1996; Fox et al., 2005). This inhibited temperament predicts depression, anxiety disorders, and negative emotionality in childhood and adolescence (Capsi et al., 1995, 1996), which are correlates of substance abuse as well as predictors. The prospective associations between inhibition and substance abuse/AUD in adolescence and adulthood have been found in a number of prospective studies in addition to that of Caspi et al. (1996) (compare to Cloninger et al., 1988; Hawkins et al., 1992; Mayzer et al., 2002). The relationships are modest, however, especially after accounting for externalizing, and seem stronger for depressive and social inhibition indicators than for anxiety symptoms (Chassin et al., 1999; Kaplow et al., 2001; King et al., 2004). Interestingly, some investigators have found that inhibition/internalizing in childhood predicts abstaining from substance use in adolescence (Shedler & Block, 1990), while others have found a negative association with substance use/abuse in adolescence and adulthood (Cloninger et al., 1988; Kaplow et al., 2001). This suggests that different aspects of inhibition/internalizing have differential associations with substance use and abuse (e.g., lower risk for social fearfulness and discomfort with novelty, higher risk for depression and stress reactivity; Kaplow et al., 2001).

Recently, two research teams working independently reported similar findings that childhood temperament/personality traits associated with *low* internalizing predicted substance use and abuse in adolescence. Dick et al. (2013) factor analyzed temperament ratings of over 12,000 children in the UK that were assessed on multiple occasions from 6 months to 5 years old and identified two largely uncorrelated temperament dimensions. One was called *emotional and conduct difficulties* and seemed to tap externalizing. In contrast, the other trait called *sociability* was characterized by lack of shyness and high social engagement and activity. Sociability predicted both alcohol use and alcohol problems at age 15.5 over and above emotional and conduct difficulties, with the effects of sociability partially mediated by the later emerging personality traits of extraversion and sensation seeking and selection into antisocial peer groups in emerging adolescence (ages 10.5–13).

Using a very different approach, Hicks et al. (2014) reported similar findings in a large sample of twins born in Minnesota that were first assessed at age 11. Specifically, they used an empirical approach to identify the traits and

behaviors present prior to initiation of substance use that best predicted substance use problems at age 17. The first trait was called *socialization* and was characterized by a propensity to conform to rules, endorse conventional values, and accept adult supervision. Low socialization had strong associations with childhood disruptive behavior disorders, parental externalizing disorders, and a composite of environmental risk. Hicks et al. then found that a trait called *boldness*—characterized by social dominance and social engagement, stress resilience, and thrill seeking—best-predicted substance use problems after accounting for socialization. Boldness was uncorrelated with socialization, childhood disruptive behavior disorders, and parental externalizing disorders and had negative associations with internalizing and a composite of environmental risk. Also, boldness was highly heritable (.71), while socialization exhibited both moderate heritable (.45) and shared environmental (.30) influences (i.e., environmental influences that contribute to similarity among relatives). Though socialization had a larger effect ($r = -.44$), boldness exhibited a small but robust ($r = .22$) incremental effect in predicting a composite of substance abuse in adolescence and young adulthood in both the development sample and a replication sample. Follow-up analyses showed that much of the effect of childhood socialization on substance use problems in late adolescence was mediated by selection into high-risk environments in middle adolescence (Hicks et al., 2013, 2014). In contrast, boldness had a direct, genetically mediated effect on substance abuse that was largely independent of the environmental context in childhood and middle adolescence.

The consistency of the results reported by Dick et al. (2013) and Hicks et al. (2014) are striking given the different approaches to identify personality traits, the different ages and nationalities of the samples, and the large sample size and sophisticated measurement and follow-up assessments of each study. Clearly, in terms of childhood characteristics that increase risk for alcohol and other drug use and abuse, there is something beyond externalizing, but it does not appear to be internalizing per se. Rather, the convergence of sociability, social dominance, stress immunity, and thrill seeking seems to increase risk for substance abuse while also decreasing internalizing. Conceptually, the sociability and boldness constructs identified in these reports are similar to low behavioral inhibition, a trait defined in young children by low social and object fear and ease in novel, uncertain, and potentially frightening situations (Fox et al., 2005). Also, Patrick, Fowles, and Krueger (2009) posited that a boldness trait characterized by high self-assurance and social efficacy, resilience to stress and coolness under pressure, and tolerance for unfamiliarity and danger underlies the interpersonal facets of psychopathy that have been associated with reduced fear-potentiated startle. Low fear-proneness is hypothesized to be the genotypic disposition underlying both low behavioral inhibition and psychopathic boldness, which are potential phenotypic expressions of constitutional fearlessness. Low temperamental fear as expressed in interpersonal contexts and a proclivity for venturesomeness then may be a temperamental risk factor for substance use problems that is relatively independent of the behavioral disinhibition liability, although it is the obverse of social inhibition.

While the findings for boldness offer an interesting new direction, the link between internalizing and alcohol use problems remains unclear. Though childhood internalizing may not increase risk for substance use problems, internalizing may moderate (i.e., magnify) the influence of externalizing traits. Alternatively, the link between internalizing and alcohol use problems may primarily be present as a function of adult psychopathology. For example, heavy alcohol use may be used to reduce the feelings of negative affect associated with social anxiety or trauma-related symptoms of posttraumatic stress disorder. This is more likely to take place in adulthood, when the social inhibition and reticence associated with high anxiety may not be sufficient to curb the need to find relief. At that point, heavy alcohol use may come into play. (See Section 5 discussion of negative affect alcoholism.) Also, internalizing may play a stronger role in the onset and maintenance of alcohol use problems for women relative to men. Whatever the case, the link between internalizing and alcohol use problems in adolescence and young adulthood is complex, such that longitudinal analyses that can clearly track their co-development are necessary to better understand the nature of their relationship. In addition to the broad internalizing and externalizing dimensions, there is some evidence that childhood sleep problems are also associated with later substance use and abuse. Wong et al. (Wong, Brower, & Zucker, 2009) observed a relationship between ratings of sleep problems at age 3 to 5 and early onset of drug use (alcohol, cigarettes, marijuana, other hard drugs). The relationship remained even when a number of other plausible mediators, including family history of alcoholism and externalizing problems (specifically, attention problems and aggression) were added into the predictive model. In other words, sleep difficulties very early in life appear to be a marker of an independent contributor to early substance involvement. Given that early alcohol use has repeatedly been identified as a proxy for elevated later risk of alcohol dependence, as well as a host

of adolescent problems including injuries, violence, and drunk driving (Gruber, DiClemente, Anderson, & Lodico, 1996), these data support a third risk pathway. Although a self-medication hypothesis, a negative emotionality hypothesis, or a central dysregulatory deficit hypothesis are all plausible mechanistic explanations for the internalizing effect, the mechanisms undergirding that relationship remain to be disaggregated.

Heterogeneity in the Course of Risk: Heterogeneity of Nonspecific Risk

As just discussed, although behavioral disinhibition expressed as early and persistent antisocial behavior is the most robust and reliable predictor of substance use problems, it remains only one of a number of risk factors that contribute to AUD. In fact, the majority of people with AUD do not exhibit a persistent pattern of antisocial behavior, indicating that there are multiple pathways that lead to AUD and that the category likely includes several subtypes based on differing etiological factors. Equifinality is a well-known systems theory concept wherein multiple, sometimes linked and sometimes disparate processes engage in a way that produces a common phenotypic endpoint. The core etiologic question then is how do people with distinct risk profiles reach this common outcome, and to what degree will their longer-term developmental trajectories converge or diverge over time?

We illustrate the interplay among key risk factors of externalizing, internalizing, and family adversity over the course of developmental by summarizing work from the Michigan Longitudinal Study (MLS; Zucker et al., 2000, Zucker, 2014). This longitudinal, high-risk for substance abuse family study has followed alcoholic men, their spouse and children, and a suitably matched but nonalcoholic set of contrast families drawn from the same high risk neighborhoods where the alcoholic families lived. All family members were assessed at 3 year intervals beginning when the target boy was 3–5 years old. A person-centered approach was used to examine the joint effects of family adversity and child risk vulnerability from ages 3 to 14 years. The adversity index assessed level of family pathology and included the severity of AUD and the presence or absence of antisocial behavior in each parent (cf. Wong, Zucker, Fitzgerald, & Puttler, 1999; Zucker et al., 2003). Although based on parental psychopathology, this index is an effective proxy for a number of other pertinent indicators of family adversity, including greater conflict, violence, economic difficulty, family crises, other psychiatric comorbidity, and trouble with the law (Zucker et al., 1996b).

The child's initial risk status at ages 3–5 was assessed with the Total Behavior Problems scale of Achenbach's Child Behavior Checklist, a global psychopathology measure that is nationally normed. Low risk was defined as being within normal limits on this index, high risk was defined as being at the 80th percentile or higher on the measure. A 2 x 2 grid was created by crossing family adversity and child behavior problems. *Resilient children* were defined by having normal to high adaptation (i.e., low risk scores) even though they were living in high adversity families. The normal risk under conditions of low family adversity group was labeled *nonchallenged* to emphasize that their behavior was unremarkable within families of low adversity that were more likely to be nurturant and encouraging. Children with high problem behaviors under conditions of high family adversity were labeled *vulnerable*, to emphasize both the continuing exposure to family difficulty and the likely high genetic load for substance use disorder. Lastly, children with high behavior problems under conditions of low family adversity were characterized as *troubled* to emphasize poor behavioral adaptation, even without the pressures of family adversity.

Figure 18.8 shows the trajectory of externalizing problems for each of the groups, and Figure 18.9 shows the trajectory of internalizing problems from preschool to early adolescence. Overall across-age group differences were significant for both externalizing and internalizing problem trajectories. The nonchallenged group sustained the lowest level of externalizing problems over the course of childhood and early adolescence, followed by the resilient

group, the troubled group, and the vulnerable group. Externalizing scores tended to decline over childhood (normative for this age range; Loeber, 1982), and there was increasing convergence in externalizing scores across the groups through middle childhood. At the transition to adolescence, the normative pattern of a developmental shift involving increased externalizing behavior was present (cf. Jessor & Jessor, 1977). Though the resilient children were not different from their nonchallenged peers as preschoolers, they showed more externalizing problems as they grew older. That is, a small but detectable convergence with the other initially more externalizing two groups starts to become manifest. At the same time, they still occupied an intermediate place, having a lower level of these behaviors than did their vulnerable peers. Additionally, the divergence of slopes between ages 9 to 11 and 12 to 14 involved a significant interaction between children's initial risk and level of family adversity. That is, externalizing problems increased more for children with the greatest initial risk status and family adversity during a period of life when the overall norm is for increasing deviant and impulsive activity.

Figure 18.9 shows the trajectories for internalizing problems; here also the nonchallenged group had the lowest scores, followed by the resilient group. Scores for the troubled and vulnerable groups were similar to each other. The figure also shows important pattern variations. During preschool and up through the early school years, nonchallenged and resilient children were significantly lower in internalizing symptoms than both the vulnerable and troubled groups, and there were no differences between the resilient and the nonchallenged children. The pattern begins to diverge following second to third grade, and by early adolescence the nonchallenged group is significantly lower than all others, and no differences exist between any of the other three groups. In other words, at this juncture the resilient children had developed a level of internalizing symptoms that was similar to both the vulnerable and the troubled children. A significant interaction effect of time and adaptation group indicated that the developmental trajectories of internalizing problems varied differently among the adaptation groups, with three of the four showing a continuity pattern, and one a discontinuity pattern.

At a more phenomenological level, the internalizing trajectory pattern of the resilient group implies that a weathering process had been taking place, wherein an initially happier adaptation gives way to the sustained exposure to an adverse, more conflictual environment involving more family stress and disruption. The result, by early adolescence, is that the level of internalizing behavior for this group was indistinguishable from the initially more troubled and vulnerable children. These data provide a poignant illustration of how the shift from normal to pathological adaptation may take place under circumstances of sustained adversity. Recall, however, that this shift only occurs in the more covert, internalizing behavior domain; the more obvious externalizing behavior differences remain, with the resilient children sustaining a pattern that differentiates them from their vulnerable and troubled peers.

The trajectory variations reflect more than just differences in nonspecific risk over time. They also are proxies for differences in probability of eventual problem drinking, other problem behavior, and alcohol dependence (Ellickson et al., 2003; Grant & Dawson, 1997). In the Michigan study, Mayzer and colleagues (2009) confirmed the first step in this chain of effect by showing that higher levels of early externalizing and internalizing behavior were predictive of both early onset of drinking, as well as higher levels of externalizing and internalizing behavior and delinquent activity in adolescence. But several steps in the causal structure are still not well enough understood. We have already discussed this caveat vis-à-vis the internalizing pathway in the section just preceding. However, a qualifier also exists for the predictive power of the externalizing pathway. Other analyses have shown that the level and rate of change of externalizing problems are partially attributable to an active environment including parental conflict and harsh and inconsistent discipline (Fuller et al., 2003; Loukas, Zucker, Fitzgerald & Krull, 2003). However, these studies cannot disentangle the nesting of high child risk in high biological risk families. It is possible that the

higher levels and persistence of problem behaviors that appears to be a socialization effect is actually the result of indirect genetic effects?

Recently, Trucco and colleagues (2015) extended these findings in two ways: by (1) using an empirical approach to parse the heterogeneity of nonspecific risk in adolescence in the MLS; and (2) by examining the interplay between genetic, personality, and environmental risk factors). Growth mixture modeling was used to evaluate whether there were distinguishable trajectory classes of externalizing problems over the course of adolescence (12–17). Additionally, the work examined the impact of parental monitoring and variants of the GABRA2 gene, a gene located on chromosome 4 that codes for the alpha-2 sub-unit of the receptor of the neurotransmitter GABA-A. Variants of GABRA2 have been associated with both AUD and externalizing behavior, and the interaction between parental monitoring and GABRA2 variants predicts trajectory classes of externalizing problems in childhood and adolescence (See also Dick et al., 2009).

In the Trucco study, three trajectory classes provided the best fit to the data. The majority of adolescents (77%) exhibited consistently low levels of externalizing. A small subset (10%) had higher initial levels of externalizing that decreased across adolescence. The last group (13%) had moderate initial levels of externalizing that increased at a nonlinear rate throughout adolescence. Both parental monitoring and parental AUD increased the odds of being in the decreasing or increasing externalizing groups relative to the low externalizing group. Further, there was an interaction between parental monitoring and *GABRA2* genotype such that carriers of the minor allele were more likely to be in the increasing externalizing trajectory in the context of low parental monitoring relative to the decreasing and consistently low trajectory groups. These results provide an excellent illustration of the interplay among genetic, environmental, and developmental influences on precursive risk for alcohol use problems that ultimately contributes to the relatively distal outcome of AUD.

VARIATIONS IN RISK AND COURSE OF THE DISORDER: EMERGENCE AND COURSE OF ALCOHOL-SPECIFIC RISK

When Does Risk for Alcohol Involvement Begin?

It is extremely rare to see a 5-year-old consuming alcoholic beverages, given that the normative expectation among youth, as well as the modal behavior in American society, is for self-initiated drinking of alcoholic beverages to commence around age 14. The problem use figure also slowly moves upward with age, with 16% of tenth graders, 25% of twelfth graders, and 40% of college students reporting binge use in the prior 2-week period. (Johnston, O'Malley, Bachman, & Schulenberg, 2009). At the same time, age progression is, of itself, not an explanation of process but rather a chronological marker of other events that lead to onset or problem use. Individual differences in age of onset are attributable to differences in the rapidity of emergence of the underlying causal event structure. The developmental question is one of specifying the events and circumstances under which they show up.

From this perspective, neither first drinking experience nor first bingeing experience are the beginnings of the process of alcohol involvement, or of the emergence of alcohol problems, abuse, and dependence. Alcohol has a place in the ritual practices of many religions, and thus allows children to have minor consumption experience well before they have made any conscious decision to drink (Hanson, 2013). Even more so, media exposure assures that some knowledge of alcoholic beverages is present well before peers offer the opportunity for drinking to take place (Smith & Foxcroft, 2009). More generally, for regular (volitional) drinking to take place, the child implicitly needs to be aware that there is a class of substances, collectively known as alcoholic beverages, and that these substances have certain properties (effects) connected to their ingestion. This involves the development of an alcohol schema; i.e., a concept containing knowledge of the features or attributes of the object and the situations in which it comes into play (Baldwin, 1992). It also involves the development of a set of cognitions—expectancies—about the situations and manner of use. These expectancies need not all be explicit; some are not verbalizable, but they play independent roles in guiding/directing the behavior (Reich, Below & Goldman, 2010). They need to be sufficiently favorable/positive to motivate the individual to engage in alcohol seeking (or at least alcohol accepting). These properties, collectively known as implicit cognitions (Weirs & Stacy, 2006) and outcome expectancies (Goldman, Reich, & Darkes, 2006), have been shown to be direct effect predictors of both alcohol and other drug use (Andrews, Tildesley, Hops, Duncan, & Severson, 2003; Stacy & Weirs, 2010).

The theoretical base for this work has been the social cognition and memory process literatures (e.g., Tiffany, l990) which has emphasized not only the representational but also the motivational attributes of internally constructed cognitive models (schemas) (Ajzen, 1991). From

the perspective of the observer, the actual decision-making may appear too rapid for this to occur. But a now voluminous literature involving carefully controlled laboratory studies has shown how the underlying details which shape the decision making can be identified. A complex interplay of affective as well as rational elements is factored into the subjective equations that underlie ongoing drinking behavior, as well as the decision-making about whether one should initiate drinking in specific situations, or refrain (Stacy & Weirs, 2010). The developmental question is, how and under what conditions are these elements learned?

Within this conceptual tradition, and using methods that allow young children to tell the experimenter about their knowledge of the rules that govern alcohol use, a number of developmentally early focused studies have shown that preschoolers in the general population already know two of the core alcohol use schemas of the larger culture: the children, even at age 3 to 5, already attribute alcoholic beverage consumption more to adults than children, and more to adult males than adult females (Noll, Zucker, & Greenberg, 1990). In addition, the ability to identify alcoholic beverages by smell (an indicator of personal exposure rather than simply media exposure) was both age graded and also based on experiences going on in the home. Older children were better at identifying these beverages than younger ones, and the ability to recognize alcoholic beverages was directly related to the amount of alcohol the parents consumed, as well as the degree to which their parents' reported use of alcohol for escape reasons (Mennella & Foresell, 2008; Noll et al.,1990).

A logical extension of this work is the examination of possible differences in schema structure in high risk populations such as children of alcoholics (COAs), for it is here that exposure differences would be most likely expected, and also where the early identification of risky cognitions would be anticipated to be of greatest long term significance. Zucker, Kincaid, Fitzgerald and Bingham (1995b) explored this possibility by examining differences in alcohol use schemas in preschooler COAs and suitably age matched children from nonalcoholic homes. They asked children to identify photographs of alcoholic beverages, and also examined the degree to which alcoholic beverage use was attributed to people depicted in common situations where beverages are consumed (e.g., at a meal, on a picnic, at an adult party). COAs were more likely to identify at least one alcoholic beverage, and were better able to correctly identify specific alcoholic beverages. Differences in the children's attributions of alcoholic beverage use to adults were again predicted by their parents' reported level of alcohol consumption. In short, alcohol schemas relating to both knowledge and use were more common in the alcoholic families.

Mennella and colleagues (1998, 2008), in a series of interesting studies, have also shown that children's exposure to alcohol in the home has significant effects on their response patterns and opinions. Mennella and Beauchamp (1998) found that children's opinions about alcohol (mouthing or not mouthing a toy among infants; liking or not liking the smell of alcohol in primary graders, is related both to level of consumption by the mother, and age of the child. Young children with escape drinking mothers were more likely to mouth a toy that was alcohol scented than those whose mothers were nonescape drinkers. In another study in the series, among early school graders, although children from both types of drinking homes identified the beer smell equally well, children of escape drinkers were more likely to dislike the smell (Mennella & Garcia, 2000). Further, children of escape drinkers took longer to decide whether they liked the odors than children of nonescape drinkers.

In a mechanistic sense, the relationships of olfactory stimuli to neural circuitry are of considerable importance. As noted by Menella and Forestell (2008):

> Unlike other sensory systems, the first cortical relay is not the thalamus but rather the primary olfactory cortex which then links with the amygdala-hippocampus complex of the limbic system. The unique processing of olfactory information and the olfactory system's immediate access to these neurological substrates underlying non-verbal aspects of emotion and memory explains why verbally identifying an odor [is] a more difficult task for children than deciding whether they like the odor. (P. 252)

It also provides another reason that early learning about alcohol is so closely tied to the child's later behavioral experience. Given the importance of this circuitry in later childhood and adolescence in determining reward responsivity and affective response, it also raises the interesting question of whether there might be some interactive relationship between such early exposure and later risk responsivity. This issue has not been examined.

Taken together, these studies indicate that there is a steady path from the very earliest learning about alcohol to the emergence of rudimentary schemas, initially one characterized by the ability to recognize the object, moving on into the development of a set of cognitive schemas about how the object/substance is used by others, and developing thereafter into an implicit and explicit expectancy structure about use. The social environment plays a major role in this process insofar as the presence of drinkers/heavy drinkers stimulates earlier movement

through this sequence. The experience of frequent exposure and easy availability set the stage for an expectancy structure that is positive, and this in turn is an important feature that primes the individual to be open to use, and possibly also to seek out use, when the opportunity presents itself. Conversely, involvement in a social environment where youth drink moderately or not at all, makes the nondrinker much less likely to begin, and if experimenting, much less likely to move into more regular use. At the same time, as described previously, individual differences in nonspecific risk are also priming the individual to engage in (or refrain from) drinking. These personality/temperament differences shape the choice of peers, which will both make the social environment a heavier (or lighter) using one, and also make access to alcohol (and other drugs) more or less available. In addition, individual differences in sensitivity of response to the drug's intoxicating effects also play a role in dampening or enhancing the movement into a heavier drinking career (Schuckit et al., 2001). Low sensitivity of response allows the individual to drink more without noticeable effect. Moreover, some individuals are energized by consumption, others find it soporific, and still others find the experience aversive. These differences in pharmacodynamic response to the drug all have a significant genetic component, and at the behavioral level are a starting point for choice of contexts and likelihood that context influences will play a significant role. The more general point is that there is also heterogeneity of course for alcohol-specific risk from early on in the drinking career.

Multiple Pathways of Alcohol-Specific Risk: Heterogeneity of Course of Problem Use

Just as there are multiple developmental pathways of nonspecific risk, parallel evidence for heterogeneity of course for alcohol-specific risk has also been found both for problem use and also for disorder. We first describe findings from the Arizona Family Study (Chassin, Barrera, Bech, & Kossak-Fuller, 1993), one of the core studies that has demonstrated heterogeneity in trajectory of precursive alcohol problems, which in turn lead into disorder. The Chassin study utilizes a high risk sample of COAs and controls. Its trajectory analyses used one of the most common problem drinking indicators, binge drinking (5 or more drinks in a row), and tracked the longitudinal course of problem use across the 12 to 23 age range. This is the age period between the very earliest-start drinking and the time where downward tapering of heavy drinking begins for the majority of drinkers—in the early to mid-20s (Chassin, Pitts, & Prost, 2002). Four trajectories of binge drinking were identified that differed in acceleration into problem use as well as maximum level of bingeing (Figure 18.10). The heaviest/highest problem users only involve about 20% subjects—even in this high-risk sample—and reach their peak use substantially earlier than the other heavy-use

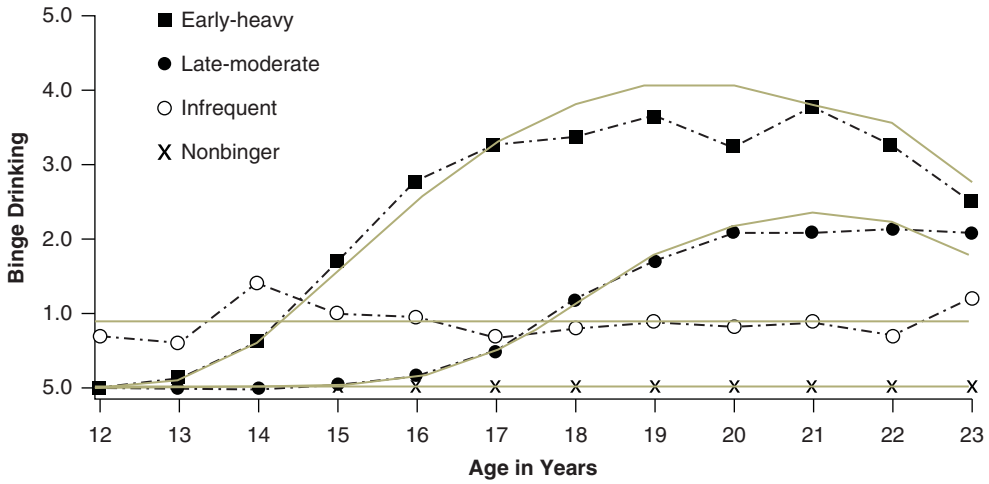

Figure 18.10 Growth curve trajectories of binge drinking from adolescence through emerging adulthood. Note: solid lines represent estimated growth trajectories for the three groups from the mixture modeling. Dashed lines represent observed means of binge drinking at each age for each group. Observed frequencies of binge drinking (past year) ranged from 0 (none) to 5 (1–2 times a week). Nonbinger group, $N = 176$, 39.5% of the sample. Early–heavy group, $N = 93$, 20.9% of the sample. Late–moderate group, $N = 134$, 30.0% of the sample. Infrequent group, $N = 43$, 9.6% of the sample. See footnote 1. *Source:* Reproduced from L. Chassin, S. C. Pitts, & J. Prost, Binge drinking trajectories from adolescence to emerging adulthood in a high-risk sample: Predictors and substance abuse outcomes, *Journal of Consulting and Clinical Psychology*, *70*(1), 72, Figure 1, 2002. doi:10.1037/0022–006X.70.1.67

group, the late-moderate bingers. Two groups show little (infrequent binger) to no problem (nonbinger) use. More involvement with drinking peers was either causal, or traveling with the heavy consumption patterns (adolescents with greater peer drinking were more likely to be in the heavier drinking groups, and the heavy-early group had the highest levels of precursive risk (alcoholic family membership, parent with antisocial personality disorder, and males were highest in externalizing behavior at baseline). Females were more likely to be in the nonbinger and infrequent groups. Perhaps most importantly for the linkage of earlier problem behavior to later problem outcome, all the bingeing groups were at higher risk for later substance use disorder. Equally importantly, speaking to the issue of early harbingers foreshadowing later problem outcomes, even the lowest frequency bingers (infrequent group) were as likely as the early–heavy group to develop drug abuse and dependence. In contrast, those without adolescent binge drinking were thereafter most likely to become full-time college students.

The Chassin group findings have been largely duplicated by nonhigh risk and general population studies examining trajectory variations from adolescence into early adulthood (Schulenberg, O'Malley, Bachman, Wadsworth, & Johnston, l996a; Windle, Mun, & Windle, 2005), as well as by studies beginning in later childhood (Hill, White, Chung, Hawkins, & Catalano, 2000). This work also has documented the importance of both precursive nonalcohol behavioral differences and context (peer drinking) as differentiators of class membership. Moreover, the Schulenberg et al. study demonstrates a point that is essential to our emphasis on the importance of understanding developmental heterogeneity, namely that the population trajectory (i.e., the summative trajectory for all individuals) is completely misleading as a characterization of developmental process for any of the individual trajectory groups; patterning conveyed by using population means does not summarize any subgroup of individual experiences.

One last point: in these studies, one problem use trajectory that systematically emerges is characterized by elevated child problems prior to adolescence and a damaged, high stress socialization environment, often enriched for family history of alcoholism. The Chassin Early-Heavy group trajectory, the Hill Early High trajectory, the Schulenberg Chronic group, and the Windle Very High Heavy Drinking trajectory group all fit this pattern. The residual trajectory class (or classes) identified have typically been less well replicated and the more recent and more precise analytic work gives some clues about why this might be. If more developmental variability exists in those lower risk, lower symptomatology subgroups, then less differentiating analyses will more often merge them, sometimes identifying them as one other group and sometimes identifying more than one.

Heterogeneity of Alcohol Use Disorder and Variations in Developmental Course of the Disorder/Phenotype

In contrast to the work on youth and early adulthood, efforts to characterize course in adulthood historically have had a more clinical focus, namely to describe differences in emergence and course of symptoms that would effectively differentiate subsets of patient populations with different clinical histories, current functioning, and longer term prognosis. In addition to their potential descriptive utility in sorting out the disparate symptomatology of alcohol use disorder, the underlying motivation for such typological classification is to identify subtypes of individuals who would respond differently to treatment regimens, and might also conceivably need different regimens for resolution of the disorder (Leggio, Kenna, Fenton, Bonefant, & Swift, 2009). To identify the subtype then provides a clinical shorthand that quickly conveys all of this information by means of a typological label.

Babor's (1996) still relevant historical review of the classification/typology literature has been able to identify these typological classifications as far back as 1850. His paper concludes that the major empirical classification studies repeatedly rediscover two types, summarized as Apollonian and Dionysian. The former is characterized by later onset of alcohol dependence, a slower disease course, fewer social complications, less psychological impairment and a better prognosis, and the latter is characterized by early onset, physical aggression, more severe symptomatology, a denser positive family history (suggesting a stronger genetic basis for the disorder), and more personality disturbance (Babor, 1996). At the same time, the simplicity leaves important features out, and the field has continued to struggle with how best to characterize these differences in clinical presentation and developmental course. The most recent summary review of this work by Leggio and colleagues (2009) identifies 12 classification typologies that characterize anywhere between two and five subtypes. From the perspective of these volumes, there are two problematic features of these classification systems that go relatively un-noticed. One is the heavy utilization of treatment samples to establish the classification scheme. This is inherently a biased activity, given the restrictions in range of variation, severity, comorbidity, and sometimes even age that are found in such clinical populations. Given

that only about 8% of those with alcohol use disorder receive treatment (Edlund, Booth, & Han, 2012), there is a broad swath of diagnosable cases that never come under scrutiny. Moreover, among those not under study are those who move into diagnosable problem, but then move out of it. The features of the disorder (and its surrounding context) that produce this are thus lost to the models of causal structure that are constructed to explain the course and variations of the disorder. At the same time, general population studies may not be heavily enough seeded with risk to allow disaggregation of rarer factors, or comorbidity that may be an intrinsic part of the disorder. Carefully selected patient samples and their cohorts (e.g., COGA) may allow investigators to address this issue, but the generalizability question needs to be kept in the forefront when doing so.

The other problematic issue is the lack of attention to full developmental course of the syndrome, and in particular, the identification of risk factors which are present prior to appearance of the clinical symptoms. In the process, these frequently nonspecific characteristics are missed and proximal causes are interpreted as critical because the distal structure is already in place. Newer studies using factor analytic and cluster analytic techniques (e.g., Moss, Chen, & Yi, 2010) have avoided the sampling bias issue by using population samples—the National Comorbidity Study (NCS) (Kessler et al., 1997) and its follow-up, and the more recent National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) (Hasin et al., 2007)) and follow-up (Dawson, Stinson, Chou, & Grant, 2008) for their analysis but they still are hindered by the developmental course issue since these studies start at age 18 and characterizations prior to that are assessed retrospectively. To address these issues, a developmentally focused conceptual analysis by the senior author led to a proposal for a four trajectory alternative to the two factor model (Zucker, 1987). It was based on epidemiologic studies that suggested there were differentiations in the life course trajectory of alcohol abuse and dependence as a function of comorbidity and life course environment. A developmentally filtered literature review of individual differences in adolescent heavy drinking patterns, their possible relationship to adult alcoholism, as well as data on the etiology of these earlier drinking patterns and their relationships to adult social adaptation outcome also contributed to the model. It consisted of three alcoholism trajectories that differed in the type of comorbidity they shared, and one alcohol-specific, noncomorbid trajectory, developmentally cumulative alcoholism (Zucker, 1987). Descriptions of course, including time of onset and extensiveness of course, were of special interest. Continued attention to the developmental issue of diagnostic continuity or discontinuity led in 1994 to a modification of the noncomorbid trajectory subtype that parsed it into three subtypes (Zucker, 1994; also see the lower half of Figure 18.11). Although the model was formulated two decades ago, prospective and retrospective studies continuing up to the present day, and covering a developmental span as far back as age 3 (Meier et al., 2013), and as far forward as 56 (Jacob, Koenig, Howell, Wood, & Haber, 2009), have repeatedly reaffirmed the core characteristics and trajectories of the subtypes (Windle & Scheidt, 2004; Jackson, O'Neill, & Sher, 2006; Jacob et al., 2005, 2009; Meier et al., 2013). At the same time, because of specific sample characteristics (life course span traversed by the study, sample-specific comorbidity characteristics), not all of the subtypes typically emerge from a single analysis. Because of the model's developmental utility, we briefly outline core elements of each of the subtypes. Table 18.2 shows the parallelism between model subtypes and the empirically derived subtypes from three of the most relevant prospective studies.

As noted, three of the types are characterized by way of their association with specific forms of psychiatric comorbidity and the three without the comorbidity are differentiated by timing and continuity/discontinuity of

AUD symptomatology. The first of the comorbid forms, the one most commonly described in the literature, is the antisocial type. This trajectory has already been described heavily in the adolescent problem behavior literature but it had not been given a clinical label by researchers (Maggs & Schulenberg, 2005; Weber, Graham, Hansen, Flay, & Anderson, 1989) until very recently, when it has alternately been described as an undercontrol pathway (Zucker, Heitzeg, & Nigg, 2011); a behavioral disinhibition pathway (Iacono, Malone, & McGue, 2008), and an impulsivity pathway (Dick et al., 2010). This is Babor's Dionysian type, also Cloninger's (1987) male-limited (type II) group, and involves a continuity pathway, a co-association of long standing between alcohol problems and antisocial behavior in its developmentally progressing forms (Hussong, Curran, Moffitt, Caspi, & Carrig, 2004; Zucker, Ellis, Bingham, & Fitzgerald, 1996a). The antisocial behavior first shows as conduct problems, later emerges into delinquent activity, and ultimately shows as antisocial personality disorder. This progression is driven by genetic diathesis (Cloninger, 1987), and is nurtured not only by a dense family presence of heavy alcohol use, but also by contact with delinquent and heavy substance using peers, poor parental monitoring, and neighborhood residential instability. The antisociality plays a central part in the emergence of the alcoholism, and in turn, the alcohol problems and alcoholism are an essential piece in the emergence of the antisocial adaptation (see Zucker et al., 1996a) for a fuller description of this type). Prospective studies by Buu, Hussong, and Mayzer and their colleagues

(Buu et al., 2009; Hussong, et al., 2007; Mayzer, Fitzgerald, & Zucker, 2009) describe how this pathway emerges in earlier life, and studies by Windle & Scheidt (2004), Jackson & Sher (2005), Meier et al. (2013) and Jacob et al. (2009) describe the process from early to later adulthood.

A second type, developmentally limited alcoholism, likewise involves a comorbid antisocial connection, but the antisociality is stage limited (i.e., this is the stage specific delinquent and impulsive activity of the adolescent problem behavior syndrome (cf. Donovan & Jessor, l985; Moffitt & Walsh, 2003). The antisociality is coupled with the problem alcohol use endemic to adolescence. Equally importantly, this age-stage is one where cortical and neurohormonal systems are changing, and in the process affect decision making and goal setting, including making judgments about alcohol, sex, sensation seeking, that are often in conflict with the social structural need to develop the cognitive skills necessary for the transition to adulthood (Brown et al., 2008; Windle et al., 2008). Howard Blane (1979) called attention to the effects of these processes on heavy drinking more than a generation ago, without giving it a formal alcoholism label (he called it frequent heavy drinking), but the trajectory of alcohol use it embodies continually is documented in the prospective literature (Table 18.2; also see Schulenberg et al., 1996a, regarding the Decreasing Binge Drinking trajectory). It drops off with cortical and neurohormonal maturation, and with the onset of the role demands and responsibilities of adulthood.

The third type begins with the emergence in childhood and adolescence of internalizing symptomatology, a phenomenon that is more likely to occur in high risk populations such as alcoholic families, where negative emotionality, family conflict, and stress are more evident (Colder & Chassin, 1993; Hussong, et al., 2008; Rolf, Johnson, Israel, Baldwin & Chandra, l988), and also where independently, the high levels of adult alcohol use provide a context in which heavier drinking is much more likely to be present. This in turn drives the progression into a trajectory of severe, and sustained alcohol related problems. This pattern, termed negative affect alcoholism, was historically seen as more common among women; more recent work qualifies that view, with the qualifier that the negative affect-heavy alcohol use linkage is restricted to women who are already problem drinkers. Under emotional stress, nonproblem-drinking women are more likely to experience depression and anxiety but not increase their consumption (Chaplin, Hong, Bergquist, & Sinha, 2008); but for already heavier drinking women, negative mood arousal produces stronger urges to drink (Rubonis et al., 1994). An earlier study by Olenick and Chalmers (1991), reported a similar finding. Women in treatment for AUD reported use of alcohol to alter negative mood 4 times as often as did women who were social drinkers. The differences for men were also present, but were significantly less powerful (the ratio was 2:1). The more general point is that even though the circumstances for high negative affectivity are present, the learning about heavy drinking as a vehicle for anxiety reduction needs to take place before the negative affect-alcohol use link will be joined.

In contrast to the comorbid subtypes, the noncomorbid trajectories schematically presented in Figure 18.11 depict a set of alcoholisms that have no demarcated childhood antecedents. They involve sustained alcohol intake, which leads to severe, alcohol related symptomatology of varying durations. No *diagnostic* comorbidity is known to have linkages to their onset, and they are identifiable more by their drinking related consequences than their nondrinking etiology. This is the type that is most often viewed as the pure example of alcoholism as an addictive disorder. It is driven by alcohol-specific vulnerabilities, including a lower sensitivity to ethanol's intoxicating effects (Schuckit, Smith & Tipp, 1997; Schuckit et al., 2001) and a greater subjective experience of activation and energy that makes consumption both more reinforcing and less aversive (Newlin & Thompson, 1990). Hill, Steinhauer, Locke-Wellman, and Ulrich (2009) proposed that a central neural vulnerability endophenotype drives the progression, but the unusual nature of her sample makes it unclear about the extent to which her findings are more generally applicable to the high-risk population of noncomorbid COAs. A second, not necessarily mutually exclusive hypothesis is that this trajectory and its other more truncated noncomorbid forms is driven by elevated environmental stress occurring in very high use social contexts that provides a support and value structure for alcohol as the drug of choice for tension reduction. Under circumstances of more time-limited stress (e.g., immediately preceding or following the breakup of a marriage), isolated abuse may occur (Leonard & Rothbard, 1999). Under circumstances where the stress is recurring (e.g., times of heightened stress related to periodic job layoffs (cf. Catalano, Dooley, Wilson, Hough, 1993; Mulia, Zemore, Murphy, Liu, and Catalano, 2013), or for those in intermittently high stress occupations, the symptomatology becomes episodic. For those whose contextual and individual vulnerability match is greatest, the alcohol seeking behavior eventually moves into a chronic adaptation. This latter trajectory has been termed developmentally cumulative alcoholism.

There are obvious parallels between these latter three trajectories and the developmentally limited but antisocially comorbid pattern of adolescence. Although the form of all four of these types is similar, for the developmentally limited pattern, individual level etiologic risk factors have already been identified, but the onset and termination of the disorder is driven by nonindividual level contextual factors, to which the individual responds. Nonresponsivity (i.e., the perseverance of the high consumption level in the face of increasing social stigma and penalty), is what differentiates the developmentally cumulative pattern from both the developmentally limited and the episodic pattern. This may also be the case for the isolated abuse variant, and in fact both Schuckit and Moos and their colleagues have specifically addressed this issue (Moos, Brennan, & Schutte, l998; Schuckit, l988). However, the longitudinal structure of these variants has been less well charted.

THE GENETICS OF ALCOHOL USE, PROBLEMS, AND AUD

Alcoholism as a Genetic Disorder

Alcoholism is a complex phenotype and the previous two sections on heterogeneity of risk and disorder drive this point home. The fact that the phenotype's expression is dependent upon the presence of an environmental object (ethanol) would suggest environmental factors play a significant role in etiology, but the evidence for a genetic contribution to alcoholism risk is also indisputable. Evidence from family, adoption, twin, and cross-fostering studies all support this conclusion. Twin studies consistently find that genetic influences account for approximately 45% of the variance of AUD and measures of quantity and frequency in adulthood with little or no shared environmental effects (Dick et al., 2009). The relative genetic and environmental influences are moderated by age however, and initiation of alcohol use exhibits both moderate genetic and shared environmental influences, as does quantity/frequency and AUD, in adolescence (Rhee et al., 2003; Dick et al., 2009). Further, longitudinal studies have found that genetic influences increase and shared environmental influences decrease with age for alcohol use and externalizing phenotypes more generally (Bergen et al., 2007). This suggests that shared environmental influences are important to initiation and early drinking, but that both genetic and nonshared environmental influences (i.e., environmental influences that contribute to differences among relatives) are determinative for long term problematic alcohol use that persists into adulthood.

Several multivariate twin studies of substance use phenotypes have also established that there is substantial common variance in genetic influences among AUD, nicotine dependence, and illicit drug dependence, as well as with their precursive nonspecific risk components, namely antisocial behavior and disinhibited personality traits (Button et al., 2006; Kendler et al., 2007; Slutske et al., 1998, 2002). Family transmission studies have also found that the transmission of a general externalizing factor best accounts for parent–child similarity for AUD, other substance use disorders, and antisocial behavior (Hicks et al., 2004). That is, rather than disorder specific risk, parents pass on a general behavioral disinhibition liability to the next generation that then increases risk for multiple externalizing disorders. A recent combined twin, adoption, and family study further demonstrated that this general parent–child transmission was primarily genetic (Hicks et al., 2013).

The findings of genetic overlap among antisocial behavior and substance use disorders prompted researchers to fit biometric factor models to estimate the heritability of the externalizing factor to estimate the extent to which their comorbidity was due to common genetic and environmental influences. These studies found that externalizing is highly heritable (70–85%) in late adolescence and young adulthood, with little or no shared environmental influences (Kendler et al., 2003; Krueger et al., 2002). These estimates are typically higher than for any individual disorder, with the externalizing factor accounting for the majority of genetic variance in each disorder. Each substance use disorder, however, also exhibits specific genetic and nonshared environmental variance. These findings are consistent with a hierarchical model of risk, involving a highly heritable nonspecific risk factor, but with the final phenotypic expression of the nonspecific risk determined by environmental and genetic influences that are unique to each phenotype.

The importance of the general externalizing factor in the emergence of symptoms of substance use disorders appears to be moderated by age, peaking in late adolescence and declining thereafter as disorder-specific effects increase (Vrieze et al., 2012). Most of the decline is attributable to externalizing accounting for less heritable variance in the individual disorders, while disorder-specific genetic and environmental effects increase with age. These findings are consistent with the interpretation that a highly heritable behavioral disinhibition liability leads to nonspecific substance use and antisocial behavior in late adolescence, but that substance specific risk factors increase in importance as people age, leading to greater specialization in substance use and the maintenance of chronic problem use.

It is important to note that variation in heritability effects either for externalizing or for alcohol problems per se is not evidence indicating weakness of a heritable effect. Rather, a characteristic of complex phenotypes such as alcoholism is that the variability in estimation is both a function of the way the phenotype (such as diagnosis) is measured, as well as the variability in the population. In turn, the population variability is itself a function of environmental exposure (e.g., alcohol availability), age structure, and population genetic variations.

Another important point is that alcohol use phenotypes are likely to vary in their genetic architecture. Even the symptoms that constituted the *DSM-IV* diagnostic categories of alcohol dependence and alcohol abuse are not unequivocally the same phenotype; that is, they may not just be indicators that differentiate severity but rather be differentiable phenotypes. This is the evidence that drove the development of the typology outlined in the previous section. Epidemiologic data support this view of multiplicity of phenotypes; approximately a third of the alcohol dependence population does not also meet criteria for abuse (Hasin & Grant, 2004). In other words, one may have physiological dependence without ever having gone through an abuse phase. Further, because alcohol is so widely available and frequency of use does not necessary result in dependence, the genetic and environmental influences on dimensional measures of quantity and frequency of use are likely to be at least somewhat distinct from those for symptoms indicative of pathological use. Evidence for this includes findings that heritability estimates for abuse and dependence tend to be greater than for measures of use (Hicks et al., 2011); this dialogue continues to remain an active one both in the genetic and the epidemiologic literature (Hasin & Grant, 2004; Ridenour et al., 2003). The issue of phenotype definition remains an essential one in attempting to identify risk genes and understand genetic influences on alcohol use and AUD.

In terms of specific genetic effects, the most robust genetic markers associated with alcohol use and AUD are variants involved in the metabolism of alcohol. The two candidate genes that protect against heavy drinking are the functional genetic variants of alcohol dehydrogenase that exhibit high alcohol oxidizing activity (ADH), and the genetic variant of aldehyde dehydrogenase (ALDH2) that exhibits low acetaldehyde oxidizing activity (Li, 2000). The ALDH2 variant is common in some Asian populations. Those who have it experience a flushing reaction, headache, palpitations, dizziness, and nausea after consuming alcohol. The aversive experience appears to be protective in the populations where that variant exists (Thomasson, Crabb, Eadenberg & Li., 1993). However, the low prevalence of the ALDH2 deficiency in individuals of European and African ancestry results in very low explanatory power for the U.S. population. High ADH activity is associated with a similarly unpleasant set of symptoms following drinking; here the genetic variants involving the ADH2*2 and ADH3*1 alleles appear to be protective (Thomasson et al., 1993). At the same time, consistent with a complex genetic model, a cross-national study by Reich and Li (1994) observed that even though Koreans have a relatively high rate of ALDH2 deficiency, alcoholism rates are very high in this population, indicating that cultural influences may override the impact of the biological feedback system (see the discussion of cross-domain relationships in Section III).

Beyond the genetic variants involved in alcohol metabolism pathways, a number of candidate genes have been identified that may contribute to etiology, but studies are not uniformly confirmatory either of a link to alcoholism or to some intermediary trait such as externalizing or internalizing behavior. Furthermore, there is little understanding of any underlying mechanisms, although currently a number of teams are aggressively pursuing this problem. For example, variants of genes in the serotoninergic (e.g., 5-HTTLPR), dopaminergic (e.g., DRD2), and monoamine oxidase A (MAO A promoter) have at times been associated with alcoholism or phenotypes associated with alcoholism, but the literature includes as many negative results as positive findings. Perhaps the most promising candidate gene thus far is the previously mentioned GABRA2. GABA is a major inhibitory neurotransmitter that is sensitive to ethanol including its anxiolytic effects (Grobin, Matthews, Devaud, & Morrow, 1998). GABRA2 has now been associated with several externalizing phenotypes including alcohol and drug dependence, antisocial personality disorder and conduct disorder, and an electrophysiological endophenotype (Dick, 2007). Also, as already noted in the section on nonspecific risk, the effects of GABRA2 may be moderated by environmental context, in particular parent monitoring (Dick et al., 2009; Trucco et al., 2015).

While sorting through the findings for candidate genes remains an ongoing task, recent advances in high-throughput genotyping technology have resulted in a sea change in gene association studies for complex phenotypes. Rather than focus on specific genes or potential regions of interest in linkage studies, these new genotyping technologies include markers that effectively cover the majority of the human genome. The most popular of this type is the genome-wide association study

(GWAS), and entails genotyping individuals on more than 1 million single nucleotide polymorphisms (SNPs). SNPs are not the only form of genetic variation, but have been of primary interest because they are a simple form of genetic variation that can be efficiently genotyped. Also, the fact that most SNPs are common fits with the common variant common disease hypothesis, that posits that the heritable basis of common diseases or disorders are likely a function of relatively common forms of genetic variation, has also made them of significant interest. Evaluations differ as to the scientific yield from GWAS (Visscher, Brown, McCarthy, & Yang, 2012). On one hand, GWAS have identified thousands of variants for dozens of traits and disorders. On the other hand, the biological significance of many of these SNPs is unclear, and virtually none of these hits have what would traditionally be considered even a medium sized effect (odds ratio > 1.30 for minor allele); even SNPs that exceed genome-wide significance tend to have a small (odds ratio 1.10 to 1.20 for minor allele) to very small effect (odds ration < 1.10 for minor allele).

The results of GWAS for alcohol use phenotypes have been relatively sparse. An early GWAS study of alcohol dependence included over 1,500 male cases and 2,300 matched controls detected two SNPs on chromosome 2 in linkage disequilibrium with the peroxisomal trans-2-enoyl-coengzyme A reductase (PECR) gene, which is involved in fatty acid metabolism and primarily expressed in the liver (Treutlein et al., 2009). A much larger study of alcohol consumption detected an association with the autism susceptibility candidate 2 gene (AUTS2) in a discovery sample of 26,317 individuals that was replicated in a sample of 21,185 (Schumann et al., 2011). The mechanism by which AUTS2 effects alcohol consumption is unclear, but it has been linked with other neurobehavioral disorders in humans and alcohol sensitivity in animals. Notably, this study failed to detect an association with the PECR gene. Several other GWAS have failed to detect any genome-wide significant SNPs. Equally importantly, no previously studied candidate genes have been identified in a GWAS. New consortium efforts are underway for both alcohol consumption and AUD with the hope that old and new efforts will eventually be combined to form the mega-samples needed to identify the subset of SNPs that account for the majority of common genetic variation contributing to alcohol use and AUD.

A more likely scenario is that understanding the genetics of complex behavioral phenotypes such as alcohol use and AUD will require delineating the interplay between genetic and environmental influences. A potentially viable strategy is that if SNPs can be identified via large consortia, smaller studies with denser assessments such that include longitudinal measures of alcohol use phenotypes and the environmental context can use the leads from GWAS to delineate the interplay among genetic and environmental influences over the course of development. Also, the pathway from genetic variation to complex phenotype is almost certainly indirect involving a multilevel, multistage, process. Links in some of these stages may not be detectable at the behavioral level. As such, delineating the mechanisms of risk will likely involve the kind of multidisciplinary approach we have described here, which involves piecing together lines of evidence from disparate methods to gain a greater understanding of the multilevel processes that are likely at work.

Gene–Environment Interplay

The foregoing not only illustrates the importance of both genetic and environmental influences on the development of AUD, but also suggests that the underlying mechanisms of risk are a function of gene–environment interplay rather than simply main effects of genes and environments. Two mechanisms of gene–environment interplay are gene–environment (GxE) correlation and gene x environment (GxE) interaction. GxE correlation refers to the nonindependence between a person's genotype and the likelihood of exposure to environmental risk, such that those with higher genetic risk also tend to experience greater environmental risk exposure (Scarr & McCartney, 1983).

Passive GxE correlations arise from parents providing both the genes and the rearing environments; hence parental AUD will also confer risk for exposure to a higher risk rearing environment. For example, Buu et al. (2007) tracked the residential migration patterns of families with and without an alcoholic father over a 12-year period. Families with an alcoholic father were more likely to either remain in or move to a more disadvantaged neighborhood (high crime, poverty, and residential instability). As a consequence, these neighborhood characteristics predicted more symptoms of alcohol, nicotine, and marijuana dependence in the offspring of these men, as well as more symptoms of antisocial personality disorder and major depression in young adulthood (Buu et al., 2009).

As children transition into adolescence and gain greater autonomy in selecting their environments, active GxE correlations become more relevant mechanisms in the development of substance use and abuse, which also emerge during the same developmental interval (Bergen et al., 2007; Scarr & McCartney, 1983). Active GxE correlations primarily arise because heritable traits increase

exposure to trait-friendly environments that then increase risk for substance use disorders. Using a longitudinal twin study, Hicks et al. (2013) found that the socialization trait construct (willingness to follow rules, accept adult supervision, and endorsement of conventional values) predicted exposure to high-risk environments (deviant peers, parent–relationship problems, academic difficulties, stressful life events) in middle adolescence, even after controlling for stability in the child's environmental context from childhood to adolescence. In turn, high-risk environments in middle adolescence mediated some—but not all—of the association between childhood socialization and substance use problems in late adolescence. Results of biometric modeling revealed that 78% of the genetic overlap between childhood socialization and substance use problems in late adolescence was accounted for by the heritable variance in the environmental measures assessed in middle adolescence. That is, to the extent that childhood socialization accounted for heritable risk in substance use problems, the mechanism was mostly indirect, via increased exposure to high-risk environments.

GxE interactions have also been documented for alcohol use and AUD, and also emphasize that the importance of genetic influences on alcohol use outcomes varies as a function of the environmental context. For example, in a Finnish study, Rose and colleagues showed that genetic influences on adolescent alcohol use were stronger in urban areas while shared environmental influences were stronger in rural areas. Later work by the same group (Dick, Rose, Viken, Kaprio, & Koskenvuo, 2001) extended these findings by demonstrating similar patterns of GxE interaction for areas with more young adults, greater migration, and higher regional alcohol sales. Other investigators have found that genetic influences on alcohol initiation and alcohol use were weaker for adolescents who were highly religious (Koopmans, Slutske, van Baal, & Boomsma, 1999) and for women who were married (Heath, Jardine, & Martin, 1989), respectively. A common thread that may be operating across these environments is one of greater social control, such that more constrained environments depress the influence of genetic factors. Such an effect is not limited to alcohol; for example, genetic influences on smoking are attenuated in the context of high parental monitoring (Dick et al., 2007). Hicks et al. (2009) provided a comprehensive test of this hypothesis by examining the impact of six different environmental variables on the genetic influence of a composite of externalizing disorders in late adolescence. For each environmental variable, genetic influences on externalizing were greatest in the context of greater environmental adversity. These findings are consistent with a conceptualization that there is a general mechanism of gene–environment interplay for externalizing disorders such that those with the greatest genetic risk are the mostly likely both to be exposed to environmental risk (GxE correlation) and to be most sensitive to the influences of environmental risk factors (GxE interaction).

Gene–Brain–Environment: The Site of Gene–Environment Relationships

These twin studies provide clues to the interplay between the aggregate effect of genes and broad environmental influences. To uncover more mechanistic processes, however, will require delineating how the effects of specific genes are expressed in brain, and how the influence of these genes on more proximal processes (e.g., greater sensitivity to alcohol cues or consumption) contribute to alcohol use problems.

In contrast to GWAS, some researchers take a hypothesis driven approach that entails a three part strategy of genotype to brain to alcohol use phenotype. These approaches do not attempt to link the gene to AUD, but rather to intermediary processes that may contribute to risk for AUD including reactivity to alcohol-related stimuli (e.g., alcohol cue reactivity). Hutchison et al. (2008) reported a multi-outcome investigation of the cannabinoid receptor 1 (*CNR1*) gene and AUD, focusing on effects for individuals with at least one C allele in SNP rs2023239. *CNR1* codes for the cannabinoid receptor type 1 (CB1) that is densely localized in brain regions associated with drug-seeking behavior including the ventral tegmental area, nucleus accumbens, prefrontal cortex, basolateral amygdala, and hippocampus. Among the many findings, post mortem analyses of human prefrontal cortex revealed greater levels for individuals with the C allele. Further, the C allele was associated with greater activation in the midbrain and prefrontal cortex elicited in an alcohol cue paradigm, greater subjective reward when drinking alcohol, and more positive outcomes after treatment with a medication (olanzapine) that targets the mesocorticolimbic neurocircuitry. In a similar study, Ray et al. (2013) investigated links between variants of the mu-opioid receptor (OPRM1) gene, neurological reactivity to an alcohol taste cues task, and alcohol use among individuals with AUD. Relative to A-allele homozygotes, carriers of the G-allele of the OPRM1 exhibited greater insula and orbitofrontal cortex activation and had stronger negative fronto-striatal functional connectivity for ventral and dorsal striatal regions when viewing alcohol versus water cues.

These studies are but two examples of a translational approach of investigating genetic risk for AUD along with neuroscience. One is that genetic variation to phenotype is almost always indirect, involving a multistage process. These stages often include genetic variation, motivational (reward), appetitive (drug sensitivity, craving), cognitive (expectancy) mechanisms, and facilitating or dampening environmental effects. Additionally, variables in these processes may only account for small amounts of variance in the clinical outcome making their detection difficult at the behavioral level. Finally, the transcriptional role of genes that codes for the structure and function of neurons is sensitive environmental inputs, and variables such as stress, learning, and social interaction impact neurological development. Thus, the brain is the playing field within which gene–environment interplay ultimately takes place.

INTERMEDIATE-LEVEL ETIOLOGY IN BRAIN

The Core Neural Model of Addiction

The most prominent and dominant conceptualization of the core nature of drug addiction over the past generation has been that it is a disorder of the brain, a product of the long term interaction of drugs upon neural circuitry that produces compulsive drug seeking and use, even in the face of negative health and social consequences (Leshner, 1997). Although social context and behavior are clearly a part of the clinical syndrome, they are seen as consequences rather than essential parts of the causal matrix. The addictive process at the behavioral level begins with reward seeking that is initially framed as seductive and hedonic. Continued pursuit of the hedonic end state through increasing use leads to diminution of effect. This in turn leads to heightened reward seeking, but simultaneously leads to a dampening of reward response and increases in stress and anxiety, culminating in withdrawal if use is not sustained. Thereafter, use is negatively motivated, since its primary goal is to ward off the negative effects.

Although we have described this as an affective and behavioral sequence, the neurophysiological model undergirding the behavior is seen as the core mechanistic structure of the disorder. It initially involves the mesocorticolimbic dopamine system, including the nucleus accumbens, amygdala, hippocampus and prefrontal cortex, as the system where the pharmacological actions of ethanol converge to produce their reinforcing effects (see review in Weiss & Porrino, 2002). This system is critical to reward processing and centrally involved in the reinforcing properties of drugs of abuse (Robinson & Berridge, 2000) and is also modified by drugs of abuse (Volkow & Li, 2004). It is proposed that with repeated alcohol use, a loss of function occurs in this dopaminergic reward system, which results in a loss of motivation for natural rewards (Koob, 2013). This effect is further exacerbated by concomitant neural alterations in the brain stress system, mediated by corticotropin-releasing factor (CRF) in the extended amygdala and hypothalamic-pituitary-adrenal (HPA) axis, which lead to aversive, anxiety-like states. A combination of these effects results in the development of negative affect. As the negative affect increases, one sees compulsive use to avoid the negative affect effects (Koob, 2013). The end result is that addictive use hijacks both the brain's reward and stress response systems, in a compulsive cycle of use, stress, negative affective experience (withdrawal), repeated use to dampen the negative affect. An additional critical feature is that drug use disrupts the frontal cortical circuits that regulate motivation, drive, and self-control and changes in the memory circuitry increase the motivational salience of the drug and drug-associated stimuli (Volkow & Li, 2004). Some caveats are typically attached to this characterization, namely that exposure to conditioned cues (social contexts of use) can be a major factor in both causing and rearousing drug craving. However, the underlying structure of the disorder is conceptualized as a neural disorder involving fundamental and largely irreversible changes in circuitry.

Domains of Vulnerability

This account of the development of addictive disorder is dynamic, but it is not developmental. It describes the unfolding of a sequence of processes, which culminate in compulsive use and negative affect. Other work, both in parallel to the studies just described, and following from it, has taken a more straightforwardly developmental perspective by framing the question whether any of these sites of action has precursive/predispositional vulnerability, which would make the likelihood of both impairment of circuitry and alcohol seeking behavior more likely.

Both clinical and preclinical evidence suggests that the mesocorticolimbic dopamine system plays a role in preexisting vulnerability to addiction (McBride & Li, 1998; Volkow, Wang, Telang, et al., 2007), and variability in dopamine signaling has been associated in animal models with impulsive behavior more generally (Dalley, Mar, Economidou, & Robbins, 2008). Findings in substance dependent populations (e.g., Volkow, Wang, Telang, et al., 2007) also suggest a common pathway for vulnerability to impulsive behavior and addiction, involving variability in

mesocorticolimbic dopaminergic function, although all of this work is suggestive, given that it has been carried out on already addicted individuals.

At the neurocognitive level, executive functioning has also been identified as a significant precursive factor in the emergence of risk, which is in place prior to any impairment from use of addictive substances. Executive functioning entails the ability to regulate behavior to context and to maintain a goal set (Miyake et al., 2000). This is a multicomponential system, including response suppression/inhibition (the ability to strategically suppress a prepotent or prepared motor response), working memory (itself multicomponential), set shifting, and interference control (Pennington & Ozonoff, 1996). To the extent these capacities translate directly to behavioral differences, they have relevance to a spectrum of activities that elevate or dampen risk. They relate to wisdom in choice of peers, understanding of the importance of context to appropriate drinking behavior, ability to desist when encouraged to drink or encouraged to continue drinking under circumstances that indicate drinking consequences (such as increasing intoxication or the ability to get to work/school the next day and function adequately) may be costly in the long term. Extensive theory has linked aspects of executive control with alcoholism risk (e.g., Tarter, Alterman, & Edwards, 1985). However, data to support that link are mixed (e.g., Finn et al., 2002) and some evidence suggests that the risk element is primarily related to response inhibition (Nigg et al., 2006) more specifically, rather than to a general vulnerability from the broader executive control system. This issue remains to be settled.

In attempting to systematize this work, theorists have conceptualized these operating structures as two core psychological systems with neural underpinning, which are in dynamic tension and modulate one another (Eisenberg et al., 1997; Rothbart & Bates, 2006; Nigg, 2000; Zucker, Heitzeg, & Nigg, 2011). One is an effortful control system (Rothbart & Bates, 2006) involved in the control of behavior and attention in the service of goals that are distal in time and represented in memory or working memory rather than by immediate incentives and cues. Effortful control reflects activation in prefrontal cortex, likely corresponding with suppression of activity in subcortical regions (particularly the nucleus accumbens and amygdala) and is largely regarded as a top-down system.

The second system is the relatively automatic incentive reactivity system, which operates rapidly, responding to novelty or incentive cues for potential near-term reward or loss by interrupting behavior. The neural process is subcortical signaling of novelty (e.g., from the nucleus accumbens or amygdala), and is heuristically seen as a bottom-up process in the brain. An emerging literature suggests there may be dysregulation in both of these systems in at-risk populations prior to the onset of problem alcohol use (e.g., Heitzeg, Nigg, Yau, Zucker, & Zubieta, 2010; Yau et al., 2012). As part of the process, top down and bottom up responses mutually influence one another (Nigg, 2000; Rothbart & Bates, 2006); thus, incentive response also involves decision making (in the context of potential reward or loss).

In addition to the operation of these specialized domains of neural function, it has recently become appreciated that brain regions with synchronized behavior, while at rest, are functionally linked, thus forming resting-state networks (Salvador, Suckling, Schwarzbauer, & Bullmore, 2005). Resting-state functional connectivity MRI investigates these network linkages, operating in the absence of an externally cued task. A number of distinct networks have been described, including a salience network and an executive control network (Seeley et al., 2007), roughly mapping onto incentive reactivity and effortful control systems respectively. Recent evidence suggests that addiction and related phenotypes, such as risk-taking, are associated with coherence within and between these salience and control networks (e.g., Liu et al., 2009; Park et al., 2010). Of particular relevance is the finding of impaired connectivity between the striatum and prefrontal cortex in alcoholics, which was related to impairments in reward-guided decision making as well as an inability to control drug-craving (Park et al., 2010). This adds to the extensive data suggesting that at both the behavioral and neural level substance use problems are associated with a dysregulation of decision-making in the context of incentives; specifically, the subcortical, involuntary elements (limbic and striatal circuitry) are overresponding to salient drug-associated stimuli and cortical control (via frontal circuitry) over this response is impaired or inhibited, leading to more drug use and the maintenance of—and failure to exit from—a use pattern (Jentsch & Taylor, 1999).

The Genetics of Neural Individual Differences

To improve our understanding of the neurobiological mechanisms underlying risk for SUD, recent efforts have focused on identifying genetic factors that determine interindividual variability in dopamine signaling and its impact on the reactivity of effortful control and incentive reactivity systems. For example, variants in putatively functional genetic variants impacting the dopaminergic system (including DRD2 141 Ins/Del, COMT val^{158}met,

SLC6A3, DRD4 Exon III 48bp-repeat, and Taq1A) have been found to impact striatal reactivity to reward (Dreher, Kohn, Kolachana, Weinberger, & Berman, 2009; Forbes et al., 2009), prefrontal activation during inhibitory control (Filbey, Claus, Morgan, Forester, & Hutchison, 2012) and prefrontal connectivity (Tunbridge, Farrell, Harrison, & Mackay, 2013). Continued investigation of how altered dopamine signaling resulting from common functional genetic variation contributes to inter-individual variability in effortful control and incentive responding will aid in identifying detailed, mechanistic pathways by which functional genetic variation ultimately contributes to SUD.

Dynamic Changes in these Systems Over the Course of Adolescence

At the same developmental time during which a major buildup of alcohol use and alcohol problem behavior is taking place, concomitantly, neural alterations in control and incentive systems are occurring. The prefrontal cortex is one of the last brain regions to mature, with cortical pruning continuing into early adulthood (Gogtay et al., 2004). Progressive increases in the white matter of this region have also been shown during childhood and adolescence (Paus, 2005). These developmental changes directly influence behavioral regulation by enhancing signaling efficiency, improving signal:noise ratio, among other effects. Thus, throughout childhood, developmental gains occur in the ability to suppress or inhibit prepotent responses and the ability to suppress irrelevant information (Paus, 2005). Functional imaging studies have shown development of prefrontal control in cross-sectional studies showing adults have greater prefrontal activation when making risky decisions (Eshel, Nelson, Blair, Pine, & Ernst, 2007), responding to rewards (Galvan et al., 2006) and inhibiting motor responses (Rubia et al., 2000). Social and emotional skills are also developing throughout childhood and early adolescence (Kolb, Wilson, & Taylor, 1992), with associated changes in amygdala (K. M. Thomas et al., 2001) and prefrontal (Steinbeis, Bernhardt, & Singer, 2012) functioning.

The mesolimbic dopaminergic system also undergoes dramatic change during adolescence (Spear, 2011). Specifically, developmental alterations occur in the projections from dopamine neurons in the ventral tegmental area to subcortical regions including the dorsal striatum and nucleus accumbens, limbic regions including the amygdala and hippocampus and cortical regions, particularly the prefrontal cortex. The nucleus accumbens is of particular importance in this circuitry, as it is responsive to incentive stimuli and contributes to directing behavior by integrating affective, contextual, and goal-directed information via inputs from the amygdala, hippocampus and prefrontal cortex (Grace, Floresco, Goto, & Lodge, 2007). Adolescence is a time of increased reward seeking and risk taking, and it is believed that alterations in the responsivity of the nucleus accumbens to incentive stimuli may contribute to this behavior (e.g., Spear, 2011). Of major significance to the issue of developmental increases in alcohol use is evidence suggesting that the relatively early maturation of subcortical systems compared with prefrontal control systems may bias the motivation of adolescents toward seeking out immediate reward and associated impulsive, risky decision-making (Casey, Getz, & Galvan, 2008; Steinberg, 2010).

In parallel to this work, an emerging literature investigating the development of functional connectivity in the resting brain shows a progressive specialization into integrated functional networks across development, suggesting the maturation of more efficient neural pathways over time (e.g., Stevens, Pearlson, & Calhoun, 2009). Behaviorally, this may translate into more impulsive behavior in adolescents as these systems cohere at different time points, with incentive response systems consolidating prior to control systems (Casey et al., 2007). Furthermore, increased coherence between nucleus accumbens and prefrontal cortex from adolescence to early adulthood has been shown to be associated with decreases in risky decision making (Christakou, Brammer, & Rubia, 2011), suggesting a developmental significance of coherence *between* networks as well. This illustrates the dynamic complexity of brain–behavior relationships related to risky and impulsive behavior across development. How these mechanisms operate and interact needs to be more fully mapped to achieve a full explanation of the emergence and maintenance of individual risk. Given the high levels of substance involvement taking place during this age period, a detailed understanding of how the development of these systems relate to risky substance use is critical.

The developmental significance of these changes, when superimposed on a social structure that is encouraging the emergence of alcohol use, is major. From studies of adult animals it is known that repeated drug use has long-lasting consequences in the brain, including: down-regulation of tonic dopamine activity (Scafidi et al., 1996), which mediates incentive motivational states; sensitization of phasic dopamine firing to drugs of abuse (Jones, Marsden, & Robbins, 1990), which is linked to habit formation and is believed to underlie drug craving, or wanting and to be critically involved in the formation of

dependence (Robinson & Berridge, 2000); and suppression of the strength of developing functional connections between mesolimbic structures and the PFC (Thomas, Beurrier, Bonci, & Malenka, 2001), leading to compromised top-down executive control over behavior. Such effects are thus potentially being superimposed on this developing circuitry in adolescents who are drinking and the neuroplasticity of the adolescent period makes the brain particularly vulnerable to neurotoxic processes. Studies exploring the impact of alcohol on the mesolimbic dopamine pathway in *adolescent* animals find that ethanol exposure induces higher extracellular baseline levels of dopamine in adolescents, which continue into adulthood (Badanich, Maldonado, & Kirstein, 2007). This suggests long-term sensitization of the dopamine system, which may mediate vulnerability to later alcoholism (Guerri & Pascual, 2010). Furthermore, there is extensive evidence from animal models that the hippocampus and prefrontal cortex are particularly susceptible to the damaging effects of ethanol in adolescence (see review in Guerri & Pascual, 2010), with implications for incentive motivation through effects on learning and memory and top-down control over behavior.

Few studies have investigated the effect of alcohol on incentive and control processes in human adolescents but those existing studies are generally consistent with the animal findings. There is evidence in adolescents with AUD of increased activation to alcohol-related pictures in the incentive motivation circuitry, including amygdala and prefrontal cortex (Tapert et al., 2003). Studies of brain structure in human adolescent drinkers have also found reduced hippocampal volume (DeBellis et al., 2000; Nagel, Schweinsburg, Phan, & Tapert, 2005) and smaller prefrontal cortical and white matter volumes (DeBellis et al., 2005). In addition, functional studies in adolescent drinkers indicate abnormal activation patterns for several cognitive tasks involving these regions (e.g., Heitzeg et al., 2010; Schweinsburg, McQueeny, Nagel, Eyler, & Tapert, 2010; Tapert, Schweinsburg, et al., 2004), suggesting that alcohol consumption during adolescence may have lasting effects on the maturation of incentive and control circuitry. It is important to understand how this circuitry matures, by mapping changes in neural response patterns associated with both risk for alcohol problems and with actual use and its sequallae. The fact that adolescence is a time of heightened alcohol consumption makes this issue of great importance.

Several other issues have not yet been addressed in the work to date. These concern the relative importance of amount and timing of alcohol (and other drug exposure) in bringing about these changes, the degree to which other environmental exposures (e.g., stress) also play a role, and the degree to which early neurocognitive vulnerabilities (i.e., precursive risk) interact with the drug exposure in producing change. One domain where these changes may already have been behaviorally marked is at age of onset of first alcohol use. Earlier age at onset is associated with a more severe course of alcoholism, drug use disorder, poorer treatment response, and higher relapse rates (Grant & Dawson, 1997, McGue et al., 2001).

An understanding of these processes will require the kind of multilevel-multisystem explanatory structure advanced at the beginning of this chapter. A full explanation will benefit from careful neurobehavioral/neurocognitive characterization that takes into account key aspects of executive functioning, motivation, and selected associated systems such as social information processing, along with a characterization of the genetic profiles that create the greatest vulnerability, as well as the social contexts where vulnerability is most likely to develop unchecked. Given the developmental changes in neural circuitry during this interval, it is essential to characterize these effects developmentally. The creation of the cross-level, cross-time model we described early in this chapter was prompted by the need to characterize this dense matrix of risk pathways that was operating. At this point, we briefly illustrate the utility of the model, summarizing findings from the ongoing Michigan Longitudinal Study (Zucker, 2014) and collateral work from other groups that together define the multilevel interactive matrix of behavioral undercontrol, arguably the strongest nonspecific risk factor for alcohol problems and AUD (Dick et al., 2010; Zucker et al., 2011).

Figure 18.12 provides a map of this developmental matrix. The numbered pathways in the figure are those for which there is already evidence for connections. These pathway identifiers are inserted here in the text, along with citations from the work that provided the evidence for the relationship(s). The most well supported pathway is between behavioral undercontrol and problem alcohol and drug use. Extensive evidence exists for the cross sectional [19, 37], and also the prospective relationship [12, 28, 29] (see extensive reviews in Zucker et al., 2008, and Zucker et al., 2011). Relatedly, ventral striatal and medial prefrontal processing show up as important neural substrates involved in the control of behavior and emotion, with dysregulated functioning of these regions related to externalizing behavior problems [18] (Heitzeg et al., 2010). Furthermore, the functional connectivity of ventral striatum mediates the relationship between undercontrolled behavior and level of drinking [34, 35, 38] (Weiland

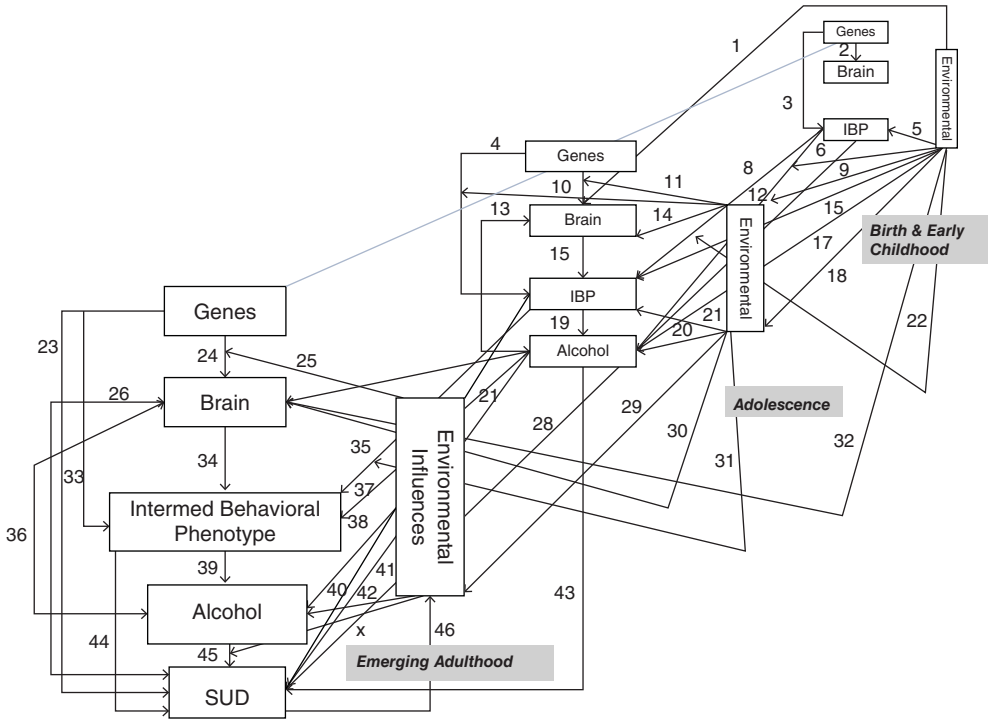

Figure 18.12 Cross-level mechanistic structure of undercontrol and related intermediate phenotypes. See footnote 1.

et al., 2012). Prefrontal control mechanisms in brain lose efficiency with alcohol use [38], which should exacerbate the development of these risky phenotypes [34] (Heitzeg et al., 2010). However, the evidence for this relationship is more indirect, and still requires some focused work to firmly establish it.

At the level of genetic influences, allelic variants of the serotonin transporter promoter polymorphism (5-HTTLPR), the corticotropin-releasing hormone receptor 1 (CRHR1), and a gene encoding the $GABA_A{}^{\alpha 2}$ receptor subunit (GABRA2) have differential effects on the phenotypic expression of undercontrol [2, 13, 36] (Twitchell et al., 2001; Trucco et al., 2015; Villafuerte et al., 2013) and negative emotionality (Glaser et al., 2014), and they also convey differential responsivity for the neural circuitry that regulates the phenotypic response [14, 24] (Glaser et al., 2014; Villafuerte et al., 2011).

Last, environmental moderation occurs at several levels of the behavioral risk pathway. Family conflict (Jester et al., 2005; Loukas, Fitzgerald, Zucker, & von Eye, 2001; Loukas, Zucker, Fitzgerald, & Krull, 2003), family cohesiveness (Jester et al. 2005), parental aggression (Fuller et al., 2003), parental distress (Loukas, Piejak, Bingham, Fitzgerald, & Zucker, 2001), and emotional support and intellectual stimulation from parents (Jester et al., 2005) all moderate the development of behavioral undercontrol [48, 49]. In addition, a more macrolevel influence, neighborhood residential instability, has effects on risk for development of problem alcohol and other drug use [9, 21, 32, 33] (Buu et al., 2007, 2009), and this in turn has long-term negative effects on where one ends up living (i.e., neighborhood quality effects) [50] (Buu et al., 2007), indicating a cascade effect from environment to problem alcohol use, back to environment of residence. There also is significant cross-time continuity/autostability to some of these environmental influences (e.g., family conflict, parental distress, stress [42, 51] (Glaser et al., 2014; Jester et al., 2005). (Because of space limitations, citations for these and all other pathway relationships are not able to be listed here. A complete listing is available from the senior author.)

FUTURE WORK AND CONCLUDING COMMENTS

In ending, we comment briefly on issues that are significant next-step challenges for the field to address: (1) the need for a more definitive understanding of the role that early use of alcohol plays in damage to brain, and an understanding also of whether or not such damage is reversible; (2) the need to provide a more articulated roadmap of what factors play a role in the development of resilience to disorder, within a risk structure that tends to encourage a

downward progression; (3) the challenge to articulate the translational implications of the burgeoning knowledge base about the brain's development and its functional operations as they translate into new treatments; (4) relatedly, the detailed understanding of mechanistic structure is not only about neural circuitry but also about the multilevel/cross-domain/cross-time evolution of risk into disorder. This understanding should translate into new foci for early identification of risk and new strategies for bringing about change, via pathways that are currently completely out of the purview of both prevention scientists and clinicians. This is the fourth obvious challenge.

Does Early Use of Alcohol Damage the Brain?

For almost a decade, there has been considerable speculation, and some evidence, that early use of alcohol damages adolescent brain in ways that may be irreversible (Zeigler et al., 2005). Given that this era is a time of increasing use and increasing heavy use, ending in consumption levels that are usually highest in the individual's lifetime, the issue is of very large public health importance. These assertions have been largely based on the animal literature (Spear & Varlinskaya, 2005), and studies assessing structural and functional differences in neurodevelopment between heavy and nonheavy using adolescents (Brown & Tapert, 2004). Our review in the previous section describes this work in some detail, and suggests some of the human studies that will need to take place to more definitively answer this question, One of the major impediments to getting a clear answer is that the definitive methodology to address the question is prospective research, so even studies begun today will take some time to provide an answer. Furthermore, although the percentage is small, the heaviest users and those at highest risk for later problem use and disorder are likely to have begun drinking prior to age 12. In addition, the highest risk group is more likely to come from high adversity environments (Buu et al., 2009), hence are exposed to a high level of environmental insults, including stress, accidents, and head injury. Prospective research begun this early is quite uncommon, and even less common are studies that recruit this early and simultaneously are carrying out assessments of neural structure and function and genetic variation. In response to this dilemma, the National Institute on Alcohol Abuse and Alcoholism recently begun a multisite initiative based out of the University of California, San Diego, with the proper assessment methods that will be following youth for the next five years (NIAAA RFAAA-12–006, 2012). At that point, a more definitive answer should become available.

Identifying the Critical Features That Permit a Resilient Adaptation While Exposed to an Otherwise Damaging Risk Structure

The risk literature has increasingly demonstrated the nestedness and stability of risk; that is, high individual risk and high adversity cluster together and predict hazardous use and poor social adaption over time. Given this major individual and social burden, the prevention challenge is to identify those factors that produce risk offset despite exposure to adversity. Researchers in the past decade have increasingly focused on the need to identify promotive and protective factors as the pathway out of risk, rather than focus on the minimization of risk. One core issue is the extent to which the social environment can be engineered to provide sufficient promotive opportunity to overcome a high risk profile (Ostaszewski & Zimmerman, 2007). Another is the extent to which efforts focused at the individual level can ultimately be strong enough to overcome a dense individual risk profile. Alternative theory and recent work have advocated a public health model as the most viable strategy, whereby the focus of intervention is at the community rather than the individual level (Zimmerman, Stewart, Morrel-Samuels, Reischl, & Franzen, 2011). Given the great public health burden of this set of problems, and the nestedness of risk at the individual level, it is essential that the field develop new techniques, and possibly a new model of resilience, to bring about a reduction in risky outcomes.

Translational Implications of Knowledge About the Operation of the Brain's Functional Response Systems

Neuroimaging work to date suggests that there may be more basic, nonbehavioral methods to determine effectiveness of intervention programming by assessing changes in brain functional response systems in areas identified as most hyper (or hypo) responsive among vulnerable youth. Knowledge of these sites of action and their relationships too risky as well as promotive/risk-preventive behavior needs to continue to be developed. Further, sites of central behavioral importance are logical sites to consider as potential targets for pharmacologic intervention. The utilization of neuroimaging methods to identify such sites of action has not yet been attempted for any areas of vulnerability except those related to attention-deficit/hyperactivity disorder. This work needs to be carried out; it has the potential to open up entirely new areas of prevention activity that focus on the mechanistic operations revealed by this research.

New Avenues and Sites for Prevention by Utilization of GxExD Effects

Within the past decade there has been increasing sensitivity to the possibility that genetic effects upon behavior are more variable and more interactive with environment, than had previously been considered the case (Rutter, Moffitt, and Caspi, 2006). This hypothesis has been fine-tuned, and confirmed in specific instances by uncovering differential susceptibility effects (Belsky & Pleuss, 2009), that is, GxE relationships that produce an adaptive outcome under conditions of positive environmental exposure and the presence of one genetic variant, and a maladaptive outcome with the same variant, under conditions of exposure to the obverse environment. They make the point that what have previously been regarded as diathesis genetic effects are, in a number of instances plasticity effects. However, these effects have not come to light because the range of environmental variation under scrutiny has either not been sufficiently broad, or because of the unawareness of the effect, environmental variation was not sufficiently disaggregated to show the effect. Equally importantly but not well enough exploited, genetic effects do not always operate uniformly across the course of development. Heritability of drinking behavior is lower in early adolescence than it is in emerging adulthood (Bergen et al., 2007). GABRA2 is associated with rule breaking at age 13–14, but not with substance abuse problems across adolescence. At the same time, rule breaking at 13–14 prospectively predicts problematic alcohol use at 17–18. However, problematic alcohol use does not predict rule breaking (Trucco et al., 2014).

This work suggests that GxExD relationships have potential to seriously inform intervention activity. At the least, they suggest that there are some seemingly negative environmental experiences that may be equally informative about what the obverse experience should be to turn the behavior around. They also suggest that there are some developmental periods when sensitivity to environmental experience will make youth more vulnerable to intervention, and some developmental periods where it may be wise to not work at change.

The Promise and Challenge of the Next Decade

Substance use disorders consistently rank in the top 5 among those illnesses contributing to the world burden of disease (Whiteford et al., 2013). And among substances of abuse, alcohol continues to be the most widely used, even despite decreases in youthful involvement over the last decade and relatively parallel increases in marijuana use over the interval. So the topic of this chapter remains a highly relevant and timely one.

During this same interval, the mechanistic understanding of this disorder and its contexts of operation has expanded dramatically, to the point that research now operates at all the levels of analysis we have described. Much of the science is quite new, parochial, and to a degree rudimentary, but the fact that some of these domains of effect were not even identifiable 5–10 years ago indicates the level of progress that has taken place. Hopefully over the next decade our ability to move the science from relatively remote and abstract to concrete and translatable will increase dramatically. It needs to, if the science is to deliver on the promises it has made to the general public about this major set of public health problems.

Substance use and substance use disorders are the focus of substantial research efforts in part because of their enormous public health significance. Worldwide, despite substantial regional variation, recent estimates place tobacco and alcohol use as two of the top three factors that determine the global burden of disease, death, and disability, with illegal drug use ranked as number 19 (Lim et al., 2012). Moreover, in addition to the worldwide burden of premature mortality and disability, substance use creates a substantial economic burden. For example, the costs associated with alcohol use in middle-income and high-income countries are more than one percent of their gross domestic products (Rehm et al., 2009). A similar picture can be seen in the United States. In the United States, cigarette smoking remains the single largest preventable cause of death and disability (Centers for Disease Control and Prevention, 2008), and the total costs of the use of alcohol, tobacco, and illegal drugs sum to $559 billion dollars per year (National Institute on Drug Abuse, 2008). In part, the high burden of substance use for mortality, morbidity, and economic cost is due to its high prevalence. For example, recent U.S. data show that 19.5% of individuals are current cigarette smokers (King, Dube, & Tynan, 2012), 2% have current *DSM-IV* drug disorders (10% lifetime; Compton, Thomas, Stinson, & Grant, 2007), and 8.5% have current *DSM-IV* alcohol disorders (30% lifetime, Hasin, Stinson, Ogburn, & Grant, 2007).

Drugs have been used in one form or another since the beginning of recorded history, for multiple purposes (including religious, recreational, and medicinal purposes). However, conceptualizations and views of drug use and drug-related problems show marked historical and social change. In terms of modern history in the United States, the early twentieth century was a time of permissive attitudes and widespread availability of substances including opiates and cocaine. Indeed, some substances were viewed as having medical benefits. Modern antidrug regulation in the United States began with the Harrison Narcotic Act of 1914 and alcohol Prohibition in 1920, and strict laws were still in place in the 1950s (Musto, 1995). After the wave of drug use following the 1960s, the modern war on drugs began under the presidency of Richard Nixon. This also marked the beginning of modern tobacco regulation in the United States. For example, health warnings on cigarette packs in the United States were introduced in 1969. Historically, at various times, drug addiction has been viewed as a medical problem, socially learned behavior, a moral weakness, criminality, and (most recently) a chronic brain disorder (Leshner, 1997).

Adolescence is the typical age of substance use onset, and some experimentation with substance use during adolescence is relatively common. This can be seen in U.S. epidemiological data including national school-based surveys such as Monitoring the Future (MTF; Johnston, O'Malley, Bachman, & Schulenberg, 2013) and the Youth Risk Behavior Survey (YRBSS; Centers for Disease Control and Prevention, 2012) as well as household surveys such as the National Survey on Drug Use and Health (NSUDH, SAMHSA, 2012) and combined school and household samples in the National Comorbidity Survey Adolescent Supplement (Swendsen et al., 2012). For example, in the National Comorbidity Survey (2001–2004 data), 78.2 % of adolescents (aged 13–18 years) had used alcohol and 24.4% had used an illegal drug. In 2011, 22% of high school students in the YRBSS and 24% of twelfth graders in MTF reported drinking five drinks on a single occasion within the past month and 18–19% of participants in the two surveys were current (past month) cigarette smokers. Marijuana is the most commonly used illegal drug, with current use reported by 23% of high school students in the YRBSS and 7.9% of those aged 12–17 years in the NSUDH. Daily marijuana use was reported by 6.6% of twelfth graders in 2011 in MTF.

Importantly, although some substance use is relatively common during adolescence, this does not imply that adolescent substance use is benign. Substance use is associated with the leading causes of adolescent mortality (accident, homicides, and suicides; Centers for Disease Control and Prevention, 2010a). Among high school students in the YRBSS, 24% reported having ridden with a driver who had been drinking and 8.2% reported driving after drinking, illustrating the potential for alcohol-related traffic accidents for many adolescents. Some of the associated risk for morbidity and mortality stemming from adolescent substance use can be attributed to the fact that adolescent consumption patterns are particularly risky. For example, compared with adults, adolescents drink alcohol on fewer days (i.e., lower frequency of use), but when they drink it is at levels of higher quantity, producing a binge pattern that creates high risk for alcohol-related consequences (Masten, Faden, Zucker, & Spear, 2008). Moreover, the fact that adolescent substance use occurs in peer contexts that are outside of adult supervision also exposes them to excess risk for negative consequences.

Preparation of this chapter was supported by Grants: RO1DA-01355 (Chassin), R01 DA01963 (Colder), 5R01DA015398–08 (Hussong) and P60AA011998 (Sher) from the National Institute on Drug Abuse and the National Institute on Alcohol Abuse and Alcoholism.

CHAPTER OVERVIEW

The current chapter applies a developmental psychopathology perspective to the literature on substance use disorders. As suggested by a developmental psychopathology perspective (see, e.g., Cicchetti & Toth, 2009), we consider substance use disorders in relation to developmentally normative substance use patterns and we consider etiological models that are multidisciplinary (i.e., biopsychosocial) and multilevel (e.g., we consider gene–environment interplay). Moreover, as suggested by the developmental psychopathology perspective, we consider multiple etiological pathways to substance use disorder (equifinality) but note that pathways are probabilistic, such that not all individuals exposed to identical risk factors will develop disorder (multifinality; see, e.g., Cicchetti & Toth, 2009).

We first define clinical substance use disorders according to recent American Psychiatric Association taxonomies (i.e., *DSM-IV* and *DSM-5*; American Psychiatric Association, 2000; 2013). We then describe epidemiological data including demographic correlates and substance use patterns, including a consideration of gateway theory, which hypothesizes that earlier substance use has a causal effect on later use. We then review evidence for age-related trajectories of substance use outcomes and the extent to which ages of onset and offset inform etiological theory, including the significance of age of substance use onset and time to disorder. Next we examine three major biopsychological etiological pathways, integrating risk factors from multiple levels and considering gene–environment interplay. We consider the deviance proneness or externalizing pathway, which conceptualizes substance use disorders within the externalizing spectrum; the stress and negative affect pathway; and the substance use effects pathway, which focuses on the pharmacological effects of substance use as motivators for consumption. For each of these pathways, we consider implications for prevention and treatment of substance disorders. Because none of these three pathways focus on macro-environments, we next consider the roles of larger social influences including neighborhoods, schools, media, and public policy. Finally, we conclude the chapter with suggestions for future research.

CLINICAL SUBSTANCE USE DISORDERS

In addition to risk for physical morbidity and mortality, adolescents are at risk of developing clinical substance use disorders. The *Diagnostic and Statistical Manual,* 4th ed., text revision (*DSM-IV-TR*; American Psychiatric Association, 2000) defined two major SUDs: substance dependence and substance abuse. Substance dependence is defined as:

> A maladaptive pattern of use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following symptoms occurring at any time in the same 12-month period: (1) tolerance, (2) withdrawal, (3) the substance is often taken in larger amounts or over a longer period than intended, (4) a persistent desire or unsuccessful efforts to cut down or control substance use (5) a great deal of time is spent in activities necessary to obtain the substance, use the substance or recover from its effects, (6) important social, occupational, or recreational activities are given up or reduced because of substance use, and (7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance. (P. 197)

The *DSM-IV* defined substance abuse as:

> A maladaptive pattern of substance use leading to clinically significant impairment or distress as manifested by one (or more) of the following occurring within a 12-month period: (1) recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home, (2) recurrent substance use in situations in which it is physically hazardous, (3) recurrent substance-related legal problems, and (4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance. (P. 198)

Because dependence is thought to be more severe, individuals who meet criteria for dependence were not diagnosed with abuse.

However, the validity of the distinction between substance abuse and dependence has been called into question. For example, item-response theory (IRT) studies show that some dependence criteria (e.g., tolerance, impaired control) are less severe than are some abuse criteria (e.g., legal difficulties; Kahler & Strong, 2006; Saha, Stinson, & Grant, 2007). Moreover, factor analyses have not confirmed two-factor solutions consistent with abuse and dependence (e.g., Harford & Muthen, 2001; Proudfoot, Baillie, & Teeson, 2006). For these reasons, the most recent taxonomy (*DSM-5*) drops the distinction between abuse and dependence. Instead there is a single substance use disorder diagnosis, which is based on 11 symptoms. Legal problems were dropped as a symptom but craving was added. There are concerns that the *DSM-5* criteria will be too liberal and overdiagnose substance disorder, producing high prevalence rates and cases with low severity (Martin, Steinley, Verges, & Sher, 2011). However, *DSM-5*

was designed to yield prevalence rates roughly comparable to *DSM-IV,* and, thus,it may produce little change in the population prevalence of substance use disorder.

Adolescent substance use disorders are diagnosed using adult criteria, although the developmental appropriateness of this practice has been questioned (e.g., Chen & Anthony, 2003; Chung & Martin 2005). Based on recent epidemiological data, a significant minority of adolescents develop a clinical substance use disorder. Rates in the most recent NSUDH data were 6.9% (ages 12–17) and 18.6% (ages 18–25) for alcohol disorder and 3.8% (ages 12–17) and 14.4% (ages 18–25) for drug disorder, with a rate of 11.4% lifetime disorders among ages 13–18 in the National Comorbidity Survey-Adolescent Supplement (Merikangas et al., 2010).

EPIDEMIOLOGICAL TRENDS IN ADOLESCENT SUBSTANCE USE

Although some substance use experimentation is common in adolescence, the prevalence of use of specific substances shows substantial variation over time with new drugs becoming popular and then waning in prevalence, in parallel with changes in perceived risk of use. A recent example can be seen in the use of bath salts, a designer drug that came to media attention in 2010 but for which use was declining by 2012 (Johnston et al., 2013). In addition to the introduction of new drugs that show brief periods of popularity, older drugs sometimes show resurgent popularity, after knowledge about the dangers of use have been lost from the culture. Johnston et al. (2013) referred to this phenomenon as generational forgetting. At the time of this writing (2013), there have been continuing and substantial declines in both adolescent alcohol use and cigarette smoking, and these declines track significant public health efforts and social policies targeted at these behaviors. The Monitoring Future Data also show 2012 declines in the use of ecstasy, Vicodin, and OxyContin. In contrast, however, adolescent marijuana use has increased, (albeit stabilized in 2012; Johnston et al., 2013), along with increases in its perceived acceptability and availability and lowered perceived risk. This may reflect broader societal trends toward increased acceptance of marijuana use, as seen in state policies concerning decriminalization and medical marijuana. Similarly, although the prevalence of cigarette smoking has decreased substantially, a variety of new tobacco products have recently been introduced, including dissolvable forms of smokeless tobacco and e-cigarettes. These new products have the potential to achieve harm reduction benefits if individuals switch from combustible cigarettes to these noncombustible alternatives. However, they also have the potential to perpetuate cigarette smoking or even to increase risk for smoking if the reinforcing effects of nicotine result in these products serving as a gateway to smoking (Hatsukami, Ebbert, Feuer, Stepanov, & Hecht, 2007). An important direction for future epidemiological research is to examine the effects of these alternate tobacco products on smoking prevalence.

Another focus of concern in recent years has been adolescent misuse of prescription medication. One review of the literature (Young, Glover, & Havens, 2012) found that, among 12–17-year-olds, misuse of pain medication and stimulants were most common, with past year rates of 4–11% for pain medication and 1.7–3% for stimulants. These trends are somewhat difficult to assess in the Monitoring the Future data because mention of some specific prescription drugs were only recently introduced. However, the general trend in categories of use suggests that misuse of prescription pain medication and tranquilizers began to rise in the early 1990s and has only recently stabilized or slightly declined (varying with different substances). The misuse of Adderall may be an exception to this decline, because the Monitoring the Future data showed a small (nonsignificant) increase for twelfth graders. Moreover, the misuse of Adderall may be even greater for college students than for high school students (and higher for college students than for their age peers who do not attend college (Kaye & Darke, 2012). Wilens et al. (2008) reviewed the literature and found past year rates of 5–9% through Grade 12 but 5–35% in college students. Not surprisingly, the most common reported reason for misuse of Adderall is to achieve cognitive and performance enhancement (Kaye & Darke, 2012).

These trends over time in adolescent substance use prevalence have several implications for understanding the etiology of substance use and for public health interventions. Johnston et al. (2013) argued that the use of specific drugs shows volatility over time, such that prevalence rates change in response to societal changes in acceptability and perceived risk, whereas the proportion of adolescents who engage in some form of substance stays more stable. The changes in use of specific substances argue for the importance of continued public health messages about consequences and risk, combined with restrictions on availability and access. However, the greater stability of the proportion of adolescents who engage in some form of substance use raises the possibility of drug substitution.

Moreover, changes in prevalence over time illustrate the importance of cultural/historical context in shaping

substance use behavior. Indeed, these cultural-historical influences can produce long-lasting cohort effects in substance use, such that specific birth cohorts carry their substance use involvement over the life span from adolescence to old age. This can be seen in an analysis of the Monitoring the Future Data in which adolescents from birth cohorts showing anti-drinking social norms had less drinking than did those whose birth cohorts were more approving or tolerant of alcohol use (Keyes et al., 2012). Indeed, the Baby Boomer cohorts have been marked by high levels of substance use involvement across different age periods, and the current aging of the Baby Boomers has led researchers to predict that there will be higher levels of substance use among older individuals in the coming years (Colliver, Compton, Gfroerer, & Condon, 2006). Moreover, these cohort effects have implications for etiological theory in terms of influences that propel drug use in different historical periods. For example, an analysis of twin data from the National Survey of Midlife Development suggests that the heritability of smoking differs among birth cohorts from 1920 to the 1960s (Boardman, Blalock, & Pampel, 2010).

RELATIONS WITH DEMOGRAPHIC FACTORS

Perhaps the strongest demographic predictor of substance is age, with adolescence being the typical time of substance use onset and escalation to higher levels of use. Emerging adulthood (age 18 to the early to mid-20s) is the age period of peak rates of substance use as well as clinical substance use disorders. Because of the importance of age-related trajectories of substance use and substance use disorders, this literature is reviewed in a separate section below. Here we discuss relations between substance use and socioeconomic status, race/ethnicity, and gender.

The relation between socioeconomic status (SES) and substance use is complex, characterized by conflicting data, many null findings, and possible variation with age, race/ethnicity, and the specific substance under consideration. Reviews of longitudinal studies have found no effects of childhood SES on later alcohol disorders (Wiles et al., 2007) but significant effects of low childhood SES on elevations in adult marijuana use (Daniel et al., 2009) and adolescent marijuana use (Lemstra et al., 2008). Lower SES also predicts greater cigarette smoking particularly in high SES neighborhoods (Mathur, Erickson, Stigler, Forster, & Finnegan, 2013).

Because many studies do not control for the effects of race/ethnicity, effects of SES could be due to race/ethnicity. Data from the Monitoring the Future Study (Bachman, O'Malley, Johnston, Schulenberg, & Wallace, 2011) found that, among non-Hispanic Caucasian adolescents, those with better educated parents reported less use of alcohol and cigarettes in eighth and tenth grades, but those effects dissipated by Grade 12. No parent education effects were detected for African American and Hispanic adolescents. Bachman et al. (2011) suggest that there are catch-up effects among non-Hispanic Caucasian adolescents from well-educated families. Similar results were found in the Add Health study (Humensky, 2010) in that higher parent SES predicted more early adult marijuana and binge drinking and the same result was found in the Panel Study of Income Dynamics data (Patrick, Wightman, Schoeni, & Schulenberg, 2012).

Similar complexity is found in studies of neighborhood SES. Karriker-Jaffe's (2011) review found more significant effects of neighborhood disadvantage for adults than for adolescents and reported that risk for substance use was associated with neighborhood advantage for adolescents. Thus, it is possible that low SES is a risk in childhood with a more complicated pattern in adolescence. The association with low SES in adulthood likely reflects both the causes and the results of substance use. Other moderators besides age may also contribute to the complex pattern of findings. For example, Trim and Chassin (2008) found that neighborhood disadvantage was associated with increased alcohol use among children of alcoholic parents whereas the opposite was true for children of nonalcoholic parents.

Finally, it is possible that the complex pattern of results reflect curvilinear relations, such that adolescent substance use is elevated at the extremes of poverty (Hawkins, Catalano, & Miller, 1992) and affluence (Luthar & Barkin, 2012), although the confounding effects of race/ethnicity preclude strong conclusions. For affluent adolescents, Luthar and Barkin (2012) suggest that risk factors for substance use include a lack of parental sanctions for substance use behavior. In terms of poverty, Costello, Erkanli, Copeland, & Angold (2010) found that American Indian children who received income supplements as a result of a casino opening showed lower rates of adult alcohol and cannabis dependence than did their non-Indian peers who did not receive these income supplements (suggesting a causal effect of poverty) and that material hardship in adolescence predicted a greater likelihood of diagnosed substance use disorder.

In terms of ethnicity, rates of adolescent substance use are highest for American Indians, followed by non-Hispanic Caucasians and Hispanics, with lower rates reported for African American and Asian adolescents

(Johnston et al., 2013; Swendsen et al., 2012). In addition, rates vary for different Hispanic subgroups (Caetano, Ramisetty-Mikler, & Rodriguez, 2009) and by nativity and time in the United States, with immigrants generally showing lower rates than native U.S.–born individuals. However, there are also complex interactions with age. For example, in the Monitoring the Future Data, Hispanic adolescents have higher rates than other groups at eighth grade, but this disappears by twelfth grade, perhaps reflecting greater school dropout among Hispanic adolescents than other groups (Johnston et al., 2013). Similarly, although in adolescence, African Americans smoke cigarettes at substantially lower rates than do non-Hispanic Caucasians, this difference reverses in adulthood, in part because of racial differences in educational attainment and marital status (Kandel, Schaffran, Hu, & Thomas, 2011). There are also complex relations between race and multiple dimensions of substance use involvement. For example, African Americans are less likely to use alcohol and generally drink at lower levels than do non-Hispanic Caucasians in both adolescence and adulthood. Yet they are more likely to experience alcohol-related problems even at equivalent levels of alcohol intake (Zapolski, Pederson, McCarthy, & Smith, 2013). Although the reasons for this are unclear, Zapolski et al. (2013) proposed multiple factors may contribute to a higher level of alcohol-related problems for African Americans compared with other groups, including drinking being more likely to occur in higher risk locations (e.g., low SES neighborhoods) that also carry increased risk for legal sanctions, self-reports that underestimate the amount of alcohol that is consumed, heritable differences in sensitivity to alcohol effects, and attitudinal intolerance of alcohol use in the African American community that leads to negative social reactions to drinking.

In terms of gender differences in prevalence, the Monitoring the Future data (Johnston et al., 2013) show that, during adolescence, males have slightly higher levels of substance use although this varies with the type of substance in question. For example, males show higher rates of heavy drinking and smokeless tobacco use than do girls, but there are few gender differences in overall alcohol consumption or cigarette smoking. Gender differences tend to increase at older ages (Johnston et al., 2013; Swendsen et al., 2012). Moreover, there is some evidence that gender differences have been narrowing for more recent birth cohorts (Keyes et al., 2012), suggesting that changing social norms may influence the extent of gender differences in substance use behaviors.

Substance use is also related to family structure, with offspring in divorced families showing higher rates. However, because divorce is associated with many other environmental risk factors (e.g., family conflict) and with genetic risk for substance use outcomes (e.g., parental alcohol and drug disorders), studies have attempted to identify the causal significance of divorce. Genetically informed studies including adoption and children of twins designs suggest that divorce has an environmentally mediated effect (D'Onofrio, Turkheimer et al., 2007; O'Connor, Caspi, DeFries, & Plomin, 2000). For example, adopted children whose parents divorce have higher rates of substance use than do adopted children from intact families (O'Connor et al., 2000). Moreover, parental divorce is associated with lifetime diagnoses of alcohol dependence over and above parental alcohol problems (Thompson, Lizardi et al., 2008). Given these findings, it is important to consider potential mechanisms by which parental divorce might increase risk for offspring substance use. Indeed, there is evidence to suggest that divorce-related impairments in parenting and parent–child relationship quality may be important mediating mechanisms. Preventive interventions that focus on improving parenting have shown beneficial effects on adolescent substance use for children from divorced families (Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011) and changes in parental monitoring, discipline, and parent–child relationship quality have been shown to be significant mediators of these intervention effects (Sandler et al., 2011).

USE OF MULTIPLE SUBSTANCES: PATTERNS OVER TIME

Adolescents tend to use multiple substances so that the use of any one drug is a risk factor for the use of other drugs (Palmer et al., 2009). Indeed, it has been argued that adolescent substance use follows a series of predictable stages such that the use of licit substances (alcohol and tobacco) is followed by marijuana use and then other illegal drugs. This stage-sequence model has been referred to as the gateway theory (Kandel, 1975) because licit substances are presumed to serve as a gateway to the use of illegal drugs. Although there are both retrospective and longitudinal data consistent with this sequence, this theory remains controversial. First, the sequence of use of different substances is not invariant across subgroups. For example, some studies of African American samples have shown that cannabis use precedes the use of cigarettes (Vaughn, Wallace, Perron, Copeland, & Howard, 2008) and alcohol (Sartor et al., 2013). Second, and most important, it is unclear whether or not the use of earlier substances in the

sequence plays a causal role in the use of drugs later in the sequence as implied by the gateway theory or, instead, whether adolescents' use of multiple substances is caused by common correlated risk factors, including a common genetic liability as has been reported for adolescent alcohol, tobacco, and marijuana use (Hopfer, Crowley, & Hewitt, 2003; Kendler, Schmitt, Aggen, & Prescott, 2008). For example, considering whether marijuana use serves as a gateway to other illegal drug use, some studies have found that the effect of earlier marijuana use on later illegal drug use is eliminated when correlated risk factors are considered (e.g., Van Gundy & Rebellon, 2010) although others find that the effect of earlier marijuana is maintained (albeit weakened) after consideration of potential confounders (Fergusson, Boden, & Horwood, 2006).

In evaluating whether earlier use of one substance might play a causal role in the later use of other substances, it is important to identify possible theory-based mechanisms by which such a causal effect could occur. Cross-sensitization (i.e., the process by which the use of one drug increases responses to other drugs) may be one mechanism underlying the gateway model. Sensitization effects have been shown in animal data. For example, pretreatment with cannabis increases opiate use (Ellgren, Spano, & Hurd, 2007). Pretreatment with nicotine increases cocaine reward (McQuown, Beluzzi, & Leslie, 2007) and also increases conditioned place preference and locomotor activation in response to cocaine (mediated through changes in gene expression). However, this result was obtained only when cocaine and nicotine were later administered together (Levine et al., 2011). The level of quantity, frequency, and duration of use that would be needed for such mechanisms to operate among human adolescents are not clear. In addition to common risk factors (including genetic risk) and sensitization as potential explanations, the early use of licit drugs or marijuana may increase later drug use indirectly because adolescent users of licit drugs or marijuana may join peer groups that promote the use of other drugs or who provide greater access to other drugs (see Lynskey & Agrawal, 2009).

Finally, in considering patterns of use of multiple drugs, it is important to consider the possibility that the use of one drug can substitute for another. The possibility of substitution effects is important from a policy perspective. For example, researchers have tested whether the minimum legal drinking age of 21 may inadvertently increase marijuana use before age 21. Using longitudinal data, Crost and Guerrero (2012) found decreases in marijuana use at age 21, the age at which alcohol use becomes legal and the age at which alcohol use increased sharply. They argue that alcohol and marijuana use can be substitutes and that policies for increasing the minimum legal drinking age can have negative unintended consequences of increasing other drug use. Although the question of drug substitution is particularly important, given the potential for unintended negative consequences of policy interventions such as increasing taxes or restricting access to substances, several cross sectional studies comparing states with differing drinking ages have not found alcohol and marijuana substitution effects (see Crost & Guerrero, 2012 for a review).

AGE-RELATED TRAJECTORIES OF SUBSTANCE USE: TYPICAL AGE-RELATED PATTERNS

As noted earlier, the typical age of onset of substance use is during adolescence and there are multiple developmental influences that likely explain this finding. Adolescence is characterized by increased autonomy from parents and greater time spent in peer contexts and outside of parental supervision. Theoretical models such as problem behavior theory (Jessor & Jessor, 1977) argue that adolescents are motivated to display independence and an image of adult status. Some forms of substance use such as alcohol and cigarette smoking are age-graded behaviors that are legal for adults but not for adolescents. Thus, use of these substances can display a social image of precocity and independence, making adolescence a period of particular risk for substance use behavior.

In addition to these psychosocial mechanisms, recent models of adolescent development have suggested that this period is characterized by a disjunction between trajectories of reward seeking and cognitive control driven by neurobiological processes of adolescent brain development. Specifically, reorganization of the approach system and slow maturation of the control/regulation system are thought to create an asynchrony such that increases in motivation for positive arousal go unchecked by an immature capacity for effortful regulation (Somerville, Jones, & Casey, 2010; Steinberg, 2008). The notion that there are neurobiological underpinnings that predispose adolescents to risk-taking behavior is consistent with an evolutionary perspective, which points to increases in risk taking and exploration during adolescence across multiple animal species and suggests that there is adaptive value of adolescent exploration and risk-taking for promoting independence and mate selection (Ellis et al., 2012).

In terms of the approach system, changes in dopaminergic systems, including density of receptors in cortical and

subcortical regions (e.g., ventral striatum), are thought to underlie increases in the salience of reward and sensation seeking (Chambers, Taylor, & Potenza, 2003). Several lines of evidence support this idea. Compared with adults, adolescents are more behaviorally and emotionally reactive to monetary incentives (Hardin, Schroth, Pine, & Ernst, 2007). Adolescents are more sensitive to positive feedback during affective decision making compared with adults and children (Cauffman et al., 2010). Reward sensitivity and sensation seeking, an individual difference thought to be linked to strong sensitivity to reward (Dawe, Gullo, & Loxton, 2004; Knyazev, Slobodskaya, Kharchenko, & Wilson, 2004), increases during adolescence (Colder, Hawk, et al., 2012; Crawford, Pentz, Chou, Li, & Dwyer, 2003). Converging lines of evidence from imaging studies suggest that adolescents compared with adults are more sensitive to reward and process reward and risk information in a way that increases the likelihood of sensation seeking and risky behavior (Bjork, Smith, Danube, & Hommer, 2007; Casey, Jones, & Hare, 2008; Van Leijenhorst et al., 2010).

With respect to the control/regulation system, pruning and differentiation of synapses and increased myelination in the prefrontal cortex continue well into adolescence, and these changes presumably enhance efficiency of the system and connectivity between cortical structures (Geidd et al., 1999; Somerville et al., 2010). Behavioral studies show continued improvement on cognitive tasks that require recruitment of the control/regulation system (Crone & van der Molen, 2004; Conklin, Luciana, Hooper, & Yarger, 2007; Hooper, Luciana, Conklin, & Yarger, 2004). Imaging studies show that adolescents are less efficient at recruiting the control/regulation system on tasks requiring cognitive control (Durston et al., 2006) and that improved performance on these tasks from childhood to adulthood is associated with increased activation of prefrontal cortical areas and connectivity between cortical and subcortical structures (Somerville et al., 2010).

Although considerable evidence has accumulated for the role of adolescent brain development in risk taking behavior and substance use, there are presumably individual differences in timing of these processes. One prediction is that youth who show more rapid changes in the approach system and commensurate increases in motivation for positive arousal, or particularly slow maturation of the prefrontal cortex and immature regulatory capacity, or both are expected to be at increased risk adolescent substance use. Few longitudinal studies have examined such questions. Two studies found that more rapid increases in behavior indicative of motivation for positive arousal (e.g., sensitivity to reward and sensation seeking) during adolescence were associated increases in drug use (Colder, Hawk et al., 2012; Crawford et al., 2003). Quinn and Harden (2013) found that slower declines in motivation for positive arousal in late adolescence were associated with escalation of drug use. Another possibility is that drug use itself can disrupt adolescent brain development, resulting in transactions between drug use and changes in the approach and control/regulation systems and a feed forward process that results in escalation to disorder (Squeglia, Jacobus, & Tapert, 2009).

If adolescence is the typical age of substance use onset with peaks in emerging adulthood, the early to mid-20s mark the typical ages of substance use decline, a phenomenon often referred to as maturing out. Psychosocial explanations of this phenomenon have suggested that it is driven by the increased responsibilities associated with the acquisition of adult roles such as marriage, parenthood, and employment that occurs during these ages. Yamaguchi and Kandel (1985) termed this process role socialization. That is, when behaviors are incompatible with the norms and obligations of social roles, an individual needs to resolve this incompatibility either by desisting from the behavior or by leaving the role. Indeed, the relation between role acquisition and declines in substance use has been empirically supported (Bachman et al., 2002), particularly for family roles (Staff et al., 2010). Of course role transitions can occur at many ages so their effects will not be restricted to early adulthood. Moreover, age-atypical role transitions such as an early transition to parenthood have not shown protective effects on substance use behavior (Little, Handley, Leuthe, & Chassin, 2009).

Although research has confirmed the relation of role transitions to changes in substance use behavior, there are other changes that occur in the early to mid-20s that could also explain age-related declines in substance use. As described earlier, over the course of adolescence and into the mid-20s, there is a gradual maturation of cognitive control systems (Paus, 2005; Steinberg, 2008), and these increases in cognitive control would be expected to reduce risk-taking behavior in general, and substance use more specifically.

Moreover, accompanying changes in cognitive control and the acquisition of adult roles and responsibilities are changes in personality. Personality is not a fixed characteristic that is immutable over the life course but, rather, shows fairly dramatic normative changes throughout adolescence and later adulthood (e.g., Roberts, Walton, & Viechtbauer, 2006). Increases in psychosocial maturity in early adulthood are demonstrated in decreased negative affectivity and increased conscientiousness and related

self-control. Indeed, recent studies have demonstrated that individual differences in age-related changes in personality including declines in behavioral disinhibition/impulsivity and negative emotionality/neuroticism and increases in conscientiousness are correlated with declines in alcohol use in emerging adulthood and early adulthood (Littlefield, Sher, & Wood, 2009). Importantly, the association between personality change and change in drinking in emerging adulthood persists even when adult role occupancies are considered (Littlefield et al., 2009). Moreover, even in late adolescence when (on average) rates of alcohol use and levels of use are increasing at the same time that impulsivity and sensation seeking) are decreasing, smaller decreases in these traits are associated with bigger increases in substance use (Quinn & Harden, 2013).

Of course, the association between age-related changes in personality and changes in substance use may reflect either the influence of personality on substance use or the influence of substance use on personality. The notion that substance use influences personality is consistent with neurobiological findings showing that neuroadaptation to chronic substance use creates a persistent negative affective state motivating continued use (e.g., Baker, Piper, McCarthy, Majeskie, & Fiore, 2004; Koob & Le Moal, 2008). What is less clear is the degree to which less severe substance use patterns alter personality traits and, if they do, how persistent such changes are. There is some recent evidence that alcohol use might influence age-related personality change, but the results are not totally consistent. Hicks, Durbin, Blonigen, Iacono and McGue (2012) found that individuals whose alcohol disorder began in adolescence and was persistent into young adulthood, did not show normative declines in negative emotionality, and suggested that alcohol use interfered with age-related declines in negative emotionality. However, Littlefield, Vergés, Wood, and Sher (2012) found that the effects of alcohol involvement on personality appeared to operate on shorter timeframes and to be dependent upon the developmental period under investigation (see also Quinn, Stappenbeck, & Fromme, 2011). At this point, the relation between personality change and substance use patterns has yet to be fully characterized but existing data suggests that there is a fairly strong association and that the relation between personality and substance use is a dynamic one.

Finally, although the prevalence of substance use and substance use disorders is lower after the mid-20s, we now know that maturing out is more complex than previously thought. For example, Vergés et al. (2013), using NESARC data, found that rates of persistence of drug disorders did not change with age and that role transitions influence drug disorders at many ages not just during emerging adulthood.

INDIVIDUAL VARIABILITY IN SUBSTANCE USE TRAJECTORIES: THE SIGNIFICANCE OF AGE OF ONSET AND TIME TO DISORDER

Both longitudinal and cross sectional research suggests that earlier age of onset of tobacco, alcohol, and illegal drug use is associated with higher risk for the development of a substance use disorder (Grant & Dawson, 1998). However, there is considerable controversy about whether this association represents a causal relation (e.g., McGue & Iacono, 2008; Odgers et al., 2008). Some studies suggest that controlling for correlated risk factors eliminates the effect of age of alcohol onset on later alcohol disorder but not the effect of early drug use onset on later drug disorder (King & Chassin, 2007). However, analyses using propensity score approaches provide support for the effect of early age of onset on later problems (Odgers et al., 2008).

Because age of first exposure in humans is heritable (at least for alcohol), it has been argued that the association between early onset of substance use and later substance use disorder may be due to a shared genetic risk for disinhibition (McGue, Iacono, Legrand, & Elkins, 2001). Genetically informative studies provide conflicting findings. Early onset of smoking is associated with increased likelihood of developing tobacco dependence (e.g., Breslau, Fenn, & Peterson, 1993) and one recent twin study found that among twins discordant for age of initiating smoking, the twin who started earlier was more likely to develop dependence (Kendler, Myers, Damaj, & Chen, 2013). There may a causal role for early cannabis exposure as well although twin studies (e.g., Agrawal, Neale, Prescott, & Kendler, 2004; Lynskey et al., 2003) suggest that much of the association is due to common genetic and environmental vulnerabilities.

Theoretically, it has been proposed that a causal relation between early onset of use and later substance use disorder could be due to differential sensitivity to substance use effects for adolescent compared with adult exposure. Accumulating evidence suggests that adolescents may be particularly sensitive to the neurotoxic effects of various substances and that adolescent exposure may produce durable neurocognitive changes. This is most likely due to the fact that adolescence is a period marked by extensive changes in the maturation of the brain characterized by extensive synaptic pruning and development of the frontal lobes (Clark, Thatcher, & Tapert, 2008; Crews, He, &

Hodge, 2007; Selemon, 2013) creating vulnerabilities to exogenous substances that affect the brain (as well as endogenous, stress-induced processes). For example, heavy exposure to alcohol in adolescence has been associated with structural and functional brain deficits, and also deficits in cognitive functioning (e.g., Hanson, Medina, Padula, Tapert, & Brown, 2011). The associated neurocognitive deficits, especially those associated with deficits in prefrontal and limbic systems (Monti et al., 2005), could pose added risk for heavier substance use and engagement in a range of externalizing behaviors (e.g., Bava & Tapert, 2010). Although a definite causal relation in humans has yet to be established due to the paucity of truly prospective designs that first assess youth prior to their first substance use exposures, rodent models of adolescent ethanol exposure (Crews, Braun, Hoplight, Switzer, & Knapp, 2000; Spear, 2000) demonstrate that adolescence appears to be a time of heightened sensitivity to persistent neurologic damage (i.e., greater deficits associated with adolescent exposures than with preadolescent or adult exposures). Adolescent cannabis exposure is associated with risk for the development of psychotic illness (Moore et al., 2007; Semple, McIntosh, & Lawrie, 2005) and the timing of the exposure appears to be limited to adolescence (and possibly to individuals with specific genotypes; Caspi et al., 2005).

In addition to age-specific vulnerabilities for neurotoxic effects that may increase risk for later substance use, adolescents may be differentially sensitive to the reinforcing effects of substance use. For example, compared with adults, adolescents experience less sensitivity to the impairing effects of alcohol, more acute tolerance, but more sensitivity to rewarding effects and social facilitation (Spear, 2011). This pattern should raise risk for adolescent heavy alcohol use and thus raise risk for subsequent alcohol disorder. Moreover, although there are few studies (Spear, 2011), some animal data suggest that adolescent exposure produces heavier adult self-administration (Rodd-Henricks et al., 2002) or greater reinforcement than does adult exposure (Adriani, Deroche-Gamonet, Le Moal, Laviola, & Piazza, 2006).

In addition to age of onset, another potentially important aspect of a substance use trajectory is the time that it takes to transition from initial use of a substance to the development of a substance use disorder. Shorter time to disorder (i.e., a telescoped trajectory) gives clues to the processes of vulnerability and protection. Some data suggest that non-Hispanic Caucasians show greater telescoping for alcohol dependence than do African Americans or Hispanics (Alvanzo et al., 2011). Findings of gender differences are mixed. For example, alcohol studies have reported greater telescoping for women (Randall et al., 1999), for men (Keyes, Martins, Blanco, & Hasin, 2010) and no gender differences (Alvanzo et al., 2011). It has also been reported that there is a faster time to alcohol dependence for individuals with anxiety disorder (Kushner, Maurer, Menary, & Thuras, 2011). A limitation of this literature is that, despite the fact that telescoping is a process that occurs over time, much of the data are based on retrospections from cross sectional studies. One study that was able to capitalize more on longitudinal data found greater telescoping effects for both alcohol and drug disorders for children of alcoholic parents and for individuals with externalizing symptomatology (Hussong, Bauer, & Chassin, 2008). Potential mechanisms underlying these findings include the possibility that children of alcoholic parents experience more positive reinforcement (or less aversive effects) from exposure to alcohol and drugs than do children of nonalcoholic parents.

ETIOLOGICAL PATHWAYS: GENERAL AND SUBSTANCE-SPECIFIC BIOPSYCHOSOCIAL MECHANISMS OF RISK AND AGE AND STAGE DIFFERENCES IN RISK PATHWAYS

There are multiple etiological pathways that underlie the development of substance use and substance use disorders, reflecting the developmental psychopathology principle of equifinality. Before reviewing these pathways, it is important to note several critical features of them. First, each of these pathways is characterized by complex gene–environment interplay. As reported in a recent review (Kendler, Chen, et al., 2012) there are substantial heritable influences on substance use disorders, with twin studies suggesting that genetic influences generally account for 40–55% of the variance across different forms of substance use disorders (more for cocaine abuse). However, the magnitude of genetic influence varies not only across different forms of substance use disorder, but also with different stages of disorder (i.e., initiation, heavy use, problem use, and clinically diagnosable disorder) and the magnitude of genetic influence varies with age. The general pattern is that shared environment influences are substantial and strongest at younger ages and at earlier stages of substance use (Kendler, Chen, et al., 2012; Stallings, Gizer, & Young-Wolff, in press). For example, Kendler et al. (2008) analyzed retrospective life calendar data from a large sample of male twins to examine genetic and family environment influences on caffeine, nicotine, alcohol, and marijuana use. They found that

family environment influences declined with age whereas genetic influences increased. Interestingly, however, family environment influences persisted (albeit at lower levels) well into adulthood. Thus, environmental influences can have enduring effects even after the age of leaving home. Perhaps early environment sets the stage for cascading influences that perpetuate substance use over ages (Haller, Handley, Chassin, & Bountress, 2010). Moreover, it is also important to ask why the magnitude of genetic influences on substance use would increase with age. This may reflect greater genetic influences on persistent use that are masked at early ages by developmentally limited experimentation. In addition (as noted by Kendler et al., 2008), the increasing role of genetic influences may reflect greater "niche picking" at older ages. That is, at older ages, individuals have greater ability to choose their own environments. However, although the evidence base from population-based, twin studies on alcohol and tobacco use and disorders is very extensive and reasonably consistent about age differences in heritability, this is far less true for illicit drug use and drug use disorders with the exception of cannabis use and cannabis use disorder (Stallings et al., in press) and so some degree of caution should be expressed in generalizing too strongly across all drugs of abuse.

In addition to age differences, the magnitude of genetic and environmental influences varies across stages of substance use such that environmental influences are stronger for substance use initiation and heritable influences are stronger for substance use problems (Kendler, Chen, et al., 2012). For example, Rhee et al. (2003) found this pattern for alcohol, tobacco, and any drug (but not for marijuana) in a sample including twins, siblings, and adoptees. Twin studies using CCC models have produced similar findings (see Kendler, Chen, et al., 2012). The differing heritabilities for substance use initiation compared with substance-use related problems or disorders raises the importance of examining stage-specific etiological influences more generally. For example, in a study of the development of alcohol dependence, Sartor, Lynskey, Heath, Jacob, and True (2007) found that although externalizing problems was a risk factor for both the initiation of alcohol use and for the development of dependence among users, initiation and dependence (conditional upon those who had already initiated) were associated with distinct predictors. Moreover, multivariate twin studies of alcohol dependence suggest that different symptoms of dependence may have different etiologies (Kendler, Aggen, Prescott, Crabbe, & Neale, 2012). These types of findings highlight that we need to think about the continuum of use to dependence as involving multiple processes and not merely the consequences of graded severity of a single process. However, as Kendler, Aggen, et al. (2012) note, stage-specific predictors of substance use disorders can only be identified in samples that are conditioned on substance exposure because risk for disorder among those who have never been exposed is unknown. Unfortunately, as Kendler, Aggen, et al. (2012) note, the extent of use that is required to create exposure is also unknown.

Finally, in considering risk pathways for substance use disorder, it is important to distinguish between general and substance-specific mechanisms. One consistent finding in the literature is that when multivariate models are fitted to examine common versus unique sources of influence across different drug classes, researchers tend to find evidence for strong common genetic influences and some degree of unique genetic influences on specific drug classes as well (Kendler et al., 2007; Tsuang et al., 1998). These findings tend to be stronger and more consistent when studying phenotypes associated with problems or substance use disorder diagnoses (as opposed to use). As noted earlier, there is substantial co-occurrence of different forms of substance use. Vrieze, Hicks, Iacono, and McGue (2012) created a common factor model of symptoms of nicotine, alcohol, and marijuana abuse using a sample of twins. They found the strongest loadings during adolescence (suggesting that a common factor is more important in adolescence) with weakening into adulthood (suggesting increasing importance of substance-specific influences with age).

Generalized risk pathways that can attempt to explain a broad general liability for substance use disorder focus either on models of the externalizing spectrum or the internalizing spectrum. Externalizing pathways suggest that a heritable predisposition to behavioral undercontrol is central to the development of multiple forms of substance use disorder (Iacono, Malone, & McGue, 2008) whereas internalizing pathways suggest that a common function of substance use is to manage negative affective states, so that substance is maintained or escalated through self-medication of negative affectivity (see Colder, Chassin, Lee, & Villalta, 2010; Hussong, Jones, Stein, Baucom, & Boeding, 2011) or that environmental stress and resulting negative affectivity influence substance use more indirectly by increasing its reinforcement value, the salience of drug-related cues in the environment, or by depleting self-regulatory resources.

However, in addition to models of broad general liability, there are unique genetic effects on regular substance use, alcohol dependence and drug use disorder that are independent of both externalizing and internalizing disorders (e.g., Kendler, Prescott, Myers, & Neale, 2003;

Krueger et al., 2002. This implies that there are also substance-specific pathways. Substance-specific accounts of risk focus on the specific effects of consumption, including the importance of individual differences in positive and negative subjective response (Morean & Corbin, 2008).

Within each of these etiological pathways, it is important to consider gene–environment interplay. This includes gene–environment correlation (rGE) such that individuals with particular genotypes may be exposed to particular environments (passive rGE), may seek out or select particular environments (active rGE), or may provoke particular environmental reactions (evocative rGE, see Jaffee & Price, 2012). It also important to consider gene–environment interaction (GxE), although great caution must be used in interpreting these data because the literature is plagued by failures of replication. When considering GxE interactions in substance use and dependence, we can entertain a range of possible mechanisms including environments that either goad or constrain use (e.g., permissive/facilitative vs. restrictive environments), and thereby facilitate or inhibit use. For example, Stallings et al. (in press) reported that twin studies tend to show higher heritabilities of substance use and other substance-related outcomes in environments characterized by easier access or more permissive attitudes (defined broadly based on religious affiliation, state taxes, school norms) than in environments with less access and less permissiveness. We can also consider environments that alter the individual in some way so that they are more or less internally motivated to use substances (e.g., early trauma leading to negative affectivity and coping motivations) or environments that synergistically interact with drug effects to heighten drug reinforcement (e.g., peer socialization in adolescence; see Sher et al., 2010).

Here we discuss the externalizing, internalizing, and substance use effects pathways in turn. However, it is important to remember that these risk pathways are not necessarily mutually exclusive and, indeed, research supports intersections among them. Moreover, these pathways have been viewed both as etiological models of the development of substance use disorders in general and also as mechanisms for the intergenerational transmission of substance use disorders (i.e., as mediators of the effects of parental substance use disorders on offspring outcomes). Thus, we begin with a discussion of parental substance use disorders as a distal risk factor for the development of substance use disorders in offspring.

Parental Substance Use Disorders

Given the substantial heritability of substance use disorders it is not surprising that substance use disorders run in families and that parental alcohol or drug disorder is associated with increased risk of substance use disorders in the next generation. Adults with a family history of alcoholism are more likely to develop an alcohol disorder (Lieb et al., 2002; Sorensen et al., 2011), with risk ratios ranging between two and three in community samples to nine in severely antisocial samples (McGue, 1994). Parent alcoholism is associated with early onset of alcohol use (Lieb et al., 2002), with greater escalation of substance use over adolescence (Chassin, Curran, Hussong, & Colder, 1996), and a more rapid transition from use to diagnosable disorder (Hussong, Bauer, et al., 2008). The risk associated with parent alcoholism is unique, over and above other parent psychopathology (Chassin, Pitts, DeLucia, & Todd, 1999; Sorensen et al., 2011) although risk for offspring drug disorders is particularly elevated when a biological parent shows both antisocial personality and drug disorder (Langbehn, Cadoret, Caspers, Troughton, & Yucius, 2003). Parental cigarette smoking (particularly trajectories of parental smoking that include early onset, steep escalation, and heavy use) is associated with smoking in the next generation (Chassin et al., 2008; Melchior et al., 2010). Finally, parental drug disorder is associated with increased risk for offspring drug disorders in adolescence (Hoffmann & Cerbone, 2002) and adulthood (Kendler, Sunquist, et al., 2012). Thus, the data are consistent in demonstrating the intergenerational transmission of risk for substance disorders. However, as noted earlier, there are multiple hypothesized biopsychosocial mechanisms underlying this intergenerational transmission including generalized risk for deviant behaviors (the externalizing pathway); generalized risk for internalizing problems (the stress and negative affect pathway); and substance-specific risk in which a history of familial substance disorder is associated with individual differences in the effects of substances. Here we review each of these pathways in turn.

THE EXTERNALIZING PATHWAY

Externalizing problems represent disruptive behaviors such as attention-deficit/hyperactivity disorder (ADHD) symptoms, delinquency, and aggression that bring a child into conflict with others. This domain of childhood behavior problems predicts adolescent substance use and substance use disorders (Hawkins et al., 1992; Zucker, 2006), although these associations are weaker for ADHD than for delinquency and aggression (Lee, Humphreys, Flory, Liu, & Glass, 2011). Moreover, there is a high co-occurrence between antisocial behavior and substance

use disorder (Kendler et al., 2003; Krueger et al., 2002). The strength and robustness of these associations have motivated researchers and behavioral theorists to formulate models of the onset and development of adolescent substance use within the broader context of antisocial behavior (Dishion, Capaldi, & Yoerger, 1999; Dodge et al., 2009; Sher, 1991). The resulting theoretical models overlap with etiological models of antisocial behavior (e.g., Patterson, Capaldi, & Bank, 1991), and integrate a diverse set of risk factors from multiple levels (the individual, family and peer context, schools) into sequential steps such that risk factors build upon each over time on a pathway to substance use. The models start early in life with child characteristics (e.g., temperament traits reflecting behavioral undercontrol and poor self-regulation) and family factors (e.g., parenting) increasing risk for early behavior problems and school difficulties, which in turn, lead to poor social adjustment and affiliation with deviant peers. Deviant peers provide access to drugs and support and reinforce drug use, and are considered to be proximal predictors of substance use. Poor self-regulation or behavioral undercontrol is conceptualized as a core vulnerability that is heritable and shapes and is shaped by the environment (parents, peers, and schools) through reciprocal processes to create a developmental cascade to substance use that gains momentum as children age. The literature documents considerable support for this conceptualization. Below we review the major domains of this developmental cascade, including behavioral undercontrol, parenting, peers, and schools. Finally, we consider the role of genetics and potential gene–environment interactions.

Behavioral Undercontrol

Behavioral undercontrol is an umbrella term that includes externalizing problems, sensation seeking, extraversion, and impulsivity. Traits reflecting behavioral undercontrol are associated with adolescent substance use (Hawkins et al., 1992), and are particularly relevant to the externalizing pathway to adolescent substance use. Individual differences in behavioral undercontrol are evident very early in life (Goldsmith et al., 1987), and poor behavioral control has been shown to predict early emerging externalizing problems in childhood (Shaw, Owens, Giovanneli, & Winslow, 2001), which in turn predict adolescent substance use (Hawkins et al., 1992; King, Iacono, & McGue, 2004). Behavioral undercontrol has been proposed as a core vulnerability that accounts for the developmental continuity between early temperament, externalizing problems, and substance use (Zucker, Heitzeg, & Nigg, 2011). Evidence suggests that the neurocognitive basis for this vulnerability involves the prefrontal cortex and related structures, including the thalamus, basal ganglia, and limbic areas. At the level of behavior, these structures have been described heuristically as reflecting three distinct systems including regulation/control and two motivational/reactive systems that include an approach system and an avoidance system (Nigg, 2000; Putnam, Ellis, & Rothbart, 2001). The control/regulation system is distinguished from the motivational/reactive systems in that the former involves effortful regulation of behavior and the latter involves automatic reactions to novelty, incentives (reward or loss), and threat (Gray & McNaughton, 2000; Putnam et al., 2001). This structural organization is consistent with triadic theories of motivated behavior (e.g., Ernst & Fudge, 2009; Ernst, Pine, & Hardin, 2006). Each of these systems has been linked to substance use in adolescence.

Control/Regulation System

The control/regulation system is controlled by the prefrontal cortex and modulates motivation and reactivity so that an individual can adapt to situational demands in the service of pursuing distal goals. Inhibition of dominant response to engage a subdominant response, planning, error detection, attentional control, and working memory are all involved in control/regulation (Luciana, 2006; Rothbart & Rueda, 2005). There is some evidence that behavior indicative of deficits in these core aspects of control/regulation predict adolescent externalizing behavior and substance use both cross sectionally and longitudinally (Khurana et al., 2013; Zucker et al., 2011). However, links between executive functioning and adolescent substance use have not been supported consistently, and in the externalizing problem behavior domain, links between executive functioning and ADHD are stronger than links between executive functioning and aggression and delinquency (Birkley & Smith, 2011; Castellanos-Ryan, Rubia, & Conrod, 2011; Handley et al., 2011).

The multifaceted nature of the control/regulation system presents a significant challenge to understanding the role it plays in the etiology of adolescent substance use. Although conceptually related, the subdomains of control/regulation (inhibition, planning, error detection, attentional control, and working memory) may not form a unitary construct and some subdomains may be more germane to adolescent substance use than others (Dick et al., 2010). There have been efforts to organize subdomains of control/regulation into a taxonomy or typology (e.g., Nigg, 2000), and such conceptually driven approaches may

help elucidate the role of control/regulation in the etiology adolescent substance use. Another important consideration in understanding the role of the control/regulation system is that it may act as a moderator of motivational/reactive systems. Tripartite models posit that the control/regulation and motivational/reactive systems operate jointly to influence motivated behavior (e.g., Ernst & Fudge, 2009). This implies a moderational model whereby strong motivational/reactive systems that go unchecked by a weak control/regulation system may increase risk for behavioral undercontrol and substance use rather than a weak control/regulation system on its own. Such moderational effects are consistent with dual process models of addiction that posit interactive effects between impulsive or automatic processes and reflective/controlled processes (Gladwin, Figner, Crone, & Wiers, 2011). Dual process models are discussed more fully later when we consider etiological pathways based on substance use effects.

An important caveat in considering the etiological role of the control/regulation system in adolescent substance use is the direction of effects. Imaging studies comparing drug using groups suggest that dysfunction in brain regions associated with memory, working memory, and attention (e.g., decreased hippocampal volume, low prefrontal cortex volume; Squeglia et al., 2009) are associated with heavy alcohol and drug use, even after periods of abstinence. However, most of this research is cross sectional leaving open the question of whether these neural characteristics associated with impaired control/regulation are causes or consequences of drug use. Neuroadaptation to substance use can diminish the capacity of the control/regulation system leading to compulsive drug use (Koob & Volkow, 2010), and the adolescent brain may be particularly vulnerable to the neurotoxic effects of drugs of abuse (Squeglia et al., 2009). Thus, it is possible that a weak control/regulation system increases risk for substance use, but also that drug use further weakens the control/regulation system.

Approach System

The approach system is controlled by the ventral striatum, mediates reactivity to appetitive stimuli, and motivates approach behavior. Evidence suggests that behavioral indices of a strong approach system are associated with externalizing behavior and adolescent substance use (Beauchaine, 2001; Colder & O'Connor, 2004; Knyazev, 2004; Knyazev et al., 2004; Lopez-Vergara et al., 2012). This system has particular relevance to drug addiction given that mechanisms of action of most drugs of abuse involve reward-related brain circuitry (Volkow, Fowler, Wang, & Goldstein, 2002). The intake of many drugs of abuse directly leads to the experience of euphoria, and using drugs because it is fun and exciting is a commonly reported motivation for drug use among adolescents (Kuntsche, Knibbe, Gmel, & Engels, 2005). Adolescents who are characterized by a strong approach system may find the potential euphoria-producing effects of drugs particularly appealing, increasing the likelihood of substance use, and escalation of substance use despite potential negative consequences. In an imaging study, Galvan, Hare, Voss, Glover, and Casey (2007) found that strong activation of the ventral striatum in anticipation of reward was associated with a composite index of risk behavior that included drug and alcohol use. However other studies suggest that *hypoactivation* of the ventral striatum is associated with drug use and behavioral undercontrol (Schneider et al., 2012), suggesting that substance use may be motivated by its ability boost a low hedonic state. Although the underlying neural circuitry remains unclear, motivation for positive arousal mediated by the approach system appears to increase risk for adolescent substance use.

Avoidance System

The avoidance system is controlled by the amygdala, mediates responses to potential aversive outcomes, and motivates reactive inhibition. Activation of the amygdala is involved in conditioned fear and in punishment-motivated learning (Murty, LaBar, & Adcock, 2012). Thus, a weak avoidance system as mediated by amygdala functioning may reduce the impact of potential punishment or aversive consequences on behavior, resulting in unchecked pursuit of reward. Few imaging studies have examined the functional significance of the avoidance system with respect to adolescent substance use, and so we focus our discussion on behavioral studies. Although there is evidence that behavior indicative of a weak avoidance system is associated with childhood externalizing behavior (Beauchaine, 2001), associations with drug use have been inconsistent. Some studies suggest that a strong avoidance system is associated with both low (e.g., Kimbrel, Nelson-Gray, & Mitchell, 2007; O'Connor, Farrow, & Colder, 2008; Simons & Arens, 2007) and high (e.g., Lopez et al., in 2012) levels of substance use. Other studies have shown no association (e.g., Kambouropolous & Staiger, 2007; Knayzev, 2004; O'Connor & Colder, 2005; Voigt et al., 2009).

One explanation for mixed findings regarding the avoidance system and adolescent substance use is that the nature

of the association may depend on age and stage of drug use. With age, substance use becomes increasingly normative (Johnston, O'Malley, Bachman, & Schulenberg, 2012). Early adolescent substance use is part of a broad array of deviant behaviors (e.g., delinquency, violence, sexual promiscuity) that violate age norms in rebellion against authority and rejection of conventional norms (Dishion, Spracklen, Andrews, & Patterson, 1996; Jessor & Jessor, 1977). Youth with a strong avoidance system may be disinclined to engage in such rule violating behavior. Yet, with age, substance use becomes more normative and there is more access to drugs and alcohol and more opportunities to use outside of deviant peer networks (Hussong et al., 2011). Thus, a strong avoidance system may be associated with late age of onset of drug use, and this may appear as a protective effect in early adolescence (or a risk effect associated with a weak avoidance system). However, once initiated, substance use may come to serve as a way of coping with emotional distress associated with a strong avoidance system (e.g., fear and anxiety), resulting in heavy substance use (see our discussion of internalizing or negative affect pathways into drug use). This developmental pattern implies that a weak avoidance system may be associated with substance use in early adolescence, but that a strong avoidance system is associated with heavy problematic levels of substance use at later ages. It is also possible that at later stages (heavy use and disorder), substance use may impact the avoidance system. As noted in our discussion of negative affect pathways, repeated intoxication–withdrawal cycles are thought to activate neural circuits, including amygdala activation, involved in stress responses and drug craving (Kober et al., 2010; Koob & Volkow, 2010) resulting in chronic negative emotional states and motivation to engage in substance use to cope with this distress. In short, a weak avoidance system has strong conceptual links to an externalizing pathway to substance use; however, the role of the avoidance system in the etiology of adolescent substance is complex and remains unclear. Clarifying the role of the avoidance system will likely require considering age and stage of use, as well as distinguishing the avoidance system as cause and effect of substance use.

In sum, there is evidence that the control/regulation, approach, and avoidance systems each affect the phenotypic expression and developmental continuity of behavioral undercontrol. An important consideration for etiological models of adolescent substance use is that neural systems underlying behavioral undercontrol mature in childhood and adolescence. Deficient maturation of the control/regulation system in childhood is thought to foster negative transactions with the social environment and the early emergence of externalizing behavior problems, and thus may play a role in the externalizing pathway to substance use. Moreover, as described earlier, brain maturation that occurs in adolescence, including the disjunction between increases in reward sensitivity/approach system and the slower development of the control/regulation system creates a vulnerability to risk taking that is important in the etiology of substance use.

Early Childhood Development of Behavioral Control

Development of the control/regulation system during the first few years of life is largely mediated by increased efficiency in executive attention, including the ability to inhibit a dominant response and engage a subdominant response, to plan, and to detect errors (Rothbart & Bates, 2006). This development corresponds to normative declines in externalizing behavior that has been documented after the third year of life (Bongers, Koot, van der Ende, & Verhulst, 2004; Colder, Mott, & Berman, 2002). Factors that may impact development of control/regulation in early childhood are of particular relevance to the externalizing pathway to substance use. Prenatal exposure to drugs and alcohol and early life stress are two such factors.

Prenatal Exposure

Maternal substance use has been linked to a range of problems including impaired growth, physical birth defects, behavioral abnormalities, low birth weight, and withdrawal. However, causal relations between fetal exposure and outcomes are difficult to establish because the exposures are nonrandom and the effects are confounded by gene–environment correlation. Moreover, although in the not-so-distant past exposure to illicit drugs received considerable media attention, many of the effects of illegal drugs are time-limited to the neonatal and early childhood period. In contrast, fetal exposure to legal drugs such as tobacco and alcohol appear to be of greater concern to maternal and child health (Chiriboga, 2003).

In terms of maternal smoking, one of its most reliable correlates is low birth weight, an effect that is most associated with maternal smoking during the third-trimester (Reeves & Bernstein, 2008). However, genetically informative studies suggest that the often reported link between externalizing disorders (e.g., ADHD, antisocial behavior) and maternal smoking is a spurious one that is genetically transmitted (Agrawal et al., 2012; D'Onofrio et al., 2008; Langley, Heron, Smith, & Thapar, 2012). For example,

D'Onofrio and colleagues (2007, 2012) compared siblings with differential prenatal exposure to substances on behavioral undercontrol. This quasi-experimental approach controls for a broad range of unmeasured genetic and environmental confounds, and thus provides a rigorous test of prenatal exposure effects on behavioral undercontrol. Findings in these studies supported a causal effect for prenatal exposure to alcohol, but not for tobacco. This suggests that the effects of prenatal exposure to drugs other than alcohol on behavioral undercontrol are likely attributable to genetic risk transmitted from substance using parents or environmentally mediated mechanisms (e.g., caregiving environment; Jaffe, Strait, & Odgers, 2012).

Prenatal alcohol exposure can cause fetal alcohol syndrome (FAS), which is a clinical syndrome characterized by growth retardation, distinct facial dysmorphology, and CNS deficits, including tremors and visual irregularities (Manning & Eugene-Hoyme, 2007). Studies examining school-age outcomes for children affected by FAS reveal a range of cognitive and behavioral problems that often persist or worsen as children mature, leading to high rates of antisocial behavior and the development of AUDs (Baer, Sampson, Barr, Connor, & Streissguth, 2003). These types of deficits and associated behavior problems are also common in children prenatally exposed to alcohol who are not diagnosed with full-syndrome FAS (Testa, Quigley, & Eiden, 2003) but have some subsyndromal spectrum disorder. Animal models suggest that fetal exposure to alcohol may lead to the development of specific drug sensitivities and preferences that may contribute to the development of AUDs (Valenzuela, Morton, Diaz, & Topper, 2012).

Although the evidence is strong for a causal effect of prenatal alcohol exposure on behavioral undercontrol, there is uncertainty about what levels of alcohol exposure confer risk to the developing fetus and whether vulnerability varies across different periods of pregnancy. Nonetheless, the most consequential effects of prenatal exposure to alcohol are on brain development, which in turn, impacts cognitive and behavioral functioning (Mattson & Riley, 1998). The specific mechanisms through which prenatal alcohol exposure operates are unclear in part because of the broad range of effects of ethanol on brain systems. Evidence from animal models suggests that prenatal exposure to drugs or alcohol impacts reward neural circuitry of the approach system (Malanga & Kosofsky, 2003), but this work has not been extended to humans. Human imaging studies suggest that prenatal alcohol exposure is associated with reduction and thinning of brain structures germane to the control/regulation system (Riley & McGee, 2005).

Early Childhood Adversity

Early childhood adversity, including child abuse and maltreatment, exposure to violence, and parental loss, is also associated with childhood externalizing behavior problems and with increased risk for adolescent drug use, and likely influences the externalizing pathway through multiple mechanisms. The most profound of these mechanisms involves detrimental effects on neural development and brain systems (Champagne, 2010) that influence stress reactivity, the approach system, and the control/regulation system (Andersen & Teicher, 2009). Early adversity enhances stress reactivity through changes in the hypothalamus-pituitary-adrenal (HPA) axis, which in turn, increases reactivity to drugs of abuse, drug sensitization, and stress induced reinstatement of extinguished drug use. However, increased stress reactivity effects are likely specific to drug use rather than broadly germane to behavioral undercontrol as the link between functioning of the HPA axis and behaviors indicative of behavioral undercontrol other than substance use has not been consistently shown (Marsman et al., 2008). Thus, although stress reactivity as mediated through the HPA axis is important for the etiology of addictive behaviors, it may not be specific to the externalizing pathway (see our discussion of internalizing pathways). More germane to the externalizing pathway are the effects of early adversity on dampening activity of the approach system (Matthews & Robbins, 2003) that may motivate undercontrolled behavior to increase low arousal, and reduced volume of the prefrontal cortex, a region central the control/regulation system (Arnsten, 2009) that may impair capacity for self-regulation.

Parenting

Parenting reflects both goal directed behaviors that parents use to socialize their children (e.g., discipline and monitoring) and nongoal-directed behaviors that create an emotional climate (e.g., warmth), and has long been considered an important influence on child adjustment outcomes. There is considerable evidence from longitudinal correlational studies that parenting exerts an influence during early childhood and through adolescence, and that similar parenting behaviors impact externalizing behavior problems and substance use (Barnes, Reifman, Farrell, & Dintcheff, 2000; Loeber & Stouthamer-Loeber, 1986). Further support for parenting effects is gleaned from intervention studies that show that changes in parenting mediate intervention effects on externalizing problems and substance use (Brody et al. 2004; Sandler et al., 2011). There is also evidence that parenting changes as children

age, and hence, it is important to consider the different role that parenting may play in early childhood versus adolescence.

Early Childhood

Inconsistent use of discipline, failure to use positive parenting strategies, low responsiveness (including neglect), and excessive use of harsh discipline (including abuse) are associated with childhood externalizing problems (e.g., conduct disorder, delinquency, and aggression; Rothbaum & Weisz, 1994). Although parenting is often assumed to influence child behavior, there is evidence for a transactional process whereby child behavior elicits parental reactions, which in turn, influence child behavior (Bell & Chapman, 1986). Patterson and colleagues have accumulated substantial support for a coercive parent–child exchanges that inadvertently reinforce and escalate disruptive behavior (Patterson, Reid, & Dishion, 1992). Transactional processes between parent and child start very early, suggesting that risk for the externalizing pathway to substance use is apparent many years prior to initiation of substance use. Children with difficult temperaments are difficult to manage and they elicit more control and negativity, less responsiveness, and rejection from parents in infancy and toddlerhood, and these parenting behaviors have the effect of exacerbating the child's difficult temperament (Kiff, Lengua, & Zalewski, 2011). Moreover, child traits reflecting behavioral undercontrol are more strongly associated with externalizing behavior problems when parenting is negative and harsh (Kiff et al., 2011; Rothbart & Bates, 2006). This supports the notion that phenotypic continuity in behavioral undercontrol is most evident in the context of poor parenting.

Many of the same parenting behaviors that predict childhood externalizing problems also predict adolescent substance use. For example, Dishion, Capaldi, & Younger (1999) found that harsh and inconsistent discipline assessed at age 9 predicted substance use at age 15. Positive parenting (e.g., discipline characterized by reasoning and discussion, and proactive family management) in early childhood protects youth from adolescent substance use (Kaplow, Curran, Dodge, & the Conduct Problems Prevention Research Group, 2002; Kosterman, Hawkins, Guo, Catalano, & Abbott, 2000). Lack of parental warmth and involvement in early childhood has also been shown to predict adolescent substance use (Kaplow et al., 2002; Shedler & Block, 1990). At least some of the effects of early parenting on adolescent substance use are mediated through externalizing behavior problems (Dodge et al., 2009). Taken together these findings suggest that early transactional processes between a difficult to manage child and poor parenting lead to the emergence of externalizing behavior, and subsequently substance use. Later in this section we discuss one of the key mechanisms by which externalizing problems lead to drug use, namely affiliation with peers who provide access to and reinforcement for drug use.

Adolescence

Developmental changes of adolescence shift the nature of parent–child interactions and parenting. In general, parents grant their children more autonomy in adolescence, and some transient reductions in parent–child closeness in early adolescence are most likely to be manifested in increased privacy on the part of the adolescent (Steinberg & Silk, 2002).

With the transition into adolescence, parenting continues to influence risk for substance use, but the relevant parenting domains include increased importance of supervision and monitoring as adolescents spend increased amounts of time in peer contexts outside of parents' presence. Several studies have found that low levels of parental monitoring and supervision predict adolescent substance use (Barnes et al., 2000; Chilcoat & Anthony, 1996; Dishion, Capaldi, Spracklen, & Li, 1995) as well as adolescent externalizing behavior (Dishion & McMahon, 1998). As in early childhood, longitudinal studies suggest reciprocal associations, such that low levels of parental monitoring/supervision predict high levels of adolescent substance use and externalizing behavior, and high levels of externalizing behavior predict low levels of monitoring (Kerr & Stattin, 2003; Laird, Pettit, Bates, & Dodge, 2003). Thus, although monitoring/supervision may play a role in controlling exposure to a risky ecological context, when youth engage in problem behavior and substance use, this can degrade parental monitoring. The mechanisms for this effect are not clear. One possibility is that when adolescents engage in problem behavior, parent–child communication decreases (Dishion, Poulin, & Medici Skaggs, 2000), perhaps reflecting the adolescent's effort to undermine parental monitoring (Stoolmiller, 1994). Evidence suggests that adolescent disclosure is the primary means by which parents obtain knowledge about their child's activities and whereabouts (Kerr & Stattin, 2000). Therefore, declines in communication may result in less effective monitoring.

Parenting reflecting positive parent–child relationship quality (high levels of parental warmth and involvement, high levels of social support, closeness) is associated with

lowered risk for adolescent substance use (Ellickson, Perlman, & Klein, 2003; Hawkins et al., 1992). Parent–child relationship quality has been conceptualized as part of a dynamic model that includes parental monitoring and discipline (Dishion & McMahon, 1998). Positive parent–child relationships enhance and motivate effective discipline and monitoring and effective parenting practices nurture positive relationships. Indeed, psychometric work suggests relationship quality, monitoring, and discipline are highly related constructs (Dishion, Li, et al. 1999; Patterson et al., 1992), and some work suggests that relationship quality predicts the effective monitoring (Barnes et al., 2000). Thus, although monitoring and supervision are important influences of adolescent substance use, it is likely that this domain of parenting does not operate alone, and it is important to consider potential dynamic associations between multiple domains of parenting.

There is also evidence that substance use-specific parenting is associated with adolescent substance use. Discussing risks of drug and alcohol use, maintaining restrictive rules about use, implementing punishments for use, and communicating disapproval of use are associated with lowered risk for adolescent substance use (Chassin, Presson, Todd, Rose, & Sherman, 1998; Henriksen & Jackson 1998; Kodl & Mermelstein, 2004; Martino, Ellickson, & McCaffrey, 2009). However, these effects are not consistently found and the field is limited by an over-reliance on questionnaire methods rather than direct observations of interactions (see Wakschlag et al., 2011, for an exception). The effects of substance use specific parenting have been weaker for parents who themselves use substances and stronger in adolescent reports than in parent reports (Chassin et al., 2005). Moreover, some parental attempts at substance-specific parenting are associated with increased adolescent use and, as with general parenting, the relations between substance-specific parenting and adolescent substance use are likely bi-directional (Huver, Engels, & de Vries, 2006).

Although the association between parenting and adolescent externalizing behavior and substance use is often attributed to environmental effects (e.g., the influence of parenting or reciprocal influences between parenting and adolescent behavior), there is evidence that some of this association may be genetically influenced, particularly in adolescence. Heritability of behavior increases from childhood to adulthood in a variety of domains, including family relationships (Bergen, Gardner, & Kendler, 2007). Using a longitudinal twin design that followed youth from age 11 to 17 years, Ludeke, Johnson, McGue, and Iacono (2013) found that genetic influences on quality of the parent–child relationship increased over time. Moreover, initial levels of genetic influence at age 11 were positively associated with increases in genetic influence. This suggests "amplification" of genetic influence as youth age into adolescence.

Peers and School Failure

Adolescent substance use largely takes place in the context of peers, and considerable evidence supports affiliation with deviant peers as an important proximal influence that promotes substance use (Chuang, Ennett, Bauman, & Foshee, 2005; Fergusson, Boden, & Horwood, 2008). One mechanism leading to affiliation with deviant peers is rejection from mainstream peer groups and peer rejection in childhood has been linked to later substance use (Dishion et al., 1995; Kaplow et al., 2002). Behaviorally undercontrolled and aggressive youth are at risk for peer rejection (Dodge et al., 2003), and rejected youth tend to gravitate toward similarly undercontrolled and rejected peers who are likely to be accepting of deviant behavior (Coie, 1990). Affiliating with deviant peers not only provides opportunities for reinforcement of deviant behavior, and but also missed opportunities to be socialized by prosocial youth. Taken together, these findings suggest that a high risk temperament, characterized by behavioral undercontrol, creates a vulnerability for early social experiences with peers that can push a child further along on the externalizing pathway to substance use.

As with peer rejection, school failure may similarly push a child further along the externalizing pathway by strengthening affiliation with deviant peers. Children who are behaviorally undercontrolled are at increased risk for school failure (Patterson, 1986). Poor grades, low educational aspirations, and low connectedness to school, and low expectation for academic success increase risk for alcohol and drug use (Bond et al., 2007; Cox, Zhang, Johnson, & Bender, 2007). Difficulties in school are thought to lead to negative labeling, rejection by prosocial peers, rejection of school, and affiliation with deviant peers who similarly reject school. In support of this notion, school difficulties predict affiliation with deviant peers (Dishion, Patterson, Stoolmiller, & Skinner, 1991; Simons, Whitbeck, Conger, & Conger, 1991). Although deviant peer groups in childhood rarely engage in substance use, they become an important context of drug and alcohol use in adolescence.

Deviant peers support an array of behaviors that violate age norms in rebellion against authority and rejection of conventional norms (Dishion et al., 1996; Jessor & Jessor, 1977). In adolescence, deviant peers provide support and

opportunities to engage in alcohol and drug use, increase the perception that use is normative, socially reinforce use, and shape attitudes favorable toward drugs and alcohol (e.g., Prinstein & Wang, 2005). A number of studies have found that adolescent substance use is predicted from that of their friends (Hawkins et al., 1992) and that these associations are evident even when peers report on their own substance use (Kandel, 1978). Moreover, the presence of nondrug-using peers in one peer context (e.g., within a close friendship group) can offset risk in another context (e.g., within a larger peer group, Hussong & Hicks, 2003).

In a recent review, Neisewander, Peartree, and Pentwoski (2012) suggested that the social and pharmacological rewards of drug use may interact synergistically to produce a more rewarding experience than either type of reward alone. They posited two neurobehavioral mechanisms for such an effect. One mechanism involves shifting the salience of incentives (either decreasing salience of aversive consequence of drug use or increasing salience of rewarding stimuli), and the other mechanism involves a drug acquiring conditioned reinforcing effects by being paired with social reinforcers. These ideas remain to be tested, but they may have particular relevance for considering the role of peer influence on adolescent drug use. Relative to children and adults, adolescents are more responsive to social stimuli, and this may be attributable to biological aspects of pubertal maturation (e.g., a proliferation of oxytocin receptors) that affect social bonding and recognition and memory of social stimuli (Steinberg, 2008). Hence, increased salience of peer relationships and social reinforcement may render adolescents particularly vulnerable to hypothesized synergistic interactions between social and drug reward. Indeed, for adolescents, the presence of peers itself activates the same reward centers that lead to risky behavior (Chein, Albert, O'Brien, Uckert, & Steinberg, 2012).

Although peer effects are most often conceptualized as social influences, there is also substantial support for peer selection effects (Burk, van der Vorst, Kerr, & Stattin, 2012; Dishion & OwEn, 2002; Go, Green, Kennedy, Pollard, & Tucker, 2010; Schaefer, Hass, & Bishop, 2012). These selection effects suggest that individuals seek to affiliate with others who are behaviorally similar to themselves (Kandel, Davies, & Baydar, 1990). Thus, adolescents with an interest in or desire to use drugs and alcohol tend to select peers with similar predilections. Fowler et al. (2007) found that twin reports of peers' substance use were largely explained by genetic influences, suggesting a genetic influence on peer selection. Genetic influences on peer selection were also reported by Cleveland, Wiebe, & Rowe, (2005) and Hill, Emery, Harden, Mendle, & Turkheimer (2008). However, peers further influence substance use outcomes over and above genetically mediated peer selection effects (Chassin et al., 2012; Harden, Hill, Turkheimer, & Emery, 2008). Thus, peer influences may serve to mediate the effects of genetic risk on alcohol outcomes. There is also support for interactions between genetic risk and peer influences. For example, Harden et al., (2008) found that adolescents who were genetically at risk for alcohol and tobacco use were also the most vulnerable to influences from their closest friends.

Gene–Environment Interplay and the Externalizing Pathway

Behavioral genetic studies suggest that both genetic and environmental (shared and nonshared) influences are important for adolescent substance use (Hopfer et al., 2003). As noted earlier, there is stronger genetic risk at later ages and for later stages of substance use. Genetic risk may be particularly important for the externalizing pathway because behavioral undercontrol has been viewed as the common heritable characteristic that underlies use of different substances as well as developmental continuity of early indicators of externalizing problems and later substance use (Iacono et al., 2008; McGue, Iacono, & Krueger, 2006; Korhonen et al., 2012). Several studies have proposed candidate genes relevant to adolescent substance use that are also germane to behavioral undercontrol, including the MAO-A gene (Nilsson, Wargelius, Sjöberg, Leppert, & Oreland, 2008), genes involving the serotonin transporter (Nilsson et al., 2005), dopamine genes (Derringer et al., 2010), and variants of the GABRA2 gene (Dick & Mustanski, 2006; Dick et al., 2013). These candidate genes seem to play a role in modulating neural reward circuitry and the capacity to inhibit behavior, and thus influence the strength and functioning of the approach, avoidance, and control systems described above. However, the functional significance of genetic risk for neurobehavioral mechanisms of substance use is not well understood (Agrawal et al., 2012). Studies that integrate neuroimaging and genetic approaches offer the opportunity to examine such mechanisms, yet few studies to date have done so (Karoly, Harlaar, & Hutchison, 2013), particularly with adolescent samples. Understanding the mechanisms of genetic risk will have important implications for treatment and prevention, and this is an important direction for future research.

In general, findings from genetic studies of adolescent substance use echo the conclusions from adult studies

(Lessov, Swan, Ring, Khroyan, & Lerman, 2004) that although heritable factors are important, there are also important environmental influences. Hence, adolescent substance use is thought to arise from complex interplay between genes and the environment, which have been studied as gene x environment interactions and (less frequently) as gene–environment correlations. Some candidate gene studies indicate that environmental factors that are involved in the externalizing pathway, moderate genetic risk for substance use. The most commonly examined environment factor in these studies has been parenting. For example, parental supervision and involvement have been found to reduce risk for adolescent substance use that was associated with the MET allele of the catechol-O-methyltransferase Val158 Met genotype, (Laucht et al., 2011) and the 5-HTTLPR polymorphism (Brody et al., 2009). Parental rule setting reduced the risk for adolescent alcohol use that is associated with the TAQA1 genotype (van der Zwaluw et al., 2010), although this genotype did not show differential effects as a function of parent rejection, overprotection, or warmth (Creemers et al., 2011). Although Dick et al. (2007) did not examine candidate genes, their twin study suggested that high levels of parental monitoring reduced genetic risk for adolescent smoking. These findings parallel those discussed earlier, namely that an early high risk temperament is more likely to predict later externalizing problems in the context of poor parenting (Kiff et al., 2011; Rothbart & Bates, 2006). Thus, there is converging evidence suggesting phenotypic continuity of behavioral undercontrol is more likely in the context of poor parenting. Other studies have found that religiosity, family functioning, and high risk contexts (e.g., the presence of adults who model use and easy access to substances) moderate genetic risk for adolescent substance use (Dick, Rose, Viken, Kaprio, & Koskenvuo, 2001; Nilsson et al., 2005; Timberlake et al., 2006); However, as noted earlier, gene–environment interactions in the candidate gene literature have been limited by failures to replicate (Duncan & Keller, 2011). Statistical interactions are notoriously difficult to detect in the behavioral sciences, largely due to small effect sizes and unreliability of measurement (McClelland & Judd, 1993). Several methodological refinements that might help advance research on gene x environment interactions include limiting consideration to those genetic variants that are linked to a relevant phenotype and moving away from candidate genes to considering aggregate genetic variants (Vrieze, McGue, Miller, Hicks, & Iacono, 2013).

As noted earlier, according to transactional models, a child's behavioral undercontrol may evoke negative responses from others (rejection from peers, poor parenting), which may shape the social context that the child experiences (e.g., selection into deviant peer groups). If the child's behavioral undercontrol is genetically influenced, then such a process would be evident in gene–environment associations (Hicks et al., 2013). Using a twin design, Hicks et al. (2013) found that externalizing problems at age 11 predicted contextual risk (a composite of deviant peer affiliations, low quality parent–child relationship, and school difficulties) at age 14, which in turn predicted substance use at age 17. Importantly, although early externalizing problems were attributable to both environmental (shared environment) and genetic influences, contextual risk mediated most of the genetic influence of early externalizing problems on later substance use. Thus, environmental influences can mediate the effect of genetic risk on substance use outcomes (Jaffee & Price, 2012).

THE INTERNALIZING PATHWAY

Although less often the focus of study than the externalizing pathway, the internalizing pathway and related negative affect models are often implicated in the etiology of drug use and disorder (Colder et al., 2010; Kassel et al., 2010; Mayes & Suchman, 2006). Research regarding the association between drug use disorders and negative affect-related disorders, like major depressive disorder, bipolar disorder and the anxiety disorders, has a long history in the epidemiological and clinical literatures (see Babor, 1996; Zucker, 2006). This research maps onto perceptions by individuals who abuse drugs that negative emotions play a key role in drug use (and vice versa; Stopka, Springer, Khoshnood, Shaw, & Singer, 2004) and that coping motives are a primary reason for drug use particularly in treatment-seeking populations (Bizzarri et al., 2007). However, developmentally informed research regarding the association between negative affect and drug use disorders is a more recent addition to this literature (Hussong et al., 2011; Masten, Faden, Zucker, & Spear, 2009; Zucker, Donovan, Masten, Mattson, & Moss, 2008).

The most frequently cited term used to describe the mechanism underlying associations between negative affect and substance use is self-medication. This lay term, however, does not have a precise definition in the scientific literature and may indeed encompass several different mechanisms (see Kassel et al., 2010). For that reason, we avoid using this overarching term to focus instead on prominent mechanisms purported to underlie negative affect–drug use associations. The first of these is the classic

negative reinforcement model (e.g., Jellinek, 1960; Wikler, 1948). This model has been offered to explain drug use as a motivated behavior with the goal of alleviating or avoiding negative affect. The model has been used to describe motives for drug use (broadly) as well as for the maintenance of established drug using patterns and addiction (more specifically). In a reformulation of the negative reinforcement model, Baker and colleagues (Baker et al., 2004; McCarthy, Curtin, Piper, & Baker, 2010) acknowledge that alleviating or avoiding negative affect remains a primary motive for drug use. However, their reformulation emphasizes interoceptive cues that signal impending negative affect associated with withdrawal symptoms as the salient conditioned stimuli prompting drug use. Through repeated pairing of these interoceptive cues (e.g., lessening of either the "throat scratch" sensation or the paralysis of pulmonary cilia associated with falling nicotine levels in the blood) with subsequent negative affect, individuals learn to detect interoceptive cues as a prompt for the use of drugs to avoid negative affect associated with the withdrawal process. Importantly, drug use conditioned on interoceptive cues may occur even before conscious awareness of negative affect. Moreover, this withdrawal-relief pairing may generalize beyond withdrawal-based negative affect to motivate drug use in response to negative affect more generally (i.e., that is not prompted by drug withdrawal) because interoceptive cues become a conditioned stimuli prompting drug use that is no longer linked directly to the source of negative affect (i.e., withdrawal versus environmental sources). The extent to which drug-induced negative affect (e.g., cocaine-induced anxiety) may occur and signal risk for relapse may depend on underlying neurobiological mediators (e.g., evidence of norepinephrine signaling in beta-adrenergic receptors; Ashton-Jones & Kalivas, 2008; Schank, Liles, & Weinshenker, 2008). Thus, negative reinforcement models may be used to explain associations between experienced negative affect and drug use as well as between conditioned precursors to negative affect and drug use.

However, negative reinforcement models are not the only mechanisms posited to underlie associations between negative affect and drug use. For example, Kaplan's (1980) self-derogation theory posits that negative affect, or distress associated more specifically with social rejection, may lead to social drift in which rejected adolescents find acceptance with nonmainstream, deviant youth. Entry into this group may serve to decrease distress, but also to increase risk for engaging in deviant behavior that is modeled and reinforced by this peer group. In contrast to the direct effect of negative affect (and antecedent interoceptive cues) on drug use posited by the negative reinforcement models, self-derogation theory posits indirect effects in which social affiliations serve to mediate the association between negative affect and drug use. Thus, affiliation with substance use-promoting peers may be a common proximal mediator for both internalizing and externalizing pathways to the development of substance use disorders.

A third model regarding the role of negative affect in drug use compares the ability to self-regulate actions and emotions, such as negative affect, to the use of a muscle (Baumeister, 2003). In this model, the ability to regulate affect, and supposedly to then avoid prolonged states of negative affect, is seen as requiring the expenditure of a limited resource. To the extent that intense effort to self-regulate has recently been expended, available responses will be depleted to respond to a new stressor or demand requiring self-regulation. Individuals with depleted resources, or ego depletion, are then viewed as vulnerable to engaging in deleterious behaviors, such as drug use, to cope with or avoid negative affect given a lack of resources to stop the impulse to use drugs in this way. Evidence supporting this model comes from lab studies in which male social drinkers drank more after exerting self-control in a stress task than those not subjected to this task (Muraven, Collins, & Neinhaus, 2002).

A fourth model of the role of negative affect is particularly relevant once drug use patterns have been established. That is, negative affect may serve to increase the reward value of drugs and to draw attention to drug cues in the environment and increase the likelihood of relapse. For example, Tull, McDermott, Gratz, Cofey, and Lejuez (2011) showed that exposure to a trauma script among cocaine-dependent inpatients resulted in increased attention to cocaine imagery among those with a post-traumatic stress disorder versus those without. Moreover, imaging studies implicate functioning in the anterior cingulate cortex (Goldstein et al., 2009) in increased sensitivity to cocaine cues and use following emotionally salient tasks and animal models indicate that the strength of this sensitivity is influenced by genetic liabilities (e.g., Ofil1 and Ofil2 on chromosomes 4 and 7 as related to stress responsivity in selectively bred strains; Vendruscolo et al., 2009).

These multiple negative affect mechanisms of drug use underscore the potential complexities that may underlie a cyclical, bi-directional association between negative affect and drug use. In addition, these negative affect models of drug use are clearly not mutually exclusive. They suggest that negative affect may play several different roles in the development of drug use. And several of them emphasize the role of negative affect as either solely occurring in

(or most evident in) the maintenance and escalation of drug use as opposed to initiation and experimental use. Nonetheless, they all suggest that negative affect may play a role that increases the likelihood of subsequent episodes of drug use.

THE NEGATIVE AFFECT–DRUG USE RELATION

A fundamental question common to all variants of negative affect models of drug use is whether there is empirical evidence for an association between negative affect and drug use disorders such that negative affect signals risk for later drug use and disorder. Surprisingly, the current literature does not offer a clear answer to this most basic question, a likely reason for the relatively lower emphasis on internalizing versus externalizing pathway models for drug use and disorder (Hussong et al., 2011).

Epidemiological studies show substantial comorbidity of negative affect-related disorders and drug use disorders (Grant, 1995; Kessler et al., 1996, 2001; Merikangas et al., 1998). For example, in an analysis of the nationally representative NESARC sample of 43,093 adults aged 18 years and over, Conway, Compton, Stinson, and Grant (2006) found clear evidence for negative affect–drug use associations. In these findings, the association between mood disorders and drug dependence (OR = 7.1) was greater than that between mood disorders and drug abuse (OR = 2.3), with a similar though dampened pattern for anxiety disorders (OR = 4.9 with drug dependence and 1.7 with drug abuse). Among those with any drug use disorder, 40.9% met criteria for a mood disorder and 29.9% did so for an anxiety disorder as compared with 19.5% and 16.2% of respondents with these disorders in the sample at large. Similar support for negative affect–drug use associations also appears in studies of adolescents. In the nationally representative MECA study, Kandel et al. (1997) report rates of anxiety and mood disorders of over 30% and 24%, respectively, for adolescents who used illicit drugs in the past year as compared with 12% and 6%, respectively, for those who had not.

Thus, the negative affect–drug use association appears well supported (although not universally so; see King & Chassin, 2008; Woiltzky-Taylor et al., 2012); more controversial is the question of directionality. Many negative affect models of drug use posit that negative affect is a precursor to drug use, though most acknowledge the bidirectionality of this association. (We defer consideration of the etiological role of drug effects for a subsequent section). Most existing epidemiological studies, however, either test the association between negative affect and drug use disorders cross sectionally or using retrospective recall (Conway et al., 2006). In their review of the literature, Degenhardt, Hall, and Lynskey (2003) reported that longitudinal studies find little evidence that depression increases risk for later marijuana abuse in community samples, and mixed support for increased depression following periods of heavy cannabis use. In contrast, other longitudinal studies show prospective prediction of polydrug use from adolescent depression (Bardone, Moffitt, Caspi, Dickson, & Silva, 1996), that depression and anxiety in childhood predict later drug use disorders in adolescence (Reinherz, Giaconia, Hauf, Wasserman, & Paradis, 2000) and that anxiety disorders in adults predict increased incidence of drug use disorders one year later (Robinson, Sareen, Cox, & Bolton, 2011). These studies may indicate that directionality for negative affect models of drug use is drug specific. However, longitudinal studies reporting these associations remain sparse for specific drugs of abuse and underpowered for these low base rate behaviors, suggesting that conclusions regarding directionality may be premature.

In addition to questions about directionality, epidemiological studies of comorbid affect-related disorders and drug use disorders have been criticized for not taking into account significant confounding factors. These include co-occurring use of alcohol and tobacco (Degenhardt et al., 2003) as well as antisociality, deviance, and externalizing symptoms (Colder, Scalco, et al., 2012; King & Chassin, 2008). Among adolescents, effects of internalizing symptoms on drug use are significantly diminished, only present in subgroups or sometimes absent after controlling for co-occurring externalizing symptoms (Kassel et al., 2010; Mason, Hitchings, & Spoth, 2007; McCarty et al., 2012; Oshri, Rogosch, Burnette, & Cicchetti, 2011). For example, in a community sample of young adolescents, externalizing symptoms in the absence of internalizing symptoms were strongly associated with marijuana use whereas co-occurring internalizing and externalizing problems were weakly associated with prospective substance use and internalizing symptoms alone were protective against later marijuana use (Colder, Scalco, et al., 2012). Given this pattern of findings and the high co-occurrence of internalizing and externalizing symptoms (Angold, Costello, & Erkanli, 1999; Lewinsohn, Shankman, Gau, & Klein, 2004), studies that examine the unique effects of internalizing symptoms in predicting drug use after controlling for externalizing symptoms are particularly informative, though rare in the literature. The current epidemiological literature thus establishes a strong association between

negative affect and drug use disorders, though the nature and uniqueness of this association remains unclear.

Importantly, even multiyear longitudinal studies may miss the time-window in which negative affect–drug use associations unfold, such that the time intervals between assessments are not well matched to the temporal relations between negative affect and drug use. Moreover, many of these studies make between-person comparisons to draw time-specific conclusions. That is, analyses test whether individuals with greater emotional distress are more likely to use drugs as compared with individuals with lower emotional distress rather than testing within-person comparisons that ask whether individuals are more likely to use drugs at those points in time when they are more distressed compared with those points in time when they are less distressed. This distinction between person- and time-specific comparisons is particularly important in the study of negative affect models of drug use because these comparisons map onto different mechanisms that may account for negative affect–drug use associations. By distinguishing person- and time-specific mechanisms that explain this association on both theoretical and analytical levels, we move the question of interest from whether these two constructs are associated to how these two constructs might be associated. Given existing complexity in the epidemiological literature, this change in focus may prove especially fruitful.

Methods that are well suited to the task of parsing person- and time-specific processes occurring on a micro time scale are daily assessment designs, such as daily diary methods, ecological momentary analysis, and experience sampling methods. Although still an underutilized technique, these studies show some evidence that negative affect signals risk for substance use in select youth (Hersh & Hussong, 2009; Hussong, Feagans Gould, & Hersh, 2008). Daily assessment designs are also increasingly being used to differentiate person- and time-specific mechanisms underlying risk for relapse among individuals receiving treatment (Shiffman, 2009). These daily assessment studies are used to capture the immediate internal experiences and external situational factors surrounding drug use as well as the acute effects of drugs and dynamic processes underlying mood-use associations. These techniques are most well developed for studies of adult alcohol and tobacco use (Shiffman, 2009), and some reservations have been raised about their feasibility with illicit drug using populations (Palij, Rosenblum, & Magura, 2003). However, work by Epstein and colleagues demonstrate that such methods may yield rich findings about illicit drug use with implications for treatment and intervention.

Participants in the Epstein studies were cocaine- and heroin-using outpatients enrolled in a methadone treatment program who responded to multiple random and event-contingent prompts to complete a 5-week intensive assessment period (5 + times per day) followed by a 20-week less intensive assessment period (2 + times per day) using PDAs. Of the 114 participants enrolled in the study, 102 participants completed an average of 75% of prompted assessments regarding drug use and craving, ranging from 22–98% per participant, with reports capturing over 4,000 assessments of drug use or craving. Importantly, a key finding of this study is that daily assessment designs with drug using samples are not only feasible, but they can also capture significant rates of craving and drug use. Analyses of concurrent mood and drug use/craving reports in these data indicated that good moods were associated with cocaine use whereas feelings of sadness or anger were associated with heroin use (Epstein et al., 2009). Similar within-day associations based on concurrent mood and use/craving assessments were also found by Cleveland and Harris (2010) in a small sample of participants drawn from a collegiate recovery community. However, other findings indicate that this essentially cross sectional finding may mask greater complexity in the time-specific mood-use/craving association. For example, hourly assessments of mood occurring within 5 hours before craving/use events showed only weak prospective associations between mood and cocaine use/craving in analyses of the Epstein and colleagues sample (Preston & Epstein, 2011). In addition, Buckner et al. (2011) found that daily mood ratings played a complicated role in moderating craving-use associations, such that predictions of anxiety sensitivity in the moment served to increase the likelihood that cravings to use marijuana predicted subsequent marijuana use. As with studies of alcohol and tobacco use, these findings provide initial evidence that mood-use/craving associations may be more complex than simple main effect predictions drawn from classic negative reinforcement models. Rather, the extent to which negative mood may serve as a signal is likely moderated by a host of other factors, as appears to be the case for alcohol use (Hussong, Hicks, Levy, & Curran, 2001; Cooper, Russell, Skinner, Frone, & Mudar 1992). Experience sampling and ecological momentary methods are one set of tools for testing such models.

In sum, strong evidence for comorbidity between negative affect-related disorders and drug use disorders has led to an emerging body of research seeking to understand the mechanisms that underlie this comorbidity. Although studies of negative affect models of illicit drug

use have lagged behind those for alcohol and tobacco use, the emerging evidence yields findings open to multiple and sometimes conflicting interpretations. To reconcile these interpretations of the literature, more complex negative affect models of drug use and disorder are needed that acknowledge (1) that several different mechanisms may underlie the association between negative affect and drug use; (2) that each mechanism may require a unique methodology to optimally test and differentiate which mechanisms are most likely to account for this association; and (3) that negative affect models may only explain drug use and disorder for a vulnerable subset of the population or within certain circumstances (Hussong et al., 2011; Zucker, 2008). Moreover, these affect-related mechanisms may (4) be differentially able to account for substance use onset, escalation, recovery and relapse; (5) differ in their applicability to substance use across different stages of the life course; and (6) may depend on the drug of abuse and form of affect under consideration. Few studies account for more than one or two of these many points of potential variation in the association between negative affect and drug use. For that reason, unaccounted for differences in samples and methodologies may be in part responsible for the disparate findings comprising this literature. However, as with any emerging process, understanding drug use and disorder from a developmental psychopathology perspective will require the consideration of mechanisms, methods matched to test those mechanisms, and more complex theoretical models to account for what is likely to be a dynamic relation between negative affect and drug use over ontogeny.

AN INTERNALIZING DEVELOPMENTAL PATHWAY

Current negative affect models of drug use largely lack a developmental perspective and none take into account developmental processes that precede adolescence. Filling this gap in the literature, is a proposed internalizing pathway to substance use and disorder that consolidates existing studies into a theoretical model positing an early emerging risk for substance use and disorder (Hussong et al., 2011). Although most relevant literature regarding this pathway focuses on alcohol use outcomes, some evidence indicates that the internalizing pathway likely also predicts drug use and disorder more broadly. This pathway posits that core deficits that drive substance-using behaviors may be heterogeneous across drug using populations, with one subgroup abusing substances as a manifestation of an underlying deficit in emotion regulation.

Some evidence for a unique core deficit underlying negative affect-related disorders and drug use disorders comes from behavioral genetic studies, an active area of study. Currently, family linkage and twin studies demonstrate modest co-transmission for internalizing disorders (primarily depression) and alcoholism in adult samples (Kendler, Neale, Heath, & Kessler, & Eaves, 1994; Merikangas, Leckman, Prusoff, Pauls, & Weissman, 1985; Zucker, 2006). Moreover, Silberg, Rutter, D'Onofrio, and Eaves (2003) report findings from a multivariate behavioral genetic analysis that genetic influences played a greater role in the comorbidity of depression and drug use in girls versus boys, though substantial environmental variance was found for both sexes. In addition, summarizing results from the Collaborative Study on the Genetics of Alcoholism, Nurnberger, Foroud, Flury, Meyer, and Wiegand (2002) reported evidence consistent with examining Negative Affect Alcoholism as a unique phenotype. Specifically, they report a higher rate of comorbid depression and alcoholism among probands of families with a higher prevalence of this same comorbidity as opposed to families with a higher prevalence of alcoholism alone. This finding spurred genetic analyses identifying two markers on chromosome 1 that indicate linkage between alcohol and depression (spectrum) disorders. Few similar studies focus on drug use disorders specifically; however, Yang, Han, Kranzler, Farrer, and Galenter (2011) found evidence for potential co-transmission related to genetic risk-based on a genome wide linkage scan, with resulting for promising candidate genes including SRD5A1, UBE3C, PTPRN2, and VIPR2. Together, these findings indicate the potential for some overlap in the genetic diathesis for internalizing and drug use disorders.

For some individuals, this deficit may emerge in early childhood as dysregulated temperament, followed by increased risk for internalizing symptoms that persist into school entry when children are then also at increased risk for poor social engagement and functioning. In social contexts supportive of drug use, these children may move into adolescence forming positive expectations for the effects of drugs, perhaps notably as a potential way of coping with their prolonged anxiety and depression. Early exposure to drug use as a way to successfully alleviate negative affect in the short-term may create strong coping motives for drug use with associated implications for mood regulation, fueling a cycle of negative affect–drug use associations likely to escalate into addictive behaviors. Core to this model, the internalizing pathway suggests that

precursors and putative risk factors for later substance use may arise early in the life course, perhaps as early as the preschool years.

Indeed, early childhood (between the ages of 2 and school entry) is a potentially critical entry point for this risk pathway for several reasons. First, the development of emotion regulation is a focal task of early childhood emerging around age 2 and showing rapid development in the preschool years (Blair & Diamond, 2008). Second, compared with their peers, children with known risk factors for later SUDs (i.e., children of alcoholic and drug using parents) show deficits in emotion regulation that emerge in this age period. For example, Eiden, Lewis, Croff, and Young (2002) found that children of alcoholic parents exhibit less adaptive and less effective emotion regulation strategies compared with children of nonsubstance abusing parents. Finally, early risk markers for substance use disorders may first become evident in this age period. Although rigorous analyses testing the prospective prediction of various forms of substance use from early indicators of emotion regulation and internalizing symptoms are few, existing studies indicate that this association may prove to be complex. For example, Ensminger, Juon and Fothergill (2002) showed that first grade boys classified as shy and aggressive had higher rates of marijuana and cocaine use in adulthood (age 32) than did their peers, though shyness alone did not predict these risk outcomes, and for women being a shy first grader reduced risk for marijuana use in adulthood. Shedler and Block (1990) also showed that adolescents (age 18) classified as frequent users on a substance use index had more symptoms of emotional distress in childhood (ages 7 and 11) than did adolescents classified as experimenters, although adolescent abstainers also showed higher rates of inhibition, shyness, and anxious traits than did experimenters. However, others do not replicate the finding of greater negative affect in abstainers than in experimenters (Tucker, Ellickson, Collins, & Klein, 2006) and some find no association predicting subsequent cannabis use specifically (Oshri et al., 2011). These findings indicate that inhibition and internalizing symptoms may play a role in early risk for later drug use, but the nature of this role, particularly relative to externalizing symptoms, remains unclear.

Thus, although early childhood is not the only developmental period in which risk for the internalizing pathway may emerge, this may be an important time for examining whether potential deficits in emotion regulation are forming as core to risk for the internalizing pathway.

Missing from previous descriptions of the internalizing pathway is a consideration of the mechanisms by which early internalizing symptoms and indices of emotion dysregulation are associated with risk for later substance use and disorder. Two potential factors, however, are the cascading effect of early childhood stress exposure and caregiving environments (see Hussong, Shadur, Reimuller, & Solis, in press). Because we view these mechanisms as working interactively, our treatment of them as distinct in the sections that follow is somewhat false. However, the parsing of risk processes into these two dominant mechanisms has clinical value, particularly in that psychoeducational and psychological interventions currently available or in development may be matched to each.

Early Childhood Stress Exposure

Two interrelated mechanisms that may mediate the relation between early childhood stress exposure and dysregulated stress reactivity, impacting subsequent risk for psychiatric disorder and drug use include alterations in neurobiological reactions to stress (particularly dysregulation of the HPA axis resulting from trauma exposure) and perceptions of decreased emotional security following violence exposure. Although early trauma, maltreatment, and severe stress exposure do not uniformly lead to functional impairment (Cicchetti, 2004), the connection between such early life stressors and subsequent substance use is generally supported (Butt, Chou, & Browne, 2011).

One factor that may, in part, explain risk for the internalizing pathway associated with early stress exposure among vulnerable children is an altered neurobiological stress response (Gunnar & Quevedo, 2007). Because the development of the neurobiological stress response related to early childhood adversity such as maltreatment is reflected in a large, complex literature (Cicchetti & Valentino, 2006), we offer here only highlights that inform risk for an internalizing pathway to substance use and disorder. Accumulating evidence regarding the negative cascading effects of early stress exposure indicate that negative life stressors in young children can lead to dysregulation of the HPA axis, which in turn heighten subsequent stress reactivity to future life stressors, and thereby create a predisposition to psychiatric disorder later in life (McCrory, De Brito, & Viding, 2010). This negative escalating cycle between neurobiological stress responsivity and environmental insult thus appears to continue past early childhood and into the adolescent years (Gunnar & Quevedo, 2007).

More specifically, studies of maltreatment indicate that early experiences of abuse and neglect predict later

neurobiological dysregulation across many systems (i.e., event-related potential responses to emotion stimuli, acoustic startle and neuroendocrine regulation; Cicchetti, 2004), including HPA dysregulation. However, whether reported dysregulation reflects a hypo- or hyperactive stress response varies across studies. As noted by Tarullo and Gunnar (2006), perhaps the most consistent findings are that maltreated children with internalizing problems have elevated morning basal cortisol whereas adults who were maltreated as children (regardless of internalizing problems) often show low basal cortisol and elevated ACTH responses to psychological stressors. DeBellis (2001, 2002 for reviews) posits that cortisol levels that have been elevated for an extended period of time following trauma may result in downregulation of the HPA axis and, in turn, low cortisol levels. These stress responses reflect adaptation over time to a chronic stress or traumatic environment. Consistent with this theory, other studies of maltreatment and the HPA axis find that participants exposed to stress have a blunted HPA response (e.g., Lovallo, Farag, Sorocco, Cohoon, & Vincent, 2012; MacMillan et al., 2009). Although some have suggested a blunted HPA response is due to comorbid psychiatric conditions that are associated with trauma exposure, a recent study by Lovallo and colleagues (2012) found that a greater number of traumatic stressors predicted a blunted HPA response in participants with no psychiatric diagnoses. This body of work suggests that despite notable consensus regarding the dysregulating impact on the neurobiological stress response of trauma and chronic stress exposure, such as that reflected in childhood maltreatment experiences, there is less consensus regarding how changes in the HPA axis emerge and change over time to mediate the relation between stress and later adjustment problems (McCrory et al., 2010). Although further study of this developmental process is needed to connect this risk pathway with the negative outcome of later affect-driven substance use specifically, some evidence suggests that compulsive drug use increases with a highly reactive HPA axis (see Andersen & Teicher, 2009) and that those populations at high-risk for substance involvement (namely, children of alcoholic and drug abusing parents) show some evidence of hypoactivity in LHPA response for older youth and adults, but these results remain inconsistent (Dai, Thavundayil, & Gianoulakis, 2002; Dai, Thavundayil, Santella, & Gianoulakis, 2007; Moss, Vanyukov, & Martin, 1995). Moreover, the direction of these effects varies across studies and little information is available on how HPA functioning is associated with drug taking in human studies, particularly in adolescents.

A second potential mechanism linking early stress exposure and later risk for affect-motivated drug use is described in the emotional security hypothesis (offered by Davies & Cummings, 1994). Emotional insecurity is characterized by disruptions in children's feelings (e.g., anxiety, hypervigilance, sadness), behaviors (e.g., inappropriate attempts to regulate family arguments), and cognitions (e.g., skewed views of dangers within relationships; see Cummings & Davies, 2002; El-Sheikh, 2005, for reviews) associated with a basic sense of individual and familial safety that become disrupted following exposure to family conflict and violence. Again reflecting a cascading risk mechanism, prolonged and repeated exposure to marital conflict appears to effectively sensitize or increase children's behavioral and emotional reactivity to conflict (Cummings & Davies, 2002). Over the long-term, children exposed to higher levels of conflict between their parents are also more likely to evidence a relatively wide range of adjustment difficulties, including behavioral, emotional, cognitive, and sleep problems (Davies, Forman, Rasi, & Stevens, 2002; El-Sheikh, Harger, & Whitson, 2001). Moreover, chaotic home environments characterized by family stress and conflict have been found to directly impact children's emotion regulation abilities (El-Sheikh & Cummings, 1997).

Providing a bridge between the emotional security hypothesis and the altered neurobiological stress response theory regarding the effects of early stress exposure, the impact of family stress and conflict impacting children's sense of emotional security appears to have physiological correlates. To date, stress responses including vagal tone, electrodermal responding, cortisol levels, and actigraphic measures of sleep have all been shown to be compromised in children exposed to high levels of marital conflict (El-Sheikh, 2005; El-Sheikh, Keller, & Erath, 2007; Pendry & Adam, 2007). DeBellis (2002) extended this link between environmental stress exposure, physiological stress responding, and problem behavior in development. He underscores that dysregulation in the major biological stress response systems associated with childhood maltreatment, trauma and conflict exposure have adverse influences on brain development that enhance vulnerability to later psychopathology, including posttraumatic stress disorder and depression that precede alcohol and substance use disorders.

Consistent with this perspective, work by Andersen and Teicher (Andersen & Teicher, 2004, 2009; Teicher et al., 2003) suggest that the effects of early stress exposure on the neuroendocrine system (i.e., HPA functioning), brain structure (i.e., smaller mid-portions of the corpus callosum

and attenuated development of the left neurocortex, hippocampus and amygdala; Andersen & Teicher, 2004), and brain function (e.g., electrical irritability in limbic structures and decreased functional ability in the cerebellar vermis), creates susceptibility to compulsive drug use (Andersen & Teicher, 2009) as well as to depression (Anderson, Teicher, Polcari, & Renshaw, 2002). These susceptibilities may only manifest as relevant brain regions and circuits mature with ontogeny. However, with maturation, this early exposure may serve to increase risk for drug use by increasing individual reactivity to drugs of abuse (as supported by animal models) or to reinstate drug-seeking behavior (as found in studies of cocaine and heroin; Andersen & Teicher, 2009).

In sum, early childhood adversity and stress exposure are linked with later risk for substance use and disorder (Butt et al., 2011), are more common among those at-risk for later substance involvement (namely, children of alcoholic parents; Hussong, Bauer, et al., 2008; Hussong et al., in press), and have implications for poorer emotion regulation both early in childhood and later in development (Cicchetti & Valentino, 2006; Gunnar & Quevedo, 2007). Two of these stressors likely include child maltreatment and family violence and conflict. Early childhood stress exposure has implications for the development of neurobiological systems associated with future responses to stress, for changes in brain structure and function, and for the development of emotional security in children, all of which impact emotion regulation and later symptomatology (for an integrative review, see Cicchetti & Valentino, 2006). These same mechanisms may then be partly responsible for early risk associated with an internalizing pathway to drug use and disorder.

The Caregiving Environment

Effective emotion regulation in children depends in part on a biological predisposition to functional regulatory capabilities, but also on the extent to which the environment supports the development of adaptive regulation skills (Thompson, Lewis, & Calkins, 2008). In early childhood, the caregiving environment plays a fundamental role in supporting the development of emotion regulation (Calkins & Hill, 2007). Although there are many ways to characterize the nature of the early caregiving environment (Cox & Paley, 2003), we highlight two aspects of this environment that are posited to be particularly important for nurturing adaptive emotion regulation. These include parenting behaviors that promote a healthy parent–child attachment system more broadly (such asresponsivity or sensitivity) as well as parenting that is specific to the socialization of emotion in children (i.e., parent emotion socialization). Although the two sets of parenting behaviors are related, the former refers to a more general style of parent–child interaction whereas the latter is focused on how parents interact with their children specifically around the issue of emotion.

Both responsive parenting styles and the specific ways parents socialize their children about emotion may be relevant for understanding the internalizing pathway to SUDs and in particular the development of poor emotion regulation during early childhood among at-risk youth, namely children of alcoholic parents. Supporting this hypothesis are several lines of research showing that (1) failure to develop secure attachments accounts for part of the association between insensitive parenting in early childhood and poor emotion regulation, (2) styles of parent emotion socialization that dismiss emotion rather than coach children in how to handle their emotions also predict poor emotion regulation, and (3) parent alcoholism is associated with both insecure attachments and insensitive parenting in early childhood. Also relevant is initial evidence showing that (4) parents with drug use disorders show detriments in parent emotion socialization and that (5) problematic parent emotion socialization is associated with greater risk for negative affect-cued substance use in adolescence.

Attachment theory posits that infants obtain an understanding of the world and what to expect from their relationships with others based on whether their caregivers are consistent, sensitive, and responsive to their needs (Ainsworth, 1979). Attachment styles reflect the nature of the parent–child relationship and are considered to be secure (i.e., children seek comfort from caregivers and respond positively when reunited with caregivers after a separation) or insecure (i.e., children may show no distress when caregivers leave and may show ambivalence or indifference when reunited with caregivers) and these patterns of behavior are evident in early childhood. Secure attachments are associated with a variety of positive outcomes for children, including the healthy development of emotion regulation (Morris, Silk, Steinberg, Myers, & Ronbinson, 2007; Thompson, 2008). Thus, parenting that is sensitive and responsive to children's needs is linked to secure parent–child relationships that in turn predict adaptive emotion regulation (Calkins & Leerkes, 2011). Alternatively, caregiving environments that are not characterized by appropriate titrations of sensitivity and responsivity have been associated with insecure attachment and decreased emotion regulation abilities

in offspring. Some of the negative parenting behaviors demonstrated by caregivers who develop insecure caregiver–child relationships have also been documented in families of children with internalizing symptoms; similarities include high levels of negativity (i.e., criticism, hostility, harshness), detachment and withdrawal (i.e., lack of responsiveness or involvement), control and conflict as well as low levels of consistency or predictability and warmth (Chorpita & Barlow, 1998; Garber & Horowitz, 2002; Ostrander & Herman, 2006). These negative parenting behaviors thus collectively increase risk for children's insecure attachment and poor emotion regulation in early childhood as well as internalizing symptoms as children mature, though these behaviors are not necessarily specific to the context of emotions within the parent–child interaction.

A more specific parenting behavior that is likely to impact children's emotion regulation is parent emotion socialization. Parent emotion socialization broadly includes the ways parents explicitly and implicitly teach their children about if, when, and how it is appropriate to feel and express emotions, and how to manage or cope with emotions (Eisenberg, Cumberland, & Spinrad, 1998). Parents socialize their children around emotions in several key ways, including their reactions to their children's emotions, their own modeling of emotion and regulation, awareness and acceptance of emotions, and direct teaching about children's emotional expression (Eisenberg, Cumberland, & Spinrad, 1998; Gottman, Katz, & Hooven, 1997). Emotion-coaching parents are aware of and accepting of children's emotions and respond supportively to children's expression of emotion through validation, teaching, and problem-solving whereas emotion-dismissing parents may minimize children's emotions and avoid teaching or problem solving around children's emotional experiences (Gottman et al., 1997). Parents' use of emotion-dismissing styles is associated with externalizing and internalizing symptoms (Lunkenheimer, Shields, & Cortina, 2007) whereas emotion-coaching styles are associated with more positive outcomes physically, socially, and academically (Gottman et al., 1997). Parent emotion socialization practices may impact children's emotion regulation skills via their influence on children's regulatory functioning at a physiological level (Gottman, Katz, & Hooven, 1996). For example, children whose parents engage in emotion-coaching strategies have higher vagal tone (i.e., an indicator of more effective regulation; Gottman, 2001).

These parenting behaviors could be particularly important for children of alcoholic parents who may receive less support for developing healthy emotion regulation strategies than do their peers. For example, alcoholic parents may engage in fewer behaviors that foster secure attachments in their children (Seifer et al., 2004). Previous studies show that parents who abuse substances are generally less engaged, less responsive, and exhibit less warmth, sensitivity, and encouragement while interacting with their children (Eiden, Edwards, & Leonard, 2002; Mayes & Bornstein, 1995; Solis, Shadur, Burns, & Hussong, 2012) which compromises the extent to which they can support their children's regulation of emotion (Beeghly & Tronick, 1994). Ingesting drugs of abuse can impair parents' functioning, including a compromised ability to attend to social cues, misattribution of children's behaviors (e.g., attributing negative intent), increased emotional arousal (Kerwin, 2005), and impaired memory and inhibition (Mayes & Bornstein, 1995), all of which may contribute to compromised parenting behaviors. Current parental substance use disorders directly predict lower levels of parental warmth and sensitivity (Eiden, Edwards, & Leonard, 2007; 2004). These insensitive parenting styles are evident even in interactions with infants. For example, compared with nonalcoholic fathers, alcoholic fathers' interactions with their infants are characterized by lower paternal sensitivity, responsiveness, positive affect and verbalizations as well as higher negative affect and aggravation (Eiden, Chavez, & Leonard, 1999; Eiden & Leonard, 2000).

Clearly, parenting behaviors that lack supportiveness and sensitivity can compromise emotion regulation in children of alcoholic parents (e.g., Beeghly & Tronick, 1994). Importantly, such parenting behaviors have been shown to mediate the relations between parental alcohol problems and children's emotion regulation and attachment (Eiden et al., 2004, 2007; Seifer et al., 2004). In a longitudinal study, fathers' and mothers' sensitivity and warmth when their children were 2 years old was shown to mediate relations between fathers' alcohol use disorders when children were aged 12–18 months and children's self-regulation at age 3 years (Eiden et al., 2004, 2007). These findings emphasize the important role of the caregiving environment in linking parental alcohol use disorders and children's emotion regulation over time.

There are currently no published empirical tests of the relation between parent emotion socialization and children's emotion regulation in substance abusing families. However, there is empirical work indicating that parent emotion socialization is an important predictor of children's emotion regulation in other at-risk samples, including low-income families (Brophy-Herb, Stansbury, Bocknek, & Horodynski, 2012), maltreated children

(Shipman et al., 2007), and families impacted by maternal depression (Silk et al., 2011). Moreover, mothers who report physically abusing their children provide greater invalidating responses and fewer emotion-coaching behaviors in response to children's negative emotions compared with nonmaltreating mothers (Shipman et al., 2007; Shipman, Schneider, & Sims, 2005). Additionally, Garber and colleagues (Garber, Braafladt, & Zeman, 1991) demonstrated that depressed mothers responded to children's negative emotion with less supportive and problem-solving behaviors than nondepressed caregivers. Furthermore, mothers with a history of childhood-onset depression were more likely to respond to their young children's sadness, anger, and fear with neglect or punishment (behaviors that could be characterized as emotion dismissing) than mothers without such a history (Silk et al., 2011).

Parental substance use can impact the emotional climate of the home, and children may find that emotional support provided by their parents is often erratic during periods of substance use (Stanley, Cleaver, & Hart, 2010). For example, mothers participating in a qualitative study reported that when they were using (specifically methamphetamine) they exhibited more extreme negative emotions with their children and would generally ignore or would not tolerate their children's emotional expressions (Brown & Hohman, 2006). These factors may contribute to children feeling unsupported in the face of stress or being unable to predict parental reactions and expectations. Collectively, this work suggests that parent psychopathology is related to parent emotion socialization and in turn to children's own emotion regulation.

Critical to the internalizing pathway, parent emotion socialization practices have also been shown to predict adolescent substance use that is associated with negative affect. In contrast to findings regarding symptomatology in younger children, Hersh and Hussong (2009) used an experience sampling approach to show that the likelihood of adolescents using substances was more strongly associated with negative mood in families characterized both by high levels of emotion-coaching and emotion-dismissing styles of parent emotion socialization, perhaps reflecting an overinvolved and critical interaction style. Although these findings are not based on a high-risk sample of children of alcoholic parents, these results suggest that parent emotion socialization practices can impact youth behaviors that are consistent with risk for progressing along the internalizing pathway.

In sum, early evidence of compromised emotion regulation is associated with caregiving environments characterized by insecure attachments, insensitive parenting, and more dismissive forms of parent emotion socialization. In adolescence, these forms of caregiving are also associated with either directly with drug use (Dodge et al., 2009; Wang, Dishion, Stormshak, & Willett, 2011) or as a moderating influence on the daily association between affect and substance use (Hersh & Hussong, 2009). Although no prospective studies directly link early caregiving environments with later affect-motivated substance use, children of alcoholic parents who are at greater risk for later substance use disorders and greater deficits in emotion regulation also are more likely to show comprised early caregiving environments involving this same pattern of deficits.

Finally, although the empirical literature described here relates family climate, parent–child attachment, sensitive and responsive parenting, and parent emotion socialization to children's emotion regulation abilities, internalizing outcomes, and substance use, these findings should not be taken as support for simple uni-directional models of parent and family environment influences on substance use outcomes. Rather, as described earlier for the externalizing pathway, there are reciprocal effects in which children both evoke particular caregiving environments and are influenced by them. Moreover, gene–environment interactions have been proposed that involve genes relevant to the HPA axis (e.g., corticotropin-releasing hormone system genes such as CRHR1), stress response (e.g., MAOA), and the sedating properties of substances (e.g., GABRA2). As described earlier, candidate gene studies suffer from failures to replicate, but there is some evidence that these genes interact with stressors including recent negative life events or early child abuse and sexual abuse to influence substance use in adolescence and adulthood (see Enoch, 2012; Wermter et al., 2010; Young-Wolff, Enoch, & Prescott, 2011).

SPECIFICITY IN THE AFFECT–DRUG ASSOCIATION

One approach to clarifying how the current data fit with the existing negative affect models of drug use is to consider specificity in both the form of affect and type of drug used. Such specificity hypotheses may be guided by theories that posit differential associations in negative affect–drug use associations as a function of both negative affect and drug use. For example, Colder et al. (2010) provided two ways of conceptualizing the relation between affective risk processes and substance use given heterogeneity in

substance use behaviors. First, negative affect may be more strongly associated with substance use that reflects more problematic or severe forms of use. Although inconsistent, findings from studies of the predictors of drug use stages often find that early stages of use (i.e., initiation and experimentation) are unrelated or only weakly related to negative affect whereas later stages of use are more strongly associated with affective predictors. Second, the relation between negative affect and substance use may depend on the class of drugs used, particularly the extent to which the drug is reinforcing or effective when used to alleviate negative affect.

Examining specificity in the association between mood/anxiety and drug disorders, Conway et al. (2006) analyzed NESARC data to examine unique patterns of association among eight specific drug disorders and nine anxiety and mood disorders. Their clearest finding was that the magnitude of mood/anxiety-drug disorder associations was inversely related to the overall prevalence of the specific drug use disorder ($r = -.67$), with the strongest associations emerging for the association between mania and opioid, hallucinogen and cocaine dependence as well as for the association between panic disorder with agoraphobia and tranquilizer, opioid and marijuana dependence.

Testing the drug specificity prediction for substance use behavior while controlling for co-occurring externalizing symptoms, our own work also shows differential prediction of drug use indicators by internalizing symptoms in adolescence. Using an integrative data analysis involving the simultaneous study of three longitudinal, community-based samples of children of alcoholic parents and matched controls (Curran & Hussong, 2009), we examined the unique and interactive effects of internalizing and externalizing symptoms in predicting alcohol use, heavy alcohol use, marijuana use, and other drug use between the ages of 11 and 22 (Hussong, Bauer, et al., 2008; Hussong, Flora, Curran, Chassin, & Zucker, 2008). Results replicate previous studies showing strong and consistent unique effects of externalizing symptoms, predicting both who is likely to use substances (i.e., between-person effects for all four substance use outcomes) as well as when youth are likely to use substances (i.e., within-person effects showing greater use of all four substances in years when youth show elevated externalizing symptoms). Internalizing symptoms also uniquely predicted both who used substances and when substance use occurred, but only for the use of drugs and not for alcohol or marijuana use. Thus, internalizing symptoms were a unique predictor only of more severe forms of substance use, after controlling for externalizing symptoms.

Existing studies also suggest that the unique effects of negative affect on drug use may be affect specific (Colder et al., 2010, Kassel et al., 2010). For example, Pardini, White, and Stouthamer-Loeber (2007) found that adolescent boys had a greater risk for later alcohol-related consequences if they reported higher rates of depressive symptoms; however, these boys had a lower risk for later alcohol-related consequences if they reported higher rates of anxiety/withdrawal symptoms. Other studies also report a protective effect of anxious/withdrawal symptoms on risk for substance use in adolescents (Kaplow, Curran, Angold, & Costello, 2001; Mâsse & Tremblay, 1997) whereas unique effects of an overall index of internalizing symptoms on substance use are more frequently nonsignificant or weak (Brook, Zhang, & Brook, 2011; Fite, Colder, & O'Connor, 2006; Hussong, Curran, & Chassin, 1998). In contrast, effects associated with depression tend to be risk promoting across studies, even after controlling for co-occurring externalizing symptoms (Ingoldsby et al., 2006; Marmorstein & Iacono, 2001; Pardini et al., 2007). Focusing on adults, NESARC findings from Conway et al. (2006) also found support for specificity with stronger associations between mood/depression and drug disorders than between anxiety and drug disorders. Panic disorder with agoraphobia was more strongly related to drug use disorders than was panic disorder without agoraphobia, social phobia, specific phobia, and generalized anxiety disorder. Among mood disorders, major depressive, dysthymia, and mania were more strongly associated with drug use disorder than was hypomania.

One explanation for this distinction is that anxious youth are more harm avoidant, and may be more likely to avoid engaging in illegal or delinquent activities as well as the peer contexts in which such behaviors are often encouraged. On the other hand, depression symptoms are less likely to be associated with harm avoidance and may reflect feelings of distress which underlie coping motives related to substance use or a lack of positive affect, consistent with a sense of anhedonia that may motivate use (Colder & Chassin, 1993). Depression symptoms are also often associated with interpersonal difficulties, which may decrease adolescents' acceptance by mainstream peers and thereby increase the likelihood of affiliating with deviant peer groups which provide access, encouragement and reinforcement for substance use (vis-à-vis the self-derogation hypothesis; Kaplan, 1980). Moreover, growing evidence suggests that alcohol use and depressive mood may share a common genetic diathesis (Kendler, Heath, Neale, Kessler, & Eaves, 1993; Kendler et al., 2003), a finding less evident for anxiety-based disorders.

IMPLICATIONS OF THE EXTERNALIZING AND INTERNALIZING PATHWAYS FOR TREATMENT AND PREVENTION

Consistent with the dominant perspective in Prevention Science (Ialongo et al., 2006), the study of early emerging risk pathways is critical to guide interventions for young children so as to reduce the need for later treatment of more entrenched problem behaviors in adolescence and beyond. Such developmental pathways inform important targets for prevention including when intervention should occur, who should receive the intervention, and what factors should be altered by the intervention. In the case of the externalizing and internalizing pathways, one implication for prevention is the need to target risk mechanisms associated with problems in the development of behavioral and emotion regulation beginning in early childhood for those most likely to experience risk associated with the externalizing and internalizing pathway, namely those with early stress exposure, maltreatment, and impoverished caretaking environments.

As noted earlier, stress exposure early in development has implications for the development of the neurobiological stress response (particularly HPA reactivity) as well implications for changes in brain structure and function that may emerge over development. These early stress experiences are also linked directly with challenges to emotion regulation and also with the development of behavioral control. Unfortunately environments in which such stress exposure are likely to occur are also likely to be those in which impoverished caretaking is available, providing poor supports for children's early development of emotion regulation and behavioral control. Much remains to be learned about how parent substance use disorder may impact these mechanisms, including the relative roles of prenatal and postnatal exposure to alcohol. Protective mechanisms that promote notable resilience observed among this at-risk population also deserve greater consideration. Understanding these risk and protective mechanisms has much to add to the development of effective prevention and intervention programs. In general, the externalizing and internalizing pathways suggest the importance of early, family-based interventions.

Drug Use Effects Pathways: The Nature of Drug Effects

It is virtually axiomatic that exposure to psychoactive substances is a necessary though not sufficient condition for the development of SUDs. Consequently, understanding the effects of substances on the organism is fundamental to developing models of the development and maintenance of SUDs. When conceptualizing the nature of these effects it is important to consider the following points. First, drugs affect the individual acutely; that is, there are time-limited effects of the drug on the organism and, presumably, it is for these acute effects (e.g., for positive or negative reinforcement) that drugs are ingested. These acute effects can have complex time courses in which the early acute effects of the drug may differ from later acute effects of the drug. Early versus later acute effects of drugs may vary in type (e.g., positively reinforcing vs. punishing) as well as intensity. Additionally, the rate or intensity of drug effects typically varies as a function of the dose and route of drug administration with routes of administration that lead to rapid changes in brain levels of the drug more likely to produce stronger effects although the specific reasons for this is a matter of some debate (Samaha & Robinson, 2005). Additionally, the general context in which drugs are consumed (e.g., emotional state, social context) can contribute to the specific type of drug effects experienced. For example, the effects of alcohol appear to differ across drinking settings (Sher, Wood, Richardson, & Jackson, 2005) and alcohol appears to enhance reinforcing aspects of social interaction (Sayette et al., 2012). As noted by Steele and Josephs (1990) in their theory of alcohol myopia, the same dose of a drug can lead to either reinforcement (e.g., pleasure or relief) or punishment (e.g., depression, or crying in one's beer) depending upon the context in which the substance is used. However, it seems likely that strong contextual moderation is more likely to characterize drug effects at intermediate doses of a substance that induces some degree of impairment and mild intoxication in contrast to very high doses that induce severe intoxication (Donohue, Curtin, Patrick, & Lang, 2007).

Drug-induced changes that are chronic, by definition, involve repeated use of the drug. So, for example, although the acute effects of certain drugs may be to transiently increase levels of, say, dopamine or serotonin activity in certain brain regions, over time a chronic pattern of use can lead to chronically low levels of these neurotransmitters. These chronic changes associated with a pattern of prior use are thought to be a key mechanism of how *use* leads to dependence. Importantly, these chronic changes associated with repeated drug use include changes in gene expression, which can then produce longer lasting neuronal plasticity. Recent research suggests that epigenetic mechanisms (including DNA methylation and histone modification) may be one process that results in these drug-use-related changes in gene expression (see, e.g., Nielsen, Utrankar,

Reyes, Simons, & Kosten, 2012; Wong, Mill, & Fernandes, 2011, for reviews). In animal data, drugs that have produced epigenetic changes include alcohol, amphetamines, cocaine, nicotine, and opiates (Nielsen et al., 2012; Wong et al., 2011).

It is important to emphasize that not all individuals who obtain a given level of exposure to a drug go on to develop dependence, highlighting the importance of individual differences (or possibly other environmental factors surrounding drug exposures) in determining those whose substance use progresses to more problematic use and those who do not. Moreover, drugs vary considerably in their apparent addictive liability. For example, some drugs such as LSD, cannabis, and Ecstasy are viewed as having relatively low addictive potential while other drugs such as heroin are viewed as being strongly addictive (Nutt, King, Saulsbury, & Blakemore, 2007). Finally, an individual can be initially exposed to substances at any stage of human development, including in utero, adding another layer of developmental complexity.

Acute Effects

Table 19.1 provides a list of various drugs of abuse that highlights the specific brain regions and neurotransmitter systems affected. It is worth noting that a commonality of all drugs of abuse is that acutely all drugs activate mesolimbic dopamine circuits, a region of the brain associated with reinforcement. These circuits are important not only in understanding the site of actions of various psychoactive drugs, but also other reinforcing activities involving consummatory behavior (e.g., eating; Volkow & Wise, 2005) and other forms of reward seeking (e.g., gambling). There is clearly some variation in the specific mechanisms of drugs of abuse since different lesions of the dopamine system have different effects on response to stimulants vs. heroin vs. alcohol, and drugs that are effective at blocking dopamine are not that effective at reducing drug seeking (Koob & LeMoal, 2006). However, the commonalities in the mechanisms of how drugs produce reinforcement underlie most theories of addiction. For those interested in the development of SUDs, the key issues concern the mechanisms of how acute effects of drugs lead to short-term problems or to chronic changes that result in compulsive drug seeking.

TABLE 19.1 Neurobiological Substrates for the Acute Reinforcing Effects of Drugs of Abuse

Drug of abuse	Neurotransmitter systems affected	Neuroanatomical regions of critical effects	Drug receptors
Cocaine and amphetamines	Dopamine Serotonin	Nucleus accumbens Amygdala	Dopamine transporter (antagonist-cocaine; reverse transport-amphetamine)
Opiates	Dopamine Opioid peptides	Ventral tegmental area Nucleus accumbens	μ and δ opioid (agonist)
Cannabis	Dopamine Opioid peptides	Ventral tegmental area	CB_1 (agonist)
Alcohol	Dopamine Opioid peptides Serotonin GABA Glutamate	Ventral tegmental area Nucleus accumbens Amygdala	$GABA_A$ (agonist) and NMDA (antagonist)
Nicotine	Dopamine Opioid peptides Norepinephrine Acetylcholine	Ventral tegmental area Nucleus accumbens Amygdala	nAchR (agonist)

Why Do People Use Drugs?

Before considering the issue of chronic drug effects that lead to dependence, it is important to consider why people use drugs in the first place. Chronic effects would not occur unless individuals were motivated to consume drugs for sufficiently long enough periods or in large enough amounts to induce chronic adaptations. Although seemingly a straightforward question, there are large individual differences in subjective drug effects and in individuals' stated reasons for using drugs. The two major theories of drug reinforcement are that drugs with addictive potential tend to either lead to positive reinforcement (e.g., as a euphoriant) or negative reinforcement (e.g., as an anxiolytic, antidepressant, or antinociceptive agent). For many if not all drugs that are positively reinforcing (e.g., stimulants, opiates), activation of dopaminergic regions associated with approach is thought to represent a key mechanism (Wise & Bozarth, 1987) with close involvement of endogenous opioid systems. As noted above, most neurobiological theories of drug addiction and drug effects focus on positive reinforcement. However, for drugs that are classically anxiolytic (e.g., benzodiazepines, barbiturates), increased GABA-ergic neurotransmission in the

septo-hippocampal system represents the neuropharmacological substrate (Gray & McNaughton, 2000). Although stimulants may represent a relatively prototypic drug class for positive reinforcement and benzodiazepines a relatively prototypic drug class for negative reinforcement, drugs can have clear effects on both systems (e.g., alcohol), and many drugs have effects on multiple neurotransmitters. For example, one recent review of self-administration studies concluded that while mesolimbic dopamine circuits might provide a virtually complete neuropharmacological account of psychostimulant reinforcement and is an important contributor to reinforcement from nicotine, alcohol, cocaine, and heroin, other nondopaminergic mechanisms are also important with these latter substances (Pierce & Kumaresan, 2006). For example, alcohol has effects on the major neurotransmitter systems of dopamine and GABA as well as norepinephrine, serotonin, glutamate and others which can explain, in part, the myriad effects it has on mood, emotions, and behavior (Sher & Grekin, 2007).

It is not surprising then that major theories of the etiology of substance use disorders tend to focus upon these two major types of reinforcement. Khantzian (1985, Khantzian, Mack, & Schatzberg, 1974) highlighted the role of the use of drugs as a coping device for those experiencing various forms of psychological distress. From this perspective, much of the underlying motivation for drug use comes from desire to relieve underlying painful affect in an attempt at "self-medication" (as described in our earlier discussion of the internalizing pathway). Although the self-medication hypothesis was developed in the context of treating severely affected clinical cases, generally similar hypotheses were generated by experimentalists studying the effects of alcohol and alcohol-seeking in laboratory rodents (Cappell & Herman, 1972; Conger, 1956). Surprisingly, while seeking euphoriant effects from drugs of abuse was presumably assumed to be a major theory of drug seeking, there is less clear discussion of this in the early literature (although various typologies of alcoholics proposed different motivational bases for drinking among different subtypes; Knight, 1937).

Regardless of the specific neuropharmacological effects underlying the use of a given drug, individuals report a range of different motivations for using drugs and these typically, though not invariably, are related to positive and negative reinforcement. Cox and Klinger's (1988) motivational model of alcohol use posited that alcohol (and presumably other drugs) are consumed for their incentive value in the context of a number of other considerations that must be considered by the user. That is, the incentive value of a substance is not merely the pharmacological effect of the drug but also the individual's learning history, both through direct pharmacological experience as well as social learning (e.g., direct observation, media, advertising) and the current incentive structure guiding his or her behavior). Thus, if individuals have few positive incentives in their lives, the incentive for using alcohol as a positive reinforcer is enhanced. Similarly, if negative incentives predominate, then individuals will be motivated to use to escape or avoid these negative incentives. Within this framework, the decision to use or not to use a drug comes down to its utilities to the user and whether the benefits outweigh the costs of using.

Using this type of model, Cooper (1994) developed a framework for assessing drinkers' motivations to drink, a model that was subsequently extended to other types of drugs. Within this model, which jointly considered both positive and negative reinforcement in conjunction with either an interpersonal or internal focus, she identified four, psychometrically distinct factors: (1) coping motives (internal, negative reinforcement); (2) enhancement motives (internal, positive reinforcement); (3) conformity motives (interpersonal, negative reinforcement); and (4) social motives (interpersonal, positive reinforcement). Most of her early work (Cooper, Frone, Russell, & Mudar, 1995) and subsequent work by numerous investigators has shown that different motives (especially enhancement and coping motives) are differentially associated with various person-variables (e.g., positive affect, personality) as well as with substance use and substance use-related consequences. It should be noted, however, that different drug use motives tend to be correlated with each other and many if not most drug users are versatile in their stated reasons for using. Consequently, although there is a tendency to classify users as using for primarily one motive or another (e.g., someone who drinks for enhancement or coping; Kuntsche, Knibbe, Engels, & Gmel, 2010), the empirical basis for this type of claim is suspect, at least in nonclinical samples of drinkers where this typological issue has been studied (Littlefield, Vergés, Rosinski, Steinley, & Sher, 2013). Additionally, although endorsement of all motives is associated with increased use, some motives such as conformity are less important for heavier users than are social, enhancement, and coping motives. Indeed, coping motives may be particularly pathologic as they show a unique effect on drinking problems even after controlling for amount consumed (Kuntsche et al., 2005).

Surveys of substances users' motives have been developed for marijuana (e.g., Lee, Neighbors, Hendershot, & Grossbard, 2009; Newcomb, Chou, Bentler, & Huba, 1988) and tobacco (e.g., Ikard, Green, & Horn, 1969;

Piper et al., 2004). As noted by Cooper, Kuntsche, Levitt, Barber and Wolff (in press), in a comprehensive review of the drug use motivational literature, there are some differences in the motives that users of different drugs report as one might expect based on variability in their subjective effects and addiction liability. Thus, some scales for assessing marijuana use motives contain motives referring to enhancing creativity or to help sleep whereas scales for assessing cigarette smoking motivations contain motives referring to addiction or habit or cognitive enhancement. However, across various scales for these very different pharmacological substances, both positive and negative reinforcement represent core motivational properties.

Although substance use motives are often viewed as relatively static, there appear to be important developmental changes in motives. For example, developmental changes in motives for drinking track developmental changes in alcohol involvement. Such findings suggest that desistance or maturing out of substance use could represent, in part, changes in the motivational structure of substance use and not, solely, role incompatibility occasioned by the assumption of adult roles (Littlefield, Sher, & Wood, 2010; Sher, Gotham, & Watson, 2004). Equally important, it highlights the importance of considering how motivations for substance use can change over stages of substance involvement.

GENETIC INFLUENCES ON SUBSTANCE USE EFFECTS

Two classes of genes warrant mention with respect to pharmacological vulnerability pathways: genes related to alcohol metabolism and genes related to nicotinic receptors. After alcohol is ingested, it is broken down into acetaldehyde, and then into acetate and water. Acetaldehyde is highly toxic but typically is rapidly down and, in most individuals, acetaldehyde levels following alcohol consumption never get very high. Drugs that create aversive reactions to alcohol like Antabuse (disulfiram) work by inhibiting the enzyme, acetaldehyde dehydrogenase (ALDH) that breaks alcohol down into acetate, resulting in a build-up of toxic acetaldehyde due to ALDH inhibition. One of the genes that code for ALDH, called ALDH2, sometimes has a variant (almost exclusively found in individuals of Asian descent) that encodes an inactive form of the enzyme, leading to an intolerance for alcohol (Shen et al., 1997) and reduced or no alcohol consumption. Although most of the genetic work on alcohol metabolizing enzymes has focused on ALDH2, there is also evidence that enzymes that metabolize alcohol into acetaldehyde (i.e., alcohol dehydrogenases; ADH) may also be associated with consumption. Specifically, variants of the ADH enzymes ADH1B and ADH1C are associated with particularly high rates of activity, leading to acetaldehyde build-up (Shen et al., 1997), also leading to some degree of aversive reaction and lower levels of consumption.

Nicotinic receptors, a subtype of acetylcholine receptor, have high affinity for nicotine and are found at the neuromuscular junction (where the nervous system connects with voluntary muscles) and the brain where they interact with acetylcholine, as well as exogenous nicotine and other substances (and modulate the effects of other major neurotransmitters). There are a number of different subunits of nicotine receptors in the brain that combine in different configurations of five subunits and combinations containing two of these subunits, $\alpha 2\beta 4$, represent a common, high-affinity site for binding nicotine (Greenbaum & Lerer, 2009). The anti-smoking drug varenicline, discussed below, is a partial agonist of receptors containing $\alpha 2\beta 4$ subunits. Although some studies have found associations between genes coding for these subunits, the findings have not been consistent (Li et al., 2006). However, variation in other nicotinic receptor subunits, particularly polymorphisms in the $\alpha 5$-$\alpha 3$-$\beta 4$ subunit cluster on chromosome 15, have been more robustly associated with smoking behavior and tobacco dependence (Bierut, 2009, 2010). It should be noted that these same polymorphisms have, in recent years, been associated with other forms of drug dependence including alcohol dependence, cocaine dependence, and opioid dependence suggesting that variation in this system might be conferring greater general liability to drug dependence than originally thought (Stallings et al., in press).

MODELS OF THE DEVELOPMENT OF CHRONIC EFFECTS AND DEPENDENCE

With repeated experience, (1) the effects of a drug tend to change; and (2) the drug taker tends to change. One of the earliest theories of how the organism develops tolerance to a substance is opponent-process theory (Solomon, 1980; Solomon & Corbit, 1974). Specifically, this theory posits that a positive (or negative) hedonic state (or A-state) elicits a countervailing negative (or positive) hedonic state (or B-state) that serves to counteract the initial state as part of a natural homeostatic mechanism. The theory further posits that with repeated evocations, the B-state

strengthens, thereby reducing the reaction to the drug (that is, the opponent B-state reduces the initial A-state). Thus, the organism's natural homeostatic mechanisms lead to reduced responsiveness to the drug with repeated experience, a phenomenon referred to as tolerance. Tolerance is thought to be important with respect to drug seeking in that it leads to higher levels of drug intake and is associated with other symptoms of dependence. Note that developmental processes are likely to be important in the development of tolerance. For example, in rodent models, chronic administration tends to yield different patterns of adaptive changes in adolescent versus adult rats (e.g., Morales, Varlinskaya, & Spear, 2011) although these changes appear to vary across type of effect being considered and various experimental parameters. In humans, it is well established that tolerance is one of the earliest dependence symptom to emerge in adolescent drinkers (e.g., Lee, Rose et al., 2011), emerging at relatively low levels of use in some individuals.

Although opponent-process theory viewed this process of adaptation as driven by internal, nonassociative homeostatic processes, it was soon discovered that these opponent or compensatory responses were related to cues surrounding drug administration. That is, we can think of the cues surrounding drug taking as conditioned stimuli and the actual direct effect of the drug as the unconditioned stimulus. Siegel and his colleagues (Siegel, 1975, 1976: Siegel, Baptista, Kim, McDonald, & Weise-Kelly, 2000) demonstrated that *conditioned* compensatory responses (i.e., akin to the hypothesized B-states in opponent-process theory) develop over the course of repeated drug administrations in response to associated external stimuli (e.g., beverage taste, hypodermic needle, social setting), or even early proprioceptive effects of the drug itself or emotions (Siegel, 2005). With repeated drug administrations, these associated stimuli become capable of eliciting conditioned compensatory responses that counteract the direct effects of the drug. In this way, tolerance can be highly situational or context dependent. Consequently, use of a drug in novel circumstances (that lack the situational cues that elicit conditioned compensatory responses) can result in an escape from tolerance (and perhaps even overdose). These situational tolerance effects have been noted for multiple psychoactive substances including opiates, alcohol, and caffeine (Siegel et al., 2000). From the perspective of opponent-process theory and Pavlovian drug conditioning theory, withdrawal phenomena can be viewed as opponent processes acting in the absence of drug effects and involving the same underlying brain systems (albeit in the opposite direction). It is for this reason that resumption of drug intake (initiating a new A-state or primary U.S.) counteracts withdrawal. It should be noted that nonpharmacological processes (e.g., visual processing) appear to involve conditioned compensatory responses (Siegel & Allan, 1998) suggesting that conditioning plays a role in a range of homeostatic adjustments and thus this type of theory is likely more general than a theory of drug effects.

Although opponent-process theory and conditioning theories of tolerance explain how tolerance develops and, how cues surrounding drugs can come to elicit reactions of their own over time (e.g., craving or even withdrawal), they do not address how chronic drug taking alters affective functioning and motivation more generally. Koob and colleagues (e.g., Koob & Le Moal, 2001) have extended opponent-process theory (and, by extension, conditioning theories of tolerance) to account for the broader hedonic changes that are often observed over the course of the development of dependence. According to Koob and Le Moal, these adaptive changes take their toll on the organism by altering the homeostatic hedonic set point by a process known as *allostasis*. That is, over time, there is a change in the natural homeostatic set point so that the B-state no longer merely acts as a countervailing force to balance the evoking A-state but, over time, alters the tonic, hedonic baseline of the individual. This type of allostatic derangement is thought to characterize chronic dependence and this deviation from the (original) natural set point to the allostatic set point is believed to represent hedonic cost to the user. That is, chronic adaptive changes to drug taking dynamically reset homeostatic mechanisms lowering the tonic hedonic set point. These allostatic changes are pernicious in that not only are increasingly large doses of a drug needed to attain a desired state (i.e., tolerance), but the underlying hedonic state further deteriorates, providing further motivation for continued substance use, setting up a vicious, downward cascade of negative affect and compensatory relief drug use. Other theorists have similarly emphasized that negative affect is a core feature of dependence that, in transaction with the larger environment, provides a motivational basis for negative reinforcement (Baker et al., 2004).

To varying degrees, all neurobiological theories of how substance use leads to substance dependence posit that addictive drugs hijack brain systems associated with reward. Robinson and Berridge (1993) in their theory of incentive sensitization posit that craving is the result of a hypersensitization of the dopamine system that increases the incentive salience of drugs and drug-associated stimuli. Critically, this incentive salience (wanting) can diverge from the pleasurable effects of drugs (liking) so that craving

can be experienced even in the absence of any expected positive experience. Although cues surrounding natural rewards (e.g., food, sex, thirst) can also take on special incentive valuates, as noted by Hyman, Malenka, and Nestler (2006), addictive drugs tend to be overvalued at the expense of other reinforcers. This, coupled with the fact that they can have a range of harms associated with them, makes them particularly problematic. That is, although the pure reinforcement value of a drug may be important for earlier stages of drug use, other processes can evolve that motivate more internally driven or compulsive drug taking.

Goldstein and Volkow (2002) argued that although most research has concentrated on the role of limbic regions in the development of addictions, there is substantial evidence implicating frontal structures, in particular the orbitofrontal cortex and the anterior cingulate gyrus. This notion is further developed by Everitt and Robbins (2005) who proposed that the transition from initial use to compulsive use is paralleled by transitions in multiple neural systems, specifically, "prefrontal cortical to striatal control of drug seeking and drug taking along with a progression from ventral to more dorsal domains of the striatum" (p. 1481). The notion that there is a transition from impulsive to compulsive use in the development of dependence is important in several ways. First, it highlights that substance use disorders can be graded by severity that is related to progression of underlying addictive processes. Second, it suggests that early-stage problematic use or mild dependence might be strongly associated with other externalizing problems (owing to shared underlying impulsive processes) but the progression to severe dependence might not be as closely tied to general externalizing and more tied to chronic drug effects. That is, different processes may need to be considered when considering risk factors for substance use versus mild substance dependence versus severe substance dependence.

THE YIN AND THE YANG OF DEPENDENCE: DUAL-PROCESS APPROACHES TO UNDERSTANDING ADDICTION

Contemporary comprehensive theories of substance dependence or addiction posit two distinct systems of addiction. Although there are a range of dual process models, at their core they all posit that problematic substance use or addiction is the product of two countervailing influences, excessive approach tendencies to use the drug and restraining tendencies that hold these processes in check (Orford, 2001). For example, Bechara (2005) posited that decision-making is based on two neural systems: an impulsive system based on the role of the amygdala signaling the affective value of immediate outcomes; and a reflective system based on the role of the ventromedial prefrontal cortex signaling the affective value of long-term outcomes. From this perspective, addictive behavior is the result of a dysfunction of the reflective system that makes some individuals vulnerable to an undue influence of immediate reinforcement (i.e., poor self-control) or, perhaps, vulnerable to the overwhelming incentive value of the substance (i.e., an excessive appetite). This theoretical perspective is useful because it provides a framework for studying functional, endophenotypic components of dependence related to approach and restraint tendencies and suggests multiple, novel targets for intervention. Unlike some traditional theories of health-related behaviors (including substance use) that assume that behavior is rational (e.g., the theory or reasoned action or the theory of planned behavior; Ajzen, 1991; Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975), dual-processes theories assume both rational and irrational processes play a critical role in addictive phenomena. Although not discussed further here, it can be noted that behavioral economic views on addiction (e.g., Heyman, 2009) view the decision-making processes underlying addictive behavior to be largely the same as those governing nonaddictive behavior but with a key difference. The nonaddicted individual makes decision to optimize his well-being by using a relatively global frame of reference in decision making while the addicted individual maintains a local frame of reference for decision making. That is, decisions concerning self-interest are based on a short-time horizon, leading to decisions that are disadvantageous in the long-term.)

As typically construed (e.g., Deutsch & Strack, 2006), dual-process theories of behavior postulate that there are two psychological systems that jointly determine behavior: (1) a rule-based reflective system; and (2) an association-based impulsive system. For the purposes of the current discussion, we will focus on the basic notion that the impulsive system is associated with the incentive value of various substances and the reflective system is associated with self-regulation and executive control; the decision to use or not use a substance involves the interaction between the two systems. Importantly, the impulsive system is thought to be activated automatically, to not use much in the way of attentional resources, and may often be unconscious. In contrast, the reflective system is dependent upon attentional resources, effortful, and largely conscious. As noted by Wiers et al. (in press), these kinds of prototypic distinctions can often be problematic in that

highly practiced reflective behaviors can become automatized and executed with minimal awareness and that impulsive processes can intrude into awareness. Despite these complexities, the general distinction would appear to have considerable heuristic value.

As noted in our earlier discussion of externalizing pathways, impulsive processes are clearly important in all forms of externalizing behavior that are associated with deficits in self-regulatory processes and executive control. However, the impulsive processes that are specifically associated with drug use (as opposed to reward seeking more generally) are thought to represent key, distinctive features of substance dependence and could map onto neuroadaptive processes such as incentive sensitization and allostasis (Berridge & Robinson, 2006). This is not to say that substance use doesn't affect the reflective system; clearly it could, either through neurotoxic effects on prefrontal brain structures subserving executive functions (e.g., Lyvers, 2000) or because the constant burden of attempting to control excessive impulsive processes can, at least temporarily, wear down self-control (Muraven & Baumeister, 2000). However, it can be argued that the impulsive system conceptually converges with what might be considered the "core" of addiction (Sher, Wolf, & Martinez, 2009). That is, if we can assess impulsive processes, we can assess processes that appear to be distinctly and directly associated with the motivational salience of drugs that, in turn, is intimately related to the neurobiological theories of addiction.

BEHAVIORAL ASSESSMENT OF IMPULSIVE PROCESSES: IMPLICIT COGNITION

To date, researchers have employed a number of tasks designed to assess the degree to which cues associated with drugs are capable of engaging impulsive processes. Most of these are considered *implicit* measures as distinct from explicit *measures* (such as the drug use motivation questionnaires referred to earlier). There are a number of different definitions as to what constitutes an implicit measure although, as a group, they tend to have certain characteristics in common, to varying degrees. According to De Houwer (2006), these include (1) the individual being assessed is unaware of what they are being assessed for; (2) the individual does not have conscious access to the cognition that is being assessed; and (3) the individual has limited control over the outcome being assessed. As described by Wiers et al. (in press), implicit cognitive tasks can be broken down into three broad classes: (1) attentional bias for drug-related stimuli; (2) memory associations; and (3) action tendencies.

Attentional Biases

To the extent that drug cues have acquired incentive salience through their association with a chronic pattern of drug use, they should be able to grab and hold attention and this biasing of attention should interfere with performance on tasks that require more nimble deployment of attention. A variety of different implicit measures show such an effect. For example, the well-known Stroop (1935) color naming task has been adapted to study how drug-related words affect the speed at which a subject can name the color it is written in (relative to control words); that is, if there is an attentional bias to drug cues, it should interfere with the ability to name colors quickly. In a recent meta-analysis of extant drug studies (primarily alcohol, 55%; and smoking, 33%), Cox, Fadardi, and Pothos (2006) found that the size of the Stroop effect was related to several variables including manipulations designed to increase drug use motivation (e.g., drug deprivation) and between-group differences in the heaviness of use. In another recent meta-analysis, Field, Munafò, and Franken (2009) examined the association between attentional bias assessed using a wide range of tasks and craving for various substances: (1) the addiction Stroop, the effect of drug cue exposure on performance on a cognitively demanding task (e.g., Sayette & Hufford, 1994); visual probe tasks (e.g., Ehrman et al., 2002); (2) the attentional blink test, which examines the effect of a prior, drug-related or control stimulus on the detection of a second, quickly presented stimulus (e.g., Waters, Heishman, Lerman, & Pickworth, 2007); and (3) late evoked-related potentials to drug-related and control stimuli. Across the 68 studies included in the meta-analysis (which were heterogeneous with respect to target drugs as well as type of attentional bias assessed), the overall correlation between subjective craving and implicit measures of attentional bias was .19. A number of variables moderated the strength of the overall association, which was stronger for illicit substances such as cocaine, heroin, and cannabis than it was for alcohol and nicotine. As discussed later, these findings open up the possibility of novel treatments that attempt to reverse or undo these biases.

Memory Associations

Although various tests of attentional bias seek to characterize the extent to which drug-related stimuli hijack attention, tests of memory associations (broadly defined) seek

to characterize the network of associations to drug-related stimuli and how automatically they are elicited. Perhaps the best-known test of memory associations is the Implicit Association Test (IAT; Greenwald, McGhee, & Schwartz, 1998), which assesses the differential association (based on reaction time) of drug-related stimuli with positive and negative attributes. Other measures include illusory memory paradigms and association tests that involve asking subjects to produce verbal responses to drug or other cues in either free or controlled association paradigms. As noted by Wiers et al. (in press) across a number of studies that use indirect test instructions (e.g., say the first word that comes to mind) word associations are robust predictors of substance use. Indeed, in a recent meta-analysis, Rooke, Hein, and Thorsteinsson (2008) found that word association tests were the most strongly associated implicit measures of various types of substance use, with a mean correlation of .40.

It should be emphasized that both measures of association and attentional bias are very sensitive to design concerns and much of this literature is confusing and conflicting. Existing meta-analyses are useful at synthesizing findings across multiple studies that vary with respect to subject population, task characteristics, and dependent measures. Although these types of measurements clearly show potential for assessing key addiction-related constructs that are difficult to assess by explicit means, the field is continuing to evolve and identify the range of variables that can affect these assessments.

Action Tendencies

A third type of implicit measure involves assessing the tendency to approach or avoid a given stimulus. In general, this research is based upon the theory that approach or avoidance behaviors are automatically activated by appraisals of the valence of a stimulus. In contrast to research on attentional bias and word association, research on the relation between action tendencies and addiction has not as yet received as much attention. Although some paradigms use association tests like the IAT to gauge approach or withdrawal (e.g., attributes such as *approach* words or *avoidance* words are used instead of more valenced words), the most clearly prototypic tasks involve having the subject perform an action that either involves moving an object towards or away from drug-relevant or control stimuli as in the stimulus response compatibility test (De Houwer, Crombez, Baeyens, & Hermans, 2001) or having subjects either pull towards or push away a stimulus (e.g., using a joystick) that varies in its drug relevance (e.g., Wiers, Rinck, Dictus, & Van Den Wildenberg, 2009). As noted by Wiers et al. (in press), to date these methods have been used with success with alcohol, tobacco, and marijuana users and provide another potential novel assessment of the motivational significance of drugs. Additionally, to the extent that approach to drug stimuli is a learned phenomenon, it raises the possibility that treatments can be developed that can help individuals unlearn these acquired tendencies.

TREATMENT IMPLICATIONS OF THE DRUG EFFECTS PATHWAYS

Understanding the pharmacological mechanisms underlying drug reinforcement and addiction provides strong justifications for some current interventions and has critical implications for the development of new ones. Although it may be most natural to think of pharmacological interventions as the most likely types to target these mechanisms, as described below both pharmacological and behavioral treatments can be considered.

Pharmacological Approaches

One type of treatment that is under investigation involves medications that prevent drugs of abuse from entering the brain. For example, one strategy that has been attempted is to develop nicotine vaccines that bind antibodies to nicotine in the blood, preventing it from crossing the blood-brain barrier and acting on nicotinic receptors in the brain. Although randomized controlled trials have yet to show efficacy of this approach (Hartmann-Boyce, Cahill, Hatsukami, Cornuz, & 2012) researchers believe that this type of strategy warrants further investigation (Fahim, Kessler, & Kalnik, 2013). Similar efforts are also being investigated for treating cocaine and methamphetamine dependence (Kosten, Domingo, Orson, & Kinsey, 2013).

Other pharmacological approaches involve simple substitution of one less harmful form of the drug in place of a more harmful form, as illustrated in nicotine replacement therapy (e.g., nicotine gum, lozenges, nasal spray, and patches). That is, many of the most harmful aspects of smoking are attributable to inhaled smoke and not nicotine per se. Randomized trials both of prescribed medication (Silagy, Lancaster, Stead, Mant, & Fowler, 2002) and over-the-counter medication (Hughes, Shiffman, Callas, & Zhang, 2003) point to efficacy of this approach. Treatment of opiate dependence has employed methadone for many years (Farrell et al., 1994) and the goal of such treatment typically is not cessation but harm reduction with major

outcome measures focusing on various harms of heroin use and retention in treatment (Mattick, Breen, Kimber, & Davoli, 2009). Replacement therapies for cocaine are also under development (Rush & Stoops, 2012).

Although substitution or replacement treatments can be used either as a bridge to abstinence or as a long-term, harm reduction strategy, treatments with medications that block the pharmacological actions of abused drugs at the receptor level (antagonists) have also been developed. For example, naltrexone, a blocker of the mu-opioid receptor, in principle, blocks the euphoriant effects of opiates and is sometimes used to help maintain abstinence in the treatment of detoxified alcoholics. Although originally developed for treatment of opiate addicts, its effectiveness for this problem is not impressive (Minozzi et al., 2011), although it has been shown to be an effective medication for treatment of alcohol dependence and other opiate antagonists are also currently under evaluation for alcoholism treatment (Rösner et al., 2010).

Some medications for addiction have properties of both agonist (substitution, replacement) drugs and antagonist (receptor blocker) drugs. Perhaps the best-known example of such drugs is varenicline, a medication for nicotine dependence that is a partial agonist, having both agonistic and antagonistic properties. Consequently, the agonistic properties provide low-level stimulation of the receptors, avoiding withdrawal, while the antagonist properties mute the effects of nicotine, in effect clamping the receptor at an intermediate level of activity. Varenicline has been shown to be an effective treatment for nicotine dependence, even when compared with other drug treatments such as nicotine replacement and bupropion, and other nicotine partial agonists are being developed (Cahill, Stead, & Lancaster, 2012).

The description provided above is meant to be illustrative by showing several different ways that drug reinforcement pathways can be exploited for developing treatments. A number of other treatments—some approved, some experimental—also exist and include drugs that work on multiple neurotransmitter systems and multiple addictive behaviors. For example, the anti-epileptic drug, topiramate, has been used to treatment alcohol dependence, obesity, and binge eating disorder (Johnson et al., 2007; Marazziti, Corsi, Baroni, Consoli, & Catena-Dell'Osso, 2012).

However, fewer drugs have been developed to address the generalized changes that occur with chronic adaptation to drugs as described earlier with respect to Koob and Le Moal's (2001) allostatic perspective and Baker et al.'s (2004) negative affect theory. These changes in the brain are thought to be attributable to overactivation of the HPA-axis. Consequently, drugs that could restore normal function to this system and prevent the negative downward spiral of inducing further allostatic derangement by self-medicating with the drug of abuse would be of great value clinically. For example, drugs that could antagonize corticotropin-releasing factor might be helpful in unstressing the addicted brain (Koob, 2010). Clearly, the more we know about the underlying neurocircuitry of drug reinforcement and dependence, the more we can identify potential targets for novel therapies.

Behavioral Treatments

There are a number of effective behavioral and psychosocial treatments for substance dependence (e.g., Klimas et al., 2013), including cognitive behavioral treatments (McHugh, Hearon, & Otto, 2010), contingency management approaches (Prendergast, Podus, Finney, Greenwell, & Roll, 2006), and 12-step programs (Ferri, Amato, & Davoli, 2006). While virtually all such treatments could be of benefit to individuals with substance dependence, they are not necessarily based upon models of pharmacological vulnerability (although treatments involving reinforcement for nonsubstance activities such as contingency management are based on the premise that drugs are reinforcers). However, to date, several treatments have been developed from the perspective of countering drug effects and novel treatments are being developed from the perspective of dual-process theories.

For example, to the extent that reactions to drug cues are learned (a perspective consistent with Pavlovian conditioned tolerance and incentive sensitization theory), it should be possible to unlearn these reactions through traditional learning techniques. Influenced by the early development of fear reduction techniques based upon extinction procedures, a number of behavior therapists have attempted to extinguish learned reactions to drug cues (e.g., the sight and smell of cigarettes, alcoholic beverages, or drug paraphernalia). Although such approaches are well motivated theoretically, to date they have not been shown to be a highly effective strategy, producing inconsistent results (Martin, LaRowe, & Malcolm, 2010). Current research in this area is seeking to find ways to make extinction-based procedures more effective with pharmacological aids to facilitate extinction. For example, the drug d-cycloserine has been shown to facilitate classical conditioning of fear in laboratory animals and several groups have tried to see if it can enhance outcome of cue-exposure therapies for substance dependence. To date the findings

have been promising in laboratory models of substance use but not with human patients, but this remains an active area of research (Myers & Carlezon, 2012) as does "thinking through" critical determinants of learning. For example, the context of learning is critical (Bouton, 2000, 2002) and important to generalization. Perhaps more important, the notion that extinction and counterconditioning procedures destroy prior learning is most likely incorrect and, extinction, rather than causing "unlearning" most likely lays down alternative learning that competes with what was learned previously (Bouton, 2002).

It should be noted that aversive conditioning approaches that seek to condition punishment cues to drugs of abuse have been used for decades with varying degrees of success. Perhaps the best known of these is emetic conditioning for alcohol dependence, which, although not used much currently, can be effective if conditioning is established (Howard, Elkins, Rimmele, & Smith, 1991). Aversion treatments in smoking (e.g., rapid smoking) have not been found to be an effective treatment approach (Hajek & Stead, 2000).

Novel learning approaches have been inspired by recent research on implicit cognition in addiction. If automatic approach tendencies are learned, it seems reasonable to see if these can retrained into avoidance tendencies. The same basic laboratory paradigms that are used to assess approach and avoidance tendencies in substance users (e.g., pulling or pushing a joystick) can be used to retrain these tendencies by arranging contingencies so that a patient's task is to, without explicit awareness, push drug cues away and pull nondrug cues towards oneself. Such an approach was employed by Wiers, Eberl, Rinck, Becker, and Lindenmeyer (2011), who found this to be an effective, adjunctive strategy in a controlled trial with a 1-year follow-up. (This approach was subsequently replicated in a new sample; Eberl et al., 2013.) Similarly, experimental treatments aimed at retraining attention away from drug cues have been developed (e.g., Schoenmakers, Wiers, Jones, Bruce, & Jansen, 2007: Schoenmakers et al., 2010) and show initial promise. One of the potentially exciting aspects of these new approaches based on implicit cognition is that they hold promise for being used in less motivated participants and they increase the range of treatment options available to those seeking help.

MACRO INFLUENCES

The etiological mechanisms described above focus primarily on the interplay between individual-level characteristics and the immediate social context (primarily familial and peer influences). However, broader social influences, including neighborhoods, mass media, and public policies (school, community, and legal policies) also influence substance use behavior. Here we review evidence concerning these macrolevel influences.

Neighborhoods

Neighborhood characteristics have been thought to influence many aspects of child adjustment (Leventhal & Brooks-Gunn, 2000). Most research in this area distinguishes two broad features of neighborhoods. *Neighborhood structure* encompasses compositional characteristics of the community (e.g., racial composition, median income, crime) whereas *neighborhood social processes* refer to a community's social organization (e.g., social cohesion and social control). Most of the neighborhood research on adolescent substance use has considered indicators of socioeconomic status (SES), a component of neighborhood structure. These studies have yielded mixed and inconclusive findings. As noted earlier for individual-level SES, some studies find that neighborhood affluence is associated with adolescent substance use (Ennett, Flewelling, Lindrooth, & Norton, 1997; Luthar & Cushing, 1999). Other studies have found that poverty is associated with increased risk for adolescent substance use (Hoffmann, 2002; Smart, Adlaf, & Walsh, 1994), or find no association (Allison et al., 1999; Brenner, Bauermeister, & Zimmerman, 2011). A much smaller number of studies have examined neighborhood social processes and findings suggest that residing in a more socially cohesive neighborhood (trust and shared values among residents) is associated with lower risk for adolescent substance use (Mayberry, Espelage, & Koenig, 2009; Winstanley et al., 2008). When neighborhood effects are found they tend to be small. In general, these findings preclude conclusions about the association between neighborhood characteristics and adolescent substance use. There is a clear need for more systematic research to clarify the etiological role of neighborhoods, and consideration of potential moderators, mediators, and to consider the ways that neighborhoods are conceptualized and measured.

Moderators of Neighborhood Effects

Inconsistent findings suggest that youth may be differentially vulnerable to the effects of neighborhood influences on substance use, and that it may be important to consider potential moderators. There are a few examples in

the literature supporting moderation. Trim and Chassin (2008) found that the effect of neighborhood socioeconomic status depended on whether an adolescent was a child of an alcoholic (COA) or not (non-COA). Residing in a higher SES neighborhood was associated with more rapid increases in alcohol use for non-COAs, whereas residing in lower SES neighborhoods predicted more rapid increases for COAs. The authors suggested that higher SES may be associated with less parental supervision and access to substance using peers for non-COAs and that neighborhood disadvantage unmasked vulnerability associated with parental alcoholism. Scheier, Miller, Ifill-Williams, and Botvin (2001) found that perceived neighborhood danger (perhaps reflecting a structural neighborhood characteristic) was associated with adolescent substance use for high, but not low sensation seekers. Sensation seeking, and possibly the broader construct of behavioral undercontrol, may leave youth particularly vulnerable to negative influences of risky neighborhoods. Age is another possible moderator. Older adolescents spend more time outside of the family home, and may be more vulnerable neighborhood influences. There is some evidence suggesting that low neighborhood SES is associated with higher levels of substance use for older compared with younger adolescents (Mennis & Mason, 2012). Taken together these moderational findings suggest that unmeasured or untested moderating variables may account for some of the mixed neighborhood findings. Related to this point is that neighborhood characteristics are embedded in sociocultural, historical, and geographical contexts (Mrug & Windle, 2009), and regional differences in neighborhood characteristics might account for mixed findings. For example, there are regional differences with respect to ethnic heterogeneity within neighborhoods, residential stability, and depth of poverty, all of which may impact social processes and neighborhood dynamics. Such differences may make it difficult to replicate findings across studies that utilize regional samples. This suggests that large nationally representative samples may be best suited for neighborhood research and that it is important to carefully consider the characteristics of regional samples when drawing conclusions across studies.

Mediators of Neighborhood Effects

Neighborhood characteristics may also be distal influences that operate through more proximal influences in mediational pathways (e.g., Murry, Berkel, Gaylord-Harden, Copeland-Linder, & Nation, 2011). Affiliation with deviant peers is one candidate mediator. Residing in high-risk neighborhoods may increase the likelihood of affiliating with deviant peers who provide access to and support for drug and alcohol use. In a longitudinal study, Gibbons et al. (2004) found that residing in a dangerous neighborhood was associated with high levels of peer substance use, which in turn predicted adolescent use. Chuang et al. (2005) found a similar pattern of effects in predicting adolescent cigarette use, but they did not formally test mediation. Parenting is another potential mediator. Disadvantaged neighborhoods characterized by poverty, low social cohesion, and social control may impair family functioning and compromise parenting, which in turn, increases risk for substance use. Although, as noted above, Chuang et al. (2005) did not formally test mediation, they found that residing in a low SES neighborhood was associated with high levels of parental monitoring, which in turn predicted low levels of alcohol and cigarette use. The protective effect of low neighborhood SES on parental monitoring was contrary to other findings in the literature and unexpected, may reflect regional variability referred to previously. The authors suggested that parents in low SES neighborhoods may use more restrictive parenting strategies to counteract a risky neighborhood context. Although not yet tested, other possible mediators include positive attitudes and weak expectancies about potential harmful effects of drug and alcohol use, and accessibility. Pro-substance use attitudes may be transmitted from adults who themselves have lax attitudes or engage in substance use. Close proximity to alcohol and tobacco outlets is associated with increased levels of use, and outlets tend to be concentrated in disadvantaged neighborhood (Hyland et al., 2003; Wieczorek, 2000).

Neighborhood Conceptualizations

Although neighborhood influences are considered important in ecological conceptualizations of child and adolescent development, there is no clear, single definition of what constitutes a neighborhood. Most studies implicitly conceptualize neighborhoods based on ecological units such census-defined block groups, tracts, or zip codes, but it is not clear whether and why these units represent the best way to define neighborhood boundaries. Another method is to take an idiographic approach and allow research participants or residents define their neighborhood themselves. Perhaps as a consequence of this lack of consensus, the assessment of neighborhood characteristics has varied widely. Different conceptualizations of neighborhood boundaries and assessment methods may yield different conclusions about the influence of

neighborhood characteristics on adolescent substance use. Importantly, boundary conceptualizations and assessment approaches utilized in most neighborhood research is not driven by a theoretical notion of what constitutes a neighborhood.

Taking an innovative, theory-based approach, Hipp, Faris, and Boessen (2012) proposed using information on social ties in the community to create neighborhood boundaries. They argued that social ties are inherent in most conceptualizations of neighborhoods, and that it is therefore important to incorporate social tie information into the creation of neighborhood boundaries. Their approach involves creating boundaries based on a combination of physical distance between residents and their social ties. Once boundaries are thus defined, then structural and social process characteristics can be assessed using multiple methods. Preliminary findings suggest that this approach produces geographically contiguous neighborhoods and a reasonable degree of homogeneity of adolescents' perceptions of neighborhood characteristics within neighborhoods. This method is appealing in that it flows from a theoretical notion of what constitutes a neighborhood (a combination of physical proximity and social ties). A disadvantage is that it is data intensive, requiring collection of sociometric data from most residents in the community. Nonetheless, such a conceptually driven method for defining neighborhoods may have utility in clarifying the role of neighborhoods in the etiology of adolescent substance use.

Media

Media influences have been studied both as risk factors for increasing substance use and as a tool for substance use prevention. Substance use is often presented as cool, fun, and relaxing in the media (Stern, 2005), and this combined with the limited regulation of alcohol and tobacco advertising suggests that the media is a potential source of pro-substance use messages. Media portrayals of substance use occur through many sources, including in-store displays, billboards, print, the Internet, television, and movies, and the amount of time adolescents spend with media exceeds the time they spend with friends and family (Rideout, Foehr, & Roberts, 2010).

Advertising

Exposure to alcohol and cigarette advertising is associated with higher rates of adolescent smoking and drinking (Anderson, de Bruijn, Angus, Gordon, & Hastings, 2009; Hanewinkel, Isensee, Sargent, & Morgenstern, 2011). Although there are restrictions on cigarette advertising, youth continue to report exposure to cigarette advertising through in-store displays, magazines, and the Internet (Centers for Disease Control and Prevention, 2005). Cigarette manufacturers have reduced advertisements in magazines with high youth readerships. However, they have shifted the brands advertised; such that brands popular with young people are more likely than brands popular with adults to appear in magazines with high youth readership (King, Siegel, Celebucki, & Connolly, 1998). Similarly, the number of alcohol advertisements that appear in a magazine is positively associated with the percent of young readers (Garfield, Chung, & Rathouz, 2003), and types of alcohol popular with youth are more likely to appear in magazines that young people read (King et al., 2009). Although cigarette advertising has been banned from television since 1971, alcohol advertising is still permitted. Adolescents exposed to more alcohol advertisements on television are at increased risk for drinking (Smith & Foxcroft, 2009) and there has been a recent increase youth exposure largely due to increases in alcohol advertising on cable television (Center for Alcohol Marketing and Youth, 2010).

Entertainment Media

Entertainment media (television, movies, music, and music videos) portrayals of alcohol, cigarette, and other drug use are largely positive, rarely show negative consequences of use, and influence adolescent attitudes about substance use (Strasburger & The Council on Communication and the Media, 2010). According to a content analysis of television programs in the year 2000, most top-rated prime-time shows mentioned or depicted substance use (mostly alcohol use), and 49% included humorous references to substance use (again mostly alcohol use; Christenson, Henricksen, & Roberts, 2000). Exposure to smoking or drinking in movies is related to rates of adolescent smoking initiation (Charlesworth & Glantz, 2005) and adolescent alcohol use (Sargent, Wills, Stoolmiller, Gibson, & Gibbons, 2006). A content analysis of 24 G-rated movies suggested that tobacco and alcohol appeared at least once in 75% of the movies, and nearly all depictions were positive (Ryan & Hoerrner, 2004). Of the top-grossing films between 1999 and 2001 with a teen as a major character, 17.1% showed teens smoking, 40% showed teens drinking, and 15.1% showed teens using other drugs, with few negative consequences of use depicted (Stern, 2005). Smoking in movies is associated with positive characteristics that are

likely appealing to adolescents, including rebelliousness, glamour, and romance, and a national study in 2009 found that many movies rated G, PG, or PG-13 showed or implied tobacco use (39%), with a higher rate in PG-13 movies (54%; Centers for Disease Control and Prevention, 2010b. A recent study found that there was a 7% per movie increase in occurrences of use or implied use of tobacco (13.1% to 14.0%) in top-grossing movies between 2010 and 2011 (Glantz, Iaccopucci, Titus, & Polansky, 2012). Most popular movies depict alcohol. A study of popular movies between 1998 and 2003 showed that 83% of popular movies depicted alcohol use, and 15.2% of G- and PG-rated movies depicted an inebriated character (Cin, Worth, Dalton, & Sargent, 2008). In short, a positive portrayal of substance use in movies is the norm. Exposure to substance use in movies is associated with increased risk for substance use (Koordeman, Anschutz, & Engels, 2012).

Music and music videos represent another source of substance use messaging. Content analysis of popular songs from 2005 suggested that over 30% included references to substance use, most of which were positive (Primack, Dalton, Carroll, Agarwal, & Fine, 2008). This study estimated that the typical adolescent is exposed to 84 references to substance use per day through listening to music. The more music that youth listen to is associated with increased risk for substance use (Primack, Kraemer, Fine, & Dalton, 2009).

Methodological Issues

Although there are clear links between media exposure and adolescent substance use, a potential critique of this research is the question of direction of effects. Rather than media exposure causally influencing the onset and escalation of adolescent substance use, it is possible that adolescent substance use leads to the selection of media and contexts that reinforce substance use behavior and attitudes (Slater, 2007). However, it may be difficult for youth to avoid exposure to pro-substance use messages given the proliferation of substance use in the media. It is also possible that links between media and substance use are attributable to common third variables. For example, behavioral undercontrol may increase an individual's preference for substance use saturated media and may also increase the likelihood of substance use, and when this variable is statistically controlled, the association between media exposure and substance use may no longer be detectable. However, accumulated longitudinal evidence from studies that have statistically controlled for potential confounding variables (e.g., personality, demographics, parenting) have shown that media exposure prospectively predicts adolescent substance use (e.g., Koordeman et al., 2012; The National Cancer Institute, 2008; Slater & Hayes, 2010).

Not all youth appear to be equally susceptible to media exposure. Several studies have examined potential moderators of the effect of media exposure, and findings suggest that behaviorally undercontrolled youth (e.g., high sensation seeking, poor self-regulation) are more vulnerable to the effects of media exposure on adolescent substance use (Stoolmiller, Gerrard, Sargent, Worth, & Gibbons, 2010; Wills et al., 2010). These studies suggest a specific subgroup that can be selected for targeted interventions. Studies have also examined mediational mechanisms, and this body of work suggests that media exposure influences adolescent substance use by increasing affiliation with substance using peers and positive attitudes about substance use (Koordeman et al., 2012; Slater & Henry, 2013). Understanding mechanisms provides additional points of intervention that may help reduce the impact of media exposure.

Although media exposure plays a role in the etiology of adolescent substance use, there are a number of issues that remain unresolved. First, measures of media exposure have focused on simple aggregations of frequency of exposure, but all portrayals of substance use in the media may not have the same impact. Aspects of socioemotional context (e.g., emotional valence and arousal, the degree to which youth identify with the portrayal) may influence the salience of media portrayals of substance use. Second, studies that have examined moderation have focused on vulnerability models (e.g., risk factors that increase vulnerability to mediate influences). However, protective mechanisms are also important and have the potential to inform intervention efforts. Focusing on factors that might buffer the impact media exposure, such as open parent–child communication, affiliation with peers who don't engage in substance use, has the potential to inform target variables for preventive interventions. Finally, media exposure may vary across age and stage of use and very little research has considered this question. Media exposure may be a more powerful influence in early adolescence during the early phases of substance use when social influences may be particularly important, but less of an influence in later stages of problem use. Very little research has examined these questions. Understanding age and stage differences has the potential to inform questions about when and for how long youth should be protected from media exposure.

Media messages have also been used in public health campaigns as an intervention to reduce adolescent substance use. Although most adolescents have seen or heard antidrug messages through a variety of sources (e.g., radio announcements, commercials, pamphlets, and posters), the effectiveness of many of these messages is unclear. However, there are examples of effective public awareness campaigns. *Truth* targeted adolescent attitudes about smoking, and involved a counter-marketing effort that provided adolescents with facts about the harms of smoking and about the tobacco industry's marketing practices. This campaign effectively promoted negative attitudes towards the tobacco industry and smoking, which in turn, predicted decisions about smoking (Cowell, Farrelly, Chou, & Vallone, 2009; Farrelly, Nonnemaker, Davis, & Hussin, 2009). A recent study used Nielsen Media Research ratings to examine the impact of anti-drug television advertising on adolescent drug use (Terry-McElrath, Emery, Szczypka, & Johnston, 2011). Results suggested that exposure to anti-drug advertisements was associated with some positive effects regarding marijuana (e.g., disapproval of use, lower odds of use, and greater perceived risk of use), but these effects varied across middle and high school youth. This suggests that the effectiveness of public awareness messages can differ across subpopulations of youth, and a crucial issue is to understand the kinds of messages that are most effective for different populations. This an important direction for future research because the idea that one type of message works for all youth does not appear to be emerging in the literature.

The National Youth and Anti-Drug Campaign (NYADC) is an informative example with respect to considering targeting public awareness messages for specific populations. The NYADC was funded by the Office of National Drug Control Policy to develop a media campaign to prevent substance use initiation and reduce use among occasional users. Initial results suggested that the campaign was not effective, and may even have had iatrogenic effects (Hornik, Jacobsohn, Piesse, & Kalton, 2008). The campaign was revamped to target marijuana use among a high-risk group, high sensation seekers. The new public service announcements were crafted to be high in sensation value (e.g., messages that elicited strong sensory, emotional, and arousal responses). Such messages have been shown to be appealing to high sensation seekers (Palmgreen et al., 1991). This revamped campaign (the Marijuana Initiative) was found to be successful at reducing marijuana use and weakening positive marijuana beliefs among high sensation seekers (Palmgreen, Lorch, Stephenson, Hoyle, & Donohew, 2007). These findings suggest that public awareness campaigns can be successful when designed to be salient to targeted groups of adolescents.

Schools and Communities

Schools and communities can implement antidrug policies and prevention programs, and provide a context within which problem substance users can be identified and connected with service providers. Antismoking policies in schools are effective at lowering rates of adolescent smoking when they are consistently enforced (Adams, Jason, Pokorny, & Hunt, 2009; Lipperman-Kreda, Paschall, & Grube, 2009). However, policies that ban smoking for students, but allow it for staff are less effective (Trinidad, Gilpin, & Pierce, 2005). Zero-tolerance policies mandate predetermined punishments (e.g., suspension, expulsion) but have not been systematically evaluated, so it is unclear if they are effective. Some schools conduct drug testing (mostly of student athletes) and drug searches, but research on these approaches is limited and inconclusive (e.g., James-Burdumy, Goesling, Deke, Einspruch & Silverberg, 2010; Yamaguchi, O'Malley, & Johnston, 2004).

Other school-based prevention efforts take the form of drug prevention programs. These programs vary widely, and can include curriculum and instruction, recreational programs, and counseling directed at students, as well as organizational and structural changes in scheduling, physical features of the school, and classroom management practices. Reviews of school-based prevention programs suggest that effective prevention programs share some common features (Botvin & Griffin, 2007; Cuijpers, 2002; Gottfredson & Wilson, 2003). These include (1) a focus on aspects of social influence, such as building skills in recognizing and resisting peer pressure; (2) providing accurate information about rates of substance use to correct misperceptions that substance use is normative; (3) increasing motivation not to use; and (4) utilizing interactive methods (e.g., facilitated discussions, small group activities). Although effective school-based prevention programs have been developed, they have not been widely disseminated, and understanding and overcoming the barriers to dissemination remains an important goal.

Community prevention programs typically target multiple aspects of the community including law enforcement, schools, religious institutions, and retailers. The broad focus of these programs is appealing given the broad array of contexts and factors known to influence adolescent substance use. Most of these programs have not been adequately evaluated and so whether they are effective is

an open question. Randomized clinical trials provide the most rigorous test of interventions, but they are difficult to implement when testing community prevention programs. A few community prevention programs have shown some promising results using randomized clinical trials (e.g., Hawkins et al., 2008; Perry et al., 2002). In addition, community-university partnerships implementing multicomponent interventions (including school-based and family-focused interventions) have shown reductions in substance use outcomes (Spoth et al., 2013).

Health Care System

Opportunities for prevention (as well as treatment) also exist within the health care system, within which routine screening and early intervention could be incorporated. Although there have been longstanding recommendations for physicians to screen adolescents for substance abuse and to provide brief interventions, and the tools exist to do so, these recommendations have not been widely implemented (Kokotailo & the Committee on Substance Abuse, 2010; Van Hook et al., 2007). Most health care providers lack the necessary training, and empirically validated treatment approaches have not been widely disseminated (Feinstein, Richter, & Foster, 2012). Indeed, although evidence-based treatments exist (Waldron & Turner, 2008), very few adolescents with drug disorders receive treatment (fewer than one in five in one study; Merikangas et al., 2011). Perhaps related to the lack of treatment services, in the United States, the juvenile justice system is the largest referral source for adolescent drug treatment (Nissen & Pearce, 2011). The Affordable Care Act will bring the possibility of transforming health care provision and substance abuse treatment to a fee-for-service model, making it easier for health care providers to be paid for screening and intervention services (Buck, 2011). The Affordable Care Act may also expand funding for uninsured persons and prevention services.

Taxation, Regulation, and Youth Access Policies

Government policies regarding taxation, regulation, and enforcement can have a strong influence on adolescent substance use by reducing access to drugs and alcohol and transmitting strong antidrug messages. Increasing taxes, and thereby increasing the cost of cigarettes and alcohol, is associated with decreases in adolescent smoking and drinking (Carpenter & Cook, 2008; Laixuthai & Chaloupka, 1993). Smoking bans in the workplace, restaurants, and other public spaces are associated with lower rates of adolescent smoking (McMullen, Brownson, Luke, & Chriqui, 2005). Laws restricting adolescents' access to cigarettes (prohibiting sales to minors or prohibiting minors from possessing cigarettes) generally show weak effects on reducing adolescent smoking, despite reductions in illegal sales (Richardson et al., 2009). This is likely due to adolescents having other means of access to cigarettes (e.g., friends, parents; Fichtenberg, & Glantz, 2002). Increasing the minimum legal drinking age to age 21 in the United States was associated with reductions in adolescent alcohol use and disorder (Carpenter, Kloska, O'Malley, & Johnston, 2007). This effect of raising the minimum drinking age suggests that similarly raising the legal age to purchase cigarettes, which is 18 years old in most states, to 21 might reduce rates of adolescent smoking.

Cigarette, alcohol, and drug manufacturers devote substantial resources to promote their products, and there have been attempts to limit adolescent exposure to these efforts. In 1971 cigarette advertising was banned from radio and television. In 1998, the Master Settlement Agreement prohibited cigarette manufacturers from directly and indirectly targeting underage youth in advertising and promotions, and several manufacturers also agreed to limit advertising to magazines with less than 15% youth readership. In 2003, the alcohol industry agreed to limit advertising in television, magazine, and radio to venues where 70% or more of the audience was 21 years old or older. As noted earlier in our discussion of advertising exposure, these restrictions may be insufficient to impact adolescent smoking or alcohol use. In summary, policymakers can play a significant role in reducing adolescent substance use by using a multipronged approach. Effective policies are likely to include implementing public awareness campaigns, limiting access to tobacco and alcohol products by raising taxes on these products, expanding tobacco bans and raising the minimum age for purchase of tobacco products to 21, limiting youth exposure to tobacco and alcohol advertising, and expanding access to evidence-based prevention and treatment services.

CONCLUSIONS

As this chapter illustrates, studying the developmental psychopathology of substance use and substance use disorders is a complex and multidisciplinary endeavor that involves both broad pathways (not specific to substance use) that underlie behavioral and affective regulation and reactivity as well as consideration of pathways that are specific

to substance use effects. Epidemiological approaches illustrate the importance of societal-cultural contexts in influencing patterns of substance use prevalence. Epidemiological data speak to the need for continuing surveillance, including assessments of newly emerging substances, providing public health messages concerning substance use risk, and monitoring the potential for drug substitution effects. Studies of age-related trajectories of substance use speak to the risk associated with early onset of use, including the potential utility of delaying onset as a means of reducing the prevalence of substance use disorder. However, although substantial empirical work has focused on antecedents of substance use transitions in adolescence and emerging adulthood, there has been less application of a developmental psychopathology perspective to study substance use outcomes in midlife and later life. Age-specific etiological factors in mid-life and late-life (including the effects of role transitions) are in need of future study. Future research on aging samples is warranted, particularly because higher substance use among the baby boomer cohort forecasts increases in alcohol problems among older individuals

Studies of the internalizing and externalizing pathways illustrate the utility of many features of the developmental psychopathology perspective, including support for the principles of equifinality and multifinality, the importance of studying pathways of risk and resilience at multiple levels and the importance of developmental cascades. Studies of the externalizing and internalizing pathway converge with studies of substance use effects in pointing to adolescence as an important period of risk, both in terms of the neurobiology of adolescent brain development creating a period of vulnerability for risk-taking behavior in general and in terms of elevated sensitivity to substance use effects. However, these pathways also clearly demonstrate that the etiology of substance use disorders has roots in early development, and the internalizing and externalizing pathways point to the importance of early adversity, parenting, and family climate as well as pre-natal exposure and gene–environment interplay in the development of capacities for both behavioral and affective self-regulation. The internalizing and externalizing pathways thus support the importance of early family-based interventions as an approach to preventing later substance use and substance use disorder (as well as associated mental health problems). Mediators common to the internalizing and externalizing pathways (including parenting and family environment and affiliation with substance use-promoting peers) support the inter-relations between the two models. Methodological approaches including the use of experience sampling methods in real time, genetically informative designs, and greater specification of the roles of individual facets of behavioral undercontrol and of negative affect are useful future directions. Moreover, given variation in etiological influences with both age and stage of substance use, studies that allow greater specification of age and stage variation are important.

Studies of the etiological pathways related to substance use effects reinforce the importance of considering stages of substance use involvement including the transition from impulsive to compulsive use. These models also point to the possibilities of novel treatment interventions, both pharmacological interventions to counter substance use effects or counter the harms of substance use effects and behavioral interventions to extinguish automatic positive associations and approach responses. One important research agenda for the substance use effects pathways is to better understand the effects of adolescent exposure to substance use, particularly possible neurotoxic effects on cognitive functioning, self-regulation, reward sensitivity, and personality development. These studies should identify the dose–response relation between adolescent substance use and its potential sequelae and should specify the role of particular substances within the context of correlated risk factors (including the use of multiple substances). At the time of this writing (2013) substantial research efforts are underway to achieve this goal through prospective studies.

Studies of macrolevel social influences suggest that public policy can have substantial impact on reducing the population prevalence of substance use including the tax policy, restricting access (including the legal age of use), and raising public awareness. Future research is needed to understand the effects of public policy on various high-risk subgroups within the population and the potential for achieving targeted effects (particularly as applied to media campaigns).

Finally, one of the greatest needs revealed by this large and complex literature is the need to narrow the gap between our growing empirical understanding of the development of substance use disorders and the preventive and treatment interventions that are available to the public. Although evidence based interventions have been developed both for prevention and treatment, they are not routinely implemented or implemented at a large enough scale to have an impact on the public health. Given the significant public health burden of substance use disorders (including mortality, morbidity, and economic cost), emerging innovations in health care delivery systems and funding models should include the provision of evidence-based prevention and treatment interventions for substance use and substance use disorders as an important priority.

BIPOLAR DISORDER: CONCEPTUALIZED WITHIN A DEVELOPMENTAL PSYCHOPATHOLOGY FRAMEWORK

Developmental Psychopathology

The purpose of this chapter is to consider how a developmental psychopathology perspective can advance our understanding of the wide spectrum of bipolar disorders (collectively referred to as bipolar disorder throughout the text). Developmental psychopathology promotes an integrative scientific approach that emphasizes the importance of investigating normative and atypical developmental processes. This perspective contends that psychopathology is best understood by considering normative processes from which symptoms may arise (e.g., Cicchetti, 1990; Cicchetti & Toth, 2009; Sroufe & Rutter, 1984). Indeed, bipolar disorder "magnifies common human experiences to larger-than-life proportions" as individuals experience both the devastating lows of depression and the extreme highs of mania (Goodwin & Jamison, 2007, p. xix). Accordingly, it is critical to consider how individuals experience and adapt to derailments from normal development, ideally from a longitudinal perspective. Additionally, recognizing that psychopathology does not exist in a vacuum, the developmental psychopathology approach attempts to discern the process by which extreme variations in emotions and behaviors become maladaptive and disrupt the path of normative development. Developmental psychopathologists are interested in the critical biological and environmental factors that prevent individuals from reaching developmental milestones and those that help protect individuals who are at high-risk for mental illness. This approach assumes a dynamic interplay between salient neu-

robiological, environmental, and psychological systems, necessitating the understanding of transactional processes (Cicchetti & Tucker, 1994). Additionally, it is recognized that developmental liabilities are likely to constrain the ease of adapting to new developmental challenges, resulting in probabilistic tendencies toward maladaptive outcomes. Those at risk for or diagnosed with bipolar disorder in childhood and adolescence typically experience challenges that interfere with an individual's ability to master normative age-salient developmental tasks. Problems often arise in regulating strong emotions, forming meaningful interpersonal relationships, or developing a sense of competency based on mastery experiences. Manic or depressive symptoms can also limit an individual's intra- and interpersonal resources, preventing the individual from navigating critical developmental transitions encountered in childhood and laying the foundation for problems that persist into adolescence and adulthood. Fortunately, while these probabilistic tendencies are critical, they are not deterministic. We now know that development is malleable, meaning that similar developmental liabilities can result in multiple outcomes (Cicchetti, Rogosch, & Toth, 1997). Given these considerations, the developmental psychopathology approach is especially relevant to the study of youth at risk for bipolar disorder and those already exhibiting these disruptions early in development.

Despite the applicability of a developmental psychology perspective to the study of bipolar disorder, research from a developmental perspective has occurred relatively recently. In part, the slow growth of this field may reflect the slow pace of research on adult bipolar disorder during much of the twentieth century. Efforts to comprehensively compile the research on adult bipolar disorder weren't published until 1990 with Goodwin and Jamison's *Manic Depressive Illness: Bipolar Disorders and Recurrent Depression*. Additionally, the field has been slow to study bipolar disorder in youth, particularly in children. It is notable that in the two-volume second edition of Goodwin and Jamison's textbook (2007), the authors included two chapters on children and adolescents: one on the description of bipolar disorder in youth and one on its treatment. Significant advances were also made around this time with the publication of two other academic books describing current knowledge (Geller & DelBello, 2005) and treatment (Geller & DelBello, 2008) of pediatric bipolar disorder.

The focus on bipolar disorder from a developmental psychopathology perspective has been recent as well. Efforts to bring attention to the paucity of longitudinal research or work that used a developmental framework to directly examine risk factors of bipolar disorder (e.g., DelBello & Geller, 2001) continue to be largely relevant today. With a notable exception (Cicchetti & Toth, 1995b), the major developmental psychopathology handbooks have rarely included a discussion of bipolar disorder (e.g., Achenbach; 1982; Cicchetti & Cohen, 2006; Lewis & Miller, 1990; Luthar, Burack, Cicchetti & Weisz, 1997). There are a few major reasons why the developmental psychopathology focus on bipolar disorder has progressed rather slowly. First, developmental discontinuity has historically been emphasized in research on bipolar disorder, as in the *DSM-III*. As one researcher observed, "For decades the field operated as though bipolar disorder sprang fully formed from the brow of young adults" (Youngstrom, 2010, p. 68). Second, in the mid to late twentieth century, evidence from behavioral genetics indicated that the disorder was primarily caused by genetic factors. These findings likely obfuscated the environmental and developmental factors involved in the etiology of the disorder and helped foster the flawed impression that mental illness was deterministic—either something one had or didn't have—rather than a set of symptoms that can change over time, depending on one's environment, personality, and treatment. Relatedly, researchers have only recently acknowledged the importance of incorporating multiple levels of analyses into models of pathophysiology (Cicchetti & Dawson, 2002). Third, a proper developmental study of bipolar disorder demanded developmentally appropriate longitudinal research (including developmentally appropriate measures of mania and depression), which is both expensive and time-consuming. As a result, foundational research on bipolar disorder utilizing a developmental psychopathology framework has only been conducted relatively recently.

With this in mind, it is noteworthy that this is the first developmental psychopathology handbook series in which a chapter is fully dedicated to bipolar disorder. That is not to say that this chapter is the first work to outline the major themes and studies in the field. This chapter attempts to build on and complement seminal texts compiled by Miklowitz and Cicchetti that evaluated bipolar disorder from a developmental perspective and gave increasing prominence to the study of bipolar disorder in children and adolescents. These works, a special issue of *Development and Psychopathology* (Miklowitz & Cicchetti, 2006) and a similar collection of work that appear in the text, *Understanding Bipolar Disorder: A Developmental Psychopathology Perspective* (Miklowitz & Cicchetti, 2010), systematically addressed the (1) phenomenology and diagnosis, (2) onset, prognosis, and course, (3) etiology/risk and protective mechanisms, (4) treatment, and

(5) personal accounts of bipolar disorder. These recent efforts significantly advanced the field by showing that a multidisciplinary developmental approach to the study of bipolar disorder has important scientific and clinical applications, and can better help elucidate both normative development and the progression of the disorder. Some of the key themes discussed in these texts will be discussed, updated, and elaborated on in this chapter.

Chapter Overview

This chapter will use a developmental psychopathology perspective to review foundational and recent research on bipolar disorder, particularly research on risk and protective factors for the illness (Cicchetti, 1990). In the first section we discuss the phenomenology of bipolar disorder. As this is a field in which scientific controversies abound, we begin this section by discussing bipolar disorder in a historical context and the circumstances leading to the current *DSM* diagnosis for pediatric and adult bipolar disorder. We summarize major themes pertaining to clinical diagnostic approaches and emerging empirically derived approaches that focus on symptom manifestations. We also briefly discuss emerging approaches that deemphasize self-report and focus on dimensions of observable behavior and neurobiological indices. We close this section by summarizing the onset and course of the disorder. In the second section of this chapter, we consider etiological theories of the illness. Family aggregation patterns of bipolar disorder have been acknowledged for the past century, but recent advances are beginning to modify our understanding of the disorder's underlying environmental and genetic mechanisms. Here, we will describe the wide range of genetic and environmental etiological theories behind adult and pediatric bipolar disorder, with a special emphasis on the new technologies and scientific advances that are informing this research. Third, because bipolar disorder is considered a neurodevelopmental disorder, we will consider some of the most important neural mechanisms that have been implicated as potential precursors or are evident in youth who are diagnosed with bipolar disorder. Although the majority of neurobiological research has focused on adults diagnosed with bipolar disorder, the focus of this section will be on the advances relevant to developmental neurobiology and psychopathology, much of which have taken place in the past decade. While the neurobiological advances cover a broad range of fields (e.g., neurotransmitters, neurohormones, neuropsychology performance), we will primarily focus on brain imaging research. We conclude the chapter with suggestions for translational research by considering how our current knowledge of these developmental and neurodevelopmental models may inform intervention science and help identify promising new directions for future research.

At the onset of this chapter, a brief overview of the use of relevant terms is needed. Throughout this text, we will focus on bipolar disorder that includes the wider spectrum of bipolar disorders, commonly including bipolar I and II disorders and sometimes cyclothymic disorder and bipolar disorder not otherwise specified (NOS). When specific diagnoses are considered (e.g., bipolar I disorder), they will be specified accordingly. Although there are considerable differences in childhood and adolescent diagnoses of bipolar disorder, "pediatric bipolar disorder" will be used when referring to the disorder among children or adolescents. It is worth noting that pediatric bipolar disorder has no official definition in the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1994; 2013), but generally refers to individuals younger than age 18 years or those who have not yet transitioned to adulthood.

CLASSIFICATION AND PHENOMENOLOGY: HISTORICAL CONTEXT AND RECENT ADVANCES

Assessment and classification systems are critically important to scientific advances and clinical care because they powerfully shape research on the etiology, course, outcomes, and treatment of emotional and behavioral problems (Achenbach, 1982). Controversies pervade the mental health professions concerning the classification of severe mental illness, especially in regards to describing how symptoms unfold across development. The first section here provides a historical context for the clinical diagnosis of bipolar disorder in adults as well as in children and adolescents. Additionally, an overview of pediatric bipolar disorder briefly summarizes the assessment, prevalence, course, precursors, and treatment of the illness. A second section is dedicated to emerging phenotypic empirical models that incorporate dimensional approaches to describe and classify mental illness. Third, we briefly describe methods that are currently being explored to classify disruptions in dimensions of behavior and biological substrates that may advance our understanding of bipolar disorder.

Clinical Diagnostic Approaches

Diagnostic Criteria for Bipolar Disorders

The established references for determining the clinical diagnosis of bipolar disorder and other mental illnesses are the *Diagnostic and Statistical Manual* (*DSM*) in the

United States and the *International Classification of Diseases* (*ICD*) in other parts of the world (APA, 2013; WHO, 1992). Although these classification systems are periodically revised, many of the early nosological themes that originally defined bipolar disorder have persisted and continue to be used in clinical practice, as is the case with the recently published *DSM-5* (APA, 2013).

Bipolar disorder (sometimes called bipolar spectrum disorder) collectively refers to the disorders involving manic, mixed, or hypomanic episodes. In the *DSM-5*, bipolar disorders include bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder not otherwise specified (NOS), all of which are principally defined by the severity, duration, and frequency of mania rather than the characteristics of depression. In the *ICD-10*, narrower definitions for diagnosing bipolar disorder exist, which exclude bipolar II disorder and emphasize euphoria rather than irritability. The classification system that underlies the *DSM* and *ICD*, the medical model, serves to identify relevant symptoms, criteria for defining syndromes (a group of symptoms that occur together), and disease processes.

Compared with other psychiatric illnesses, bipolar disorder is unique in that it is characterized by two extreme, discrete mood states and accompanying clusters of symptoms, one of which is also found in major depressive disorder. The *DSM-5* primarily distinguishes bipolar disorder from depression on the basis of the presence of manic or hypomanic episodes. Mania, the defining feature of bipolar I disorder, consists of a cluster of symptoms lasting at least 7 days, including abnormally elevated, expansive, or irritable mood; inflated self-esteem or grandiosity; decreased need for sleep; pressured speech; racing thoughts; distractibility; increased goal-directed behavior or psychomotor agitation; and involvement in pleasurable activities that fail to sufficiently account for potential negative consequences (APA, 2013). Mania is associated with impaired functioning, which at times may be severe enough to result in psychosis, hospitalization, or incarceration. By contrast, hypomania (the defining symptom of bipolar II disorder and cyclothymia) involves an abnormally elevated, expansive, or irritable mood that lasts for 4 days with the presence of at least some of the other symptoms that define mania. While hypomanic symptoms must be severe enough to be observed by others, they are not present to the same degree and do not result in the same level of impairment as manic episodes.

Diagnosis of Bipolar Disorders in Adults

Core conceptions of melancholia and mania have been documented since Ancient Greece, beginning with Aristotle, Soranus of Ephesus, and Aretaeus of Cappadocia (reviewed by Goodwin & Jamison, 1990, 2007), and are largely similar to modern diagnostic criteria. Nevertheless, the major breakthrough in the diagnosis and categorization of bipolar disorder came at the turn of the twentieth century. Emil Kraepelin, considered the founder of modern scientific psychiatry, wrote an introductory textbook (1899), in which he described how psychotic illnesses can be differentiated into two categories: (1) manic depressive illness (now referred to as bipolar I disorder); and (2) dementia praecox (now referred to as schizophrenia). Kraepelin viewed manic depressive illness as a manifestation of recurrent endogenous affective illness. This view set the stage for the idea that bipolar disorder and unipolar depression are etiologically related disorders (Angst & Sellaro, 2000). It was not until the 1950s that the distinction between unipolar and bipolar depression gained popularity (Goodwin & Jamison, 2007), and this distinction was not formally incorporated into standard diagnostic criteria until the 1980s (with the *DSM-III*). Alongside the effort to separate bipolar disorder from depression, the subtyping of bipolar disorder became increasingly common in the latter half of the twentieth century, and ultimately led to the first formal classifications of bipolar disorder, cyclothymia disorder, and bipolar disorder NOS as independent subtypes of bipolar disorder in the *DSM-III* (1980). In early conceptualizations, hypomania could be present in cyclothymia disorder or bipolar NOS. The *DSM-IV* (American Psychiatric Association, 1994) introduced the additional category of bipolar II disorder, which was characterized by hypomania (as opposed to the full-blown mania that characterized bipolar I disorder). Although this categorical system has endured in the *DSM-5* (American Psychiatric Association, 2013), there continues to be considerable controversy regarding the characterization of hypomania and the etiological relationship between the different bipolar disorders (e.g., Merikangas et al., 2014).

Diagnosis of Bipolar Disorders in Childhood and Adolescence

Over the last several decades, there have also been important changes to the criteria for the diagnosis of bipolar disorder in children and adolescents. Although there is now undeniable evidence to suggest that bipolar disorder can develop prior to late adolescence or adulthood (Luby, Belden, & Tandon, 2010), the field continues to be fraught with intense controversy regarding the criteria for diagnosing these disorders in childhood and early adolescence. As noted by Goodwin and Jamison (2007), there is an important historical backdrop for these ongoing debates: beliefs about severe mental disorders during the first

half of the twentieth century were heavily influenced by psychoanalytic theory, which focused primarily on adult psychopathology. Disruptions in child development were of relevance primarily as explanatory mechanism for adult psychopathology and garnered little attention on their own behalf (reviewed by Faedda et al., 1995). A full consideration of childhood psychopathology was further hampered by the belief that cognitive developmental prerequisites were necessary for some types of psychopathology to emerge (Glovinsky, 2002). As a result, by the 1960s, there was considerable consensus among mental health professionals that bipolar disorders were limited to adults. This belief was reinforced by a prominent review article published by highly respected scientists who examined the available psychiatric literature between 1884 and 1954 and concluded, "The occurrence of manic depression in early childhood as a clinical phenomenon has yet to be demonstrated" (Anthony & Scott, 1960).

Starting in the 1980s, evidence slowly began to accumulate that refuted the widely held belief that bipolar disorder was exclusively an adult illness. Although there were notable differences in the symptoms of children versus adults, researchers encountered increasing numbers of children whose externalizing and internalizing behaviors were characteristic of adult bipolar disorder (Geller & Luby, 1997). These researchers identified a cluster of symptoms that were largely incompatible with other diagnoses, including elated mood, hypersexuality, grandiosity, and delusional thinking. At the same time, the scientific reports describing the clinical phenomenology of children with manic symptoms highlighted a number of crucial differences between adult and pediatric bipolar symptomatology that incited debate over the application of the diagnosis of bipolar disorder to children. For instance, in a 1997 review, Geller and Luby pointed out that children with manic symptoms most frequently displayed a nonepisodic, rapid-cycling, mixed-manic state and that they frequently exhibited comorbid disorders such as attention-deficit/hyperactivity disorder (ADHD) and conduct disorder (CD). These diagnoses were subsequently referred to as pediatric bipolar disorder, which attempted to signify the atypical developmental presentation of the disorder in children and adolescents.

There is considerable confusion and controversy as to which criteria are appropriate for use with children and adolescents when defining manic or hypomanic symptoms and episodes. The major issues of the debate are questions about the relationship between child development and mental illness: do the differences between childhood and adult-onset bipolar disorder reflect fundamentally different disorders, or do they share the same genetic and neural underpinnings and differ in presentation for developmental reasons? To address this question, Willcutt and McQueen (2010) identified five competing models of the relation between pediatric-onset bipolar disorder (PBD) and adult-onset bipolar disorder: (1) pediatric BD is not a valid diagnosis; (2) PBD and adult-onset BD are a single developmental disorder; (3) PBD and adult-onset BD are distinct disorders; (4) PBD is a more severe form of adult-onset BD; and (5) individuals with PBD and adult-onset BD both have significant comorbidities which may be best for characterizing the illness and prognosis of BD (for a similar model see Carlson, 2005).

Although it is unlikely that any one of these articulated models will be quickly validated (McClellan et al., 2007), newly emerging evidence regarding the biological, social, and psychological markers of pediatric bipolar disorder are already starting to shape the debate about how to best categorize and diagnose the illness. As outlined by Luby, Belden, and Tandon (2010), three efforts to define pediatric bipolar disorder have received the most attention. One approach typically referred to as a narrow definition for pediatric bipolar disorders entails strict adherence to the *DSM* criteria (e.g., Leibenluft, Charney, Towbin, Bhangoo & Pine, 2003). This approach emphasizes homotypic continuity across development and suggests isomorphic problem presentations in childhood, adolescent and adulthood. That is, this perspective suggests that children with bipolar disorder should have the same symptoms as adults and that these symptoms should not change as the child matures. This model also implies that the etiology of pediatric bipolar disorder is essentially identical to adult bipolar disorder. A second approach involves adherence to the *DSM-IV* criteria with the exception of a shorter duration criteria for mania in children (e.g., Geller et al., 2002). This model also suggests that pediatric and adult-onset bipolar disorders share an identical etiology and course, but stresses that childhood development prevents the expression of sustained episodic moods, which become visible only in adolescence and adulthood. This model attempts to incorporate evidence that many children with mania-like symptoms do not express the well-demarcated mood episodes that characterize adult bipolar disorder and suggests that developmental features should be more fully articulated in the definitions of pediatric bipolar disorder.

The third approach represents a broader definition of pediatric bipolar disorder, with less adherence to *DSM-IV* criteria, and the use of alternative criteria for pediatric bipolar disorder that would include severe irritability

and mood lability, rather than well-demarcated mood episodes (e.g., Biederman, Faraone, Chu, & Wozniak, 1999). Many youth that fit this broader definition of pediatric bipolar disorder may now be diagnosed with the new *DSM-5* disorder called disruptive mood dysregulation disorder (DMDD), which functions as an intermediary between pediatric bipolar disorder and problematic (but not disordered) behavior. DMDD allows children to be diagnosed with a disorder (and thereby receive treatment) who present some characteristic symptoms of mania, particularly severe irritability and hyperarousal, but who lack the well-demarcated mood episodes seen in bipolar disorder (Johnson & McGuinness, 2014; Leibenluft, 2011). By establishing DMDD and leaving the criteria for bipolar disorder largely unchanged (as noted previously the *DSM-5* does not have separate criteria for PDB), the *DSM-5* has largely maintained a strict definition of pediatric bipolar disorder. Further, by classifying DMDD as a depressive disorder rather than with the bipolar and related disorders, the *DSM-5* has responded to preliminary evidence that the two sets of symptoms, albeit similar, have unique etiologies (e.g., Leibenluft, 2011).

Phenomenology of Bipolar Disorders in Childhood and Adolescence

Research to date considering the assessment, prevalence, course, predictors and treatment of pediatric bipolar disorder have been plagued by the definitional controversies described already; some researchers have studied pediatric bipolar populations using a broad definition, whereas others have used a narrow definition. The heterogeneity of the patient populations with pediatric bipolar disorder (e.g., sometimes but not always including prepubertal children) has made it difficult to interpret research on the illness. Nevertheless, the preponderance of available evidence relies on these diagnostic systems (and the varied ways that pediatric bipolar disorder has been defined) and provides a starting point for future research that is more agile at attending to developmental psychopathology principals in understanding the phenomenology of pediatric bipolar disorder.

Assessment. Given the current uncertainty and disagreement over the diagnostic criteria for pediatric bipolar disorder, the development and use of empirically validated, developmentally sensitive assessment tools for children will greatly enhance our understanding of the illness. Currently available assessment tools are limited in that virtually all of them are downward extensions of measures used to assess symptoms or diagnose adults with bipolar disorder. As a result, these measures are often inapplicable to the symptoms of children and do little to enhance our understanding of their thoughts, emotions, and behavior that fall outside of the specific *DSM* or *Structured Clinical Interview for the DSM* (SCID) criteria (Luby, Belden, & Tandon, 2010). This is especially important given that in clinical practice, the clinical interview is the most commonly used approach to assess and diagnose individuals of all ages with bipolar disorder. In research settings, semistructured and structured diagnostic assessments are typically used, with the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS; Kaufman et al., 1997) being the most commonly administered measure to children.

A few assessment measures are starting to use developmentally adjusted criteria. One is the Washington University version of the KSADS, which asks patients for information about symptoms beyond those in the *DSM* but does not require that all symptoms be presented simultaneously to qualify for the diagnosis of a bipolar disorder (Geller et al., 2002). Similarly, the modified Preschool Age Psychiatric Assessment (Luby & Belden, 2006; Luby, Belden, & Tandon, 2010) has developmentally adjusted diagnostic criteria that are designed to distinguish between other common problems (e.g., ADHD). Importantly, there is strong evidence of reliability and validity when narrow definitions of bipolar disorder are used to diagnose adolescents (and potentially children) using these structured diagnostic interviews (Findling et al., 2001; Youngstrom, Birmaher & Findling, 2008).

In addition to diagnostic interviews, questionnaires and checklists may provide information about a range of behaviors relevant to bipolar disorder (as reviewed by Fristad & Algorta, 2013; Johnson, Miller, & Eisner, 2008; Youngstrom, 2007). Some adult checklists that evaluate symptoms of adult bipolar disorder have been applied to children and adolescents, including self-report and parent-report versions of the Young-Manic Rating Scale (Fristad, Weller, & Weller, 1992). Parent and child reports of the General Behavior Inventory (Youngstrom, Findling, Danielson, & Calabres, 2001) have been useful for identifying bipolar symptoms, however, other broad-based psychopathology scales have been shown to address the bipolar phenotype with more limited success (e.g., Bipolar Phenotype of the Child Behavior Checklist; Diler et al., 2009; Faraone et al., 2005). Finally, some specific indexes have been developed including the Child Bipolar Questionnaire, the Child Mania Rating Scale, and the Mood Disorder Questionnaire for Adolescents. Although development of these assessment tools continues, advances in understanding bipolar disorder within the

broader context of psychopathology are likely to inform future measurement tools for pediatric bipolar disorder. Alternatively, Youngstrom (2010) recently proposed an approach to assessment that considers key developmental tasks involved in emotional development and motivational systems. As the field evolves and more is learned about the developmental progression of bipolar disorder, it will be useful to combine the use of more established assessment approaches with more experimental efforts to bridge our understanding of developmental psychopathology of the illness. Many of these themes and controversies inherent to assessment bear out as other aspects of phenomenology are characterized.

Prevalence. Prevalence estimates show that severe mental illnesses such as bipolar spectrum disorder are rare but still represent a significant societal cost (e.g., Kleinman, Lowin, et al., 2003). Although the lifetime prevalence of bipolar I disorder among adults is only around 1.3%, bipolar spectrum disorders occur in 3–7% of the population (Akiskal et al., 2000; Kessler, Chiu, Demler, & Walters, 2005; Soutullo et al., 2005), and are "responsible for the loss of more disability-adjusted life years (DALYs) than all forms of cancer or major neurologic conditions such as epilepsy and Alzheimer's disease, primarily because of its early onset and chronicity across the life span" (Merikangas et al., 2011, p. 241). In contrast to the well-documented prevalence of adult bipolar disorder, there is a dearth of clear epidemiological data on the frequency of pediatric bipolar disorder. Epidemiological studies suggest that pediatric bipolar disorder (ages 6–18) occurs at a rate of between 1 and 2.9%, and subthreshold symptoms occur with a frequency of around 4% to 6% in the United States population, roughly the same prevalence as adult bipolar disorder (Lewinsohn, Klein, & Seeley, 1995; Merikangas al., 2010; Soutullo et al., 2005). In one of the only large-scale epidemiological studies that assessed bipolar disorder in children and adolescents (Kim-Cohen et al., 2003), the rate of bipolar spectrum disorder was 3%. The incidence of bipolar disorder in prepubertal children has not been precisely determined but is thought to be lower than that of postpubertal populations (Ghaemi & Martin, 2007; Luby, Belden, & Tandon, 2010). Although these rates are likely to change as advances are made characterizing bipolar disorder in children and adolescents, they provide a starting point to understand the scope and societal impact of this severely impairing problem.

There are a number of reasons for the difficulty researchers have had in determining the prevalence of bipolar disorder in youth, including methodological limitations, sample identification issues (e.g., complications associated with diagnosing bipolar disorder in youths) and clinical bias (e.g., limitations in developmentally sensitive measures). One major problem has come from the unparalleled rise in the diagnostic rates of bipolar disorder among youth. In a community setting in the United States, there was a 40-fold increase in the diagnosis of bipolar disorder in children and adolescents between 1994 and 2003 (Moreno et al., 2007). This dramatic increase has led many clinicians and researchers to question the validity of the bipolar disorder diagnostic criteria for children (e.g., Leibenluft & Rich, 2008), which has complicated estimates of the disorder's prevalence among youth. Likewise, the sizeable variation in prevalence rates between countries has also undermined efforts to determine the true prevalence of pediatric bipolar disorder. This variance is especially pronounced between the prevalence of pediatric bipolar disorder in the United States and Europe (Soutullo et al., 2005). For instance, American hospital discharge rates for pediatric bipolar disorder were 12.5 times higher than those in England (James et al., 2014). And while the prevalence of pediatric bipolar disorder in an American clinic was 4%, the rate was only 1.2% in Denmark and 1.7% in Finland (Soutullo et al., 2005). As some authors have pointed out (e.g., Stringaris & Youngstrom, 2014; Soutullo et al., 2005), these data do not necessarily mean that the true prevalence of pediatric bipolar disorder varies between countries. Rather, the differences could be due to administrative prevalence such as diagnostic practice, clinician bias against pediatric bipolar disorder in Europe, or overdiagnosis in the United States, and not primarily genetic or environmental factors. Thus, it is still extremely difficult to determine how the true prevalence of pediatric bipolar disorder varies between countries, as each nationality seems to have a unique definition of the illness.

Onset and Course. One key finding is that the onset of bipolar disorder commonly occurs during adolescence and even childhood. In retrospective research studies on adults with bipolar disorder, participants commonly report that problems were first evident in adolescence, and a smaller number report symptoms dating to childhood (Lish et al., 1994; Meyer & Carlson, 2010). Accordingly, two, three, and sometimes four distinct onset ages for bipolar disorder have been identified (Grigoroiu-Serbanescu et al., 2014). One cluster is in midadolescence (age of onset below 18 or 22, depending on the study). A second age of onset is in the mid-20s to 30s. Indeed, most (e.g., 85%) of individuals who will develop bipolar disorder do so before age 35 (Lin et al., 2006). Late onset is typically defined as an onset

after age 35 or 40. Data from prepubescent children are sparse but could potentially represent an additional cluster (see reviews by Bauer et al., 2014; Meyer & Carlson, 2010).

Some researchers are starting to argue that the age of onset is one of the most important clinical features of bipolar disorder, but more studies are needed to show whether each age-of-onset accompanies a unique set of symptoms or even a unique etiology (Meyer & Carlson, 2010). A recent systematic review did not find robust evidence of significant differences in the genetics of early-onset bipolar disorder compared to adult-onset BD, but pointed out that most studies in this field have been underpowered (Kennedy, Cullen, DeYoung & Klimes-Dougan, 2015). Saying that, it has been well-documented that an earlier onset is associated with a worse outcome for the disorder, including greater severity of depression and mania, greater drug and alcohol abuse, greater number of episodes, more rapid cycling, higher suicide rates, and fewer days euthymic (Lin et al., 2006; Post et al., 2010; reviewed by Diler, Birmaher, & Miklowitz, 2010; Luby, Belden, & Tandon, 2010; Meyer & Carlson, 2010). In fact, prepubertal onsets have a poorer prognosis than postpubertal onsets and the adolescent-onset group tends to have poorer functional outcomes than the adult onset group, including higher and more severe rates of psychosis (Perlis et al., 2004) and higher rates of rapid cycling, comorbidity with anxiety, substance abuse, alcohol abuse, and suicide attempts (Lin et al., 2006; Ortiz et al., 2011). One potential cause of the poorer prognosis of early-onset bipolar disorder is its frequent comorbidity with ADHD and conduct disorders (Masi et al., 2006, 2008). There is growing evidence that prognosis is more guarded in the presence of other psychiatric disorders, substance use disorders, and early stress and trauma (reviewed by Goldberg, 2010). This trajectory is largely consistent with core principles of developmental psychopathology that highlight the importance of mastery of developmentally appropriate tasks relevant to cognitive, social, and emotional functioning (Cicchetti & Toth, 1995). Indeed, early failures to master these developmental tasks set a probabilistic course for a more deleterious outcome. Although the etiological relationship between early-onset bipolar disorder, ADHD, and conduct disorders is not fully understood, there is initial evidence that the pediatric bipolar disorder-ADHD subtype represents a distinct disorder with a somewhat independent genetic origin, as will be discussed in the Etiology section of this chapter (Biederman et al., 2013).

In addition to patterns in the onset-age of bipolar disorder, there are also some general patterns that are evident regarding the course of the disorder. For starters, bipolar disorder is an episodic disorder. There is a high probability (70–100%) that children and adolescents with bipolar disorder will recover from an index episode (reviewed by Diler, Birmaher, & Miklowitz, 2010), although only around 40% will return to premorbid functioning levels (reviewed by Goldberg, 2010). The process of stabilization has been found to take about nine months for bipolar I and II (Birmaher et al., 2006).

There is also evidence to suggest that different outcomes are associated with the type of mood episode that individuals first experience. A manic onset tends to have a predominately manic course while a depressed onset tends to have a predominately depressed course. A manic onset typically tends to have a better prognosis than a depressed onset (Forty et al., 2009; Perugi et al., 2000). There is also evidence that the ratio of depressive to manic episodes increases with age (Judd et al., 2002). These data suggest that the etiology of the disorder is more complex and varied than the current diagnostic criteria allow. If anything, one could reason that a manic-onset bipolar disorder would have some notable genetic and neurobiological differences from the depressed-onset bipolar disorder. More research is needed to more fully identify these different subtypes of the disorder (and to identify their relationship to bipolar I and bipolar II disorder).

Manic and depressed episodes are typically recurrent and relapses are common among adolescents and adults with bipolar disorder (as reviewed by Diler, Birmaher, & Miklowitz, 2010). Up to 75% of these youth will experience one or more recurrences within 2 to 8 years after their first diagnosis. Additionally, specific patterns of relapse are evident. For example, youth diagnosed with bipolar I disorder typically have recurring mania or hypomania. Youth diagnosed with bipolar II, cyclothymia or bipolar NOS tend to have more frequently recurring depressive (rather than manic) episodes. It becomes increasingly rare that depression will convert to bipolar disorder through the early to midadult years.

Another major finding from epidemiological research is that the prevalence, onset, course, and prognosis of the disorder differ between males and females (reviewed by Alloy, Abramson, Walshaw, Keyser, & Gerstein, 2006; Baldessarini, Tondo, & Visioli, 2014). In adults, there are no gender differences in the rate of bipolar I disorder, but women are more likely than men to be diagnosed with bipolar II disorder. The course of the disorder also differs considerably for each gender (Baldessarini, Tondo, & Visioli, 2014). Bipolar disorder in women is characterized by a predominantly depressive course, and they are more likely to have a first episode of depression. In contrast,

men are more likely to be characterized predominantly by a manic/hypomanic course and to have a first episode as a manic/hypomanic episode. Bipolar disorder has been found to have an earlier onset in men than in women (Grant et al., 2005), perhaps indicating that gender may moderate prognosis and long-term outcomes. But while men are more likely to have a prepubertal onset, adolescent-onset bipolar disorder tends to affect men and women relatively equally (Birmaher et al., 2009). In adolescence but not adulthood, young men are also more likely to recover from the first manic episode than are young women (DelBello, Hansemann, Adler, Fleck, & Strakowski, 2007). Considerable progress has been made in characterizing bipolar disorder in youth and with refinement of existing conceptualization and assessment practices we are optimistic of the advances that are likely to be made to this current knowledge base.

Prodromes and Precursors. One of the most critical contributions of developmental psychopathology is its emphasis on considering the progression of problems as they unfold across development. A growing number of researchers are using knowledge about the course of bipolar disorder to find ways to detect the onset of the disorder before the major symptoms are apparent. These researchers have employed a number of approaches to detect prodromes of the disorder, and some have proven to be more successful than others. Although one of the most popular is the retrospective identification of prodromes, these approaches are limited in that biases and lapses in memory are likely to significantly influence the findings. To overcome this limitation, some researchers have reviewed medical records to identify early signs of the illness. Better yet are prospective longitudinal research studies, which provide a more definitive approach to identifying the specific prodromes that increase the risk of bipolar disorder. These studies typically focus on groups at high-risk for developing the disorder, including the offspring of bipolar parents and relatives of affected individuals. Most the studies consider childhood or adolescent precursors of adult bipolar disorder and less information is known about the precursors to pediatric-onset bipolar disorder. Although the attention given to prodromes for bipolar disorder has been relatively recent, this work has critical implications for translational efforts. The neurobiological precursors to bipolar disorder will be addressed in Section IV, but in this section we briefly discuss evidence of emotional and behavioral precursors to pediatric and adult-onset bipolar disorder.

Virtually all of the symptoms of bipolar disorder may be evident early in the life span, long before a formal diagnosis of the disorder is made. There is considerable evidence that depression, and to a lesser degree, hypomania is a common precursor of bipolar disorder in adults (e.g., Baldessarini, Tondo, & Visioli, 2014). One retrospective study found that subthreshold manic and depressive symptoms characterizing the prodrome were present for an average of 10 months prior to the onset of adolescent bipolar I disorder (Correll et al., 2014). A chart review of child and adolescent medical records was conducted on bipolar adults (Scott-Gurnell et al., 2014). As children, these adult patients generally manifested a range of symptoms that resembled forms of hypomania or mania. However, elevated mood was not typically part of the presentation; rather, anxiety and irritability were more prominent. Despite the similarity of symptoms, only 23% had been diagnosed with bipolar disorder in childhood. Some of these differences may be attributed to developmental trajectories associated with different types of bipolar disorder (Baldessarini, Tondo, & Visioli, 2014). That is, patients with bipolar II were most likely to present initially with depression (77%) while patients with bipolar I were likely to present initially with depression (46%) as well as psychosis or mania (13 to 22%).

There is growing evidence that both homotypic and heterotypic continuity are evident in bipolar disorder (Rutter, Kim-Cohen & Maughan, 2006). Over the past decade, Duffy and her colleagues have continued to revise a model in which bipolar disorder is shown to evolve through a series of phenotypically different clinical stages for bipolar disorder in adolescence (Duffy, 2010, 2013). These authors proposed a clinical staging model of bipolar disorder, suggesting that the early natural history of bipolar disorder unfolds in a series of predictable clinical stages. In Duffy's (2010) first model, in childhood there was a progression from asymptomatic (well) status to the nonmood disorders (e.g., significant anxiety, sleep, or neurocognitive disturbances such as attention deficit disorder, learning disorders, distortions in reality testing). In adolescence, these problems resulted in minor or major mood disturbances, depression, and eventually mania. Additionally, substance abuse was evident during or after the mood disturbances. Subsequently, these authors have focused more extensively on the role of early anxiety in this developmental progression (Duffy et al., 2013). Most recently, they proposed that offspring of lithium responders are more likely to show the earlier identified progression, in contrast to the offspring of lithium nonresponders who were more likely to have a more varied early course characterized by neurocognitive disturbances and develop psychotic disorders (Duffy et al., 2014). Klimes-Dougan and colleagues have

recently elaborated on key factors of this model that more centrally implicate disturbances in reality testing and other indexes of neurocognitive disturbances. For instance, they have documented differences in thought problems and neurocognitive deficits in offspring of bipolar and unipolar parents (Klimes-Dougan et al., 2006, 2013; Narayan, Allen, Cullen, & Klimes-Dougan, 2013) and evaluated thought problems as precursors of bipolar disorder and other psychotic problems (Klimes-Dougan et al, 2013; Meyer et al., 2004).

Finally, there is growing evidence that youth with bipolar disorder NOS (i.e., subthreshold bipolar symptoms) show a high risk of converting into bipolar I or II disorder. Although hypomanic symptoms in adolescence are common, transient, and typically not predictive of subsequent psychopathology (Tijssen et al., 2010), there is growing evidence that bipolar NOS is a prodrome of pediatric bipolar disorder. One study found that 33% of youth with bipolar NOS converted to bipolar I or II over an 18-month period (Martinez & Fristad, 2013). Another study found that 45% of youth with bipolar NOS converted to bipolar I or II within a 5-year period (Axelson et al., 2011). Although no specific symptom patterns were predictive of conversion, in both studies, a significant family history for bipolar disorder predicted conversion. Nevertheless, given the paucity of longitudinal research that has tracked illness trajectories, these existing models await further revision and elaboration.

Treatment. Intervention research on youth with bipolar disorder has been largely based on traditional phenotypic categorical models of the disorder. There has been considerable controversy around the treatment of these children and adolescents, especially regarding the administration of psychiatric medications to young children (Geller & DelBello, 2008; Luby, Belden & Tandon, 2010). Although substantially less intervention research has been conducted on youths than on adults, the results show some similarities and some differences across development. Unlike psychopharmacological treatment in adults, in which mood stabilizers like lithium or valproate are considered the first-line of therapy (APA, 2002), antipsychotic medications are not typically the first-line medications in children and adolescents. Additionally, antidepressant medications are used in both populations, although there remain concerns about the possibility of antidepressant-induced manic episodes (Correll, Sheridan, & DelBello, 2010). Undoubtedly, more research is needed to determine how to maximize symptom relief while minimizing side effects.

Psychosocial intervention is also highly recommended for youth with bipolar disorder. These interventions are not only essential for minimizing the burden of antipsychotic medications but also for maximizing recovery (e.g., McClellan, Kowatch, & Findling, 2007). Significant progress has been made in the last 10 years in developing and validating psychosocial interventions for bipolar youth (reviewed by Fristad & Algorta, 2013; Miklowitz & Goldstein, 2010). Family-based treatments (e.g., multifamily psychoeducational psychotherapy, family-focused therapy) show the most promise for effectively treating bipolar disorders in youth. There is some evidence noted for individual therapies, including cognitive behavioral therapy, however most other individual therapies (e.g., dialectic behavioral therapy) are currently undergoing efficacy trials and continue to be considered exploratory. Finally, there is growing interest but virtually no empirical support for complementary and alternative treatments (CATs) including supplements of vitamin D and fatty acids. Virtually all of the findings to date are based on relatively small-scale clinical trials. In summary, pharmacological and psychological interventions show some efficacy in the treatment of bipolar disorder in youth. Yet findings often show that remission rates are highly variable, suggesting that the continued development of treatments should be a high priority for this field and that exploring personalization of treatment options may be fruitful.

Empirical Approaches

Dimensional Approaches: Considering Symptoms and Clusters of Symptoms

There are emerging empirical approaches for understanding the broader taxonomic structure of psychopathology and symptom aggregation. It is hoped that these models will help clarify the taxonomic relationship between mental illnesses based on empirical evidence, statistical modeling, and etiology, rather than on consensus among researchers. Empirically based models of illness should enable clinicians to conceptualize, assess, and treat illnesses based on the way specific clusters of symptoms naturally develop, rather than through the artificially defined categories of disorders used by the *DSM* (Krueger & Markon, 2011). In light of the debate over the relationship between pediatric and adult bipolar disorders, these models pose special relevance for the developmental psychopathology of bipolar disorder. Indeed, many empirical approaches were first tested within the context of early developmental psychopathology research. These approaches were only later applied to adult psychopathology, including bipolar

disorders. While these empirical approaches have greatly advanced phenotypic classification systems for behavioral and emotional problems by providing a parsimonious model of symptom patterns, the evidence has not fully determined how well these approaches further the classification of severe mental illness, problems characterized by an episodic course, and symptoms of mania and depression across development.

In the 1970s, Achenbach and colleagues (Achenbach & Edelbrock, 1978) pioneered the use of empirical methods to validate dimensional taxonomies for common childhood emotional and behavioral problems. Their empirical classification approach developed a hierarchical-dimensional model of first-order factors (initially termed *undercontrol* and *overcontrol* but eventually called *internalizing* and *externalizing* behaviors) and second-order factors (e.g., social withdrawal and aggression; Achenbach, 1992). Although some second-order factors loosely mapped onto specific disorders identified in the *DSM* (e.g., conduct disorder symptoms), the model contended that common emotional and behavioral problems existed on a spectrum of internalizing and externalizing behaviors, rather than inside of discrete categories. They also established thresholds demarcating clinical significance for extreme problems and emphasized the value of understanding the full profile of the child's problems rather than any one problem by itself. Thus, this method represents an important early effort to address many of the challenges our current classificatory systems face in categorizing co-occurring problems or comorbid diagnoses. Although these approaches to identifying problem status were initially thought to be most applicable to the developing organism (given the belief that, by adulthood, disease processes were more firmly differentiated and would lead to the symptoms identified in established diagnostic systems; Nottelmann & Jensen, 1998), many now believe that dimensional approaches are equally relevant to adult psychopathology.

It was not until the 1990s that significant progress was made in developing taxonomies for adult disorders that were more encompassing, including those highly relevant to bipolar disorder (e.g., Mineka, Watson, & Clark, 1998). One major advance came from efforts to use quantitative hierarchical models to map the broader array of adult psychopathology along a dimensional spectrum (e.g., Krueger, 1999; Krueger & Markon, 2006). Like the models with children, these hierarchical-dimensional models consist of higher order factors of internalizing and externalizing problems in adults and second-order factors for internalizing problems (distress-based and fear-based problems), rather than the more standard groupings of anxiety and mood problems used by the DSM. This finding with respect to higher order factors has been replicated repeatedly, and the internalizing–externalizing spectrum has become a well-validated tool to model the taxonomic relationship of many common mental illnesses and comorbidities (Kessler et al., 2011). More recently, Krueger and Markon (2011) argued that dimensional-spectrum models of mental illness can also incorporate low prevalence symptoms and complex disorders (e.g., psychosis). In the following section, we discuss more specifically how these models might be relevant to bipolar disorders.

Dimensional Approaches Relevant to Bipolar Disorder

Despite the growing prominence of dimensional-spectrum models of mental illness, most models have focused on common Axis I or Axis I and II symptoms, syndromes, or disorders. In this body of work, the bipolar disorders are generally not represented or underrepresented for a variety of reasons (e.g., the difficulty of assessing mania and psychosis by lay interviews; Kessler et al., 2011; Markon, 2010). As we will summarize, efforts to taxonomically model the symptoms of bipolar disorders have been made using hierarchical and person-centered analytic approaches. The person-centered method of latent class analysis (LCA) assigns individuals to subtypes based on the similarity of their diagnostic profiles. In contrast to factor analysis, LCA can better accommodate phenomena with low base rates.

Consistent with the *DSM* tradition of defining bipolar disorder as a mood disorder (e.g., *DSM-IV*), some researchers have argued that bipolar disorder, particularly the depressive phase of the illness that is predominant for many individuals, fits within the internalizing problem spectrum. Watson revised some of his earlier models and proposed a quantitative hierarchical model for the *DSM-5* which was modified from his tripartite model of depression and anxiety (Watson, 2005). In this model, bipolar disorder had identical loadings on fear, distress and externalizing factor structures, which Watson used to argue that bipolar disorders should be kept as a third diagnosis subclass (along with distress and fear disorders). Keyes et al. (2013) evaluated the meta-structure of Axis I and II disorders using exploratory and confirmatory factor analyses. This study identified a thought disorder factor that, along with fear and distress disorders, was a subdomain of the internalizing dimension. However, both mania and bipolar disorder type I and II exhibited notable associations with the distress and thought disorder subdomains.

Indeed, a growing number of researchers have argued that the bipolar disorder would be more accurately placed in a psychotic or thought disorder spectrum, though they admitted that this placement is far from perfect (Goldberg, Andrews, & Hobbs, 2009; Kotov, Chang, et al., 2011; Kotov, Ruggero, et al., 2011). Some of the most compelling research supporting this position comes from high-risk samples, in which the bipolar disorders are better represented than in epidemiological samples. Kotov, Ruggero, et al. (2011), for example, tested groupings of 25 target disorders on outpatients seeking psychiatric treatment. They found that the best-fitting model of psychopathology was a five-factor hierarchical model composed of internalizing, externalizing, somatoform, antagonism, and, most relevant here, thought disorders (which included psychosis, mania, and cluster A personality disorders). The authors argued that mania shared unique features with these other disorders, including frank psychosis, disorganized thoughts, tangential speech, and bizarre behavior. And like the review by Goldberg, Andrews, and Hobbs (2009), Kotov, Ruggero, and colleagues (2011) admitted that there were notable dissimilarities between the bipolar disorders and the other thought disorders that will require further study. These differences included the negative symptoms of schizoid personality disorder and schizophrenia which are absent in mania, and differences in the early environmental adversities, biomarkers, and course of the disorders. Goldberg et al. (2009) went so far as to argue that bipolar disorder could be viewed as an independent cluster, though the review only compared bipolar disorder to two other disorders, and did little to situate the disorder within the broader range of psychopathology.

Using a person-centered method of latent class analysis, Vaidyanathan, Patrick, and Iacono (2011, 2012) found a five-class model of psychopathology that best fit data from a large epidemiological sample ($n = 5{,}877$). This study was notable for two reasons. Using LCA, the authors largely replicated previous models of externalizing and internalizing (fear and distress) disorders. Second, the authors found that bipolar I disorder is part of a unique cluster of disorders which the authors called the multimorbid class (due to limitations in the epidemiological survey, only bipolar disorder I was considered in the study). This class, representing 3.95% of the sample, also includes the nonaffective psychoses (schizophrenia, schizoaffective disorder, schizophreniform disorder, delusional disorder, and others). What sets this model apart from the research discussed above is that the multimorbid class does not fit exclusively within an internalizing, externalizing, or psychotic class, as other researchers posited. Rather, individuals in the multimorbid class had the highest rates of nearly all psychiatric disorders, including most internalizing, externalizing, and psychotic disorders. This helps explain why the bipolar disorders are extremely difficult to classify. While more research and larger samples will be needed to fully clarify the taxonomic placement of the bipolar disorders, current research has shown that the disorders have substantial overlap with other forms of psychopathology and have an unusual relationship to other internalizing and externalizing disorders. Although these models stand in contrast to Kraepelin's (1921) influential clinical observations and dichotomized nosology of manic-depressive insanity and dementia praecox (schizophrenia), they were predicted by early researchers like Bleuler (1924) who emphasized some of the similarities between bipolar disorder and other psychotic disorders. Some exciting new work on the structure of positive emotion will warrant further examination as experience seeking, but not joviality (which is closely linked with life satisfaction), is positively linked with manic and externalizing symptoms (Stanton & Watson, 2014). Further advances in taxonomies and classification serve as a foundation for advancing our understanding of the prevalence, incidence, course, and treatment of bipolar disorders across all ages.

Neuroscience-Informed Approaches to Understanding Psychopathology

Using existing diagnostic classification systems, the field has focused on identifying biomarkers and endophenotypes for bipolar disorder. Biomarkers are measurements that quantify specific biological processes involved in an illness, and they can be used to aid in diagnosis and in tracking disease progress. Ideally, biomarkers would enable clinicians to definitively diagnose an illness by finding neurobiological abnormalities that only exist in one specific disorder. Biomarkers would also have the potential to help revise psychiatric classification systems by defining disorders based on tangible, quantifiable criteria, rather than on the presentation of various symptoms. A review of the available research suggested that mechanisms associated with risk for bipolar disorder may involve abnormalities in frontal-limbic circuitry as well as peripheral biomarkers (e.g., oxidative stress, inflammation and) and genetic biomarkers (e.g., genes involved in calcium ion channels, circadian rhythm, and cell growth; Frey et al., 2013). Some caution is needed in taking this approach, as the use of any individual biomarker is likely to have insufficient explanatory power for susceptibility for bipolar disorders. Despite these important leads, neuroscience research has

come up against some significant challenges in the search for reliable biomarkers of bipolar disorder. One major challenge is that the clinical phenotype is highly complex and somewhat heterogeneous, and it has been difficult to link symptoms and neurobiological abnormalities with their genetic origins. One approach that does not rely primarily on traditional categorical definitions of bipolar disorder is that of endophenotypes. Endophenotypes are conceptualized as intermediates between genes and symptoms or syndromes. They include neurocognitive, neurochemical, neuroanatomical, and endocrine traits that are thought to have a simpler and more specific genetic basis than the whole illness. Gottesman and Gould (2003) identified five criteria that a trait must have to be considered an endophenotype. They contend that an endophenotype is (1) associated with a specific illness; (2) heritable; (3) state independent but age adjusted (i.e., it is still present even when the illness is remitted but it is dependent on the individual's age and development); (4) inherited together with the illness in families; and (5) identified in the relatives of an affected proband at a higher rate than in the general population. Beyond offering researchers more basic, homogenous traits to study (which should have clearer genetic and neurobiological etiologies), endophenotypes could eventually allow clinicians to identify at-risk populations before they experience a mood episode. As discussed briefly later in the chapter, specific neuropsychological deficits in attention, working memory, verbal memory, and executive functioning could constitute possible endophenotypes for bipolar disorder.

Other approaches also do not rely primarily on traditional categorical definitions of bipolar disorder. Recent initiatives have encouraged a shift in new research toward examining dimensions of behavior and underlying neurobiological substrates that characterize features or mental illness, independent of *DSM* diagnoses (e.g., Hyman & Fenton, 2003; Insel, 2009; Morris & Cuthbert, 2012). Major governmental funding in the United States through the National Institute of Mental Health (NIMH) is now supporting and promoting a move to reconceptualize mental disorders within these research domain criteria (RDoC). The goal of RDoC is to enhance understanding of the etiology of diseases and to develop more effective prevention and interventions. RDoC essentially serves to uncouple research from clinically familiar categories to focus on fundamental mechanisms of psychopathology (Sanislow, Pine, Quinn, et al., 2010), though there is little consensus as to how researchers can best do this (Insel, Cuthbert, Garvey, et al., 2010). The NIMH has identified five domains of core relevance and invited the scientific community to measure, develop, and revise these domains to promote scientific advances in this field: positive valence systems, negative valence systems, cognitive systems, systems for social processes, and arousal and regulatory systems. The units of analysis to characterize these domains include genes, molecules, cells, neural circuits, physiology, behavior, self-reports, and paradigms. Although RDoC is a very recent initiative, its underlying philosophy shares some similarities with developmental psychopathology: evaluating multiple units (or alternatively referred to by some as multiple levels) of analysis has been heralded as one of the most important features of developmental psychopathology research (Cicchetti & Dawson, 2002). While these RDoC approaches are just beginning to be applied to research relevant to bipolar disorder (Fristad & Algorta, 2013), existing multidisciplinary research serves as a foundation for identifying the etiology and course of the illness and could help to guide RDoC research on bipolar disorder. An example is work by Urosević, Abramson, Alloy, et al. (2010), who considered an aspect of the positive valence system in their behavioral approach system (BAS) dysregulation model across individuals with more broadly defined bipolar disorders, including bipolar disorder not otherwise specified. These efforts are directed toward more fully understanding larger patterns of atypical functioning across both dimensions of behavior and biology, as well as more specific mechanisms of pathological conditions. With this knowledge, it is hoped that interventions can be developed that more directly target these core disturbances.

ETIOLOGY OF BIPOLAR DISORDER

Like most mental disorders, the specific causes of bipolar disorder are still unknown. However, beginning with the detailed family aggregation patterns observed by Kraepelin, researchers have considered bipolar disorder to be primarily a genetic condition. It has nevertheless been a long journey fraught with many disappointments to identify the specific genetic underpinnings of the illness. No longer saddled with the illusion that simple genetic models can fully account for the course and onset of the bipolar disorders, researchers are now beginning to embrace the complex interactions between development, biology, and environment that affect risk and protection.

Environmental Theories of Bipolar Disorder

Historically, environmental and biological etiological theories of the bipolar disorders have been considered separately, with less emphasis being placed on the environmental causes of the illness. Current models are beginning to acknowledge the critical importance of both environmental and genetic etiological factors, particularly in regard to the role development plays in mediating the interaction of genes and environment. As a prominent researcher noted, only viewing bipolar disorders in biological terms is inadequate in that "genetic and biological processes are unable to fully account for differences in the expression, timing, and polarity of symptoms" (Alloy et al., 2005, p. 1,044). It is now widely accepted that nongenetic factors account for up to 40% of susceptibility to the disorder, and that they play an even larger role in influencing the course, onset, and severity of the illness. Notably, many researchers are starting to recognize the importance of developmental timing; that is, the way environmental and genetic factors interact differently across development. There is also growing interest in how a range of environmental factors impact developmental trajectories, and how these factors affect biological substrates at sensitive periods of development, when brain plasticity is most evident. Thus, despite the current paucity of literature that focuses on the developmental staging of bipolar disorder, we expect that the research on the course of bipolar disorder during the periods of early development (perinatal through toddlerhood) and adolescence will garner increased attention in the near future. In this section we focus on two key environmental factors that can increase risk for bipolar disorder: (1) life stressors, primarily with regard to family dynamics; and (2) environmental hazards.

Life Stressors

There is ample evidence that life stressors play a major role in the onset, severity, and prognosis of several mental illnesses, including bipolar disorder. Elevated stress has been documented in children at risk for bipolar disorder, both in interpersonal and noninterpersonal domains of functioning (e.g., Ostiguy et al., 2009; Radke-Yarrow, 1998). A review of the literature found that 50% of patients recall a major life event preceding their initial episode of bipolar disorder (Johnson & Roberts, 1995), although within the context of bipolar disorder negative life events (e.g., being fired) tend to precede depressive episodes, whereas positive life events (that may also be stressful, e.g., a promotion) tend to precede manic episodes (e.g., Johnson et al., 2008). The connection between life stressors and mood episodes appears to be strongest early in the course of the illness. and there is some evidence to suggest that later episodes of depression and mania are not as closely associated with identifiable life stressors as early episodes (e.g., Hillegers et al., 2004; Post, 2007). In other words, life stress tends to increase risk of bipolar disorder when it occurs at younger ages, though the reasons for this are not yet understood.

There are a host of ways life stressors may affect the onset and course of mental illness. Life stressors may disrupt social rhythms which in turn lead to instability in biological circadian rhythms (Johnson & Roberts, 1995). For example, starting college can upset meal times, bed times, exercise routines and so forth, in additional to the emotional stress caused by the new social demands and more stringent academic requirements. These alterations to circadian rhythms can impact the stability of the endocrine system by deregulating hormone secretion. Indeed, there is considerable evidence that social disruptions are linked to the onset of mood episodes among individuals with bipolar disorder. For example, Boland et al. (2012) reported that, when experiencing life events of the same magnitude and valence, participants with bipolar disorder showed significantly greater levels of disruption in their social rhythms and greater sleep loss compared with normal controls. A number of authors have also found that schedule disruption was associated with an onset of manic symptoms (Boland et al., 2012; Grandin et al., 2006; Malkoff-Schwartz et al., 2000). Although these studies do not necessarily clarify whether social rhythm disruptions cause manic episodes or result from the underlying disorder, the fact that Interpersonal and Social Rhythm Therapy, which helps patients stabilize and regularize social rhythms, is an effective therapy for bipolar disorder suggests that social rhythm disruptions have a causal role in the onset of mood episodes (Frank et al., 2005).

Social support is an environmental factor that may serve to mitigate the effects of life stressors on the course of bipolar disorder. There is evidence that a strong support system may lessen the negative impact of life stressors (e.g., Moon et al., 2014). In the context of bipolar disorder, Greenberg et al. (2014) recently concluded that limited social support is associated with heightened risk for depressive and manic episodes, and that support networks are negatively impacted by manic episodes. One can imagine a vicious cycle in which mood episodes decrease social support and thereby increase the likelihood of additional mood episodes.

Disruptions in the Family Environment. Taking a developmental perspective, the family (and the way family dynamics change over time) provides a particularly important context for considering the impact of early support systems and stressors on the onset and course of bipolar disorder, as well as risk and adaptation. When parents are struggling with their own mental health needs or are overburdened by caring for a child who is suffering from bipolar disorder, they may have limited internal resources to attend to the developmental needs of their child and may thereby intensify the child's risk of psychopathology. It should be noted that the specific ways parents can affect a child's susceptibility to psychopathology are complex and multifaceted because the family is a changing entity that plays different roles across a child's development. Paralleling the concept of normative psychosocial stages in individual development, researchers have explored stages in the life cycle of the nuclear family (Nye & Berardo, 1966; Parsons & Bales, 1955). Weissman, Paykel, and Klerman (1972) identified the primary parenting role of raising an infant as nurturance, of the school-age child as enculturation, of the adolescent as emancipation, and of the young adult as termination of the parental role. While some research to date has focused on environmental risks associated with the first stage of parenting (e.g., attachment), much of research on family risk factors has yet to apply developmentally sensitive approaches or to consider parenting roles as they change over time. It is important to identify the specific developmental stages and ways these parents can increase a child's risk of bipolar disorder. Clinicians would then know the most important periods to help guide parents in caring for their children and diminishing future rates of psychopathology.

The general patterns of family interactions are important to consider because of the evidence that increased stress and deficient social support play a significant role in the onset and course of bipolar disorder. Not only are disruptions in emotion regulation (termed *expressed emotion,* or EE) within the family an important risk factor for severe mental illness, but parents can also model poor emotion regulation and increase their child's susceptibility to the illness (Brown, Birley, & Wing, 1972). The pioneering work by Miklowitz and his colleagues (Miklowitz et al., 1988) pointed to the importance of family processes for bipolar disorder, specifically the role of expressed emotion in families with a history of psychopathology. Specifically, high levels of expressed emotion within families are associated with increased rates of relapse, longer periods of hospitalization, and poor social adjustment in bipolar patients (Miklowitz, 2007; Miklowitz et al., 1988). These findings are particularly important because disrupted patterns of emotion socialization are evident in families at risk for bipolar disorder. One study found that bipolar parents are more likely to respond to offspring's anger with anger (Klimes-Dougan & Harris, 2007). In this same sample, Narayan, Chen, Martinez, Gold, and Klimes-Dougan (in press) found that mothers with bipolar disorder were more likely to have aggressive interactions with their spouses than controls, and the use of these aggressive tactics was associated with the use of aggressive conflict tactics by adolescent offspring when interacting within the family. Other studies have found that low family cohesion and high conflict characterize families with parental bipolar disorder (Chang, Blasey, Ketter, & Steiner, 2001; Moreno et al., 2012; Romero et al., 2005) and families in which a child suffers from bipolar disorder (Belardinelli et al., 2008).

There is also evidence that bipolar parents are more likely to have difficulties creating intimate relationships with their children, thereby increasing their child's risk for bipolar disorder. For example, in prospective observational research using the strange situation, insecure attachment in toddlerhood was found to be more prevalent in offspring of bipolar mothers than in controls (e.g., DeMulder & Radke-Yarrow, 1991; Zahn-Waxler, et al., 1984). This finding has sometimes (e.g., Harnic et al., 2014), but not always, been borne out in retrospective high-risk studies using self-report indexes of attachment among young adults at risk for bipolar disorder (e.g., Doucette et al., 2013). In any case, there is evidence that the capacity for attachment was significantly compromised in adults with bipolar disorder (Greenberg, Rosenblum, McInnis, & Muzik, 2014). Parents can contribute to unhealthy family dynamics in other ways. Elevated reports of physical, sexual, and emotional abuse have been documented in children at high risk for bipolar disorder (Moreno et al., 2012). Abuse histories in childhood, of parents with or without bipolar disorder, have been found to relate to several clinical characteristics of adult bipolar disorder, including earlier age of onset, increased suicidal risk, more rapid cycling, more depressive episodes, more Axis I and II comorbidities, a worse course of illness, and treatment resistance (Etain et al., 2013; Garno et al., 2005; Leverich & Post, 2006).

Despite the host of identified risks associated with poor family dynamics on the onset and course of bipolar disorder, there are a number of characteristics of bipolar families that may promote supportive care and enhance protective factors. Preliminary evidence suggests that bipolar parents may have fewer children than nonbipolar parents (Moreno et al., 2012). Given that bipolar parents

tend to have less stable unions, are more likely to be single parents, and may have primary caregiving roles, having the opportunity to direct their attention to the care of fewer children may be advantageous for both the parent and child's mental health. Additionally, when children at risk for mental illness are co-parented by at least one healthy parent, their risk for psychopathology is diminished (Garcia-Amador et al., 2013). While genetics is certain to play a role, there is also empirical evidence that families have better dynamics when at least one co-parent is healthy (Garcia-Amador et al., 2013). There are also some hints in the literature that critical aspects of parenting may remain highly adaptive. In one study, growing up with a bipolar parent did not result in parents being perceived more negatively unless the young adult was diagnosed with psychiatric problems or bipolar disorder (Reichart et al., 2007). Also when euthymic bipolar adults rated their family of origin, they were perceived to be very similar to that of controls (Cooke, Young, Mohri, Blake, & Joffe, 1999). Overall, recent research reveals the importance of understanding the context of a child's development, including family dynamics, to accurately gauge the impact of risk and protective factors on the onset and course of bipolar disorder.

Developmental Hazards

There are other nongenetic factors that may influence risk and adaptation, including obstetric complications, teratogen exposure, and the seasonal variation in light exposure. While there is evidence that perinatal teratogen exposure and trauma during the birth process play a role in serious psychopathology, their role in the etiology of bipolar disorder has not been fully substantiated. Only very preliminary research is available to determine whether other teratogens such as in-utero exposure to alcohol (O'Connor et al., 2002) or early exposure to heavy metals such as lead or mercury (Pamphlett, 2014) are associated with bipolar disorder. Similarly, there is tentative support for obstetric complications being associated with bipolar disorder. For example, children at high risk for bipolar disorder have more obstetric complications than controls (Moreno et al., 2012). A follow-back study showed that obstetric complications were evident at a higher rate in patients with bipolar disorder than in their unaffected family members (Kinney, Yurgelun-Todd, Tohen, & Tramer, 1998). Retrospective results also suggest that the number of perinatal insults experienced by a child (e.g., drug exposure, birth trauma) increases the prediction of pediatric bipolar disorder (Pavuluri, Henry, Nadimpalli, O'Connor, & Sweeney, 2006). These studies have enormous design challenges that limit the understanding of the short and long-term effects of early exposure to hazards but nevertheless suggest an important area of further inquiry.

Although it is well-established that early childhood exposure to hazards increases the risk of some forms of psychopathology, there remains some question as to whether neurodevelopmental anomalies are associated with elevated risk for bipolar disorder. To more comprehensively address this issue, Murray and colleagues (2004) provided a convincing model that shows that different developmental hazards are involved in schizophrenia and bipolar disorder. Starting from the idea that schizophrenia and bipolar disorder share a common genetic etiology, they identify important environmental factors that are associated with different risk trajectories. They note modest differences in complications in pregnancy and delivery between these two risk groups, with complications being more highly associated with schizophrenia than bipolar disorder. They also identify anomalies in neuropsychological functioning and brain morphology that are most pronounced in those suffering from psychotic disorders. Additionally, some of the assets found to be associated with bipolar disorder (e.g., high IQ and school performance; MacCabe et al., 2010) would be less likely to occur after exposure to early hazards. They conclude that risk for schizophrenia but not bipolar disorder is increased by early insults that impair neurodevelopment. It is possible that hazards may be seen more in those suffering from bipolar disorder than in controls, but the highest risk for hazard exposure is associated with schizophrenia. Nevertheless, teratogen exposure later in adolescence and early adulthood may also be a risk factor for bipolar disorder, as the brain continues to undergo development during those periods. Here, the evidence generally mirrors that for schizophrenia and other psychotic disorders. While it is not clear if cannabis use increases the overall risk for bipolar disorder (as evidence shows for schizophrenia), cannabis use has been associated with an earlier age of onset for bipolar disorder and a worse prognosis (Gonzalez-Pinto et al., 2008; Lagerberg et al., 2011, 2014). In these studies, however, it is still not clear if cannabis use causes a worse prognosis or if greater cannabis use results from a more severe form of the disorder.

A host of other potential hazards that are currently being researched may also contribute in small but additive ways to our understanding of the etiology of bipolar disorder. Seasonal variation and light exposure patterns have recently been suggested to represent environmental hazards for those at risk for the disorder. There is some support for a theory that the springtime increase in solar

sunlight (insolation) is associated with an earlier age of onset (Bauer et al., 2012). Also, among patients diagnosed with bipolar disorder, there is a modest preponderance of births in the winter and spring months (Torrey, Miller, Rawlings, & Yolken, 1997). This insolation factor has been found to be especially important for those at high family risk for mood disorders and for initial depressive episodes as opposed to initial manic episodes (Bauer et al., 2014). Stability of the light–dark cycle is important in maintaining circadian rhythms, stimulating vitamin D synthesis, and regulating moods and may warrant further consideration as an etiological factor in bipolar disorder. Some researchers have also suggested that dietary habits and microbial agents could also increase susceptibility to severe mental illness by potentially impacting neural functioning and increasing oxidative stress (reviewed by Yolken & Torrey, 2008).

Overall, this research remains preliminary, but may deepen our understanding of the diversity of environmental factors that can increase risk for bipolar disorder. While environmental hazards do not account for most cases of bipolar disorder or cause the disorder by themselves, efforts to develop complex models of how stage-salient hazards might interact with other environmental stressors and genetics are needed to enhance our knowledge of risk and protective factors for bipolar disorder and to develop intervention strategies that can minimize the impact of these environmental hazards. The interplay between environmental, developmental, and genetic factors continues to be an important focus of research. We believe that this multi-modal focus is the best strategy to fully explicate the causes of bipolar disorder.

Biological Theories of Bipolar Disorder

Behavioral Genetics

Historically, family studies have served as a foundation for behavioral genetics research and can be divided into family risk studies and adoption studies. In a basic sense, these studies help determine the overall heritability of a disorder, the specific phenotypes that appear to be independently heritable, and the environmental factors that can increase susceptibility to a disorder. Despite the advances of molecular genetics and the methodological challenges associated with this highly heterogeneous and relatively rare disorder, family risk studies continue to provide some of the most robust, consistent, and novel findings about the heritability of the bipolar disorder. Family risk studies relevant to bipolar disorder fall into two major categories: twin studies and proband relative identification. There have been relatively few adoption studies on bipolar disorder, so they will not be discussed in this section. They generally support the primarily genetic basis of bipolar disorder (see Goodwin & Jamison, 2007, for a more extensive review).

Twin studies evaluate how often monozygotic twins (sharing nearly 100% of DNA) or dizygotic twins (sharing roughly 50% of DNA) are concordant or discordant for a characteristic of interest. The data obtained from these studies have conclusively shown that monozygotic twins are at a significantly higher risk of developing bipolar disorder than dizygotic twins, when one twin has the illness (Kato et al., 2005; Smoller & Finn, 2003). According to one study of 67 twin pairs in the United Kingdom, heritability estimates were found to be 89% (Craddock & Sklar, 2008). Other studies indicate that the monozygotic twin of a bipolar proband has a lifetime susceptibility of 40–70%, about 60 times the rate of the general population (Craddock & Jones, 1999; Craddock & Sklar, 2013; Smoller & Finn, 2003; Tsuang & Faraone, 1990). Concordance rates between monozygotic twins were typically between 5% and 10%, very similar to that of nontwin siblings (Smoller & Finn, 2003). The findings from twin studies suggest that bipolar disorder has one of the highest genetic susceptibility rates of any mental illness (Shih, Belmonte, & Zandi, 2004). Indeed, having a family member who is diagnosed with bipolar disorder is the best-known predictor of bipolar disorder in both children and in adults. Twin studies, especially longitudinal twin studies, also have the potential for advancing our understanding of the risk and protective factors for bipolar disorder. For instance, when only one co-twin has the disorder, researchers can investigate whether any specific unshared environmental factor may have increased or decreased susceptibility. The recent trends toward multisite collaborations in twin studies offer a positive sign that this approach will play a prominent role in the future of psychiatric genetics.

The second major type of family risk study evaluates the rates of bipolar disorder in relatives of a proband. Given the relatively low incidence of bipolar disorder, the most commonly-used family risk study design involves recruiting all available first-degree relatives of a proband for participation in the study. Occasionally, a more restricted approach is used to identify extreme risk populations that involve multiple family members diagnosed with bipolar disorder (e.g., Maziade, Rouleau, Gingras, et al., 2009). Family proband studies do little to model the developmental progression of bipolar disorder, but like twin studies, the results of family-proband studies have been robust and consistent in asserting the high degree of heritable susceptibility to bipolar disorder. Whereas the

lifetime prevalence of bipolar disorder (strictly defined) is around 1% of the general population (Merikangas et al., 2011), the most recent and comprehensive familial studies have shown that first-degree relatives of a proband have a lifetime prevalence of 5–10%, around eight times the rate of the general population (Craddock & Jones, 1999; Craddock & Sklar, 2013; Lichtenstein et al., 2009). Taken together, these studies have led to heritability estimates (the proportion of total phenotypic variation caused by primarily additive genetic factors) ranging from 0.59 to 0.93 (Bienvenu, Davydow, & Kendler 2010; Kieseppa et al., 2004; Lichtenstein et al., 2009; McGuffin et al., 2003), though some researchers have suggested that heritability estimates often discount shared and unshared environmental factors (Bentall, 2009). Finally, it is also possible that family risk studies considering unaffected individuals in middle and older adulthood may characterize a resilient sample and can be used to identify risk and protective factors for the disorder (Frangou, 2011).

Offspring studies are a specific type of family risk studies which focus on the offspring of parents (one or both) with bipolar disorder. Offspring are considered high risk because they are likely to incur risk both from environmental and genetic contributions (between 4 and 15% will develop bipolar disorder, compared with 0- 2% of offspring of healthy parents) (Birmaher et al., 2009; Lapalme, Hodgins, & LaRoche, 1997). Due to the fact that a sizeable proportion of offspring will develop bipolar disorder and that the peak age of onset is between 16 and 30 years (the majority of individuals who will develop bipolar disorder will do so before they are 25 years old; Merikangas et al., 2011), studying offspring before the age of highest risk is a powerful way to evaluate risk progression and identify precursors of the illness by using prospective longitudinal methodology that carefully addresses variation in development (e.g., Meyer et al., 2004; Radke-Yarrow, 1998).

Offspring studies also provide a broader understanding of risk and resilience. Consistent with principles of multifinality, only a minority of offspring of bipolar parents will develop bipolar disorder, but up to 40–50% of the offspring of parents with bipolar disorder (O-bipolar disorder) will develop other moderate to severe forms of psychopathology during childhood and adolescence (Birmaher et al., 2009; Lapalme, Hodgins, & LaRoche, 1997). There is also some preliminary evidence to suggest that the onset of emotional and behavioral problems may be delayed in offspring of bipolar parents relative to other risk groups, although by adolescence the rates of psychopathology in offspring of bipolar and unipolar parents are comparable (Klimes-Dougan et al., 1999, 2006). Other longitudinal evidence uses repeated measurement approaches to identify differential developmental trajectories of low-incident, highly deleterious outcomes including suicide (Klimes-Dougan, Free, Ronsaville, Stilwell, Welsh, & Radke-Yarrow, 1999) and disturbances in reality testing (e.g., Klimes-Dougan et al., 2013).

While family, twin, and offspring studies have been typically used to document the primarily genetic etiology of bipolar disorder, these studies are increasingly being used to identify the importance of specific environmental factors that increase susceptibility to bipolar disorder (e.g., Brietzke et al., 2012; Johnson, 2005). For example, the fact that concordance between monozygotic twins is noticeably lower than 100% indicates that both shared and unshared environmental effects play a significant role in susceptibility to the disorder, with Lichtenstein and colleagues providing evidence that unshared environmental factors have the more substantial influence (Lichtenstein et al., 2009; Uher, 2014).

Family and twin studies have also shown that the heritability of bipolar disorder is more complex and multifaceted than was originally thought. In particular, these studies offer compelling evidence that the different bipolar disorders have unique genetic underpinnings and that many of the common symptoms and comorbidities that accompany bipolar disorder have an independent genetic etiology. For instance, a number of family and twin studies indicate that bipolar II disorder is a highly heterogeneous disorder that often has a tenuous genetic relationship to bipolar I disorder (Barnett & Smoller, 2009; Smoller & Finn, 2003). They also show that many symptoms and comorbidities of bipolar disorder have a genetic basis (that is often independent of the genetic basis of bipolar disorder). These include specific comorbidities like alcohol abuse and phenotypic features like suicidality, rapid-cycling, lithium-responsiveness, and psychosis (see Barnett & Smoller, 2009; Craddock & Sklar, 2013). Family studies have also documented a large shared genetic etiology between bipolar disorder and schizophrenia, and to a lesser extent, between bipolar disorder and major depression (e.g., Lichtenstein et al., 2009; McGuffin et al., 2003)

Of particular importance to developmental psychopathology, family risk studies are beginning to clarify the genetic etiology of pediatric bipolar disorder. For example, Wozniak and colleagues (2012) found that the odds ratio for bipolar I disorder in first-degree relatives of a proband was 6.96 and that relatives of a bipolar youth were 4 to 14 times more susceptible to bipolar disorder, compared with relatives of a nonbipolar disorder proband. Although these authors argued that pediatric

bipolar I disorder is a valid diagnostic entity that is directly related to adult-onset bipolar I, others have suggested that pediatric bipolar disorder is an independent homogenous subset of adult bipolar disorder and as such does not predominately share the same genetic profile (Faraone, Glatt, & Tsuang, 2003). Additionally, there have been questions about the relationship between ADHD and bipolar disorder in children and adolescents for some time. Though some researchers note that bipolar disorder and ADHD must have common genetic elements based on the high frequency of the comorbid disorder (ranging from 70 to 98%) and their similar phenotypic presentation (Schimmelmann et al., 2013), some recent accounts have found that pediatric bipolar I disorder, ADHD, and *comorbid* pediatric bipolar disorder–ADHD independently breed true in families, meaning that each disorder has a largely unique genetic origin (Biederman et al., 2013). This line of research is important because, although the results remain tentative at best, they represent efforts to consider etiological contributions to pediatric bipolar disorder rather than relying on the assumptions that downward extensions of adult pathology models are relevant to youth.

Molecular Genetics

While family and twin studies continue to be an important and oft-used tool to assess the heritability of bipolar disorder, over the past 25 years, molecular genetics research has become the dominant paradigm in psychiatric genetics research. Perhaps more than most other fields, progress in genetics research has been inextricably tied to technological advancements, whose breakneck pace has led to rapid and dramatic paradigm shifts in the field. These advances have dramatically refined our understanding of the etiology of most psychiatric illnesses. While early family studies led researchers to search for a few bipolar genes that followed a Mendelian pattern of inheritance, newer research has shown that complex psychiatric disorders are caused by thousands of genetic variants, the majority of which only marginally increase one's risk of a disorder (Craddock & Sklar, 2013). Recent research has also definitely outlined the shared genetic etiology between many common psychiatric disorders and are beginning to show how development and the environment interact with genes to increase or decrease susceptibility to an illness. Although the most advanced molecular genetics methods have currently identified only a small number of bipolar-risk genes, researchers have now identified more potentially profitable directions to uncover the causal genetic elements that underlie bipolar disorder.

Linkage Studies. Before the advent of high-powered, computationally driven association studies, geneticists relied on lower resolution techniques. The first of these was the gene linkage study, which gained prominence in the 1990s. Linkage studies typically use pedigrees from 10 to 100 large families with multiple affected individuals and are most effective when used to identify rare gene variants with relatively large contributions to the susceptibility of a disease (Craddock & Sklar, 2013). In essence, they are used to find positional candidate genes by narrowing the major areas of genetic susceptibility from the entire genome to specific chromosomes and chromosomal regions (Juli, Juli, & Juli, 2012). Although more than 40 linkage scans for bipolar disorder have implicated a handful of chromosomal regions, these results have largely been conflicting, inconsistent, and unreplicated (Barnett & Smoller, 2009). The most comprehensive meta-analysis specifically implicated chromosome 6q, 8q, and 9p (McQueen et al., 2005). A recent review of linkage studies identified 15 other candidate regions that have been implicated in bipolar disorder, but acknowledged that there is little cross-study reproducibility of these findings (see Juli, Juli, & Juli, 2012). These findings suggest that bipolar disorder is instead likely caused by many common genetic variations, each of which having a small additive effect on overall susceptibility that would be too small to observe with linkage studies. Linkage studies have dwindled in popularity as researchers have reasoned that the thousands of genes involved in bipolar disorder will require more powerful and precise tools than linkage studies can provide.

Candidate Gene-Association Studies. The increasing evidence that bipolar disorder was caused by a large number of genes with small effects has caused a paradigm shift in psychiatric genetics over the last 15 to 20 years. Advances in molecular genetics allowed for gene-association studies, in which researchers could identify specific common variations with small effects. Gene-association studies were originally used to study candidate genes based on evidence from chromosomal regions identified in linkage studies, post-mortem examination of brain tissue, as well as existing models of neurobiological anomalies (Barnett & Smoller, 2009; Craddock & Sklar, 2013). Many candidate gene studies on bipolar disorder have focused on genes involved in serotonin transporters and receptors (SLC6A4 and HTR2A), catechol-O-methyl transferase (COMT), brain-derived neurotrophic factor (BDNF), tryptophan hydroxylase 1(TPH1), D-amino acid oxidase activator (DAOA or G72), neuregulin (NRG1), and disrupted in schizophrenia (DSC1 and DSC2) (Juli et al.,

2012; Seifuddin et al., 2012), but these studies have primarily yielded negative, inconsistent, and irreproducible findings (see Szczepankiewicz, 2013 for a more in-depth review). A recent meta-analysis reviewed 487 candidate gene studies and did not identify a single significant finding after correcting for multiple testing (Seifuddin et al., 2012). Candidate–gene association studies have very rarely examined pediatric bipolar disorder. One available study, although underpowered, failed to show a connection between candidate genes and the disorder, including for BDNF, SLC6A4, and COMT (Mick et al., 2009).

The results of these studies indicate that our current biological understanding of the disorder is either incorrect or incomplete. In retrospect, the failure of gene-candidate studies is not entirely surprising (see Barnett & Smoller, 2009; Craddock & Sklar, 2013; Seifuddin et al., 2012). Candidate gene studies (along with linkage studies) are methodologically flawed because they are premised on the limited etiological validity of current classification systems as well as our incomplete understanding of the neurobiology of a disorder. Although it is possible that some candidate genes still play a role in bipolar disorder as rare variants or types of genetic variations not captured by gene-association research, at a minimum, they suggest that the disorder's neurobiological mechanisms are far more complex and multifaceted than is currently believed, and likely involve a large number of genetic factors and distinct neurological pathways (Seifuddin et al., 2012).

Genome-Wide Association Studies. The next major advance in genetics research, genome-wide association studies (GWAS), allowed researchers to identify susceptibility genes without relying on a priori hypotheses about candidate genes. This meant that GWAS could identify new genetic variants involved in bipolar disorder and create new etiological hypotheses based purely on data from gene-assays, without any need for prior theories of the disorder's neurobiology. Put simply, GWAS use micro-chip gene assays to selectively genotype tens of thousands of individuals and correlate their genotype with phenotypic data, thereby showing which variants are involved in an illness. GWAS largely focus on single-nucleotide polymorphisms (SNPs), which are variants in the individual nucleotides that make up genes (although the gene-assays can also be used to identify some structural variants). A SNP typically represents one version of a gene (an allele) with a unique impact on an individual's phenotype. GWAS attempt to pick up on this (modest) association, although in the future GWA studies may be able to achieve larger sample sizes and use gene-assays with greater resolution to study the role of low frequency and rare SNPs in psychiatric disorders (Gratten et al., 2014). Most common SNPs have fairly small effects and do not dramatically affect one's phenotype, but the combined effect of thousands of small SNPs can be significant. The popularity of genome-wide association studies has resulted from major advances in genotyping (and statistical analysis) which have increased their resolution, and dramatically lowered their cost.

Despite the successes of GWAS with a handful of diseases (e.g., breast cancer, Crohn's disease, diabetes, cystic fibrosis), novel findings from GWA studies have not progressed as quickly as researchers originally expected, especially for complex heterogeneous polygenic disorders like mental illnesses. With regards to bipolar disorder, most GWAS have only found a small handful of genes involved in the disorder. The largest GWA study to date included nearly 12,000 individuals with bipolar disorder and over 50,000 controls and identified only two loci with genome-wide significance, the cell surface protein gene ODZ4 and the calcium ion channel subunit gene CACNA1C (Psychiatric GWAS Consortium-Bipolar Disorder Working Group, 2011). Other genes that have been commonly implicated by GWAS include other calcium ion channel subunits (e.g., CACNA1D and CACNB3; PGC-Bipolar Disorder Working Group, 2011) and cell-surface or extracellular matrix proteins involved in inter-cellular communication (e.g., ODZ4, ANK3, NEK4-ITIH1,3,4, and NCAN). As Scott and colleagues (2009, p. 7,505) stated, many of the results from GWAS indicate that "subtle differences in neural development or neuroplasticity may underlie mood disorders," although the specific neurobiological functions of the genetic variants identified by GWAS are not fully understood (Cichon et al., 2011; see also Craddock & Sklar, 2013; Szczepankiewicz, 2013).

These early GWA studies have also served to enhance our understanding of the relationship between different mental illnesses and the heterogeneity of patients diagnosed using *DSM* criteria (Doherty & Owen, 2014). For example, researchers recently found that the genetic correlation of SNPs between schizophrenia and bipolar disorder is 0.68 ($\pm$0.04) and that the correlation between bipolar disorder and major depression is 0.47 ($\pm$0.06), suggesting that there is major etiological overlap between the different disorders (CDG-PGC et al., 2013). SNP-based calculations also determined that individuals diagnosed with bipolar disorder form a relatively heterogeneous group, with SNP correlations ranging from 0.55 and 0.88 for individuals diagnosed with a bipolar disorder (CDG-PGC et al., 2013). These results reinforce a number of family and twin studies which found minimal explicit connection

between bipolar I disorder and bipolar II disorder and raise questions about the validity of current categorical diagnostic criteria, like the *DSM* or *ICD*. Despite the ability of GWAS to help determine the etiology of a disorder, there have been very few GWA-related studies on pediatric bipolar disorder and their results not been very significant. The few that we could locate were typically underpowered or unconventional. Rather than attempting to find novel SNPs among a pediatric bipolar population, they typically searched for the presence of SNPs that had already been implicated in adults within a small pediatric bipolar sample (e.g., Schimmelmann et al., 2013). Although amassing a large pediatric bipolar population will be difficult, a true GWA study could definitively show the relationship between pediatric and adult-onset bipolar disorder.

In spite of the value of these findings, the discrepancy between the heritability of a disorder estimated by family studies and the relatively small number of genes identified by GWAS has been a source of disappointment and contention (this problem is referred to as missing heritability). The issue of missing heritability has led some researchers to ask whether alternative forms of genetic variance underlie bipolar disorder (and other complex polygenic illnesses) that cannot be identified by GWAS. Recent statistical software called Genome-wide Complex Trait Analysis (GCTA) has provided answers to this question. GCTA allows researchers to compute the proportion of heritability that is caused by common SNPs (Lee & Chow, 2014; Yang, Lee, Goddard, & Visscher, 2011). GCTA indicates that 23–27% of the variance in liability of bipolar disorder is caused by thousands of common SNPs with small effect sizes (schizophrenia has been estimated to involve 8,300 SNPs which are responsible for up to 50% of the *genetic* variance) (CDG-PGC, 2013; Ripke et al., 2013). This means that the other proportion of genetic variance is caused by rare SNPs and structural variants (including copy number variants) that are too infrequent to be identified by the current gene-arrays and sample sizes used. The findings from GCTA are tremendously important because they affirm the idea that GWAS, however disappointing thus far, are the correct tool to determine a large portion of the genes involved in complex mental illnesses. The disappointing results of GWA studies are not due to the absence of common SNPs in the etiology of these illnesses, but due the fact that their sample sizes are simply too small to identify the tiny contributions of thousands of independent polymorphisms (Gratten et al., 2014). When researchers are able to gather extremely large numbers (hundreds of thousands) of bipolar participants, the results are likely to be similar to recent, ground-breaking research on schizophrenia. One study employed more than 36,000 subjects and 113,000 controls and identified over 120 SNPs from 108 independent loci (Schizophrenia Working Group of the PGC, 2014; Gratten et al., 2014). Indeed, among the well-studied mental illnesses, there is a clear correlation between the number of loci identified and the sample sizes used in the studies (Gratten et al., 2014). Although amassing such large samples may take a decade or longer to accomplish, intersite collaborative efforts have already proven successful in gathering large subject pools (e.g., the Psychiatric GWAS Consortium and the Wellcome Trust Case Control Consortium).

Future research on psychiatric genetics will also be better able to identify rare variants (discussed in the next section) with moderate-to-large effect sizes through new technological advances (e.g., next-generation sequencing or full-genome sequencing; Cruceanu et al., 2013). The current DNA microarrays that are used to identify common SNPs are unable to tag very rare variants (primarily structural variants and uncommon SNPs), which are responsible for a sizeable proportion of genetic liability for bipolar disorder. When the cost of genome sequencing falls far enough, gene-association studies using whole genomes will become perhaps the predominant tool used to identify rare variants. Likewise, whole exome-sequencing (high-throughput DNA sequencing), which evaluates only the protein-coding portion of the genome (the exome) is being increasingly used as a technique to identify rare and de novo variants using smaller sample sizes. While little is known about the significance of exomic variation in bipolar disorder, this approach has shown some promise when applied to other serious mental illnesses like autism (Gratten et al., 2014). In the coming decade, it is hoped that researchers will be able to quantitatively determine the role of rare SNPs and rare structural variants in the mental illness, as has been done with common SNPs.

Structural Variation and Copy-Number Variants. Structural variations refer to genomic inversions, translocations, and copy-number variants (CNVs; insertions and deletions). In contrast to sequence variations (single nucleotide variations in a string of DNA), structural variants are large-scale changes in the organization of DNA, ranging from alterations to a few kilobases to changes in many megabases. As mentioned already, structural variants tend to be very rare (with a frequency of less than 0.001) and have fairly large effects (between 2 and 20 times the effect size of common SNPs; Gratten et al., 2014). This section will focus primarily on copy number variants, as CNVs have been the most studied form of structural variation in

psychiatric genetics. These variants are receiving increased attention in the study of complex mental illnesses due to evidence that common SNPs explain only about a quarter of total genetic liability. Researchers reason that rare CNVs (and rare SNPs) with large effect sizes must therefore be responsible for a large portion of genetic susceptibility not already accounted for by common SNPs, as rare variants would not be tagged by the microarrays currently used in GWAS. Although the specific contributions of CNVs are largely unknown and are likely to vary considerably between different illnesses (Gratten et al., 2014), CNVs have already been implicated in illnesses like velocardiofacial syndrome, intellectual disability, schizophrenia, and autism (Kirov et al., 2014; Malhotra & Sebat, 2012). Theoretically, CNVs (and rare SNPs) should become easier to identify as newer genotyping assays and larger sample sizes are used, as is the case with rare SNPs (Gratten et al., 2014).

With regard to bipolar disorder, only a small handful of studies have evaluated the role of CNVs and current findings have been mixed. While a few studies have identified a small number of CNVs which appear to occur in both bipolar disorder and schizophrenia, (Lee, Woon, et al., 2012), other investigators found that CNVs were far more frequent in individuals with schizophrenia compared with individuals with bipolar disorder or controls (Grozeva et al., 2010). Given that CNVs have been linked to cognitive deficits, and cognitive deficits are more highly associated with schizophrenia than bipolar disorder, it has been hypothesized that the greater cognitive impairment in schizophrenia is more closely linked with CNV anomalies. Other groups of researchers have found evidence that a type of CNV, called singleton deletions, occur more frequently in individuals with bipolar disorder than in schizophrenia, but these results have not been replicated (Rucker & McGuffin, 2012).

Though preliminary, there have also been a few promising findings from CNV studies with direct relevance to developmental psychopathology. First, one study found evidence that CNVs occur more frequently in early-onset bipolar disorder (before 21) compared with the adult-onset disorder (after 21), suggesting that there is a unique genetic etiology to the early-onset disorder (Priebe et al, 2011). A second study found that de novo CNVs (structural changes which spontaneously appear in a child's DNA and are not found in her parents) are more common in early-onset bipolar disorder (Malhotra et al., 2011). This result is especially intriguing when we consider two other findings from recent studies. First, there is evidence that de novo CNVs are influenced by environmental factors, like parental age (in the case of bipolar disorder) and maternal nutrition (in the case of schizophrenia) (Frans et al., 2008; Lee et al., 2012). In fact, the age of onset of bipolar disorder has been found to be earlier in offspring of older fathers, especially for women and families with little history of mental illness (Grigoroiu-Serbanescu et al., 2012). One would expect to see a higher rate of *de novo* mutations in older fathers because their spermatogonial cells are continually replicating and continually introducing new mutations. Second, a number of studies have found that CNVs play a crucial role in neurodevelopmental disorders like intellectual disability and autism (Girirajan et al., 2011; Gill, 2012), indicating that there could be a unique connection between early-onset bipolar disorder and genes that affect neurodevelopment. Taken together, these pieces of evidence affirm the idea that environmental circumstances can directly affect the genetic basis of bipolar disorder and that the early-onset of bipolar disorder may have a genetic etiology that is closely related to other neurodevelopmental disorders. In a larger sense, some researchers argue that rare CNVs (especially *de novo* CNVs) may cause each instance of psychiatric illness to have a unique genetic etiology (Malhotra & Sebat, 2012). This would suggest that attempts to class disorders by etiology may be an extremely difficult enterprise, and would raise questions about the possibility of treating mental illness if each case is caused by a different set of rare variants. In total, research on the role of CNVs in bipolar disorder has been limited but promising, and certainly warrants further study (see Malhotra & Sebat, 2012, for a more general discussion of the role of CNVs and rare variants in psychiatric genetics).

Nonadditive Genetic Mechanisms

While the heritability estimates derived from family studies reflect mainly additive genetic factors, there are other genetic mechanisms that could play a role in the onset of the illness. We now turn our attention to the two most researched alternative genetic mechanisms that are likely to hold some explanatory value for the etiology of bipolar disorder, gene–environment (GxE) interactions, and epigenetics. Both domains of research accept the idea that the environment can modify an individual's genetic susceptibility to illness. But while GxE researchers attempt to find specific risk genes that can be activated by particular events, epigenetics research investigates the ways that environmental experiences can affect how the genotype is expressed. Stated another way, epigenetics research aims to find the mechanism of gene–environment interactions, and not simply the genes involved. Other nonadditive genetic mechanisms, like epistasis (gene-gene interactions) are growing in importance, but are beyond the scope of this

chapter. We will conclude by examining the oxidative-stress model of bipolar disorder in an effort to show how genetic theories of bipolar disorder can be integrated with current neurobiological research.

Gene–Environment Interactions. In a basic sense, current GxE associational studies are very similar to candidate gene-association studies (discussed previously) in that they attempt to find a correlation between a particular population sample and specific preselected genetic variant. In this case, the sample populations include individuals with bipolar disorder who have and have not experienced certain environmental influences, like childhood abuse, cannabis use, or life stressors. Much of this research is an extension of a substantial body of literature which documents how specific environmental influences can increase or decrease the risk of mood-disorders, including childhood trauma, life stressors, and social support (e.g., Brietzke et al., 2012; Johnson, 2005; Miklowitz & Johnson, 2009). In a larger sense, gene–environment research has been stimulated by evidence that genetic factors were only partly responsible for the disorder (e.g., the discordance between monozygotic twins or the fact that heritability estimates are substantially lower than 100%) but still caused distinct patterns of symptoms that were related to environment influences, like the relationship between bipolar disorder and childhood-sexual abuse.

Since the first major paper on psychiatric GxE interactions (Caspi et al., 2003), there has been a tremendous interest in the field, followed by considerable controversy and heated debate about the acceptability of these approaches, particularly when using SNPs (Burmeister, McInnis, & Zöllner, 2008). The most positive findings have come from epidemiological data which show a clear correlation between neural changes, childhood stress, and knowledge that bipolar disorder is highly heritable. For instance, researchers have documented significant neuronal variation between individuals with and without bipolar disorder who have been subject to childhood trauma like physical or sexual abuse. This evidence indicates that individuals with bipolar disorder have a genetic susceptibility to the disorder that can be triggered by childhood trauma, leading to unique pathophysiological changes in the brain (Brietzke et al., 2012). These studies also suggest that GxE are highly dependent on an individual's development. Many of the neurological changes triggered by environmental stress vary dramatically with age, meaning that there is a specific window of neural development which increases a child's vulnerability to stress (Brietzke et al., 2012). Therefore, bipolar disorder not only appears to be influenced by gene–environment interactions, but also by gene-environment-development interactions which can heighten susceptibility to the disorder at certain ages, but not at others. In fact, a recent study by Miller and colleagues (2013) has given preliminary evidence of a gene–environment–development interaction involved in bipolar disorder with the brain-derived neurotrophic factor (BDNF) val66met genotype could exacerbate the effects of childhood sexual abuse on the severity and chronicity of bipolar disorder (Miller et al., 2013). Other researchers have demonstrated that the serotonin transporter gene 5-HTTLPR polymorphism increases the rate of recurrent (rather than single-episode) depression when individuals have experienced childhood stress (Uher et al., 2011). Importantly, these studies reveal a threefold connection between genetic predisposition, environmental stress, and development as risk factors for bipolar disorder. Still, the results of gene–environment studies have been fairly inconclusive when researchers have sought to identify *specific* GxE interactions by using candidate gene-association studies (cGxE). As with conventional candidate-gene association studies, researchers have not encountered anywhere near the number of GxE interactions that they originally expected. This is likely due to the fact that the majority of genetic variants involved in bipolar disorder have very small effects, making identification in cGxE studies quite difficult, especially when current cGxE studies do not use a developmental perspective to inform their genetic theories (Vrieze, Iacono, & McGue, 2012).

Epigenetics. In its contemporary usage, epigenetics refers to chemical changes to the genome that do not affect the specific ordering of DNA nucleotides but alter gene expression (the process by which a DNA sequence is used as a template for protein production). This typically occurs in two ways. First, epigenetic modifications be covalent modifications of the DNA bases themselves (typically methylation) which affect the ability of DNA to be transcribed and expressed. Methylation causes genes to become silenced or underexpressed, while demethylation and hypomethylation cause genes to be expressed or overexpressed. Second, epigenetic modifications can occur to the histone proteins that make up the larger organized structure of DNA, called chromatin. Enzyme-guided processes like the methylation, acetylation, and phosphorylation of histones can affect how tightly the DNA in a cell is packed. When DNA is packed very tightly, genes cannot be expressed and are effectively turned off.

Although the mechanisms of epigenetic modification are not completely understood, there are a few major features that make it an important subject of genetics research on bipolar disorder. First, epigenetic modifications affect the expression of an individual's genotype without actually altering her DNA sequence. This means that even if someone has a gene that predisposes her to an illness, that gene could be silenced by epigenetic modification and could not meaningfully affect her phenotype. Second, unlike an individual's genome which is permanent and unchanging (except in the case of very rare mutations), epigenetic modifications can frequently occur as a result of environmental influences. For instance, researchers have observed changes in the methylation (and expression) of genes that affect drug-seeking behavior after administering cocaine to subjects (Kumar et al., 2005). Although the expression of DNA can also be affected by environmental influences (e.g., stress causes the release of cortisol which affects the expression of genes), these effects are usually transient. By contrast, environmentally induced epigenetic modifications can be long-lasting and persistent, especially if they occur early in development (Bredy, Sun & Kober, 2010). In some animal models, epigenetic modifications that occur in childhood persist into adolescence and adulthood (Kofink et al., 2013; Meaney 2010). Despite our limited understanding of the mechanisms and significance of epigenetic modifications in humans, environmentally induced epigenetic modifications hint at the complexity of molecular biology and complicate our current understanding of psychiatric genetics.

Within the past ten years, a surge in research on epigenetics has demonstrated that epigenetic modifications are likely to play a role in many psychiatric illnesses, including bipolar disorder. Researchers have shown that a handful of genes involved in bipolar disorder are affected by epigenetic alterations. These include peptidylprolyl isomerase E-like (PIPIEL) which is involved in dopamine transmission and the neuroendrocrine system; brain-derived neurotrophic factor (BDNF); the serotonin receptor 5HTR1A; the regulation of DNA methyltransferases, which are involved in epigenetic DNA methylation; the HLA complex group 9 gene (HCG9), which is thought to play a role in stress response and neuronal death; and catechol-O-methyltransferase (COMT) genes (see Bredy, Sun, & Kobor, 2010). By either methylating or demethylating these genes, epigenetic modifications are correlated with an increased susceptibility to bipolar disorder (though it is not clear to what extent), presumably because they increase the effects of genes that are involved in the disorder. This hypothesis is supported by the physiological mechanisms of drugs that reduce the symptoms of bipolar disorder. The mood stabilizer valproate, for instance, inhibits the enzyme histone deacetylase, thereby reducing gene expression (Kato et al., 2005). Other effective bipolar medications, like S-adenosyl methionine (SAM), appear to increase DNA methylation and reduce gene expression (Kato et al., 2005). It is notable that the preliminary epigenetics studies show a clear concordance with GWAS findings, suggesting that epigenetic modifications and genotypic susceptibility go hand-in-hand. That is, the genes that seem to be affected by epigenetic modifications are genes that have been implicated by GWAS, and these epigenetic modifications appear to cause the overexpression of risk genes and the underexpression of protective genes, like BDNF. But because researchers have largely only studied candidate genes, like those identified by GWAS, it is not clear how epigenetic modifications affect the thousands of other genetic variants involved in the disorder.

The most exciting feature of epigenetics research is the connection between environmental influences, epigenetic modifications, and development. Researchers have recently shown that epigenetics is a dynamic process whereby environmental stresses can effectively turn susceptibility genes on or off, including genes for behavioral traits related to mood disorders. For example, genes involved in drug use, vulnerability to stress, anxiety, and fear-related learning and memory can be epigenetically modified by environmental influences like early-life trauma and intense stress (Bredy et al, 2010). This means that an environmental trigger could be necessary to activate susceptibility genes for a psychiatric disorder, like bipolar disorder. In other words, epigenetics could be responsible for the widely observed connection between environmental influences and genetic predisposition to an illness (e.g., Miller et al., 2013). Indeed, epigenetics could be one major reason why there is a fairly substantial discordance rate between monozygotic twins for psychiatric illnesses, as researchers have shown that monozygotic twins have very different genome-wide epigenetic patterns by the time they reach adulthood (Bredy et al., 2010). Although these twins have the same genes, the way these genes are actually being expressed is quite different. Other researchers, however, have proposed that de novo copy number variants could also be responsible for this phenomenon (Malhotra & Sebat, 2012).

Crucially, there is strong evidence that epigenetic modification of susceptibility genes are highly influenced by

an individual's development. There appears to be critical periods of brain development where certain genes can be epigenetically modified, with repercussions that last into adolescence and adulthood (Kofink et al., 2013; Pishva et al., 2014). Although much of this evidence has come from research with animals or through indirect research on humans (and should therefore be cautiously applied to the developmental psychopathology of bipolar disorder), the findings are still provocative. For example, researchers have shown that the level of maternal care in young mice is associated with epigenetic modification of genes involved in the hypothalamic-pituitary-adrenal (HPA) axis, which plays an important role in stress-management and depression. These early-life epigenetic modifications caused changes in gene expression and behavior that lasted into adulthood (see Pishva et al., 2014). By contrast, adolescent or adult mice exposed to similar stressors (like lack of maternal care) would not experience epigenetic modifications to their DNA. Research on children has indicated that humans have a similar developmental window where environmental stressors can cause long-lasting changes in gene expression, due to epigenetic mechanisms. A handful of studies on humans have illustrated a connection between childhood trauma and epigenetic modifications which persist into adolescence and adulthood, and ultimately increase susceptibility to psychiatric illness (Pishva et al., 2014). Taken as a whole, these studies help to elucidate the etiology of bipolar disorder and suggest that determining its genetic origins will require more than the identification of SNPs. Instead, these studies suggest that the environment can interact with an individual's genes in a manner that is sensitive to stages of human development. New research in epigenetics aims at bridging the gap between animal-research and work on humans. Advances in biotechnology and molecular biology are slowly starting to allow for genome-wide epigenetic profiling of individuals with bipolar disorder, which should help to elucidate the prevalence and importance of epigenetic modifications in the disorder. Although epigenetic research on psychiatric illnesses is promising, much more work is still needed to be done before we understand the role of epigenetic modifications in the etiology of bipolar disorder.

Oxidative Stress. One recent model of bipolar disorder shares similarities with the two models of gene–environment interactions discussed earlier, and suggests that bipolar disorder is influenced by oxidative stress in the brain. Put simply, oxidative stress refers to the activity of reactive oxygen species (typically generated in cells as byproducts of metabolism), which can degrade cellular macromolecules like proteins and DNA, trigger cell-death, and result in epigenetic modifications to DNA (see Andreazza, 2012). It should be pointed out that research on oxidative stress differs from research on GxE interactions and epigenetics because it does not typically attempt to pinpoint specific genes or environmental interactions which can increase susceptibility to bipolar disorder. Oxidative stress is not a field of genetics research but rather one model of the way that genes and environmental influences can interact in a complex manner. If models of oxidative stress continue to be supported by research, it seems likely that researchers will search for genes that contribute to oxidative damage.

The two major models of oxidative stress include the theory of Allostatic Load (AL) and the theory of accelerated aging (AA), both of which contend that certain psychiatric illnesses are a result of long-term neurodegenerative damage from oxidative stress caused by long-term environmental stressors and genetic susceptibility (Rizzo et al., 2014; for a developmental psychopathology perspective on allostatic load see Cicchetti, 2011). Proponents of these theories cite findings from post-mortem evaluation of brain tissue and neuroimaging studies which indicate that oxidative damage is heightened in individuals with bipolar disorder, leading to many of the same physiological and neurocognitive impairments seen in normal patterns of aging (e.g., shortened telomeres, slowing cognition, reduced brain weight and volume, and cardiovascular conditions; see Rizzo et al., 2014). Although the literature on oxidative stress and psychiatric illness is still relatively small, it could signal an important future direction for the field. The most advanced theories of oxidative stress are multi-causal and multi-disciplinary: they suggest a complex interaction between genetic vulnerability to oxidative damage, environmental stressors that increase oxidative stress, and specific periods of neural development (Rizzo et al., 2014). And in contrast to current etiological models which portray bipolar disorder as a cyclic disease, many models of oxidative stress and accelerated aging contend that bipolar disorder is a progressive disease with symptoms that change over time. Rather than treating bipolar disorder as a static illness, these models indicate that bipolar disorder will have vastly different profiles as the illness progresses, and may require unique strategies for treating it at different stages in the life span.

NEUROIMAGING FINDINGS IN PEDIATRIC BIPOLAR DISORDER AND HIGH-RISK POPULATIONS

Bipolar disorder has widely been characterized as a neurodevelopmental disorder and accordingly, research in

the neural mechanisms of bipolar disorder represent an important domain of discovery. Before neuroimaging technology was available for the study of the brain there were a range of methods that were used to study brain functioning in bipolar populations. Early efforts to understand the morphology and cytoarchitecture of the brain involved postmortem evaluations. Although this methodology has still not been applied to the study of pediatric bipolar disorder, contributions of this work was important. For example, research in adults showed evidence of subtle volumetric differences in regions hypothesized to contribute to the pathogenesis of mood disorders such as basal ganglia, locus ceruleus, and dorsal raphe, (reviewed by Baumann & Bogerts, 2001). Additionally, electroencephalography (EEG) research on bipolar disorder was initiated in the 1950s. Some of the important contributions of this work include evidence of asymmetry in bipolar patients (Clementz, Sponheim, Iacono, & Beiser, 1994). This research showed that patients with bipolar disorder demonstrated heightened right hemisphere activity, consistent with hypotheses concerning nondominant hemisphere involvement in the regulation of elated mood. Finally, research assessing neuropsychological functioning has made major contributions to our understanding of bipolar disorder. Cognitive impairments have been consistently identified in patients with bipolar disorder on measures of attention, working memory, verbal memory, and executive functioning (e.g., cognitive flexibility; reviewed by Quraishi & Frangou, 2002; meta-analysis by Lee, Hermenst, et al., 2014), with these deficits generally evident in the euthymic state (meta-analysis by Arts et al., 2007; Bora et al., 2009; Mann-Wrobel, Carreno, & Dickinson, 2011; Robinson et al., 2006; Torres et al., 2007). Research examining neuropsychological functioning in children and adolescents with bipolar disorder shows a remarkably similar, although not always as robust a pattern of deficits as those of adults (reviewed by Horn, Roessner, & Holtmann, 2011; Joseph et al, 2008). There is also evidence that identified functional deficits in some of these neurocognitive tasks may precede the onset of bipolar disorder. For example, deficient functioning has been noted in relatives of bipolar probands (Arts et al., 2007; Bora et al., 2009; Robinson et al., 2006) and offspring of bipolar parents (Klimes-Dougan et al., 2006). Most notably, there is preliminary evidence that the presence of executive functioning deficits and working memory impairments in at-risk offspring of bipolar parents can predict the later onset of bipolar disorder (Meyer et al., 2004). At the same time, Savitz, Solms, and Ramesar (2005) identified a number of studies that did not find cognitive or academic impairments in youth who went on to develop BD, though measure of academic performance may not be an appropriate measure of impairments in verbal memory or executive function. Nonetheless, some of these well-established methodologies will continue to provide a critical role in advancing our understanding of the pathophysiology of bipolar disorder for they provide complementary information with the more recently-used imaging technologies that now allow scientists to view the workings of the brain in real-time.

There has been considerable progress in recent decades in the ability to examine the neural underpinnings of psychiatric illness through the application of various types of brain imaging techniques. The majority of neurobiological research has focused on adults diagnosed with bipolar disorder, with research approaches including more invasive brain imaging technologies (e.g., positron emission tomography and CT scans) that have limited application in youth because of radiation exposure, for instance. The focus of this section will be on the advances relevant to developmental neurobiology and psychopathology using exclusively noninvasive imaging technologies, much of which have taken place in the past decade. This research has begun to identify the aberrant neural circuits that are implicated in bipolar disorder, shedding light on the pathophysiology of the disease and providing the foundation for conceptualizing treatments that could be targeted to impact abnormal circuitry. In this section we will first review neuroimaging findings in pediatric bipolar disorder (organized by imaging modality). We will then describe how pediatric bipolar findings differ from other psychiatric populations. A discussion of developmental trajectories will incorporate an examination of findings differentiating pediatric bipolar from adult bipolar disorder, results on at-risk populations, and longitudinal results. Finally, we review the extant research examining how existing treatments impact abnormal circuitry in youth with bipolar disorder before discussing implications for the future. A detailed summary of the available, but limited, research is provided.

Volumetric/Morphometry Studies

The most cumulative neuroimaging data on bipolar disorder in children and adolescents is available from studies that have used high-resolution T1-weighted images to measure the volume of brain structures. Similar to the general pattern of findings in adults, many of these studies have implicated key frontolimbic structures such as the amygdala, hippocampus, basal ganglia, and cortical regulatory regions, reflecting abnormalities in the circuitry which is thought to subserve emotion regulation, memory and motivated behavior (Phillips et al., 2003).

Amygdala

Several studies have found that youth with bipolar disorder have smaller amygdala volumes than healthy controls (Chen et al., 2004; DelBello et al., 2004; Dickstein et al., 2005; Kalmar et al., 2009). Recent reviews and meta-analyses suggest that decreased amygdala volume is more consistently observed in youth than in adults with bipolar disorder (Pfeifer et al, 2008; Savitz & Drevets, 2009; Usher, Leucht, Falkai, & Scherk, 2010). One study found that while left amygdala size was positively related to age in a sample of bipolar youth ranging from 10 to 21 years of age, the healthy control group showed an inverse relationship between amygdala size and age (Chen et al., 2004). In addition, a meta-analysis of studies that examined amygdala volumes in children, adolescents, and adults with bipolar disorder reported that children and adolescents with bipolar disorder had significantly smaller amygdala volumes than typically developing children, whereas amygdala volumes in adults were nonsignificantly larger than the healthy adults (Pfeifer et al., 2008). Taken together, it appears that there may be a developmental trajectory in youth with bipolar disorder in which early on, patients have abnormally small amygdala volumes, but over time, while their healthy counterparts show a trajectory of decreasing amygdala volume, bipolar youths' amygdala volumes increase.

Hippocampus

Savitz and Drevets (2009) recently conducted a comprehensive review of studies examining neural circuits implicated in mood disorders and found that, in contrast to MDD, in which hippocampal volumes are consistently smaller (particularly in chronically, severely depressed older adults), there were no differences in hippocampal volume in patients with bipolar disorder. However, in the pediatric literature, several studies (but not all [Chen et al., 2004]) have found smaller hippocampal volumes in samples of youth with bipolar disorder. In a study of 43 youths with bipolar disorder and 20 healthy controls, Frazier and colleagues reported smaller hippocampal volumes in the bipolar disorder group, which was driven predominantly by the female subjects (Frazier et al., 2005). In a multimodal analysis of 18 children with bipolar disorder in the manic phase and 18 matched controls, Gao and colleagues found decreased gray matter volume in the left hippocampus in the patient group (no sex effects were reported), which was inversely related to manic symptoms as measured by the Youth Mania Rating Scale (Gao et al., 2013). Bearden et al (2008) focused on the three-dimensional morphology of the hippocampus. They found decreased hippocampal volumes in bipolar disorder youth compared with case controls. Specifically the subiculum region of the hippocampus was the region most implicated. Interestingly, this region has projections to the prefrontal cortex (PFC) and thus may represent some disturbances in frontotemporal neurocirciutry. In addition to a possible link with manic symptoms, it is conceivable that lower hippocampal volumes in pediatric bipolar disorder could underlie the memory deficits seen in this group (Joseph et al., 2008), although this link has not been directly studied.

Other Subcortical Regions

In contrast to abnormally low amygdala volumes in pediatric bipolar patients, studies have found increased volumes of basal ganglia regions (e.g., putamen, caudate, globus pallidus) and thalamus in youth with bipolar disorder compared with controls (Adleman et al., 2012; DelBello et al., 2004; Wilke et al., 2004). However, one study found reduced volumes of the left nucleus accumbens in youth with bipolar disorder compared with controls (Dickstein et al., 2005). In contrast, a recent examination of basal ganglia structures in adults with bipolar disorder found volume reductions in the globus pallidus and putamen, but no group differences in the nucleus accumbens or thalamus (Womer et al., 2014). The heterogeneity of findings across studies could reflect the small samples that are typically used for imaging studies and may reflect developmental changes due to a different mix of age-groups in each study. This hypothesis would require longitudinal measurement to examine change in basal ganglia volumes with maturation in those with versus without bipolar disorder. Implication of these brain areas, which are known to be involved in generating positive affect, may provide some clues as to the emergence of manic symptoms in youth with bipolar disorder.

Cortical

In addition to the subcortical regions discussed above, various studies have reported that in comparison to healthy controls, pediatric patients with bipolar disorder have smaller volumes of cortical areas such as the left dorsolateral PFC (Dickstein et al., 2005), frontal, temporal parietal and occipital lobes (Frazier et al., 2005; James et al., 2011), as well as smaller gray matter in medial temporal lobe and orbitofrontal cortex (Wilke et al., 2004) and in the anterior cingulate cortex (Gao et al., 2013; Wilke et al., 2004). These deficits have been linked with impaired cognitive functioning in working memory, executive function,

language, and verbal memory (James et al., 2011) and may underpin some of the reduced capacity for emotion regulation in youths with bipolar disorder.

Functional MRI

Numerous studies have now used functional magnetic resonance imaging (fMRI) to examine brain functioning in youth with bipolar disorder. A common approach has been to utilize an experimental paradigm in which participants view emotional faces, and the blood-oxygen-level-dependent (BOLD) signal associated with the task is examined in patients versus control groups. A larger BOLD signal reflects greater blood flow to specific regions of the brain and therefore increased brain activity in that region. Kim and colleagues (2012) evaluated youth and adults with bipolar disorder and healthy controls using an fMRI task that presented angry, fearful, and neutral faces. Compared with healthy controls, both pediatric and adult bipolar samples showed greater activation in the right amygdala in response to fearful faces. When more global patterns of response were evaluated that included responses to all emotional stimuli, only the youth with bipolar disorder showed excessive activation in the right amygdala. Another fMRI study tested a facial expression task on youth with bipolar spectrum disorder, a matched nonbipolar clinical group, and a control group. Compared with the other two groups, the bipolar spectrum group showed lower fusiform activation when viewing facial expressions across a range of emotions, suggesting deficits in the visual processing brain regions (Perlman et al., 2013). Whole-brain analyses have also been conducted on euthymic adolescent patients with bipolar disorder and healthy controls when viewing emotional facial expressions (Garrett et al., 2012). In this study, the bipolar disorder group showed lower dorsolateral prefrontal cortex activation but greater amygdala and hippocampal activation. Limbic hyperactivation was observed in youth with bipolar disorder using another face viewing paradigm (Rich et al., 2006). Youth with bipolar disorder rated neutral emotion faces as more hostile than the control group, and showed greater activation in the amygdala, nucleus accumbens and other brain regions when rating how hostile the face appears or how much fear they experienced. Although some of the youth in bipolar disorder group were euthymic, within-patient group differences were not observed. Together, these studies suggest that limbic hyperactivity to negative emotion may be trait-related rather than state-related for youth with bipolar disorder. More recently, Adleman and colleagues (2013) reported that children with bipolar disorder exhibit impaired memory for emotion faces as well as elevated fusiform activation during the processing of these faces. Since the fusiform cortex is known to be critical for the processing of face information, it may be that increased activation in patients reflects a greater neural demand to accomplish the task in comparison to controls. Further, Adleman et al. reported that elevated fusiform activation was correlated to manic symptoms, suggesting it may represent a state and trait biomarker of bipolar disorder in children.

Another application of fMRI is to measure functional connectivity. Since functionally connected regions have synchronized resting-state BOLD signal (Biswal, 1995), comparing BOLD signal across different brain regions can be used to estimate brain connectivity within networks of interest. Two studies have been published to date using resting-state fMRI to assess brain connectivity in youth with bipolar disorder. Wu and colleagues used an automated method to examine resting-state functional connectivity across the entire brain (Wu et al., 2013). They identified three networks, an affective network, an executive network, and a sensorimotor network. In youth with bipolar disorder ($n = 34$), the affective and executive networks had greater involvement of the dorsal anterior cingulate cortex (ACC), than that seen in controls ($n = 40$). Dickstein and colleagues examined functional connectivity in 15 youth with bipolar disorder and 15 controls, and reported that the patient group had greater negative connectivity between left dorsolateral PFC and right superior temporal gyrus than the control group (Dickstein et al., 2010). Another study examined regional homogeneity (ReHo), which is a data-driven approach for examining resting-state data that measures connectivity between nearby regions throughout the brain, in 15 adolescents with bipolar disorder versus 15 healthy controls (Xiao et al., 2013). Patients showed lower ReHo than controls in several cortical areas, but greater ReHo in several limbic areas. Furthermore, elevated limbic ReHo was correlated with manic symptoms. Functional connectivity can also be examined using a task, rather than the resting state. Two studies utilizing an emotion face task have documented reduced frontolimbic connectivity in adolescents with bipolar disorder compared with controls (Rich et al., 2008; Wang et al., 2012).

In yet another application of fMRI, researchers can measure the amplitude of low frequency fluctuations (ALFF) of resting-state BOLD signal. This measure has been shown to be highly correlated with cerebral blood flow (Zou et al., 2009). Lu and colleagues (2014) applied this method in a sample of pediatric bipolar patients

(predominately bipolar I disorder). Compared with the control group, patients showed significantly lower ALFF in left precuneus, left superior parietal lobule, and bilateral inferior occipital gyrus, but greater ALFF in the bilateral caudate and left pallidum. Additionally, there was a significant positive correlation between the ALFF value of the left pallidum and level of manic symptoms, suggesting that increased baseline neural activity in this region may be important for generating mania.

In summary, the extant research using fMRI to examine neural circuitry in pediatric bipolar disorder have utilized very different approaches but have broadly implicated abnormalities in cortical-limbic circuits in these young patients. These findings shed light on how regional brain dysfunction manifests at a network level in these patients. Future research using more uniform methods and larger samples is needed to support and extend these early findings.

Neuroimaging Assessment of White Matter

As has been found in adults with bipolar disorder (Tighe et al., 2012), early research examining white matter in pediatric bipolar disorder using T2-weighted images noted elevations in white matter hyperintensities (areas of increased signal which are thought to reflect a brain abnormality that could have numerous etiologies) in these patients (Botteron et al., 1995; Pillai et al., 2002). However, more recent and expanded work looking at 35 affected and 45 unaffected offspring of parents with bipolar disorder along with 40 healthy controls found that the proportion of low-grade white matter hyperintensitites was similar across groups (Gunde et al., 2011). Nevertheless, interest in white matter as a key part of the pathophysiology of bipolar disorder in youth and adults has continued and, with the advent of more advanced technologies such as diffusion tensor imaging, has led to some progress in understanding of the disorder.

In the past decade, several studies have applied diffusion tensor imaging (DTI) to examine white matter in pediatric patients with bipolar disorder. DTI measures the diffusion of water, and provides an estimate of whether water molecules can diffuse freely (isotropic movement) or if they are restricted in their movements (anisotropic movement), as in the case of a barrier such as an axon. Greater limitation of white matter diffusion is therefore suggestive of a greater degree of white matter microstructure imposing a limitation to diffusion of water molecules. In general, these studies have all indicated lower fractional anisotropy (FA), an indicator of white matter integrity, in the patient group compared with controls. This general finding is thought to be a reflection of greater disorganization of the white matter connections in the brain, which might subserve some of the deficits in emotion regulation and impulse control in these patients. Common locations of low fractional anisotropy include the corpus callosum, internal capsule, and cingulum. However, the location of white matter deficits has varied across studies, suggesting that the abnormality may not necessarily be specific to circuits involving emotion regulation.

In the first DTI study of pediatric bipolar disorder, Frazier and colleagues (2007) examined 10 children with bipolar disorder, 8 healthy controls, and 7 at-risk children with a first-degree relative with bipolar disorder. The bipolar disorder group showed lower FA than both other groups in cingulate and paracingulate white matter. In addition, patients showed lower FA than controls in right and left superior frontal tracts, left orbitofrontal white matter, and right corpus callosum body. Both patients with bipolar disorder and the at-risk groups had lower FA than controls in the superior longitudinal fasciculus bilaterally (Frazier et al., 2007). In a study of 13 children and adolescents with pediatric bipolar disorder, 13 children with ADHD and 15 healthy controls, Pavuluri and colleagues (2009) reported that both patient groups had lower FA in the anterior corona radiata. Also, the ADHD group had lower FA in the anterior limb of the internal capsule and the superior region of the internal capsule in comparison to both other groups (Pavuluri et al., 2009). Barnea-Goraly and colleagues examined 21 adolescents with bipolar disorder who were also the offspring of a bipolar parent and 18 age and IQ matched healthy comparison participants. Adolescents with bipolar disorder had lower FA values than controls in the fornix, left midposterior cingulate gyrus, corpus callosum, in fibers extending from fornix to thalamus, and in parietal and occipital chorona radiata bilaterally. There were no correlations between FA and clinical measures (Barnea-Goraly et al., 2009). Saxena and colleagues found lower FA in the genu of the corpus callosum and in the anterior commisure in 10 youth (aged 7–17) with bipolar disorder versus 10 healthy controls. In the patient group, FA values were negatively correlated with a lifetime history of aggression (Saxena et al., 2012). James and colleagues assessed youth diagnosed with bipolar disorder with psychosis (age 11–18) and found decreased FA was in the anterior corpus callosum. These changes were associated with differences in cognitive functioning (James et al., 2011). One limitation that is common across many bipolar studies is that the patients are frequently medicated, raising the potential confound that differences

in neural structure and function are due to the medication and not the disorder. A recent study suggests that this may be an important issue. It examined white matter integrity in 18 unmedicated children and adolescents with bipolar disorder and 18 controls, and found no significant group differences (Teixeira et al., 2014).

In summary, DTI studies to date of pediatric bipolar disorder have been fairly small in size. They have generally suggested impaired white matter integrity, but there has not been a consensus on the location of the abnormalities. Few studies have been able to identify within-patient group correlations with dimensions such as symptom severity, limiting conclusions about the biological meaning of the findings. Given the ongoing development of white matter during adolescence (e.g., Giedd, 2004; Paus, 2010), it is important to recognize that there may be a wide variation in white matter integrity (among both sample and control groups) that may make the identification of clinically relevant abnormalities more difficult, even with closely matched control samples.

Spectroscopy

Magnetic resonance spectroscopy (MRS) is a technique that measures the concentration of a range of neurometabolites in specific areas of the brain. MRS can provide additional insight into the state of the brain in vivo that complements other imaging methods. Several MRS studies have been used in cross sectional designs to investigate biomarkers associated with bipolar disorder. These studies typically measure a standard set of neurometabolites within hypothesized regions of interest. The following summarizes key findings according to the neurometabolite that was measured.

N-acetyl-aspartate (NAA)

NAA is thought to be a marker of neuronal density and viability. Reduced NAA could reflect abnormal dendritic arborization and neuropil, supporting a neurodevelopmental hypothesis for the pathophysiology of bipolar disorder. Most, but not all (Patel, DelBello et al., 2008) studies of pediatric bipolar disorder have found lower NAA in patients than controls. A study of 15 children and adolescents with familial bipolar disorder (offspring of one or two parents with bipolar disorder) and 11 healthy controls examined neurometabolites in the dorsolateral prefrontal cortex (DLPFC). This study reported lower NAA levels in the right DLPFC, but no differences in myoinositol or choline levels, two other commonly studied neurometabolites (Chang et al., 2003). In another study, Cecil and colleagues reported a trend for lower NAA and creatine levels in the cerebellar vermis in 9 children aged 8–12 years with bipolar disorder in comparison to 10 group-matched healthy controls (Cecil et al., 2003). Sassi and colleagues (2005) reported lower NAA in the dorsolateral prefrontal cortex in in 14 adolescents with bipolar disorder (mean age 15.5) in comparison to 18 healthy comparison subjects using MRS. They also reported that NAA levels were negatively correlated with number of previous episodes. In a larger study, Olvera and colleagues reported lower NAA in the left dorsolateral prefrontal cortex in 35 children and adolescents with bipolar disorder (mean age 13.2) in comparison to 36 matched healthy controls. Furthermore, it appeared that the finding of low NAA was primarily driven by the early puberty group as opposed as to the children in other developmental stages (Olvera et al., 2007). Another relatively large MRS study was conducted on 43 children with bipolar disorder (mean age 13.2) and 38 healthy controls. The authors reported that the patient group had lower concentrations of NAA and choline-containing compounds in bilateral medial prefrontal cortex, and lower creatine compounds in the left medial prefrontal cortex. They also found lower NAA and creatine compounds in left DLPFC white matter (Caetano et al., 2011). In contrast, in a study of 28 adolescents with bipolar depression versus 10 controls, Patel and colleagues found greater concentrations of NAA in the ACC and bilateral ventrolatral PFC in the bipolar disorder group compared with controls (Patel, DelBello et al., 2008).

Choline-Containing Compounds

Choline-containing compounds provide information about cellular membrane integrity. Patel and colleagues found increased left ventrolatral PFC concentration of choline in 28 adolescents with bipolar depression in comparison to controls (Patel, Cecil et al., 2008). Caetano et al. reported that in their study of 43 children with bipolar disorder and 38 previously described healthy controls, patients showed lower concentrations of choline-containing compounds in bilateral medial PFC (Caetano et al., 2011). However, Chang and colleagues reported no differences in choline levels in the right DLPFC in their aforementioned study (Chang et al., 2003).

Glutamate and Glutamine

Glutamate is the most pervasive excitatory neurotransmitter in the brain. In spectroscopy studies, it is commonly measured along with glutamine, since their MRS signals are difficult to separate. Increased glutamate/glutamine

has been a relatively consistent finding in adult studies of bipolar disorder; this finding is thought to reflect elevated excitatory neurotransmission, and may be relevant to pathophysiological mechanisms in bipolar involving excitotoxicity, or the pathological process by which excessive nerve stimulation leads to nerve damage over time (Yüksel & Ongur, 2010). An early MRS study reported that 10 children aged 6–12 years with bipolar disorder (after a drug washout) showed higher levels of gluatamate/glutamine in the frontal lobes and basal ganglia than10 age-matched healthy control subjects (Castillo et al., 2000).

Myoinositol

Myoinositol is a chemical involved in intracellular signaling and has been implicated in bipolar disorder and in the mechanisms of action for lithium. Patel and colleagues found increased prefrontal cortex concentration of myoinositol in 28 adolescents with bipolar depression in comparison to controls (Patel, Cecil et al., 2008). In a study of 11 children with bipolar disorder and 11 healthy controls, Davanzo and colleagues (2001) reported that patients showed a trend toward greater ACC myoinositol than controls (Davanzo et al., 2001). In another study of children and adolescents with familial bipolar disorder (offspring of one or two parents with bipolar disorder), Cecil and colleagues reported elevated myoinositol levels in the cerebellar vermis in the children aged 8–12 years with bipolar disorder ($n = 9$) in comparison to controls ($n = 10$) (Cecil et al., 2003).

More recently, other approaches using MRS have been explored in pediatric bipolar disorder. In contrast to the studies discussed above which used protron spectroscopy, Sikoglu and colleagues (2013) used phosphorus MRS to assess markers relevant to mitochondrial activity. This study found that although there were no group differences in pH between patients (8 youths with bipolar disorder) and controls ($n = 8$), frontal pH was correlated with age in the bipolar disorder group. Inorganic phosphate levels were lower in the patients, and global phosphocreatine to inorganic phosphate levels was higher in subjects with bipolar disorder compared with the healthy group. These findings represented early evidence for mitochondrial dysfunction in youth with bipolar disorder (Sikoglu et al., 2013) and are in line with a growing body of research in adults implicating dysfunctional mitochondrial functioning and oxidative stress in the neurobiology of bipolar disorder (Andreazza, 2012).

Studies Comparing Pediatric Bipolar Disorder to Other Pediatric Psychiatric Groups

Due in part to the controversy over the diagnosis of bipolar disorder in children, there has been a growing interest in developing biomarkers that could be used clinically to distinguish between psychiatric disorders. A handful of studies have emerged comparing children and adolescents with bipolar disorder to other psychiatric groups, as a first step in the search for neuroimaging-based biomarkers to differentiate psychiatric diagnoses. Frazier and colleagues (2008) used structural MRI to assess children and adolescents aged 6–17 years with either bipolar disorder ($n = 35$) or schizophrenia ($n = 19$) and a healthy group ($n = 29$). They reported that boys with schizophrenia had the smallest left amygdala volumes, and that girls with bipolar disorder had the smallest left hippocampal volumes. Exploratory analyses also suggested larger right nucleus accumbens volumes in bipolar disorder patients compared with controls (Frazier, Hodge et al., 2008). Using MRS, Davanzo and colleagues (2003) measured neurometabolite levels in 10 young patients with bipolar disorder, 10 with intermittent explosive disorder, and 13 normal comparison subjects. They found that the bipolar disorder group showed greater myoinositol levels than both other groups in the ACC, but no significant neurometabolite differences were noted in the occipital cortex (Davanzo, Yue, et al., 2003). Moore, Biederman, Wozniak, and colleagues (2006) used MRS to examine children aged 6 to 13 years with ADHD and no comorbid disorder ($n = 15$), ADHD plus bipolar disorder ($n = 8$), or no psychiatric disorder ($n = 7$). In contrast to the aforementioned studies, this study found that only the ADHD children showed a significant difference from controls: ADHD children showed greater glutamate/glutamine to myoinositol compound ratios than controls, while no differences in brain chemistry were identified between children diagnosed with early onset bipolar disorder and healthy controls (Moore et al., 2006). In summary, the studies examining neuroimaging biomarkers to distinguish youths with bipolar disorder from other psychiatric diagnoses have been few, small in size, and have yet to reveal a consistent pattern of findings. Even when group differences are present, there is often considerable overlap between individuals with different disorders, making it quite difficult to find biomarkers that are exclusively indicative of one illness. Nonetheless, the application of multi-method imaging and cognitive to examine a range of biomarkers in the same sample might

be useful to clarify how potential findings such as reduced hippocampal volume, elevated myoinositol and cognitive impairments might be integrated. Considerable research using larger samples and uniform methods will also be necessary to discover and validate reliable biomarkers for pediatric bipolar disorder that could be translated to a clinical setting.

Potential Precursors of Bipolar Disorder

There is some evidence to suggest that anomalous functioning of the stress system is evident even before the onset of bipolar disorder. Olsavsky et al. (2012) assessed youth (8 to 18 years of age) who were diagnosed with bipolar disorder, youth who were at risk for bipolar disorder (no history of a mood disorder but having a first degree relative with bipolar disorder), and healthy controls in the scanner while they either passively viewed fear or happy faces or while they rated the intensity of these faces. Both the bipolar and the at-risk groups exhibited greater activation of the amygdala while viewing fearful faces than controls (but no differences were found for viewing happy faces). Ladouceur and colleagues (2013) assessed a group of healthy offspring of bipolar parents and found that, relative to healthy controls, bipolar offspring exhibited greater right ventrolateral prefrontal cortex (VLPFC) (BA47) activation in response to positive emotional distracters and reduced VLPFC modulation of the amygdala in response to both the positive and negative emotional distracters. The authors suggest that alterations in the functioning of frontolimbic systems implicated in voluntary emotion regulation may represent neurodevelopmental markers of risk for future onset of bipolar disorder. Roberts, Green, Breakspear, et al. (2013) used MRI to examine young adults (age 18 to 30) who had at least one first-degree relative diagnosed with bipolar disorder within the context of an emotional go, no-go task. The at-risk group showed reduced recruitment of the inferior frontal gyrus during inhibition of emotional stimuli. Many of the at-risk participants were diagnosed with MDD at the time of the scan. Together, these studies indicate that key frontolimbic abnormalities can be identified in at-risk youth, prior to the onset of illness.

In the aforementioned studies that focus on children and adolescents younger than age 18 who are at risk for bipolar disorder, the study design can only provide limited information about whether abnormalities in these youths represent risk or protective mechanisms. Because only a small minority (approximately 10%) of these younger at-risk youth will go on to develop bipolar disorder, it is important to also consider research in which participants are past the age of elevated risk to distinguish if these problems are a precursor to (and therefore a biological marker for) bipolar disorder. Family risk studies that examine neurobiological markers in participants who are past the typical age of disease manifestation are critically important to understanding protective factors. Krüger et al. (2006) assessed transient sad mood in middle-age adults (mean of 38 years) diagnosed with bipolar disorder and their siblings. Using positron emission tomography (PET), they found that all participants showed increases in cerebral blood flow in the dorsal/rostral anterior cingulate cortex and anterior insula, and decreased cerebral blood flow in the orbitofrontal and inferior temporal cortices. Cerebral blood flow in the medial frontal cortex differed across groups, with adults diagnosed with bipolar disorder showing decreased activation while their unaffected sibling showed increased activation of this regulatory brain region during transient sadness. The authors go on to suggest that this sibling response may represent a compensatory effect in youths that are at familial risk for bipolar disorder, which may be a marker of resilience in this group.

Developmental Trajectories

Given the important neurodevelopmental changes that take place across the window of time when bipolar disorder emerges, and the important differences in neurobiology that exist between youth and adult-onset bipolar disorder, an understanding of how and when neural abnormalities first appear and develop over time is greatly needed.

Cross sectional studies comparing adolescents and adults with bipolar disorder have helped to identify neurobiological continuities and discontinuities between the two populations. This line of research may help us understand differences in the manifestation and developmental progression of bipolar disorder over time. Weathers et al. (2012) examined neural circuits mediating motor inhibition under conditions of successful and unsuccessful response inhibition in children ($n = 16$) and adults ($n = 23$) with bipolar disorder, along with healthy children ($n = 21$) and healthy adults ($n = 29$). During successful inhibition, both child and adult bipolar groups showed lower activation of left ventral prefrontal cortex and right nucleus accumbens compared with healthy controls. However, during unsuccessful response inhibition, the anterior cingulate

cortex dysfunction varied developmentally, with lower activation in youths with bipolar disorder than controls, and greater activation in adults with bipolar disorder than controls. This research group later reported results from the sample using a cognitive flexibility task (Weathers et al., 2013). In that study, children with bipolar disorder showed greater activation in frontal, temporal, and parietal activation than controls, whereas adults with bipolar disorder showed hypoactivation in those areas.

Another approach is to study adults with bipolar disorder of the same age but with different onset times (childhood/adolescence vs. adulthood) to better characterize the unique features of early-onset bipolar disorder. Compared with the approach discussed above, this methodology has an advantage in that it does not compare groups of vastly different ages and neural development, which could serve as a confounding factor in the comparison of adult and pediatric bipolar disorder. A recent study found that pediatric-onset bipolar disorder had lower fractional anisotropy (i.e., lower white matter integrity) than those with adult-onset bipolar disorder in the anterior limb of the internal capsule (Lu et al., 2012). Together with findings discussed earlier suggesting that (1) children and adolescents with bipolar disorder may have smaller amygdala volumes than their healthy counterparts, in contrast to adults with bipolar disorder who do not show this finding (Pfeifer et al., 2008); (2) patients with early-onset bipolar disorder show greater numbers of copy number variations in their DNA (Malhotra et al., 2011; Priebe et al., 2011); and (3) patients with early-onset bipolar disorder have higher rates of ADHD (Biederman et al., 2013), these converging cross sectional findings suggest that the neurobiology of bipolar differs according to the developmental time period when it emerges. However, there are still many unknowns with respect to how these neurobiological indices change over time, along the course of illness and during the transition into and through adulthood.

Despite the mounting evidence that pediatric bipolar disorder is associated with abnormal neurobiological development, only two studies have utilized a longitudinal design to examine how the trajectory of brain development may be different for youth who eventually develop bipolar disorder compared with healthy controls and high-risk youth who do not develop bipolar disorder. First, Adleman et al. (2012) examined brain volumes over the course of two years in youth with either narrow phenotype bipolar disorder (using explicit *DSM-IV* criteria, including well-demarcated mood episodes), severe mood dysregulation (SMD; per Leibenluft's definition, described above), or healthy controls. At baseline, both bipolar disorder and SMD groups showed greater volume of dorsolateral prefrontal cortex (DLPFC) and insula. Additionally, the bipolar disorder group showed larger globus pallidus volumes than controls. After two years, the bipolar disorder group, but not the other groups, showed an increased volume of the superior/inferior parietal lobule and the precuneus. The precuneus mediates attention shifting and is involved in episodic memory retrieval and theory of mind, along with being a part of the default mode network (Cavanna & Trimble, 2006). It may be that this increase in the default mode network regions in the bipolar disorder group could underlie a tendency in these patients to have a smaller reduction in the default mode network with increasing task demands (Costafreda et al., 2011). In the second study, Gogtay and colleagues examined longitudinal morphology in a small group of high-risk participants prior to and after converting to bipolar I disorder in adolescence (Gogtay et al., 2007). This study used gray matter density analyses to identify regional differences and changes across time. In adolescents that eventually developed bipolar I disorder, cortical gray matter increased in the left temporal cortex and decreased bilaterally in the anterior cingulate cortex, including the subgenual cingulate cortex. Notably, this pattern was distinct from a pattern that has been identified in childhood-onset schizophrenia.

Treatment Effects

Research examining the effects of psychotropic medications on the brain in pediatric samples is of critical importance. And like the debate over the rapidly increasing numbers of youths being diagnosed with bipolar disorder, there has been an accompanying controversy around the treatment of these children and adolescents with mood-stabilizers and anti-psychotic medications. Although there are some studies examining how existing treatments might impact and potentially restore abnormal circuitry, the location and direction of these changes has varied across studies rendering them somewhat inconclusive. Additionally, variability in treatment response rate suggests that individual characteristics may be important to consider when making treatment decisions. In contrast to the severe paucity of studies documenting change in neural circuitry over time in youth with bipolar disorder, there have been more (but still too few) imaging studies examining how existing treatments might impact and potentially restore abnormal circuitry in this population.

First, there is some early evidence from cross sectional studies that treatment with mood-stabilizing medications

leads to beneficial effects, as indexed by various imaging techniques. Although a longitudinal design is optimal for determining the impact of treatments on the brain, some early studies compared medicated and unmedicated patients to gain some initial clues as to how interventions may affect brain anatomy and function. One such small cross sectional study examined hippocampal volumes in 17 adolescents with bipolar disorder and 12 healthy controls, and reported that among the patients, those who were being treated with lithium had larger hippocampi than those not on lithium (Baykara et al., 2012). This report was consistent with other studies suggesting that lithium has a neuroprotective effect (Machado-Vieira, Manji & Zarate, 2009) and indicates that lithium could promote or facilitate the generation of new neurons in the hippocampus that had previously been hampered by the disease process. Another volumetric study examined subgenual anterior cinculate cortex (sgACC) volumes in 51 children and adolescents with bipolar disorder and 41 healthy controls, and reported that current use of a mood stabilizer was associated with greater sgACC volumes (Baloch et al., 2010). The restoration of sgACC volume would address a well-known abnormality in bipolar disorder (Ongur, Drevets & Price, 1998). Using MRS, Moore and colleagues compared 10 children with bipolar disorder in the manic phase who were not being treated with an antipsychotic medication with eight children with bipolar disorder who were stably treated with the antipsychotic risperidone. Results showed that the untreated group had (1) lower glutamate/glutamine in the ACC; (2) higher severity of manic symptoms; and (3) a negative correlation between clinical and ACC glutamine levels (Moore et al., 2006). Another MRS study of 22 children and adolescents with bipolar disorder (seven unmedicated) and 10 healthy controls that also examined the ACC reported that unmedicated subjects with bipolar disorder had lower glutamine levels than both other groups; no group differences were found with regards to glutamate (Moore et al., 2007). These cross sectional MRS findings provided the basis for hypothesizing that when successful, bipolar treatments may serve to restore abnormal glutamate/glutamine levels in the ACC. However, as we will show, this hypothesis has not been borne out with longitudinal work.

In the first study to longitudinally examine the impact of treatment on neurometabolites in pediatric bipolar disorder, Davanzo and colleagues examined 11 children with bipolar disorder (mean age 11.4 years) and 11 normal controls before and after a 7-day course of lithium using MRS. At baseline, the patients showed a trend toward greater ACC myoinositol than controls, and after treatment, there was a significant reduction in myoinositol and creatinine in the patients, especially among responders (Davanzo et al., 2001). In a later study, however, Patel and colleagues showed myoinositol changes in the opposite direction with lithium in the later phase of treatment: in 28 adolescents with bipolar disorder in the depressed phase, there were no significant changes between baseline to day 7, but myoinositol levels in the right and left dorsolateral prefrontal regions increased between day 7 and day 42 (Patel et al., 2006). Together, these studies preliminarily suggest that lithium treatment could lead to an initial decrease in myoinositol in the ACC followed by an increase in myoinositol in the dorsolateral prefrontal cortex after several weeks of treatment. In a separate publication of their study, Patel and colleagues (2008) reported that medial ventral prefrontal N-acetyl-aspartate (NAA) concentrations decreased over time, with endpoint concentrations significantly lower than baseline concentrations. They did not find NAA concentration changes for left or right ventral lateral prefrontal cortices (Patel et al., 2008). A decrease in NAA with treatment does not reflect a normalization pattern (the majority of MRS studies listed above reported abnormally low NAA in pediatric bipolar disorder). Additional research is needed to determine whether this decrease in NAA with treatment represents a spurious finding, a true mechanism of lithium, or adaptive change in the setting of other changes in the brain with lithium treatment.

In the first longitudinal study to examine the effects of an atypical antipsychotic medication on brain metabolites in pediatric bipolar disorder, DelBello and colleagues (2006) examined hospitalized adolescents with bipolar I disorder ($n = 20$) before, during and after treatment with olanzapine monotherapy. Ten healthy controls were also scanned at the same time intervals but received no treatment. In the first week, manic adolescents had an increase in right lateral ventral prefrontal choline. Remitters showed greater increase in ventral medial prefrontal NAA compared with nonremitters. Baseline medial ventral prefrontal choline was greater in remitters than nonremitters (DelBello et al., 2006). The authors interpreted their findings by suggesting that when olanzapine is successful, the mechanism of action may involve increasing neuronal viability, and that olanzapine-induced increases in choline may lead to alteration in cell membrane metabolism or second messenger pathways that have been implicated in the pathophysiology of bipolar disorder. A more recent study reported the impact of a course of 8 weeks of treatment with quetiapine or placebo on neurometabolites in the ACC in adolescents with bipolar disorder ($n = 26$).

Results indicated that post-treatment, responders had lower myoinositol than responders. However, no metabolites that were measured were noted to have changed significantly as a result of treatment, nor were there any pretreatment neurometabolite measures that predicted treatment response (Chang et al., 2012).

A small-scale treatment study was conducted in which eight adolescents with bipolar disorder (either type I, type II or not otherwise specified) were scanned prior to and following an 8-week trial of the anticonvulsant lamotrigine (Chang et al., 2008). At baseline, amygdala activation in response to negatively emotional stimuli was correlated with severity of depressive symptoms. Participants with greater improvement in depressive symptoms across the 8-week trial had greater reductions in amygdala activation. While this initially appears promising, this pattern has been shown in studies of adults with major depression using PET, in which reduction of amygdala metabolism was correlated with reductions in depression symptoms with antidepressant treatment (Drevets, Bogers, & Raichle, 2002). Therefore, it can be hypothesized that reduced amygdala activation after treatment with lamotrigine, which has an FDA indication for bipolar depression in adults, is a more general measure reflective of recovery from depression as opposed to a direct drug effect.

Finally, Miklowitz and colleagues (in press) evaluated brain changes associated with family-focused therapy in a small group of youth with bipolar disorder ($n = 12$) and evaluated a small group of healthy controls at baseline ($n = 12$). They conducted fMRI during an implicit emotion task at baseline (before therapy) and after 4 months of therapy. At baseline, bipolar youth relative to controls showed hyperactivation of the posterior cingulate cortex and hypoactivation in the dorsolateral prefrontal cortex. Associated with treatment, bipolar youth showed decreased activation of the amygdala and increased activation of the dorsolateral prefrontal cortex. Also, greater increases in dorsolateral prefrontal activation were associated with improvement in manic symptoms.

In summary, emerging research has been conducted using neuroimaging techniques before and after treatment to examine neural mechanisms associated with response to a range of treatments for pediatric bipolar disorder. There is some suggestion from these studies that currently available treatments for bipolar disorder exert measurable changes in the brain, although the location and direction of these changes has varied across studies. Although prechange–postchange tests have not always yielded strong results, analyses examining responders versus nonresponders have been more fruitful, as have some approaches analyzing correlations between treatment response and brain changes. This suggests that some of the early signals being identified may represent mechanisms of response (improvement) rather than simply drug effect. Additional research with larger samples is needed to confirm and extend these findings and to develop reliable biomarkers of treatment response that could be applied in clinical practice.

Summary

Abnormalities in neural circuitry mediating emotion information processing have been found to be implicated in bipolar disorder. As reviewed above, the extant body of neuroimaging research in pediatric bipolar disorder has broadly implicated neural circuitry that has also been implicated in emotion regulation. Across imaging modalities, the findings have suggested large-scale structural changes, multiple functional abnormalities, and even differences in cellular functioning as reflected by neurometabolite abnormalities. This circuitry involves the medial prefrontal cortex and reciprocal limbic connections with the amygdala, hippocampus, ventral striatum, hypothalamus, and brain stem (Ongur & Price, 2000; Savitz & Drevets, 2009). Emerging evidence suggests that the structure, activation, and chemistry of these regions are frequently altered in youths with bipolar disorder, and that the pattern of abnormalities is not always the same in youths as those seen in adults with bipolar disorder. Additional research is needed that uses multiple methods to integrate the different neurobiological measures and to provide a more over-arching model for the disorder. Research examining how developmental trajectories in youth with bipolar disorder may be abnormal is still in its infancy but shows promise for shedding light on the neurodevelopmental basis for the illness. The extant work examining treatment effects on neurobiological indices provides the foundation for the future generation of translational research integrating neuroimaging with clinical trials. The next steps in this research will require larger and more homogenous samples to confirm initial findings, and should test novel treatments that might more successfully restore healthy developmental trajectories in youth with bipolar disorder.

TRANSLATIONAL IMPLICATIONS

Translational research refers to the application of knowledge gained by basic science research to clinical applications such as the characterization, treatment, and

prevention of pathology. In this section, we identify major themes that will continue to guide future research and discuss some translational implications by once again returning to the core principles of developmental psychopathology. Addressing the core features of the illness by developing hypothesis-driven early interventions and preventive strategies are high-priority goals for the field (Insel, 2009). It is imperative to continue to conduct foundational research to enhance our understanding of how psychopathology unfolds across development (Lee et al, 2014).

Better Classification Will Lead to Better Prevention and Intervention Strategies

The traditional classifications of mental illnesses have a number of limitations for understanding and treating bipolar disorder. Because the *DSM* is still the primary framework for the diagnosis of bipolar disorder in youth and adults, research to identify the prevalence, course, precursors and treatment of the disorder almost exclusively relies on these categorical approaches to design studies. The current categorical criteria often lump together patients with very different collections of symptoms (and likely very different etiologies for their illness). As McNally (2012) has pointed out, two individuals can be diagnosed with the same disorder without sharing a single symptom. By fostering heterogeneous definitions of disorders, it is possible that the *DSM* may now impede research on mental illnesses, rather than assisting it (Cuthbert & Kozak, 2013; Uher, 2013). Many agree that a new approach to classification of mental illness is needed.

The hope is that some of the most serious flaws associated with the categorical approach can better be addressed by employing empirically derived dimensional models of developmental psychopathology. Recent research using dimensional approaches have already started to shape ways the macrostructure of psychopathology is being viewed by the psychiatric community (e.g., Krueger & Markon, 2006). Consideration of symptom aggregation patterns may also help to address some of our current challenges in determining whether children with broadly defined pediatric bipolar disorder (e.g., DMDD) or common patterns of comorbidities (e.g., comorbid pediatric bipolar disorder-ADHD) should be treated the same as children with the narrowly defined bipolar I and II disorders (Biederman et al., 2013). Clarifying the etiological relationship of these disorders has significant clinical implications. For example, it is possible that under these more varied conditions, the standard treatments for bipolar disorder may not be effective. Determining which sets of symptoms respond to specific treatments could help prevent young children from being prescribed medications that would have side effects and not actually ameliorate their condition. Personalized intervention strategies may prove to be effective in altering the course of bipolar disorder by matching specific interventions to specific problem profiles rather than adopting more traditional one-size-fits-all approaches. Additionally, although there continues to be some debate about the progressive nature of bipolar disorder, clinical staging models may also guide intervention selection. For example, relatively benign prevention and intervention strategies (e.g., CBT, social rhythm therapies) could be deployed when developmental perturbations are first detected, leaving more advanced and virulent forms of the illness to be treated with psychopharmacological interventions which carry more significant potential side effects.

Better Understanding of the Etiology and Neurobiology Will Lead to More Effective Preventive and Intervention Strategies

Ideally, empirically based diagnostic criteria will clarify the etiology of specific symptoms, facilitating the development of more effective ways to intervene. While the atheoretical approach to classification was initially a reaction to outdated etiological theories that had dominated earlier versions of the DSM, researchers are increasingly recognizing that effective treatment of psychopathology will require etiologically valid diagnoses. Some of the advances will likely be informed by a better understanding of the neurobiological and genetic underpinnings of the illness. For example, if researchers determine that pediatric-onset bipolar disorder is continuous with adult-onset bipolar disorder, it could indicate that bipolar medications typically used with adults could be effective among youth.

Efforts to develop classification systems that go beyond a complete reliance on self-reports and instead attempt to connect core disruptions in behavior with the underlying neurocircuitry are a priority for the field. These efforts will eventually help develop a neuroscience-based definition of bipolar disorder that is informed by critical contextual factors. This general approach has been promoted by RDoC and is sometimes referred to as a psychoneurometric approach (Morris & Cuthbert, 2012; Moser et al., 2014; Patrick, Durbin & Moser, 2012); one that reconceptualizes clinical disorders in terms of dispositional constructs and their neurobiological underpinnings. Indeed, this approach is leading to answers about how different interventions reduce the symptoms of mental illnesses at a

neurobiological level. For example, there is now evidence that offspring of parents who are lithium responders show a different profile of symptoms from offspring of parents who are lithium nonresponders (Duffy et al., 2002). It is hypothesized that these subgroups may show varied responses to intervention depending on their underlying neurobiological features. Recent research has also been conducted using neuroimaging techniques before and after treatment to examine neural mechanisms associated with response to a range of treatments for pediatric bipolar disorder. Although pharmacological and psychological interventions show some efficacy in the treatment of pediatric bipolar disorder, remission rates are highly variable. Given that any one risk or protective factor is not likely to lead to development of interventions, the use of data aggregation methods across systems, or big data approaches as it is sometimes called, might be an important tool for characterizing the etiology of bipolar disorder and suggesting ways to intervene (McIntyre et al., 2014). It is possible that by examining core symptoms, behaviors, or underlying neurobiological markers of bipolar disorder, progress can be made in identifying more precise predictors of treatment responses, along with identifying neurobiological targets for intervention.

Longitudinal research is needed to understand the natural history of the illness, as "a deficit occurring early in development can give rise to a cascade of more complex deficits as different brain regions mature and interact over time … with environmental events and other contextual factors" (Casey, Oliveri, & Insel, 2014, p. 351). Special issues of *Development and Psychopathology* (edited by Masten & Cicchetti, 2010) have focused on developmental cascades, which are central to developmental psychopathology and are crucial to understanding how cognitive and neurobiological deficits can change throughout development. As part of this special issue, Klimes-Dougan et al. (2010) addressed developmental trajectories in children at risk for bipolar disorder. They demonstrated that self-regulation deficits identified in offspring of bipolar and unipolar depressed parents show very distinct developmental paths across childhood and into adolescence, with offspring of unipolar parents cascading into internalizing pathology and offspring of bipolar parents tending to cascade into thought problems. Information about the trajectory of the illness will inform prevention and intervention science, by identifying typical developmental periods which intervention might be most suitably targeted as well as bringing attention to the importance of developmentally sensitive intervention strategies.

The most effective way to study the developmental progression of psychopathology is through multiple levels of analysis. As some researchers have pointed out, brain development occurs across different systems in synergistic and antagonist manners: "Early in development, brain circuits across different regions interact dynamically. The cumulative consequences of these interactions among developing systems alter the course of development" (Casey et al., 2014, p. 351). Capturing this dynamic interaction requires research from multiple perspectives. Developmental psychopathology frameworks are at the forefront of this challenge, with special issues of *Developmental and Psychopathology* focusing on multiple levels of analysis relevant to externalizing (edited by Burnette & Cicchtti, 2012) and internalizing (edited by Cicchetti & Natsuaki, in press) pathology.

Better Understanding of Risk and Protection Will Lead to More Effective Preventive and Intervention Strategies

Protective factors should be more fully examined to develop more effective prevention and intervention strategies. Towards this end, it is important to keep in mind that some risk and protective factors are common to most forms of psychopathology. For example, there is now evidence that parenting dynamics can affect the onset of bipolar disorder (Meyer et al., 2006) and relapse after recovery from mania in youth (Geller, Tillman, Craney & Bolhofner, 2004). Additionally, the structure provided by parents in childhood, predicts cortisol reactivity among offspring of bipolar parents in adolescence (Ellenbogen, Hodgins, Linnen & Ostiguy, 2011). Together this evidence suggests that etiological models should account for familial and environmental factors, which may be a potential target for intervention (as in family-focused therapy and Interpersonal and Social Rhythm Therapy). It is also important to be aware that risk factors for some conditions can be protective factors for other conditions and should not be viewed as being intrinsically detrimental or beneficial. For example, positive affect, optimism, and goal-directed behavior are often identified as protective factors for mental illness (Vahia, Chattillion, Kavirajan & Depp, 2011). Fredrickson and Branigan (2001) have explored how positive affect may be an evolutionarily derived characteristic because it increased the stability of communities. They suggest that our ancestors likely built personal resources, including resources for survival, during safe and satiated moments, by playing and exploring when positive affect predominated. However, positive affect, optimism, and goal-directed behavior have also been

found to be characteristic of bipolar disorder or prodromes of the disorder (Johnson, 2005b). Some research has also linked bipolar disorders to profile of other assets that are rarely systematically associated with mental illness, including heightened creativity, academic achievement, and intellectual performance (Johnson, 2005b; Murray & Johnson, 2010). Accordingly, a number of considerations will need to be made to incorporate this knowledge into prevention and intervention strategies, like recognizing that rapidly increasing positive affect in an individual suffering from bipolar depression may actually stimulate a manic episode, rather than helping the individual return to a euthymic state.

In summary, translational applications for developmental psychopathology principles will be important for prevention and intervention. Success in this field is likely to draw from advances in phenomenological, etiological, and neurobiological research on bipolar disorder in youth. Longitudinal research and intervention studies will be critical for continuing to address many of the gaps in our current understanding of this neurodevelopmental disorder. We are still learning how the normal brain develops and which neural features are associated with atypical brain development and a poor prognosis (e.g., Fristad & Algorta, 2013). It is highly likely that some of the current challenges in effectively treating bipolar spectrum disorders in youth would be ameliorated by more fully understanding the development of the illness.

SUMMARY AND CONCLUSION

Developmental psychopathology is a conceptual approach that addresses development and variation in development, with a particular emphasis on mechanisms and processes associated with adaptation and risk (Cicchetti & Cohen, 2006; Rutter, 2013). In the last 25 years, we have seen significant advances in our knowledge of bipolar disorder in youth (Fristad & Algorta, 2013), including the publication of major reviews of progress in understanding bipolar disorder from a developmental psychopathology perspective (e.g., Miklowitz & Cicchetti, 2010). This chapter strove to continue these efforts by summarizing progress in three of the domains in which developmental psychopathology has most powerfully shaped our understanding of the risk and protective factors for bipolar disorder: phenomenology, etiology, and neurobiology. Innovative progress is also expected in these three domains in the future.

Beginning with a historical review of the diagnosis of bipolar disorder, we have described some of the major changes to the conceptualization and categorization of the illness. The current controversy over the diagnosis of pediatric bipolar disorder has drawn attention to some major limitations facing psychiatry and clinical psychology, and has prompted a reconceptualization of the basic assumptions guiding research on bipolar disorder. For much of the twentieth century, researchers largely ignored the possibility that bipolar disorder could begin in childhood and adolescence. Clinical and epidemiological research has provided convincing evidence that bipolar disorder is commonly evident prior to adulthood, spawning research in this topic. The often heated controversies about appropriate criteria for bipolar disorder in youth have begun to dissipate with researchers now acknowledging the value of specifying the approach for characterizing bipolar disorder, with some groups focusing on narrow definitions and other groups focusing on broad definitions. Different definitions may be advantageous for answering different research questions (e.g., narrow definitions may be more consistent with adult pathology). Also, clarifications have been made to characterizing the onset and course of bipolar disorder. The age-of-onset may be the crucial factor determining the severity and type of bipolar disorder that individuals eventually experience.

Beyond the traditional, categorical diagnostic approaches used to characterize psychopathology, empirical approaches using phenotypic dimensions are being increasingly explored. Empirical models have been important in characterizing the macro-structure of more common forms of psychopathology in children and adults. Empirical models are also showing that bipolar disorder has less in common with unipolar depression than was once believed. Rather, these models indicate that bipolar disorder is closely aligned with thought disorders like schizophrenia and cluster A personality disorders, as well as broader indexes of internalizing and externalizing psychopathology. These more recent approaches to classification complement the views inherent to developmental psychology, in which risks for mental disorders and mental disorders themselves are considered largely dimensional phenomena (Rutter, 2013). This work on the phenotypic classification of symptoms, syndromes, and disorders is foundational to advancing the developmental study of pediatric bipolar disorder and continues to be pivotal in facing the challenge of how best to treat youth suffering from this illness.

In the first section of this chapter we also discussed definitions of psychopathology that focus on behavior and underlying neurobiological substrates, rather than relying exclusively on phenotypes based largely on subjective

experiences and self-reports. While these models are still imperfect and incomplete, the Research Domain Criteria (RDoC) initiative and the growing prominence of work that serves to identify biomarkers and endophenotypes reflect a major shift in the field toward another type of empirically based definitions of mental illness. These efforts should also help researchers eliminate the heterogeneity that has slowed and frustrated research on bipolar disorder, particularly pediatric bipolar disorder. Ultimately, this research intends to establish more valid and reliable characterizations of symptoms, syndromes, and disorders, which should allow clinicians to treat the true causes of an illness. Progress in understanding the causes and underlying neurobiological mechanisms of bipolar disorder in children and adolescence will need to incorporate developmentally appropriate theories and assessment strategies.

The second section of this chapter focused on etiological theories of bipolar disorder. Although the specific causes of bipolar disorder are still unknown, our current etiological models of mental illness have progressed sufficiently to incorporate greater complexity and to embrace the myriad of interactions between biology, the environment, and development. We started our discussion of etiology by considering the important—though somewhat limited—research on environmental contributions to bipolar disorder. While there is strong evidence that biological contributions to bipolar disorder are important, nongenetic factors are responsible for up to 40% of illness susceptibility. That is, environmental stresses and hazards dramatically affect the risk, onset, and course of bipolar disorder in a number of different ways. Life stress, particularly when experienced in early childhood, is thought to have a deleterious impact on adaptation. The results support this more general pattern of risk shared by many stress regulatory disorders (e.g., depression and schizophrenia), showing an increased risk for bipolar disorder in those who experience early life stress. By contrast, the evidence for links between early hazards and susceptibility to bipolar disorder (e.g., perinatal insults and complications) is less clear. The model proposed by Murray and colleagues (2004) contends that patients with schizophrenia, but not those with bipolar disorder, exhibit critical developmental differences related to such early insults. It is possible that hazards introduced later in development have a similar impact on the ongoing development of the neurobiological system (e.g., marijuana use in adolescence) and may negatively impact the onset and course of bipolar disorder, similar to the way they increase risk for schizophrenia. Although to the specific role of environmental stresses and hazards still remains speculative and requires further investigation, recent findings point to the potential importance of examining developmentally sensitive environmental risk factors for bipolar disorder. Models that more fully incorporate environmental contributions to bipolar disorder and consider the biological embedding of experiences represent an important area of continued inquiry.

The second half of the etiology section reviewed the genetics of bipolar disorder. Genetics research is beginning to contribute to models that illustrate how genes are probabilistic and not deterministic causal factors for bipolar disorder, and how the environment can influence genetic risk for an illness. Recent behavioral and molecular genetics research has not yet adequately investigated the genetics of pediatric bipolar disorder, but it has started to make significant progress in mapping the genetic etiology of adult mental illnesses. Behavioral genetics studies have fairly consistently shown that between 60% and 90% of susceptibility to bipolar disorder is caused by additive genetic factors. While bipolar disorders were once thought to be caused by a few bipolar genes, evidence from extensive family and twin studies—along with the failure of gene-linkage research—has definitively shown that this is not the case. Instead, genome-wide association studies (GWAS) and statistical analysis like genome-wide complex trait analysis (GCTA) are showing that bipolar disorder—like most complex psychiatric illnesses—is most likely to be caused by thousands of common single-nucleotide polymorphisms (SNPs) with very small effects and by a smaller number of rare variants (both SNPs and structural variants) with fairly large effects. This pattern of susceptibility likely explains why current GWA studies with relatively small numbers of participants and low-resolution microassays have only been able to identify a few causal genetic variants (the problem of missing heritability). Nonetheless, existing genetics research has advanced our understanding of commonalities and differences between what we currently consider different classes of psychiatric disorders (e.g., bipolar disorder shares a large portion of its genetic composition with schizophrenia). Finally, although they remain speculative and less understood, several promising approaches are being considered for understanding the way that genetic risk for bipolar disorder can be affected by environmental factors, including epigenetics and specific gene–environment interactions. Genetics research continues to advance very quickly, and while it is likely that the genetic architecture of bipolar disorder will be complex and multifaceted, we remain cautiously optimistic this progress will eventually translate into better methods for

characterizing bipolar disorder and will aid in enhancing intervention options.

In the third section of this chapter, we turned our attention to the structure and function of the brain in youth diagnosed with bipolar disorder, another rapidly growing field of research. We briefly reviewed neurocognitive studies and then more comprehensively reviewed neuroimaging studies on pediatric bipolar disorder across a wide range of modalities including volumetric analysis, task and resting-state functional MRI, diffusion tensor imaging, and spectroscopy. These studies have documented substantial differences in the neuroanatomy and neural functioning of youths with bipolar disorder in comparison to healthy controls, youths with other psychiatric disorders, and even adults with bipolar disorder. Some of the major differences involve brain regions implicated in emotional regulation, such as limbic regions (e.g., amygdala, hippocampus, and cingulate) and cortical regions such as the dorsolateral prefrontal cortex. Some core documented differences are that bipolar youth show smaller amygdala volumes; hyperactivation of limbic regions; less white matter integrity in the corpus callosum, internal capsule, and cingulum (though the specific areas of difference has varied between studies); and abnormalities in some neurometabolites (e.g., N-acetyl-aspartate, choline-containing compounds, glutamate/glutamine, and myoinositol) that reflect possible decrements in the status of cellular health and function in the brain. These studies, while still somewhat preliminary due to small and heterogeneous sample sizes, support theories that bipolar disorder involves neurodevelopmental abnormalities (abnormal dendritic arborization and neuropil), elevated excitatory neurotransmission and excitotoxicity, and abnormal intercellular signaling. While the studies searching for neuroanatomical biomarkers for the disorder that can reliably distinguish it from other disorders have generally been few, small in size, and inconsistent, future use of multiple imaging modalities, larger samples, and more uniform methods could help identify potential biomarkers. Neuroimaging studies have also been used to determine potential precursors to bipolar disorder and its developmental trajectory in youths. These studies support the notion that there are neuroanatomical precursors to the disorder, including key frontolimbic abnormalities. They have also shown that the neurobiology of the bipolar disorder varies according to the developmental period in which it first emerges (e.g., childhood or adulthood). Finally, treatment research has shown preliminary evidence that anomalous brain functioning can be normalized with medication and points to some possibilities for using neuroimaging to predict response to treatments. We believe this line of research has great potential for continuing to help characterize the neurobiological underpinnings of bipolar disorder, and to shape our ideas about susceptibility to the illness and its course and outcomes.

In closing, this is an extremely exciting time for the developmental study of bipolar disorder. The past two decades have witnessed technological innovations and methodological advances that have laid the foundation for current research. Empirical models of mental illness are combining with new information from genetics, neuroimaging, and longitudinal studies to paint a more accurate and complex picture of bipolar disorder. We are finally starting to understand how the disorder progresses and the role that development and environment play in the onset, course, and prognosis of the illness. While years of research will be required to more fully elucidate the etiology, along with risk and protective factors, the direction of research is becoming clearer. New frontiers in biological psychopathology research on bipolar disorder will include longitudinal designs examining risk and protective factors and continued examination of brain-behavior relationships using multiple levels of analysis across a range of participants (e.g., individuals not fitting traditionally defined psychiatric categories). Much of this research is still in its infancy, and it may be another decade before many of the fundamental questions about pediatric bipolar disorder are answered. What is important to recognize is that researchers are beginning to question some of the long-standing assumptions about bipolar disorder, and are searching for empirical answers using longitudinal, multidisciplinary research approaches. Prevention and intervention research must draw from the advances yielded by phenomenological, etiological, and neurobiological research to help relieve the suffering of those diagnosed with bipolar disorder.

INTRODUCTION

Schizophrenia is regarded as a developmental disorder because it involves abnormal function of multiple brain regions and neural circuits that become apparent during development (Weinberger, 1987). Thus, most individuals present with symptoms of schizophrenia during late adolescence or young adulthood. Childhood onset of the disorder is considered rare, associated with more severe positive and negative psychotic symptoms (Table 21.1), and with worse prognosis than the later onset disorder (Frazier et al., 2007). However, well-designed epidemiological outcome studies that include a large representative number of subjects with different ages of onset and illness severity are needed to confirm this assumption.

This chapter first introduces the reader to the need for a developmental approach to diagnose schizophrenia in children, the related clinical and research implications of the challenges involved in making this diagnosis, and the differential diagnosis. It then describes risk factors and premorbid features related to development of the disorder. The next section reviews the impaired cognition, social cognition, and self-disturbance that occur during the acute and chronic phases of the illness.

A detailed review of structural imaging findings sheds some light on the developmental mechanisms underlying the multiple areas of functioning involved in this disorder and their associated symptoms. After briefly reviewing the functional imaging and genetic findings in early-onset

Avolition (lack of motivation)

schizophrenia, the chapter describes the treatment and course of the disorder.

Since schizophrenia is a neurodevelopmental disorder, it should serve as a model for the application of Cicchetti and colleagues (Cicchetti, 2006; Cicchetti & Toth, 2009) five developmental psychopathology principles: (1) examination of processes involved in the interaction between adaptive and maladaptive development over the lifetime course and factors involved in resilience; (2) a multiple level analysis that incorporates an interdisciplinary perspective; (3) prevention and intervention initiatives based on theory and research of biological and psychological developmental processes; (4) incorporation of cultural contexts into study designs and treatment initiatives; and (5) translational research.

As will become evident in the research reviewed in the different sections of this chapter, most of the research on child and adolescent onset schizophrenia has not applied these five principles. In addition, there is a dearth of knowledge about the variables that contribute to resilience to childhood and adolescent onset of schizophrenia, the course of the early-onset disease, and its long-term outcome. To fill this gap, in its different sections the chapter incorporates findings of studies on risk factors for adult schizophrenia and of studies on the nonpsychotic relatives and individuals at clinical risk for schizophrenia. The chapter concludes with suggestions for possible future research directions that incorporate the five developmental psychopathology principles.

DIAGNOSIS

The Need for a Developmental Approach

The primary symptoms of schizophrenia, hallucinations, delusions, and formal thought disorder, represent abnormalities of skills, including cognition, language, reality testing, judgment, and organization of thoughts, that develop during childhood and adolescence. Hallucinations (sensory percepts in the absence of an external sensory stimulus) involve impaired reality testing and ability to differentiate between internal and external perception of auditory, visual, tactile, olfactory, or gustatory stimuli. Delusions, pervasive erroneous beliefs despite evidence to the contrary, also represent impaired reality testing and judgment.

The clinical term, formal thought disorder, denotes poor use of language to formulate, organize, and express thoughts so that the listener can make sense of the child's speech (the meaning of each sentence, the ongoing topic of conversation, logical sequence of expressed thoughts), as well as who and what the child is referring to across sentences. It also reflects impaired online monitoring and self-initiated repair of how coherently the child expresses thoughts.

Since the skills involved in these symptoms develop during middle childhood and mature in early adolescence, the manifestations of hallucinations, delusions, and formal thought disorder might differ in children of different ages. Additional *DSM-IV-TR* (APA, 2000) symptoms of schizophrenia, grossly disorganized or catatonic behavior and negative symptoms, also pose diagnostic challenges. Unlike catatonic behavior (which is rarely found in youth under age 15), these symptoms can also occur in children with and without psychopathology.

The Challenges Involved in Applying a Developmental Approach

There are four main reasons why pediatric professionals are challenged when they need to rule in or out a diagnosis of schizophrenia during middle and late childhood. First, they receive inadequate or sparse training on age-related changes in cognition, language, reality testing, and judgment. Second they are infrequently exposed to schizophrenia in children during their medical, psychological, social work, or other mental health training. Third, they sometimes mislabel children's out-of-control or bizarre behavior as disorganized and psychotic. Fourth, they might also feel ill equipped to differentiate normal developmental phenomena, such as imaginary friends and a vivid creative imagination, from both hallucinations and delusions.

A lack of training on how normal and deviant development of children's basic and higher-level discourse language skills present is an additional important obstacle. More specifically, a child professional might have difficulty understanding what a child is talking about because the child has formal thought disorder, a language disorder, intellectual disability, or severe anxiety. The term thought disorder has also been somewhat loosely used as a

synonym of schizophrenia. As such, its connotation varies across users from the impaired thought content found in delusions to the disorganized communication of thoughts found in formal thought disorder.

The challenges emanating from lack of training and exposure and inaccurate use of terms, such as thought disorder are further complicated by the difficulty child mental health-care professionals have obtaining information about psychotic symptoms from children. Most importantly, children resist talking about their psychotic symptoms. They are scared both because they perceive their hallucinatory experiences as unusual and the content of their hallucinations might be threatening (e.g., a voice threatens to kill the child). Although children try to seek comfort or protection by telling their parents about these experiences, parents often respond by telling their children that they are just imagining things. Aware that these experiences are not ordinary, they then conclude that their parents think that they are crazy or at best do not understand what they are experiencing. As a result, they refrain from mentioning recurring hallucinations to their parents and to other adults.

Children who also have magical thinking (another normal developmental phenomenon in middle childhood) might be scared that if they talk about their hallucinations, they will come true. For example, if a voice commands a child to kill his sibling, the child might be scared that talking about this act is tantamount to actually doing it.

Parents or teachers might misinterpret a child's anxiety as disorganized behavior. Moreover, because of their poor insight, children with schizophrenia are poor informants about this symptom. Confirmation of disorganized behavior, therefore, warrants direct observation by an experienced child clinician.

Taken together, these challenges highlight the importance of providing child mental health professionals with developmental guidelines on how to reliably assess symptoms of schizophrenia in children of different ages. This is particularly important because young children are usually the best informants about their psychotic symptoms, disorganized behavior, and what appear to be negative symptoms. The wide range of psychiatric disorders included in the differential diagnosis of childhood schizophrenia described below underscore the need for child mental health professionals to include these skills in their professional toolbox. Due to space limitations, interested readers can find more details on techniques to obtain information from young children on psychotic symptoms and a wide range of behaviors and emotions in Caplan and Bursch (Caplan & Bursch, 2012).

Developmental Guidelines for the Assessment of Psychotic Symptoms

Hallucinations

79%–100% of children and adolescents with schizophrenia have auditory hallucinations, 30.3–78.9% have visual hallucinations, one third have olfactory hallucinations, and less than one fourth have tactile and gustatory hallucinations (McKenna et al., 1994; Russell, Bott, & Sammons, 1989). Auditory hallucinations are commanding, conversing, persecuting, and religious (McKenna et al., 1994; Russell et al., 1989).

As previously mentioned, children typically do not voluntarily tell mental health professionals that they have hallucinations. But they do respond to sensitive developmentally based questions about these experiences. A nonthreatening open-ended question, such as, Does your imagination ever play tricks on you? helps introduce the topic. If the child answers in the affirmative, one should proceed to ask, What tricks? The child might warily answer with a word, such as *noises*, *at night*, *a dream*, or *scary*.

Additional probing questions—What kind of a noise? What does the noise sound like? Who makes the noise? Is it a noise or a voice? What does it say?—help determine the form and content. Once the child responds to questions on the details of the experience (e.g., Is it one or more than one voice? Whose voice is it? What does the voice say? In what language does the voice speak?), one should ascertain if it is associated with subjective distress (How does that make you feel when you hear. . . .?). To determine if the child has poor reality testing, one should find out if the child tries to make it stop and how convinced the child feels about it being a real experience that does not go away.

Similar questions help inquire about visual, tactile, olfactory, and gustatory experiences. It is important to avoid using questions such as, Do you hear voices *that no one else hears*? or Do you see things *that no one else sees*? Since these questions make children feel that the interviewer is suggesting they are 'crazy' or 'weird,' they typically deny these experiences.

To help children talk about these difficult topics, professionals should use concrete action-based language rather than the abstract and vague language used in the following example: Do you have unusual (strange, weird) experiences like seeing things? The connotation of being crazy in the words, unusual, strange, and weird, might make children resistant to talk about their hallucinations.

Hallucinations are rare before age seven. Therefore, reports of hallucinations in children under 7 might represent mislabeling or misinterpretation of behaviors. This

concern is particularly warranted in intellectually disabled or language delayed children. Examples include the concern that a child covering his ears with or without a fearful response or agitated behavior is having an auditory hallucination or that a child looking at something with a fixed look while laughing, mumbling, or acting fearfully might be experiencing a visual hallucination. Most importantly, one can make a reliable and valid assessment of hallucinations only in a child who is able to verbalize the phenomenon.

Hallucinations also need to be differentiated from normal developmental phenomena. Imaginary friends are invisible or personified objects with whom children under age 7 have a sustained form of play, pretence, daily routine, and even arguments (see review in Trionfi & Reese, 2009). In contrast to children with schizophrenia, these children are sociable and have a high level of language skill and good reality testing (Trionfi & Reese, 2009).

It is also necessary to determine if children's fears are age-appropriate or reflect the child's living conditions before concluding that they represent hallucinatory experiences. For example, a child who lives in a neighborhood with frequent drive-by shootings reports hearing gunshots every night when trying to fall asleep. Vivid nightmares might appear real and cause fear when children first wake up. If, however, the child feels as if the dream experience continues during the day, the possibility of a hallucinatory experience needs to be ruled out.

While falling asleep or if they wake up during the night, children might also experience visual illusions (e.g., a pile of clothes on a chair might look like a monster). These misinterpretations of visual stimuli are differentiated from hallucinations by the child's good reality testing for the imaginary quality of the experience when awake in the morning.

Delusions

Delusions often have bizarre content in schizophrenia, and can be persecutory, referential (refer someone's action to one-self), controlling, somatic, religious, self-accusatory (delusions of guilt), and nihilistic (McKenna et al., 1994; Russell et al., 1989). Due to the abstract nature of the concept of delusions, in contrast to hallucinations, no single question is suitable to tap into the delusional process in young children. Clinicians can access information about children's delusions using concrete questions (Table 21.2).

Like hallucinations, delusions are rare in children under age seven, and should be differentiated from normal developmental phenomena, such as fantasies and magical thinking (thoughts and wishes are equated to actions). If a child is cognizant of the imaginary or wishful thinking quality of these thoughts, they do not represent a delusion. Morbid fantasies (repeated elaborate thoughts involving aggression) might be precursors of delusions if they are pervasive and if the child will act on the basis of these thoughts. Given the high level of violence in the media and children's computer games, it is important to differentiate media or game induced recurrent thoughts about violence from delusions.

For example, a child repeatedly thinks about and plans how to kill, blow up, or maim others despite the possible consequences, and says that this will make him very happy. When asked what will happen if he carries out the plan, he responds that he does not care as long as the people are dead, blown up, or badly hurt. This child's pervasive aggressive thoughts, willingness to act on his thoughts, and poor reality testing suggest that they are precursors to delusions.

TABLE 21.2 Questions on Delusions for Children

Delusion Type	Questions
Message	Do people on TV, YouTube, or the Internet say things only for you? What do they say?
Persecution	Are there people who do bad or mean things to you or your family? What do they do?
Reference	When you walk in the street (cross the play ground at school), do kids look at you and talk about you? What do they say?
Somatic	When you look at yourself in the mirror, is there any part of you that looks strange or different? How about inside your body, is everything in there okay?
Thought broadcasting	Do people on TV, YouTube, or the Internet talk about what you are thinking?
Thought insertion	Can people put thoughts into your head and make you think what they want you to think?
Thought withdrawal	Can they take thoughts out of your head and not let you think what you want to think?
Thought control	Do people know what you are thinking? Do you know what other people are thinking?
Motor control	Do you sometimes feel like someone else, not you, is in your body and makes it work?
Guilt	If you do something wrong or bad, do you forget about it or keep on thinking about it? If something bad happens to someone you know, and you had nothing to do with it, do you feel you made that happen?
Nihilism	Do you sometimes worry that the world is going to end?
Grandiosity	Do you have special powers? What special powers? What things can you do that no one else can do? Like what?

TABLE 21.3 Definition and Examples of Thought Disorder

Thought Disorder	Definition	Example
Formal Thought Disorder		
Illogical thinking	Inappropriate or inadequate reasoning or contradiction	I left my hat in her room *because her name is Mary*.
Loose association	Unpredicted topic change to an unrelated topic	I: Why's that not Tim? S: *I call my mom sweetie*.
Cohesion		
Conjunctions	Ties together contiguous clauses (sentences)	The witch gets burned *and* that's the end of the story.
Referential cohesion	Pronoun, demonstrative, definite article, or comparative referring to person/object in the preceding spoken text	A boy called *Peter* saw a ghost. He was scared.
Unclear reference	Pronoun, demonstrative, definite article, or comparative referring to person/object unmentioned in prior text	I went and looked at *the guy* to see what *they* did.
Ambiguous reference	Referent that can apply to more than one person or object	*Her mother* made a costume and *she* was happy.
Exophora	Reference to immediate environment during conversation	I: Did you like that story? S: *Open this toy*.
Lexical cohesion	Ties between ideas by word repetition, synonym, antonym	The kids were *bad*. Tim was bad too.
Repair of the Organization of Thoughts		
Repetition	Clarifies what was said by repeating word(s)	'Cause he wants . . . '*cause he wants* to play with him.
Postponement	Adds background information to clarify referent	And she knew *when she found the kitten* she knew that was what was making the girl happier.
False starts	Starts, but does not complete an idea	*And um I don't* . . . Manniken said but I want to play.
Fillers	Word(s) that fill pauses without changing the meaning	*Well, like,* I don't know, it's just scary.
Revision of Linguistic Elements		
Referential	Clarifies the referent	She would have *Anne would have* to take care of her.
Word choice	Modifies word choice	Play with him and make *give him* some wishes.
Syntactic	Corrects syntactic error	The picture you're drawing *you drew* looks funny.

Disorganized Speech or Formal Thought Disorder

DSM-IV TR signs of formal thought disorder include illogical thinking and loose associations. In contrast to delusions, formal thought disorder involves the form rather than the content of children's communication, and is best ascertained by listening to a child's speech. Table 21.3 presents the thought disorder signs and examples found in children with schizophrenia.

To evaluate formal thought disorder (Caplan, Guthrie, Komo, Tang, & Asarnow, 2000), one should obtain speech samples of adequate length from children. But, young children do not spontaneously talk at length (i.e., in paragraphs) about a topic. Children in this age group need an adult's help to induce them to speak in mini-paragraphs of 1–3 utterances through what or how action-based concrete questions, described in detail in (Caplan & Bursch, 2012).

For example, in response to the question, What do you like to do when you come home from school? a child might answer, Watch TV. To get the child to talk more about this, one can ask, What TV shows are your favorite? What do you like about . . . show? I have never seen . . . show. What happens in the story? What is the best part of the story? What don't you like about the story?

Alternatively, in response to the initial question, a child might answer, I have a snack and watch TV (2 utterances). A child with loose associations will unpredictably change the topic of conversation without preparing the listener for the topic changes and respond, My sister is in fourth grade. A child with illogical thinking might answer to the same question, I nap because I have a lot of energy. The causal phrase *because I have a lot of energy* contradicts the act of napping and is illogical.

Younger children with schizophrenia have significantly more thought disorder than older children with this disorder (Caplan et al., 2000). This finding reflects the previously described protracted course of language development, particularly of higher-level discourse skills involved in the organization, processing, and abstract contextual aspects of discourse (inferences, metaphors, jokes, sarcasm). Thus, onset of schizophrenia during ongoing maturation of language-related brain regions (described in more detail in the Imaging section) might underlie the more severe thought disorder in younger compared with older children with the disease.

In addition to thought disorder, children with schizophrenia also have impaired basic linguistic skills (Blanchard et al., 2010; Caplan, Siddarth, & Gurbani, 2010;

Hollis, 2003; Kumra et al., 2000; Nicolson et al., 2000; Rhinewine et al., 2005). Although the severity of thought disorder and of linguistic deficits were significantly associated in 37 subjects with schizophrenia with a mean age of 13.6 (2.7) years, the patients with average linguistic skills (54%) also had thought disorder (Caplan et al., 2010). This finding, together with no relationship between thought disorder signs and other psychotic symptoms, premorbid symptoms, and IQ, suggested that thought disorder is a core feature of childhood onset schizophrenia (Caplan et al., 2010).

From the developmental perspective, it is essential to differentiate thought disorder from the difficult to understand or disorganized speech of children who have problems understanding language or expressing themselves due to a language disorder or intellectual disability. Since most clinicians do not have prior training on how to assess language and discourse skills in typically developing children of different ages, ruling in or out formal thought disorder poses a difficult diagnostic challenge. In such cases, referral to a speech and language therapist would help clarify the diagnosis.

Disorganized Behavior and Negative Symptoms

As previously noted, a reliable and valid assessment of disorganized behavior requires direct observation by a child mental health professional who knows how to determine possible reasons for young children's disorganized behavior. This nonspecific symptom can reflect fear, anxiety, anger, oppositionality, mania, encephalopathy (brain dysfunction/damage due to a neurological or metabolic disorder), or psychosis.

Regarding negative symptoms (Table 21.1), affective flattening and anhedonia are rare in children. In addition, what appears to be impoverished content of speech (alogia) in a young child might reflect a child's difficulty understanding the interviewer's questions due to immaturity, a language disorder, or intellectual disability. It often simply indicates that the interviewer is asking the child developmentally insensitive questions. Similarly, avolition (lack of motivation) in a young child could mean that an activity is boring, difficult, or not what the child wants to do. Therefore, mental health professionals need to use a developmental approach to clarify the nature of behaviors that appear to be negative symptoms in young children.

The Clinical and Research Implications

Comprehensive clinical assessment commensurate with a child's developmental level is essential to determine if hallucinations, delusions, and formal thought disorder represent schizophrenia, another type of psychosis, or other psychiatric disorders. Due to the developmental challenges involved in the diagnostic evaluations of young children, the psychotic nature of symptoms that appear to be related to other psychiatric disorders sometimes go unrecognized. Misdiagnosis and incorrect treatment of schizophrenia can have deleterious metabolic, neurological, and cognitive effects as described in the section on Treatment. Furthermore, since a diagnosis of schizophrenia is associated with a stigma, an incorrect diagnosis can cause significant repercussions for children and their families.

From the research perspective, misdiagnosis and the inclusion of a heterogeneous rather than a homogenous well-defined group of children in a study of this relatively rare disorder can result in erroneous or at best diluted findings. To help the reader face the diagnostic challenges, the next section describes the diagnostic categories that should be included in the differential diagnosis of psychotic symptoms and early-onset schizophrenia.

The Differential Diagnosis

The previous sections on hallucinations, delusions, and formal thought disorder emphasized the importance of ruling out normal developmental phenomena that might lead to a misdiagnosis of these psychotic symptoms. Two child population studies, one conducted in New Zealand on 788 children, aged 11 years (McGee, Williams, & Poulton, 2000) and one in Japan on 761 children, aged 11 and 12 years (Yoshizumi, Murase, Honjo, Kaneko, & Murakami, 2004), found hallucinations in 8% and 21% of these typically developing children, respectively. Using structured psychiatric interviews (McGee et al., 2000) and self-report instruments (Yoshizumi et al., 2004), these cross sectional studies found mainly anxiety, dissociation, and inattention in the children compared with those without hallucinations. Thus, the presence of hallucinations in a young child highlights the importance of a careful diagnostic assessment to first rule out more commonly occurring psychiatric disorders, as well as the more infrequent disorder, schizophrenia.

Application of clinical acumen to this diagnosis is further emphasized by two important prospective findings. The first is the relatively low rate of conversion to schizophrenia in follow-up studies of first episode psychosis in youth (Cannon et al., 2008). The second is the transient nature of atypical psychotic symptoms, particularly in children with a history of abuse and neglect, and evidence of dissociation (Hlastala & McClellan, 2005).

TABLE 21.4 Developmental Approach to Differential Diagnosis of Childhood and Adolescent Onset Schizophrenia

Disorder	Symptoms	Differentiate vs. schizophrenia (Sz)
Psychotic disorders		
Affective psychoses		
Depression	Irritability and angry mood	Appropriate facial expression of affect vs. inappropriate or incongruent affect in Sz
	Hallucinations, delusions, suicide	Mood congruent vs. bizarre content in Sz
	Negative signs	No affective flattening and anhedonia
Bipolar disorder	Mania, irritability, or angry mood	Appropriate facial expression of affect vs. inappropriate or incongruent affect in Sz
	Hallucinations, delusions	Mood congruent vs. bizarre content in Sz
	Distractibility, flight of ideas, increased motor activity	Mood congruent vs. association with internal preoccupations (hallucinations and delusions) in Sz
Schizoaffective	Irritability, anger, depression, mania	Appropriate facial expression of affect vs. inappropriate or incongruent affect in Sz
	Delusions, hallucinations, suicide	Mood congruent vs. bizarre content in Sz
Organic psychoses		
Epilepsy	Fixed hallucinations, delusions	Changing in Sz
	No loose association	Loose associations in Sz
	No negative signs	Negative symptoms evolve over time in Sz
Degenerative disorders	Hallucinations, delusions, thought disorder early in illness	Disorientation and significant loss of cognitive and linguistic skills in degenerative disorders vs. schizophrenia
Drug-induced psychosis	Often persecutory hallucinations, delusions	
	No negative signs	
Dissociative psychosis	Multiple past diagnoses	
	Threatening and protecting voice	Bizarre hallucinations, delusions in Sz
	No subjective distress	Significant subjective distress in Sz
Transient (psychotic-like) psychosis		
Schizophrenia, prodrome, spectrum disorder, psychosis NOS, muldimensionally impaired children, multiplex developmental disorder, schizotypal personality disorder	Vacillating reality testing for hallucinations, delusions	Does not meet frequency, duration, severity of Sz diagnostic criteria
Developmental disorders		
Autism spectrum disorders	Circumscribed preoccupations	Good reality testing vs. Sz
Fears and anxiety disorders		Good reality testing vs. Sz
Disruptive disorders		
Attention-deficit/hyperactivity disorder	Poor attention span	Impaired attention associated with hallucinations and delusions in Sz
Oppositional defiant disorder	Discipline related oppositionality	Hallucination and delusion induced oppositionality in Sz

Table 21.4 presents the diagnostic categories and disorders that should be included in the differential diagnosis of childhood onset schizophrenia. It highlights the symptoms of these disorders that pose diagnostic challenges from the developmental perspective and how to differentiate them from symptoms of schizophrenia.

Psychotic Disorders

Affective Psychosis. Depression with psychosis in middle childhood is frequently associated with the types of hallucinations and delusions found in schizophrenia but not with formal thought disorder (Ulloa et al., 2000). Whereas the content of hallucinations and delusions in affective psychoses (depression, bipolar disorder) is mood congruent, it is bizarre and unrelated to mood in schizophrenia. For example, a boy with psychotic depression who has delusions of guilt might experience auditory hallucinations that command him to kill himself because he is a bad person. A manic girl with a grandiose delusion that she is the world's best gymnast might have conversing auditory hallucinations in which she hears her peers talk about her amazing gymnastic skills. In contrast, a child with schizophrenia who believes that there is a slug in his nose (somatic delusion) might experience an auditory

command hallucination to kill himself to rid himself of the slug. The bizarre content of this hallucination is not mood congruent.

Negative signs are an inclusionary diagnostic criterion of both depression and schizophrenia. Young children with depression are often irritable and angry rather than sad, and do not present with the affective flattening found in adults and adolescents with depression and in youth with schizophrenia. Although depressed children rarely experience anhedonia, this symptom is prominent in adolescents with schizophrenia and in teen depression.

Negative symptoms could also represent side effects of high antipsychotic drug doses. Since young children rarely monitor and verbalize the side effects of drugs on their behavior, they are not good informants for this type of information. A parental report that the negative symptoms developed with increasing medication doses would support this diagnostic possibility. Persistent negative symptoms, together with worsening of hallucinations and delusions, in a young depressed child treated with an antidepressant drug, would suggest the likelihood of schizophrenia.

Schizophrenia is the eleventh leading cause for suicide in the general population with suicidal acts occurring in 20–50%, suicidal ideation in 50%, and eventual death by suicide in 4–13% of patients with schizophrenia (see review in Montross, Zisook, & Kasckow, 2005). There have been no studies to date, however, on the incidence and prevalence of suicidality in early-onset schizophrenia. Suicidal behavior needs to be assessed in every psychotic child. As for hallucinations and delusions, mood incongruency and bizarre content of suicidal ideation help confirm schizophrenia rather than an affective disorder.

Unlike their adolescent counterparts, however, young children with schizophrenia do not usually think a lot about death and dying, spontaneously tell mental health professionals about suicidal thoughts and plans, nor confirm these symptoms when asked about them in front of their parents. Due to fear that their parents will be angry with them if they have these symptoms, it is necessary to evaluate them without their parents to ask them about suicidal ideation and plans.

Dissociative Psychosis. In addition to a past psychiatric history of unsuccessfully treated prior multiple psychiatric diagnoses and abuse (physical, sexual, or emotional), the auditory hallucinations of youth with dissociative psychosis usually involve familiar people from the child's life with one threatening and one protecting voice (Hornstein & Putnam, 1992). Visual hallucinations appear as apparition-like images (Hornstein & Putnam, 1992). In contrast to children with other psychotic disorders, children with dissociative psychosis do not appear to be distressed by their hallucinations. Delusions, other than thought withdrawal and insertion, and formal thought disorder are not features of this disorder (Hornstein & Putnam, 1992).

Organic Psychoses. Among the neurological disorders, pediatric epilepsy is infrequently associated with psychosis during (ictal), after (post-ictal), and between seizures (interictal) (see review in (Kanner & Dunn, 2004)). Ictal psychosis includes unchanging, stereotyped, unimodal (involving one sensory system), and subjectively distressing hallucinations, as well as delusions (mainly forced thinking). Unlike schizophrenia, affective psychoses, and dissociative psychosis, children with ictal psychosis do not recall the content of their hallucinations or delusions unless they occurred during an aura that was not followed by a generalized tonic-clonic seizure.

Similar to schizophrenia, children with interictal psychoses have multimodal hallucinations that vary in content and form, delusions, and formal thought disorder (Caplan, Shields, Mori, & Yudovin, 1991). However, they do not have negative signs or mood congruent psychotic symptoms. Postictal psychosis is rare in children (Kanner & Dunn, 2004).

Psychosis can occur in early stages of neurological disorders, such as acute disseminated myelitis (Krishnakumar, Jayakrishnan, Beegum, & Riyaz, 2008) and subacute sclerosing panencephalitis (Caplan, Tanguay, & Szekely, 1987), and in medical disorders, such as systemic lupus erythematosus with involvement of the central nervous system (Sibbitt et al., 2002). At disease onset, the hallucinations, delusions, and formal thought disorder are stereotyped and pervasive in contrast to the variable and nonstereotyped form and content of psychotic symptoms in schizophrenia. They disappear as the illness worsens with evidence for disorientation, confusion, and loss of cognitive functions and language.

Delirium, secondary to a medical illness with central nervous system effects or a primary neurological illness, presents with sudden confusion together with fluctuating awareness (waxing and waning of orientation, cognition, and language skill; see review in Smith, Brink, Fuchs, Ely, & Pandharipande, 2013). Youth with schizophrenia are usually oriented (time, place, situation) and their level of awareness does not fluctuate. Variable impairment of both receptive and expressive language with disorganized, disjointed, or incoherent speech and in severe cases, loss of speech, suggest delirium rather than schizophrenia.

Visual hallucinations without auditory hallucinations can be seen in delirium, but not in schizophrenia. If a child talks to herself or has a focused look associated with mumbling, picking, fear, or laughter, this might suggest that she has delirium with auditory or visual hallucinations. However, as previously mentioned, a reliable and valid assessment of hallucinations can be done only with a child who can verbally confirm the hallucinatory experience.

Iatrogenic Psychoses. Corticosteroids can cause psychosis with persecutory delusions and auditory hallucinations with or without altered conscious level and disorientation (see review in Stuart, Segal, & Keady, 2005). Adderall XR, atomoxetine, modafinil, oral and transdermal methylphenidates can trigger persecutory, visual, and tactile hallucinations in children (Mosholder, Gelperin, Hammad, Phelan, & Johann-Liang, 2009). Several mood stabilizers, also used as antiepileptic drugs (ethosuximide, levetiracetam, phenytoin, topiramate, vigabatrin, zonisamide, and felbamate) can induce psychosis in youth with epilepsy (see review in Caplan & Bursch, 2012) but not in youth with bipolar disorder.

Transient Psychosis and Psychotic-like Disorders. Psychosis not otherwise specified (NOS), schizophrenia prodrome, schizophrenia spectrum disorder, multidimensional impairment, multiplex developmental disorder, and schizotypal personality disorder have several features in common. They include children or adolescents who do not meet diagnostic criteria for schizophrenia in terms of the duration, frequency, severity, and prevasiveness of symptoms. For example, an adolescent feels that the world in which he lives is a set with actors (like the *Truman Show*) who are there to observe him. Sometimes he thinks this is his misperception while at other times he is convinced that his life is a setup. Vacillating impairment of reality testing, as in this case, is a feature of the prodromal syndrome, described in detail in (Miller et al., 2003).

The large number of diagnostic categories included under transient psychotic disorders might also reflect the developmental difficulties involved in diagnosing early-onset schizophrenia. In addition, clinicians are reticent to make this diagnosis because of its stigma; the metabolic and neurological side effects of antipsychotic drugs; as well as evidence that children followed for two or more years no longer meet diagnostic criteria for schizophrenia (see review in McClellan & Stock, 2013) and that only 35% of 291 prodromal youth followed convert to schizophrenia (Cannon, 2008).

Youth with schizoaffective disorder meet criteria for schizophrenia but also have prominent affective symptoms. The dimensional versus categorical debate on the diagnosis of schizophrenia, schizoaffective psychosis, and affective psychoses is evident in the adult but not the child literature (see review in Abrams, Rojas, & Arciniegas, 2008). The dimensional theory proposes that these three disorders differ in the extent of psychotic versus affective symptoms. Thus, schizophrenia involves mainly positive psychotic symptoms whereas affective psychoses have prominent affective symptoms. But both affective and positive psychotic symptoms are evident in schizoaffective disorder.

The categorical theory maintains that each of these three diagnostic categories have separate characteristic features. Although adult studies find poor diagnostic reliability for schizoaffective psychosis (see reviews in Abrams et al., 2008), this does not appear to be the case in youth with schizoaffetive disorder (Frazier et al., 2007).

The NIMH group compared children with multidimensional impairment to treatment resistant youth with schizophrenia (Nicolson et al., 2001). In addition to hallucinations and delusions, 19 children with this diagnosis had impaired control of impulse, attention, and affect, as well as poor interpersonal skills despite their wish to have friends. They also had variable developmental delay and autistic symptoms. At the 8-year follow-up, their diagnoses included schizoaffective disorder ($N = 1$), psychosis NOS ($N = 15$), schizotypal personality disorder ($N = 1$), as well as comorbid bipolar disorder ($N = 12$) and major depression ($N = 4$).

The heterogeneous nature of these additional axis I diagnoses, their prominent affective component and psychotic symptoms in most of the subjects at follow-up question the validity of this diagnostic entity. Prior to the introduction of the prodromal syndrome and multidimensionally impaired diagnoses, researchers diagnosed these children with schizotypal personality disorder (Asarnow, 2005) and multiplex developmental disorder (van der Gaag, Caplan, van Engeland, Loman, & Buitelaar, 2005).

Developmental Disorders

Autism Spectrum Disorder. This diagnostic category poses diagnostic challenges when children's circumscribed preoccupations involve imagination and fantasy. In such cases clinicians should determine if the child is aware of the imaginary nature of his preoccupations, and whether the child will act on them. For example, a boy repeatedly thought he was in a time machine. When in the time machine, he talked about and enacted relevant scenes, events, and stories. He was well aware that there is no such thing as a time machine and that this was his imagination. But, he also repeatedly

drew pictures with snakes, monsters, the devil, and people in coffins. He became scared, agitated, and nonverbal when asked about these drawings. Subsequently he was able to say that the devil threatened to place him alive in the coffin with the snakes and monsters. He believed that they were watching him all the time so that they could catch him. This child met diagnostic criteria for both Asperger syndrome and schizophrenia by virtue of his visual and auditory hallucinations, as well as persecutory delusion.

Anxiety Disorders

These disorders are included in the differential diagnosis to emphasize that not all forms of worry, repeated thoughts, or difficulties separating from parents mean a child has a generalized anxiety disorder, obsessive-compulsive disorder, or separation anxiety disorder, respectively. Hallucinations or delusions might underlie these symptoms.

Attention Deficit Hyperactivity Disorder (ADHD)

Although concentration problems are found in ADHD, some children confirm these difficulties when their attention is distracted by hallucinations and recurrent delusions.

Oppositional Defiant Disorder

Irritable affect and associated oppositional behavior in response to hallucinations and delusions might be incorrectly diagnosed as oppositional defiant disorder if their underlying psychotic symptoms are not apparent.

Summary and Conclusions

- A developmental approach is essential for a reliable and valid diagnosis of:
  - Positive psychotic symptoms: Hallucinations, delusions, formal thought disorder
  - Negative psychotic symptoms: Affective flattening, anhedonia, avolition, alogia
  - Disorganized behavior
- The differential diagnosis of childhood onset schizophrenia includes a wide range of psychiatric disorders.
- An accurate diagnosis is a critical prerequisite for:
  - Treatment given the severe adverse effects of antipsychotic drugs
  - To ensure reliable and valid research findings

COGNITION

Low IQ, a central feature of schizophrenia, has led to the suggestion that schizophrenia is a cognitive illness (Kahn & Keefe, 2013). Some researchers consider impaired executive functions (attention, abstract thought, planning/organizing, inhibition and self-monitoring) as core illness deficits (see review in Neill & Rossell, 2013). Others maintain that they reflect lower level or general cognitive deficits (see review in Neill & Rossell, 2013).

Similar to adults with schizophrenia (see review in Kahn & Keefe, 2013), 54 childhood and adolescent onset patients, aged 10–18 years, in a North American multisite study had global cognitive dysfunction with mean IQ scores that were 2 standard deviations lower than 52 normal controls (Rhinewine et al., 2005). In addition as found in adults with this illness, during the two years before and 1.7 years after onset of psychotic symptoms, 31 early-onset youth with schizophrenia in the NIMH cohort had an irreversible decrease in IQ with no subsequent changes during the 13 years after psychosis onset (Gochman et al., 2005).

In contrast, despite no change in symptoms and in both the type and dose of medication, 20 patients from the Maudsley Early-onset Schizophrenia Study with onset of schizophrenia before age 17 had stable intellectual functioning and planning ability over a 4 (+/- 1.08) year period (Frangou, Hadjulis, & Vourdas, 2008). Methodological differences, namely, treatment resistance in the NIMH subjects and the small sample of the Maudsley study might underlie these different findings.

But unlike adult schizophrenia, there also appears to be a downhill course over time in aspects of cognition other than IQ. Frangou et al. (Frangou et al., 2008) reported deterioration in verbal memory and learning, attentional control, and perseverative errors during their 4-year follow-up study of 20 adolescents with schizophrenia. Similarly, a 5-year follow-up study of 17 youth with schizophrenia revealed a significant increased impairment of attention and set shifting (Jepsen et al., 2010). Thaden et al. (Thaden et al., 2006) found poor performance with increasing age and task difficulty on a Continuous Performance Test in 59 adolescents with schizophrenia compared with 55 control subjects. Involvement of the dorsolateral prefrontal region in adult schizophrenia (see review in Fornito, Yucel, Patti, Wood, & Pantelis, 2009) and maturation of this brain region during adolescence (Lenroot & Giedd, 2006; Muftuler et al., 2011) might underlie the age-related increase in executive function deficits in adolescents with schizophrenia.

Regarding clinical variables, the severity of cognitive deficits is associated with negative symptoms and poor premorbid adjustment involving academic achievement (Rhinewine et al., 2005) and social isolation (Thaden et al., 2006). The type of diagnosis, whether schizophrenia compared with schizoaffective disorder (Hooper et al.,

2010) or schizophrenia versus psychosis NOS (Kumra et al., 2000), is unrelated to the profile and severity of cognitive impairments.

Antipsychotic drugs also appear to have a minor effect on cognitive function. A large multicenter double blind randomized controlled study of 116 early-onset schizophrenia and schizoaffective disorder patients treated with olanzepine, molindone, and risperidone showed only a modest effect on neurocognitive impairments (Frazier et al., 2012).

Family and clinical high-risk studies shed additional light on the central role of cognition in schizophrenia. The parents of 79 children with schizophrenia had significantly more motor, attention, and visual spatial processing impairments compared with the parents of 190 children with ADHD and 115 community controls in the UCLA Family Study (Asarnow et al., 2002). Using the same motor speed test as in Asarnow et al. (Asarnow et al., 2002), 67 parents of the treatment resistant childhood onset schizophrenia NIMH probands performed similar to 76 parents of community controls (Gochman et al., 2004). They also did not differ from the parents of the community controls on general intelligence, working memory, and vocabulary tests. Sample size differences in the control groups of these studies, 114 in Asarnow et al. and 76 in Gochman et al., might have contributed to the different motor speed findings.

Unlike their parents, 24 siblings (mean age of 19.3 years (SD = 7.0)) of the NIMH probands with schizophrenia had impaired motor speed compared with the 38 community controls, aged 17.8 years (SD = 9.0). De La Serna (de la Serna et al., 2011) also found low IQ index, logical memory, and perceptual organization scores but no significant differences in performance on visual tasks in 26 nonpsychotic siblings, aged 7–16-years old, compared with 33 control subjects.

The importance of familial loading for schizophrenia and cognition is apparent in the children of parents with schizophrenia. Twenty-five children, aged 9–12 years, each with a parent who had schizophrenia, had borderline to mildly impaired working memory and poor response inhibition during a motor task that continued at the 2.6 year follow-up (Ross, Wagner, Heinlein, & Zerbe, 2008). De la Serna (de la Serna et al., 2011) also described significantly lower IQ index, poor logical and visual memory, as well as worse perceptual organization scores in 20 offspring of schizophrenia parents, aged 7–16 years, compared with aged-matched 33 healthy control subjects. Although the offspring groups in both the Ross et al. and de la Serna et al. studies had high ADHD rates, similar cognitive deficits in those with and without ADHD suggest that ADHD did not account for the cognitive findings.

Finally, adolescents at clinical or high risk for schizophrenia (schizophrenia prodrome) have significantly lower verbal IQ, verbal memory and learning, as well as attention scores than controls but intermediate scores between those of individuals with first episode psychosis and controls (see review in Addington & Barbato, 2012). Although stable over time, these cognitive impairments do not predict conversion to psychosis.

Yet, both global and specific cognitive deficits in childhood and adolescence appear to be risk factors for adult onset schizophrenia (see meta-analysis in Dickson, Laurens, Cullen, & Hodgins, 2012). In fact, children ($N = 28$), aged 9–12 years, with a triad of putative antecedents for schizophrenia (Laurens et al., 2007) (Table 21.5) who had average IQ, performed significantly worse on tests of scholastic achievement, verbal memory, visual memory, working memory, verbal fluency, and inhibition than 27 typically developing children (Cullen et al., 2010).

Summary and Conclusions

- Is schizophrenia a cognitive disorder?
  - Youth with schizophrenia have low IQ, slow processing speed, and impaired verbal memory and learning, visual spatial, and motor skills.

TABLE 21.5 Childhood Triad of Putative Antecedents[1] of Adult Onset Schizophrenia

Symptom	Type
Psychotic-like experiences	Thought reading
Informant = child	Special messages
Source = interview	Being followed or spied on
	Hear voices
	Body changes that cannot be understood
	Under control of special power
	Mind reading
	Has special powers
	Sees things no one else can
Developmental delay and abnormalities	Motor and speech
Informant = parent, professional	Current coordination, unsteadiness problem
Source = questionnaire	
Social	Emotional symptoms
Informant = child, parent	Conduct problems
Source = Strengths & Difficulties Questionnaire[2]	Hyperactivity
	Peer problems

[1] Described in Laurens et al. (2007)
[2] Goodman (2001)

  - As they get older, they also have impaired attention and executive function.
  - After the initial decline in IQ and age-related appearance of executive function deficits, the cognitive deficits are stable over time.
  - The severity of cognitive deficits is related to negative symptoms and poor premorbid adjustment.
- Similar cognitive deficits are evident in:
  - First-degree relatives (parents, siblings, offspring)
  - Youth at clinical risk for schizophrenia
  - Children with a triad of putative antecedents of schizophrenia
- Studies are warranted to determine:
  - How cognition and its impairment differentially contribute to resilience and vulnerability to schizophrenia
  - The short- and long-term effects of deficit focused cognitive, linguistic, and educational rehabilitation

SOCIAL COGNITION

A meta-analysis of studies conducted to date on social cognition in adult schizophrenia found significant impairment compared with controls in theory of mind, emotion processing, emotion perception, and social perception (Savla, Vella, Armstrong, Penn, & Twamley, 2012). Social cognition impairments in these patients were significantly associated with duration of illness and inpatient status (Savla et al., 2012), as well as negative symptoms, disorganization, and cognitive deficits (Mancuso, Horan, Kern, & Green, 2011).

Social cognition studies have not been conducted in early-onset schizophrenia. However, a large group of 79 ultra high-risk subjects and 30 first episode psychosis patients, aged 13–25 years, had worse emotion recognition of both facial emotions and prosody than 30 control subjects (Amminger et al., 2012). Similar deficits in emotion processing, theory of mind, and social relationship perception in 54 adolescent and young adult prodromal subjects (18.25 (3.12) years) vs. 34 controls (18.95 (2.91) years) suggest impairments of these aspects of social cognition prior to the onset of schizophrenia (Green et al., 2011). Furthermore, the clinical importance of social cognition is highlighted by the relationship, above and beyond the effects of ongoing psychotic symptoms, of baseline social cognition measures with the 12-month follow-up functional outcome (work, social, and independent living) of 55 first episode psychosis patients (Horan et al., 2011).

Summary and Conclusions

- Impaired social cognition is evident in adult schizophrenia, ultra high-risk, prodromal, and first episode psychosis patients.
- Its association with clinical severity and functional outcome emphasizes the need for social cognition studies in early-onset schizophrenia.

RISK FACTORS

Identifying the risk factors and premorbid features of schizophrenia (Table 21.6) is important because together

TABLE 21.6 Risk Factors for Schizophrenia (Sz)

Stage	Risk Factors	Early-onset	Adult Onset
Perinatal	Infections	Not studied	Influenza, Herpes simplex Type 2, Toxoplasma gondi, rubella, measles, and upper respiratory tract infections
	Obstetric	Related to speech and language delay in Sz but not to increased likelihood of diagnosis	Fetal hypoxia
Infancy	Development	Delayed motor, speech milestones	Delayed motor, speech milestones
		Deviant language	Erratic infant development (pandysmaturation)
Childhood	Motor		Poor gross and fine motor coordination, unusual movements
	Language		Poor verbal skills
	Social	Autism spectrum disorder symptoms	Solitary, withdrawal
	Academic	Poor premorbid academic adjustment	Poor school performance
	Environmental		
	Demographic	Poverty, urban	Poverty, urban
	Cultural	Immigrant status, minority	Immigrant status, minority
	Adversity	Not yet studied	Trauma, abuse, neglect
	Cannabis	Toxic effect, self medication, poor outcome	Toxic effect, earlier onset

with family history, they act as clinical markers that can facilitate early detection of individuals at risk and of those who might be resilient for the disorder. In addition, they have developmental implications, and help predict the severity, course, and outcome of the illness (see review in Cole, Apud, Weinberger, & Dickinson, 2012). But, only few retrospective studies have examined the risk factors and premorbid features of early-onset schizophrenia. In contrast, several large prospective birth cohort and offspring studies have identified the perinatal, infancy, and childhood risk factors and premorbid features of adult onset schizophrenia and conversion to schizophrenia in youth with the schizophrenia prodrome. Given the importance of early detection and treatment of children and adolescents at risk for schizophrenia, this section includes the findings of these studies.

Perinatal Factors

Early-onset Schizophrenia

Since Mednick's pioneer Finnish birth cohort study demonstrated increased influenza A2 during the second trimester of pregnancy of individuals hospitalized for schizophrenia in adulthood (Mednick, 1988), numerous studies have examined the role of perinatal factors in schizophrenia (see review in Brown & Derkits, 2010). Only two retrospective studies have been conducted to date on obstetric complications in children and adolescents with schizophrenia. The NIMH study found no significant differences in the number of obstetric and perinatal complications in 36 early-onset schizophrenia patients and their 35 nonpsychotic siblings (Nicolson, Malaspina, Giedd, Hamburger, Lenane et al., 1999). Based on parent interviews and birth records, Margari et al. also found no significant between group differences in the prepartum, peripartum, and postpartum complications of 21 Italian children with schizophrenia and 21 children with migraine (Margari et al., 2011).

The NIMH study also found delayed speech and language development in the children with refractory schizophrenia who had more obstetric complications compared with those with normal language development (Nicolson et al., 2000). Unlike the children with normal speech and language milestones, those with more obstetric complications also had higher familial loading for schizophrenia.

Birth weight, an indirect measure of the health of the intrauterine environment, reflects the severity of prenatal adversities (Haukvik et al., 2013) that might potentially impact behavior, cognition, and brain development. It is related to vulnerability for impaired academic, nonacademic, and physical education performance in adolescents at genetic risk for schizophrenia (Forsyth et al., 2012).

Adult Onset Schizophrenia

Prospective birth cohort studies have demonstrated greater likelihood of schizophrenia in individuals exposed to influenza, Herpes simplex Type 2, Toxoplasma gondi, rubella, measles, and upper respiratory tract infections. The window for vulnerability appears to be the first half of pregnancy and particularly early on in pregnancy (see review in Brown & Derkits, 2010).

A higher number of obstetric complications also increased the likelihood of schizophrenia in patients with onset of the disorder prior to but not after age 17 in the Philadelphia site of the National Collaborative Perinatal Project (Cannon et al., 2000). These age-related findings together with no schizophrenia in the 73 probands of 63 siblings, despite their obstetric complications, suggested a specific vulnerability for obstetric complications in individuals with earlier onset schizophrenia.

The findings from other Collaborative Perinatal Project sites and birth cohort studies confirm the importance of obstetric complications in individuals with genetic risk for schizophrenia (see review in Brown, 2011). In addition, perinatal infections and obstetric complications are also more prevalent in infants born to mothers with schizophrenia (Suvisaari et al., 2012).

But, the presence and number of perinatal complications in birth cohort (Cannon et al., 2002; Rosso et al., 2000) and offspring studies (Forsyth et al., 2012; Marcus, Hans, Auerbach, & Auerbach, 1993; McNeil, Fish, & Schubert, 2011) were unrelated to impaired receptive language skills, delayed motor development, and poor motor coordination in subjects diagnosed with schizophrenia in adulthood. Findings are also inconsistent regarding the association of birth weight with adult onset schizophrenia in these studies (see review in Fineberg, Ellman, Buka, Yolken, & Cannon, 2012).

Summary and Conclusions

- Although obstetric complications are not increased in early-onset schizophrenia, they are related to delayed language development and a family loading for schizophrenia.
- Low birth weight is associated with poor academic, nonacademic, and physical education performance in adolescents with a familial loading for schizophrenia.
- Perinatal infections and obstetric complications, not birth weight, increase the likelihood of schizophrenia in adult subjects with a family history.

- The different child and adult study findings reflect small sample size, retrospective study design, different obstetric complication categories, and items in the child studies, as well as the refractory illness of the NIMH study subjects.
- Prospective birth cohort studies are warranted to determine if perinatal complications and birth weight are associated with vulnerability for early-onset schizophrenia.

Risk Factors During Infancy

Early-onset Schizophrenia

Based on chart reviews and parents' retrospective reporting, delayed motor development is found in 72% (Watkins, Asarnow, & Tanguay, 1988) of these patients and language delay or deviant language in 44–72% (Hollis, 1995; Nicolson et al., 2000).

Adult Onset Schizophrenia

Pandysmaturation, defined as delayed cranial development, together with delay or erratic development of at least one motor milestone, differentially predicted schizophrenia outcome in the offspring of mothers with schizophrenia compared with the offspring of mothers with other psychiatric diagnoses or affective disorders and mothers without prior psychiatric diagnoses or psychosis (Fish & Kendler, 2005; McNeil et al., 2011). The Swedish High-risk Project study demonstrated that among the 75 offspring of mothers with schizophrenia those with pandysmaturation were 34 times more likely to have schizophrenia at age 22 than the offspring of 75 mothers with affective disorders and 91 mothers with no psychiatric diagnoses (McNeil et al., 2011). Since controlling for genetic risk for schizophrenia attenuated the risk, these authors concluded that pandysmaturation reflects a genetic risk for schizophrenia.

In contrast to subjects with normal development, the Dunedin birth cohort subjects with pan-developmental delay involving motor, language, and social skills self-reported psychotic symptoms at age 11 met criteria for a schizophrenia spectrum disorder diagnosis at age 26 (Cannon et al., 2002). Slow motor development, in particularly walking, and delayed onset of speech were evident in the 30 individuals diagnosed with schizophrenia between age 16 and 43 in the British Medical Research Council National Survey of Health and Development survey of 13,687 births in England, Scotland, and Wales in 1946 (Jones, Murray, Rodgers, & Marmot, 1994).

Likewise, in the 1966 Northern Finland birth cohort (N = 9901) followed for 31 years, age at attainment of milestones (standing, walking, speech, toilet training) was linearly associated with hospital registry diagnosis of schizophrenia ($N = 100$) and other psychoses ($N = 55$) (Isohanni et al., 2001). Furthermore, the previously described (see section on Cognition and Table 21.5) large study that screened for putative antecedents of schizophrenia in 548 low-income U.K. youth, aged 9–12 years, identified speech/motor delayed development in 9.2% of boys and 4.1% of girls (Laurens et al., 2007).

New evidence also highlights the possible role of perinatal variables on infant vulnerability for core deficits of schizophrenia, such as abnormal sensorimotor gating (Ross et al., 2013). Abnormal sensorimotor gating, reduced inhibition or gating of the P50 component of the cerebral auditory evoked response to the second of paired sounds given 500 msec apart, occurs in infants of mothers with psychosis (Hunter, Kisley, McCarthy, Freedman, & Ross, 2011). Genes associated with schizophrenia, including CHRNA7 and neuroregulin, phosphatidylethanolamine-(PEMT) (Ross et al., 2013), and environmental factors, such as the pregnant mother's diet, determine fetal levels of acetylcholine and hippocampal $\alpha 7$ nicotinic receptor density. Phosphatidyl choline dietary supplementation during and after pregnancy increases the acetylcholine level and improves sensory gating in the infants of healthy mothers both with and without the CHRNA7 gene compared with placebo treated mothers (Ross et al., 2013). Thus, phosphatidyl choline supplementation, a perinatal environmental factor, might prevent the development of aberrant attention even in individuals with a genetic predisposition (CHRNA7 gene) for poor sensorimotor gating and schizophrenia (Ross et al., 2013).

Summary and Conclusions

- Children with schizophrenia, high-risk offspring of mothers with schizophrenia, and children at risk for adult onset of schizophrenia, have delayed motor and speech milestones.
- Abnormal sensorimotor gating during early infancy might normalize with phosphatidyl choline supplement even in the presence of a genetic predisposition to schizophrenia.

Childhood Risk Factors

Abnormal Development

Early-onset Schizophrenia. Social withdrawal during childhood and adolescence appears to be a specific vulnerability factor for schizophrenia. A retrospective chart review of 101 children, aged 7–13 years, found significantly

more children with premorbid social impairment in the 61 who developed schizophrenia between age 14 and 17 than in the 49 with other types of psychosis (Hollis, 2003). Additional retrospective reports by parents and review of medical charts describe premorbid symptoms of autism spectrum disorders in 25–87% of children with schizophrenia (Margari et al., 2011; Nicolson et al., 2000; Watkins et al., 1988).

Adult Onset Schizophrenia. Social maladjustment at age 4 and 7 years (Bearden et al., 2000), parent-based reports of social withdrawal between ages 9 and 14 years in birth cohort studies and in youth with putative antecedents of schizophrenia (see meta-analysis in Matheson et al., 2013), and social withdrawal during childhood in young adult first episode schizophrenia patients (Tarbox, Brown, & Haas, 2012) revealed a significantly increased likelihood of schizophrenia during adulthood. The British Medical Research Council National Survey researchers also noted more individuals with solitary play and speech difficulties at age 4 and 6 years in the preschizophrenic subjects than in the controls (Jones et al., 1994).

Compared with the 3, 5, and 9-year old healthy controls, the Dunedin study subjects who later developed schizophrenia had more than one soft neurological sign and performed poorly on standard tests of motor skill (Cannon et al., 2002). Subjects who met criteria for schizophrenia during adulthood in the Philadelphia cohort of the Collaborative Perinatal Project birth cohort and their unaffected siblings had deviant motor coordination at age 7 years, unusual movements (tremors, tics, spasms, or athetoid movements of the head and neck, arms and shoulders, hands, legs and feet, or trunk) at age 4 and 7, and poor language scores (Bearden et al., 2000; Rosso et al., 2000). Similarly, abnormal development of gross motor skills, verbal memory, and attention (Erlenmeyer-Kimling et al., 2000), as well as impaired motor coordination (Marcus et al., 1993; Schiffman et al., 2009) during middle and late childhood was found in the offspring of parents with schizophrenia.

Poor Academic Performance and Cognition

Early-Onset Schizophrenia. As previously mentioned (see section on Cognition), the U.S. multisite early-onset schizophrenia study reported worse premorbid academic adjustment among 54 adolescents with schizophrenia with significantly lower cognitive scores and negative symptoms after onset of the disorder (Rhinewine et al., 2005).

Adult Onset Schizophrenia. The Philadelphia Perinatal Collaborative birth cohort study reported significantly lower picture arrangement, vocabulary, and coding scores on the Wechsler Intelligence Scale for Children scores at age 7 in 32 subjects diagnosed with schizophrenia during adulthood and their 25 unaffected siblings compared with 201 nonpsychiatric comparison subjects (Niendam et al., 2003). The premorbid patients, however, had significantly lower coding scores than their unaffected siblings.

Summary and Conclusions

- Abnormal social development during early childhood is evident in early-onset schizophrenia and in individuals at risk for adult onset schizophrenia.
- Motor abnormalities are found in middle and late childhood in individuals at risk for adult onset of the disorder and in the offspring of schizophrenia parents.
- Additional premorbid features of early-onset and adult schizophrenia include poor school performance and low IQ.

Demographic and Cultural Factors

Based on the Israeli Army Draft Board and Psychiatric Registry, high population density (Weiser et al., 2007); perceived poor family functioning (Weiser, Reichenberg, et al., 2008), lower socioeconomic status (Goldberg et al., 2011), and acculturation (Weiser, Werbeloff, et al., 2008) are important premorbid environmental risk factors for psychiatric admission of 15–18-year old males with schizophrenia. Population and case-control studies have identified similar premorbid demographic risk factors for schizophrenia onset in adults in several countries (see review in Brown, 2011). These include being urban vs. rural, a first-, second-, and third-generation migrant, an ethnic minority in a nonethnic neighborhood, non-White in a predominantly White environment, poor, and experiencing cultural disparity in the dominant culture. Putative childhood antecedents of adult onset schizophrenia also occur at a significantly higher rate in African-Caribbean youth than in White U.K. youth irrespective of migration status (Laurens, West, Murray, & Hodgins, 2008).

Summary and Conclusions

- Urban environment, poverty, minority or immigrant status, and poor family functioning are risk factors for early-onset schizophrenia.

Childhood Adversity: Trauma, Abuse, and Neglect

Early-Onset Schizophrenia

In a large Irish study of 1,112 school-based adolescents, aged 13–16 years, childhood trauma (physical abuse and

bullying) was bidirectionally associated with psychotic symptoms over a 3- and 12-month follow-up (Kelleher, 2013). There was a dose dependent relationship between the severity of bullying and the risk for psychotic experiences. Thus, the incidence of psychosis gradually decreased with the cessation of bullying.

Toth et al.'s thought disorder findings on a subgroup of 242 maltreated and 158 nonmaltreated children, aged 10–12 years, imply a possible role of childhood adversity on core symptoms of schizophrenia (Toth, Pickreign Stronach, Rogosch, Caplan, & Cicchetti, 2011). The 91 children who experienced abuse (mainly physical abuse, neglect, and emotional maltreatment) had significantly more illogical thinking and mean scores in the clinical range compared with the 43 nonmaltreated and age-matched children (6.8–13.4 years). The significant association of younger age and more abuse incidents with higher illogical thinking scores implied possible early effects of abuse on the development of language-related brain regions, such as the superior temporal gyrus and inferior frontal gyrus, that are involved in the thought disorder of childhood schizophrenia (Borofsky et al., 2010; see details in the Imaging section).

Supporting Toth et al.'s findings, a two-year prospective study demonstrated a higher rate of abuse, neglect, and dissociation in 20 adolescents diagnosed at baseline with atypical psychotic symptoms compared with 23 with schizophrenia (Hlastala & McClellan, 2005). However, the atypical psychosis group met criteria for PTSD and depression but not for psychosis two years after being diagnosed with atypical psychosis.

Clinical Risk Studies

Several international large-scale studies have confirmed an association between abuse during childhood and psychotic symptoms in adolescents, young adults, and older adults. One third of a large Australian sample of first episode psychosis patients ($N = 704$), aged 15–29, had a history of physical or sexual abuse during childhood, as well as past psychiatric diagnoses, including PTSD, depression, substance abuse, suicide attempts, and poor premorbid functioning (Conus, Cotton, Schimmelmann, McGorry, & Lambert, 2010). An Australian prospective study of 233 subjects at ultra high risk for psychosis, aged 15–30 years, over a mean period of 7.5 years, identified a childhood history of sexual abuse but no other types of trauma as a significant risk factor for transition to psychosis (Thompson et al., 2013). Similarly, a Dutch prospective study over a three-year period on 4045 subjects, aged 18–64 years, described a significant association of childhood abuse reported at baseline with the onset of positive psychotic symptoms (Janssen et al., 2004).

Among 5782 subjects, aged 15–64 years from the US National Collaborative Survey (childhood trauma) and 8582 subjects, aged 16–74 years from the British Psychiatric Morbidity Survey, two or more traumas predicted psychosis in a dose dependent relationship (Shevlin, Houston, Dorahy, & Adamson, 2008). Of interest, childhood physical and sexual abuse in the US sample but physical injury and exposure to domestic violence during childhood in the U.K. study increased the risk for psychosis. Underscoring the importance of the number of traumatic events, a recent meta-analysis of large-scale cross sectional and prospective cohort studies confirmed a dose dependent relationship of childhood adversity (physical, sexual, emotional abuse, and neglect) with psychosis (i.e., psychotic disorder, schizophrenia, or schizoaffective disorder) (Varese et al., 2012).

Finally, a retrospective report of childhood abuse was associated with current positive psychotic-like symptoms in 533 young adults who were Met carriers of the Val66Met brain derived neurotrophic factor (BDNF) compared with the Val homozygotes (Alemany et al., 2011). These findings, together with evidence for gene-environment interaction in determining resilience or maladaptive depression, rigid personality, or substance abuse in maltreated children (Cicchetti & Rogosch, 2012) underscore the need for markers of vulnerability for psychosis following childhood maltreatment.

Summary and Conclusions

- Childhood adversity (trauma, abuse, or neglect) is associated with:
  - Illogical thinking during childhood
  - Adult onset schizophrenia, particularly in Met carriers of the Val66Met BDNF

Cannabis

The psychotomimetic effects of cannabis trigger onset of schizophrenia. Despite earlier age of onset in adult studies (De Hert et al., 2011), 468 cannabis users, aged 14–29 years, did not have a significantly earlier onset than the 157 noncannabis users with first-episode psychosis (Schimmelmann et al., 2011). Within the cannabis user subgroup, however, subjects who began using cannabis at age 14 years or earlier had a significantly earlier onset of psychotic symptoms than those with use after age 14.

Regarding the severity of psychosis, cannabis use at baseline was also related to higher illness-severity, lower

psychosocial functioning, less insight, lower premorbid functioning, and longer duration of untreated psychosis. But, only those youth with continued cannabis use during the follow-up period had a worse long-term outcome. Interestingly, most of the subjects in this study stopped using cannabis once their condition improved with antipsychotic treatment. Thus, there is a potential confounding among the onset of psychotic symptoms, the drug's psychotomimetic effects, and its use to self-medicate psychotic symptoms.

Among environmental factors, urbanicity (Kuepper, van Os, Lieb, Wittchen, & Henquet, 2011) and maltreatment (Harley et al., 2010), risk factors for schizophrenia, described under demographic risk factors, are also more frequent in individuals with schizophrenia who use cannabis than in nonusers. But both cannabis use and trauma were independently related to the risk of experiencing psychotic symptoms in 211 Irish youth, aged 12–15 years (Harley et al., 2010).

Two large prospective cohorts from the Greek National Perinatal Study ($N = 1636$) and the Netherlands Mental Health Survey and Incidence Study (NEMESIS) ($N = 4842$), also demonstrated that the psychosis inducing effect of cannabis use at age 19 was stronger in the subjects who experienced abuse at age 7 (Konings et al., 2012). In the Greek sample the abuse was limited to physical punishment (spanking of variable frequency) but it included emotional, physical, psychological, or sexual abuse in the Dutch sample.

To examine genetic effects and their interaction with these environmental factors, the Dutch Genetic Risk and Outcome in Psychosis (GROUP) investigators examined clinical and subclinical psychotic symptoms (schizotypy) in 590 controls and 1066 families with 1057 unaffected siblings and 1120 patients with nonaffective psychotic disorder, aged 16–50 years (Genetic et al., 2011). Both siblings and patients had significantly higher rates of cannabis use than controls. Furthermore, significantly more sibling cannabis users had clinical and subclinical psychotic symptoms than nonusers. But, there was no association between psychotic liability and cannabis use in the siblings. These findings led the GROUP to two conclusions. First, familial liability for psychosis increases susceptibility to the psychotomimetic effects of cannabis. Second, the tendency in siblings to use the drug reflects environmental not familial effects.

Several studies have examined if single-nucleotide polymorphisms (SNPs) play a role in the psychotomimetic effect of cannabis and in the risk for developing schizophrenia. Estrada et al. reported that the age at emergence of psychotic symptoms was significantly earlier among 80 Spanish adolescent psychotic inpatients who were Val/Val genotype carriers of catechol- O-methyltransferase (COMT) than among the Met carriers (Estrada et al., 2011). The Dunedin birth cohort study also demonstrated that carriers of the COMT Val158 allele were most likely to develop schizophrenia at age 26 if they had used cannabis during adolescence (Caspi et al., 2005). The Dutch GROUP reported that the SNP in AKT1 (rs2494732) not COMT moderated the short-term psychotomimetic effects of recent cannabis use and risk for psychotic disorder in 801 psychotic patients (van Winkel, 2011).

Summary and Conclusions

- Cannabis use in young adolescents can induce schizophrenia and is associated with increased illness severity.
- Earlier onset of schizophrenia in cannabis users is found in COMTVal158 carriers.
- Studies are needed to determine the role played by the interaction of familial loading for schizophrenia, demographic factors, childhood adversity, and early cannabis use in determining vulnerability or resilience for early-onset schizophrenia.

IMAGING OVERVIEW

In contrast to the previously described areas of research, a large number of imaging studies, in particular structural imaging studies, have been conducted on childhood and adolescent onset schizophrenia patients, their siblings, and typically developing youth. To help the reader understand the developmental implications of the imaging findings in schizophrenia, this section first describes the findings of structural imaging studies, magnetic resonance imaging (MRI), and diffusion tensor imaging (DTI) on normal brain development during childhood and adolescent.

It then reviews the findings of studies on global and regional cerebral gray and white matter cortical volume, cortical thickness, gyrification, white matter tracts, and subcortical structures in early-onset schizophrenia. A brief summary about the relationship of these findings to clinical symptoms and to functional impairment is provided for each of the reviewed brain structures and their associated networks. The imaging section concludes with a short description of the findings of functional imaging, connectivity, and graph theory studies in early-onset schizophrenia. Figure 21.1 orients the reader to regions of the lateral and superior surface of the cortex.

NORMAL BRAIN DEVELOPMENT

Gray Matter

Normal development of cortical volume, measured by manual drawings, voxel based morphometry (VBM), or Free Surfer (see review in Keller, 2009), has an inverted U–cubic trajectory with early accelerated increase followed by a progressive decrease during adolescence (Raznahan, Shaw, et al., 2011). It is a function of age- and gender-dependent change in cortical thickness and surface area, which in turn reflect growth of the external convex cortical area and gyrification and their relationship with age and gender. Later peaks in the cortical volumes of boys compared with girls are accounted for mainly by boys' faster and more sustained increase in surface area (Raznahan, Shaw, et al., 2011). These findings are based on more than 1250 prospective magnetic resonance imaging (MRI) scans of 647 typically developing subjects, aged 3–30 years.

The direction of change in cortical volume and thickness proceeds in a posterior to anterior direction (Sowell et al., 2004) with earlier peaks in the parietal lobe (girls: 10.2 years boys: 11.8 years), followed by the frontal (girls: 11.0 years, boys: 12.1 years) and temporal lobes (girls: 16.7 years, boys: 16.2 years) (Lenroot & Giedd, 2006) (Muftuler et al., 2011) (Figure 21.2). Of note, these brain regions include the heteromodal association cortex of the frontal, temporal, and parietal lobes that play an important role in higher-level integrative perceptual, cognitive, linguistic, and executive functions (attention, memory, planning, organization, emotional regulation, and social decision making). Thus, these higher order association and phylogenetically newer areas mature only after the lower order and phylogenetically older visual and somato-sensory regions (Gogtay et al., 2004).

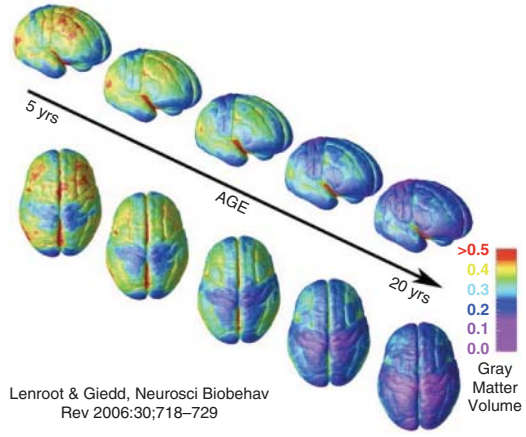

Figure 21.2 Right lateral and top views of the dynamic sequence of gray matter maturation over the cortical surface. The side bar shows a color representation in units of gray matter volume. Fifty-two scans from 13 subjects each scanned 4 times at approximately 2-year intervals. See footnote 1. *Source:* Reprinted with permission from R. Lenroot & J. Giedd, Brain development in children and adolescents: Insights from anatomical magnetic resonance imaging, *Neuroscience and Biobehavioral Review, 30*(6), 718–729, 2006.

The ridges (convex curvature) of the brain are called gyri and the faults between them (concave curviture) are the sulci. The architecture of the gyri and sulci might play a role in connectivity and reflect plastic changes that occur as a result of pruning and environmental influences during development (see review in White, Su, Schmidt, Kao, & Sapiro, 2010). Gyrification, development of the folding surfaces of the brain is measured with the gyrification index, defined as the ratio between the lengths of coronal outlines for the brain including and excluding the sulcal regions (White et al., 2010). Depending on how the gyrification index is measured (for more details, see White et al., 2010), it is either constant from age 3 (Raznahan, Shaw, et al., 2011) or decreases with age in the left and right frontal, medial temporal lobes, and parietal and frontal lobes (Su, White, Schmidt, Kao, & Sapiro, 2013).

Normal maturation of the gray matter of subcortical structures occurs earlier than in the cortex with a more attenuated relationship with age (Brain Development Cooperative, 2012). There is an age-related increase in the volume of the thalamus (Brain Development Cooperative, 2012; Muftuler et al., 2011), amygdala, and hippocampus (Ostby et al., 2009), and a decrease in the volume of the caudate and globus pallidus (Brain Development Cooperative, 2012; Ostby et al., 2009). Findings are inconsistent regarding the cerebellum with some studies showing a decrease (Ostby et al., 2009) and others an increase through age 11 in cerebellar volume (Brain Development Cooperative, 2012). These subcortical structures are involved in sensory integration (thalamus), motor sequencing (caudate globus pallidus), memory (putamen, caudate, hippocampus, cerebellum), cognition and language (thalamus, cerebellum), facial recognition and empathy (thalamus), fear and anxiety (amygdala) (see reviews in (Behrens et al., 2003; D'Angelo & Casali, 2013; Middleton & Strick, 2000; Mullally & Maguire, 2014).

White Matter

Like gray matter volume, white matter volume is also measured using manual drawings, VBM, and Free Surfer of MRI scans. Diffusion tensor imaging (DTI) measures water diffusion displacement in neural fibres, such as nerve or brain white matter, and provides information on white matter integrity (see review in Beaulieu, 2002). The degree of water diffusion restriction or fractional anisotropy is sensitive to multiple biological processes including variation in the number and density of axonal membranes, myelination, and fiber organization.

Age related increase in white matter volume proceeds simultaneously in a more or less linear manner in the parietal, frontal, and temporal lobes based on 601 subjects, aged 3–25 years, who underwent 897 scans (Lenroot & Giedd, 2006). This process continues until age 25 years in the frontal and temporal lobes. The rate of change is steeper in boys than in girls (Lenroot & Giedd, 2006; Perrin et al., 2008) and boys have higher fractional anisotropy than girls in corticospinal, long-range association, and cortico-subcortical fibers (Herting, Maxwell, Irvine, & Nagel, 2012). Continuous and symmetric myelination of major fiber tracts that connect lower motor neurons, subcortical structures, such as the thalamus and basal ganglia, and occipital lobe with the frontal lobe, temporal with frontal lobes, the corpus callosum, and the cingulate begins in early childhood and continues through adolescence (Peters et al., 2012). As described for the gray matter volume changes, parallel maturation of children's cognitive, linguistic, executive function, and social skills imply an important role for these developmental changes in white matter volume and tracts.

Ventricles

Findings are inconsistent regarding age-related changes in the lateral ventricles. The previously described large prospective study by Lenroot et al. (Lenroot & Giedd, 2006) reported increased lateral ventricular volume with age in their 3–25 year old healthy subjects. Likewise, Ostby et al. (Ostby et al., 2009) demonstrated that an increase in age was associated with larger lateral ventricle volume in 171 subjects, aged 8–31 years divided into five age groups. The Brain Cooperative's smaller cross sectional study of 325 younger subjects, aged 4.5–18 years, did not confirm this relationship (Brain Development Cooperative, 2012). There appear to be no age effects for the volumes of the third and fourth ventricles (Ostby et al., 2009).

Asymmetry

The asymmetric distribution of cortical gray and white matter is stable across age with gray matter rightward asymmetry in the frontal and temporal lobes but leftward asymmetry in the occipital and parietal lobes (Brain Development Cooperative, 2012). There also is rightward asymmetry in the white matter of the temporal lobe but left asymmetry of frontal, parietal, and occipital lobe white matter. Although the subcortical structures including the lateral ventricle also have a leftward asymmetry, there is a rightward asymmetry in the putamen (Brain Development

Cooperative, 2012). In terms of gender effects, males have greater leftward asymmetry for gray matter in the parietal lobe and rightward asymmetry of the putamen compared with females (Brain Development Cooperative, 2012).

Summary and Conclusions

Gray Matter

- Cortical volume, thickness, and surface area increase during early childhood and gradually decrease from middle childhood through young adulthood in an anterior-posterior direction.
- Thalamic volume increases, volumes of caudate and putamen decrease, and findings are inconsistent regarding age-related changes in cerebellar volume.
- Volume of the lateral not the third and fourth ventricles increases with age.
- Parietal lobe, occipital lobe, thalamus, and lateral ventricle have leftward asymmetry and frontal lobe, temporal lobe, and putamen have rightward asymmetry.
- Gyrification index decreases with age in bilateral frontal, medial temporal and parietal lobe.

White Matter

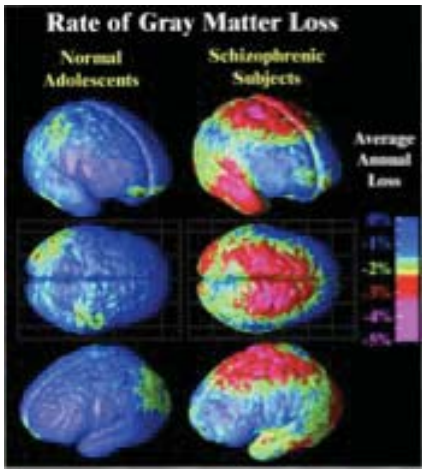
- Myelination increases with age in cerebrum and major fiber tracts that connect lower and upper motor neurons and subcortical and cortical structures.
- Asymmetry is leftward for lobes other than the temporal lobe.

SCHIZOPHRENIA

Cerebrum: Global Structural Abnormalities

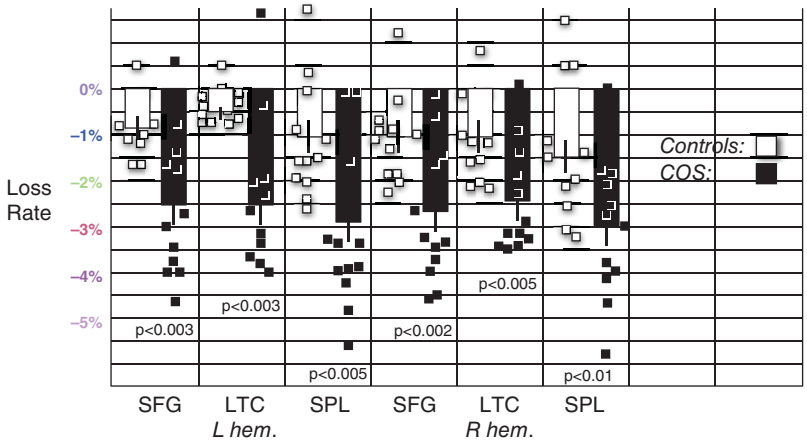
Gray Matter

Prospective studies conducted by the NIMH group on brain development in treatment resistant childhood and adolescent onset youth with schizophrenia and healthy controls provide important information on how schizophrenia impacts brain development. Thompson et al. (Thompson et al., 2001) investigated three dimensional maps of brain changes derived from repeat MRI scans over a 5-year period in 12 children with schizophrenia with a mean age of 13.9 years compared with 12 age and gender-matched healthy control subjects (Figure 21.3). They found significant between group differences in the previously described normal age-related cortical thinning. The children with schizophrenia had significantly more loss of gray matter than the control group.



Earlier loss, evident in the parietal lobes, proceeded to the frontal cortex, then to the dorsolateral prefrontal cortex and finally to the temporal cortices in a back to front pattern. The dorsolateral prefrontal cortex and superior temporal gyrus were the last regions to undergo gray matter loss. This progressive spread over time involving the parietal, sensorimotor, supplementary motor, and temporal cortices did not include the inferior frontal lobe. A Spanish multisite Child and Adolescent First-Episode Psychosis Study (CAFEPS) of 61 children and adolescents with schizophrenia, aged 15.5 years, compared with 70 healthy controls also revealed a significant decrease in frontal lobe gray matter volume over time (Arango et al., 2012).

In contrast to adults with schizophrenia (see review in Fornito et al., 2009), involvement of the dorsolateral prefrontal lobe and frontal eye fields came late in the process. Comparison of the younger and older schizophrenia patients in the NIMH study demonstrated parietal involvement in the younger subjects but frontal involvement in the older subjects.



Highlighting the interaction between the neuropathology underlying the disorder and ongoing brain development, these findings suggest that the structural abnormalities in childhood onset schizophrenia evolve over time to resemble those of later onset schizophrenia. Thompson et al. concluded that cortical thinning in early-onset schizophrenia reflects illness rather than medication effects on brain development. This conclusion was based on similar, albeit less severe, cortical thinning patterns in children with psychosis NOS, who were matched on IQ and antipsychotic medication with the early-onset schizophrenia patients (Thompson et al., 2001).

Vidal et al. (Vidal et al., 2006) used the same approach to study dynamic changes in the medial hemisphere surface in early-onset schizophrenia, psychosis NOS, and control subjects. They found a left greater than right dorsal to ventral pattern of progressive gray matter loss that involved the superior medial frontal and precentral gyri of the frontal lobe as well as the cingulate. Medial limbic regions (hippocampus, parahippocampal gyrus), however, were uninvolved in this process. In terms of the time course, whereas the anterior medial frontal regions were involved throughout the study, progressive gray matter loss in the cingulate occurred late in the follow-up MRI scans. As for the lateral, superior, and inferior cortical regions studied in Thompsons et al. (2001), similar but attenuated findings in the psychosis NOS subjects supported the authors' conclusions that their findings did not reflect antipsychotic drug effects.

A cross sectional and prospective study of 49 NIMH early-onset schizophrenia subjects, mean age 14.7 years,

(a)

(b)

Figure 21.3 Average rates of gray matter loss in normal adolescents and in schizophrenia. (A) Three-dimensional maps of brain changes, derived from high-resolution magnetic resonance images (MRI scans) acquired repeatedly from the same subjects, reveal profound, progressive gray matter loss in schizophrenia (Right). Average rates of gray matter loss from 13 to 18 years of age are displayed on average cortical models for the group. Severe loss is observed (red and pink; up to 5% annually) in parietal, motor, and temporal cortices, whereas inferior frontal cortices remain stable (blue; 0–1% loss). Dynamic loss is also observed in the parietal cortices of normal adolescents, but at a much slower rate. (B) Average gray matter loss rates were computed for all 24 subjects in superior frontal gyri (SFG), lateral temporal cortices (LTC), and superior parietal lobules (SPL) in both brain hemispheres. Error bars indicate the standard error of the sample means, by region, in controls and patients. Individual loss rates (in percent per year) are plotted (■, patients; □, controls), showing significant group separation, despite some outliers. See footnote 1. *Source:* Reprinted with permission from P. M. Thompson, C. Vidal, J. N. Giedd, P. Gochman, J. Blumenthal, R. Nicolson, A. W. Toga, & J. L. Rapoport, Mapping adolescent brain change reveals dynamic wave of accelerated gray matter loss in very early-onset schizophrenia, *Proceedings of the National Academy of Sciences of the United States of America, 98*(20), 11650–11655, 2001. Copyright 2001 Naitonal Academy of Sciences, U.S.A.

found no differences between the patients and 50 age- and gender-matched healthy control subjects in cortical thickness asymmetry in both the lateral and medial cortical surfaces (Bakalar et al., 2009). However, Collinson et al. (Collinson et al., 2003) reported gender-related asymmetry difference in their cross sectional Oxford study of 33 early-onset schizophrenia subjects (mean age, 16.8, age of onset 15.7 years) relative to 30 age-matched controls (18 boys, 12 girls). The male patients ($N = 22$) had reduced leftward asymmetry and the female patients ($N = 11$) less rightward asymmetry compared with the control subjects.

Regarding gyrification, White et al. (White, Andreasen, Nopoulos, & Magnotta, 2003) reported that 42 youth with schizophrenia whose mean age was 17.7 years had significantly flattened curvature in frontal and parietal sulci but more steeped or peaked curvature in the occipital

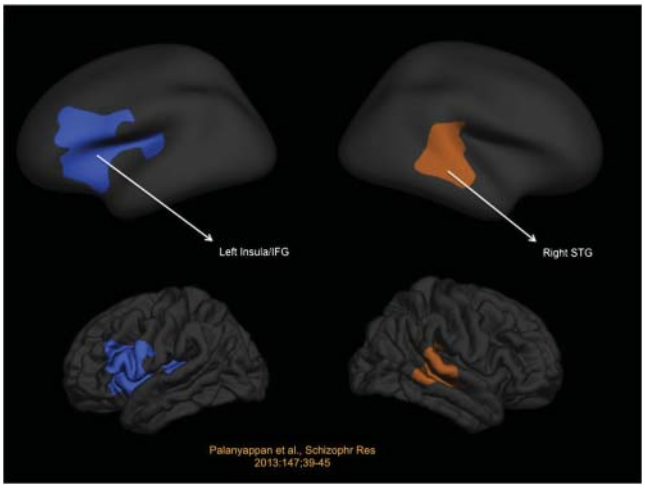


Figure 21.4 Clusters showing significant alterations in the gyrification index in adolescents with schizophrenia. Top panel: Clusters displayed on inflated average image (fsaverage). Bottom panel: Clusters displayed on the pial surface of the fsaverage image. Left hemisphere is shown on the left, right hemisphere is on the right. See footnote 1. *Source:* Palanyappan et al. Schizophr Res 2013: 147; 39–45.

gyri than 24 age- and gender-matched adolescents. Given current theories on the role of pruning in the formation and maturation of gyri and sulci (see review in White et al., 2010), these authors suggested that this finding might reflect illness-related abnormal cerebral and subcortical connectivity.

Supporting this theory, the amount of folded compared with unfolded cortex was increased in Broca's area (inferior frontal gyrus) extending to the interior insula and decreased in the superior temporal gyrus in Wernicke's area and the posterior insula in 18 early-onset schizophrenia subjects studied at Oxford compared with 19 controls, aged 13.5–17.8 years (Palaniyappan et al., 2013; Figure 21.4). In contrast to this left lateralized finding in the patients, gyrification in Broca's area and in the insula was right lateralized in the control group. Follow-up of these subjects over a two-year period demonstrated a significant reduction in gyrification in the patients but an increase in the controls. These authors suggested that early-onset schizophrenia might impact gyrification and sulcation during active pruning in brain regions involved in language (Broca's and Wernicke's areas) as well as in self-awareness and the ability to differentiate self from non-self (insula).

White Matter

Unlike the exaggerated and accelerated normal cortical thinning in children and adolescents with schizophrenia, the white matter growth rate of the 12 NIMH prospectively studied children with schizophrenia was significantly slower in the right hemisphere (frontal, temporal, parietal, and anterior cingulate) compared with healthy controls (Gogtay et al., 2008). In addition, it proceeded in a front to back direction in the patients with the greatest effect size in the right parietal lobe.

Thus, the patient group's baseline frontal lobe white matter volume was significantly smaller than that of the control group, and the between group differences became more evident in the posterior brain during the follow-up period. A cross sectional DTI study also reported significantly decreased white matter integrity in both parietal lobes of 19 early-onset schizophrenia youth, aged 13–19 years, compared with 20 age, gender, and socioeconomic-matched controls (Kyriakopoulos, Vyas, Barker, Chitnis, & Frangou, 2008).

Cerebrospinal Fluid

Since the brain is housed in a closed space, decreased gray and white matter volumes lead to expansion of cerebrospinal fluid and increased ventricular volume. Like the findings in adults with schizophrenia (Andreasen et al., 2011), two-year follow-up MRI scans of 39 early-onset schizophrenia patients from the NIMH study whose mean age was 14.5 years revealed a progressive increase in their lateral ventricle volume compared with 43 typically developing peers (Sporn et al., 2003).

Association with Clinical Symptoms, Cognition, and Premorbid Risk Factors

Clinical Symptoms. The previously described widespread gray (Thompson et al., 2001; Vidal et al., 2006) and white matter cortical abnormalities (Gogtay et al., 2008) in childhood onset schizophrenia were related to lower overall functioning. Worse severity of illness, reflected in duration of psychiatric hospitalization, also correlated with a significant reduction in frontal lobe gray matter volume in 61 children and adolescents with schizophrenia compared with 70 controls studied over two years in the CAFEPS (Arango et al., 2012).

Increased scores on the Scales for the Assessment of Positive Symptoms (SAPS) (Andreasen, 1983), such as hallucinations, delusions, and loose associations, were associated with a higher rate of gray matter loss in the temporal lobe (mainly superior temporal gyrus) and medial surface of the frontal, parietal, and cingulate regions (Thompson et al., 2001; Vidal et al., 2006). Scores on the Scales for the Assessment of Negative Symptoms (SAPS) (Andreasen, 1983), including alogia, anhedonia,

and affective flattening, were related to frontal lobe gray matter loss (Thompson et al., 2001).

Cognition. The increased rate of gray matter loss (other than on the medial surface) (Thompson et al., 2001) and abnormal white matter development (Gogtay et al., 2008) were associated with lower IQ in the 12 NIMH schizophrenia patients. Baseline gray matter deficits also predicted lower follow-up IQ of these patients (Thompson et al., 2001). A cross sectional study demonstrated that smaller total gray matter volume in 52 early-onset schizophrenia subjects (18 with onset by age 13 and 36 with onset by age 18) compared with 48 healthy controls correlated with the patients' poor performance on executive, attention, verbal memory, motor, and sensory motor tasks (Kumra et al., 2011). The decrease in the gyrification index in the Oxford cohort of adolescents with schizophrenia followed for two years was related to impaired categorical fluency (the ability to list as many words as possible that are related to a specific category within a given time) (Palaniyappan et al., 2013).

Premorbid Risk Factors. Among the 60 NIMH childhood onset schizophrenia subjects followed every two years for 5–8 years, the children with more premorbid poor social interaction, delayed speech and language development, as well as motor problems that were evident more than one year before the onset of psychosis had a higher rate of gray matter loss than those with fewer premorbid problems (Sporn et al., 2003).

Summary and Conclusions

- Schizophrenia onset in childhood and adolescence impairs ongoing cerebral development with:
  - A progressive decrease in cortical gray matter volume and thickness — parietal → frontal → temporal lobe on the lateral and superior surface and — superior frontal lobe → cingulate on the medial surface.
  - An abnormal increase in white matter growth and volume, particularly in the right hemisphere.
  - A parallel increase in cerebrospinal fluid volume, mainly in the lateral ventricles.
- Temporal lobe and medial cortical surface gray matter loss and reduced white matter volume are associated with positive psychotic symptoms and poor overall functioning.
- Frontal lobe gray matter loss is related to negative symptoms and longer duration of illness.
- Lower IQ, extensive neuropsychological deficits, and premorbid social, speech/language, as well as motor difficulties are associated with gray matter loss and smaller volume.

Lobar, White Matter Tract, and Subcortical Structural Abnormalities

Structural abnormalities in the frontal, temporal, and parietal lobes, major white matter tracts, the corpus callosum, the cingulate, thalamus, hippocampus, basal ganglia, and cerebellum highlight the extensive brain damage and associated broad range of impairments involving cognition, language, emotions and affect, social skills, sensory, and motor functions in schizophrenia.

Lobar Abnormalities: Frontal Lobe

Frontal Lobe Function. Figure 21.1 describes the different parts of the frontal lobe. The prefrontal cortex is the association cortex of the frontal lobe that integrates a variety of information due to its extensive connections with other parts of the brain (Fuster, 2001). It includes the medial and orbital regions, involved in emotional behavior, as well as the lateral frontal lobe that "provides the cognitive support to the temporal organization of behavior, speech, and reasoning" (Fuster, 2001, p. 319). The level of complexity of processing by the frontal lobe appears to increase from the posterior to the anterior frontal pole and from ventral/lower to dorsal/upper frontal lobe areas (Fuster, 2001).

Connectivity of the orbital frontal area with the temporal pole, amygdala, and thalamus (Kubota, 2013) underlies its role in the regulation and control of social emotional functions. The connections of the lateral prefrontal cortex with the temporal, parietal, thalamus, cerebellum, and caudate subserve working memory, attention and other executive functions, including organization, planning, and monitoring (Fuster, 2001).

The inferior frontal gyrus includes the pars orbitalis, pars triangularis, and pars opercularis that are integrally involved in syntactical complexity, semantics, phonology, and speech production, respectively (Friederici, 2012) (Figure 21.1). These inferior frontal lobe regions are connected to the language-related regions in the temporal and parietal lobes through the long superior, middle, and inferior longitudinal fascicles and shorter arcuate and uncinate fascicles (white matter tracts) (Friederici, 2012) (Figure 21.5).

Through its connectivity with cortical and subcortical brain regions, the prefrontal lobe participates in the broad range of higher cognitive functions including perception, sensory-motor integration, language, cognition, and social behavior (Fuster, 2001). Two frontal lobe areas, the anterior cingulate and anterior medial prefrontal cortex, play a role in the initiation of motor acts (movement, speech), spontaneity, attention, and emotion (Fuster, 2001), in envisaging the perspectives of others (theory of mind) (see review

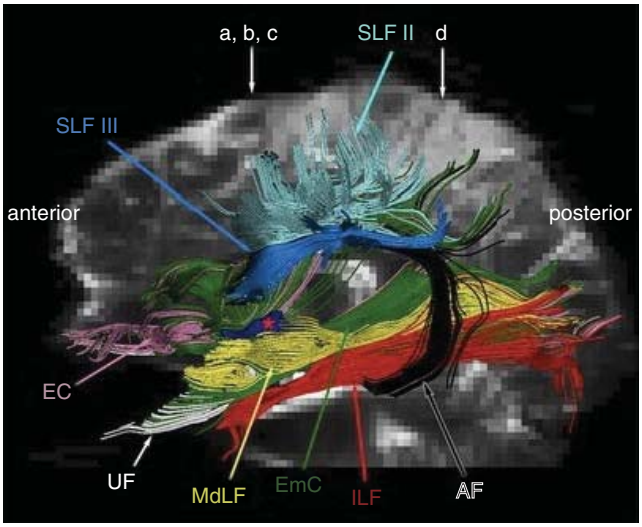

Figure 21.5 White Matter Tracts. SLF II and III = Superior longitudinal fascicle, ILF = Inferior longitudinal fascicle, MdLF = Middle longitudinal fascicle, UF = Uncinate fascicle, EC = External capsule. EMc = Extreme capsule. See footnote 1. *Source:* Springer and *Brain Structure and Function* 213(3), 2008, page, "The extreme capsule in humans and rethinking of the language circuitry," Makris and Pandya. Used with kind permission from Springer Science and Business Media.

in Frith & Frith, 2003), and in the ability to differentiate self from external sources (see review in Wang, Metzak, & Woodward, 2011). They also are part of the default mode network involved in internal processing thinking while at rest (Liu et al., 2013).

Schizophrenia. In terms of regional frontal lobe findings in early-onset schizophrenia, Kumra et al. (Kumra et al., 2011) reported significantly smaller superior frontal lobe gray matter volume in 52 youth aged 10–19 years with schizophrenia compared with 48 matched healthy controls. A smaller cross sectional study of 25 healthy controls and 25 adolescents with schizophrenia with onset between ages 11 and 15 years demonstrated gray and white matter volumetric and DTI abnormalities in the left inferior frontal lobe (Douaud et al., 2007). As previously mentioned, 25 adolescents, aged 14.2–18.4 years, had abnormal gyrification in Broca's area when compared with 25 control subjects (Palaniyappan et al., 2013).

Association with Clinical Symptoms and Cognition. Given the previously mentioned broad range of functions that the frontal lobe subserves, it is not surprising that a variety of psychotic symptoms are related to structural abnormalities in different parts of the frontal lobe. As evident from Table 21.7 on adult studies, the inferior frontal and medial and lateral orbital frontal regions are differentially involved in positive and negative psychotic symptoms,

TABLE 21.7 Symptoms, Cognition, and Frontal Lobe Regional Structural Abnormalities

Symptoms and Cognition	Regions	Reference
Positive		
Hallucinations	Anterior inferior frontal + connections with posterior temporal lobe	(Catani et al., 2011)
Formal thought disorder	Inferior frontal Orbital frontal	(Sans-Sansa et al., 2013)
Impaired insight Delusions of misattribution	Orbital frontal (pars orbitalis)	(Orfei, Piras, Macci, Caltagirone, & Spalletta, 2013)
Poor attribution of salience Reality distortion	Anterior cingulate	(Palaniyappan , Mallikarjun, Joseph, White, & Liddle, 2011)
Negative		
Flattened affect, anhedonia poverty of speech and of content of speech	Orbital frontal	(Sans-Sansa et al., 2013)
Cognition		
Memory decline	Orbital frontal	(Nestor et al., 2013)
Theory of mind	Ventromedial and ventrolateral prefrontal Anterior cingulate	(Hirao et al., 2008; Hooker, Bruce, Lincoln, Fisher, & Vinogradov, 2011)

poor insight and reality testing, misattribution of salience, memory decline, and poor theory of mind.

Only two early-onset schizophrenia studies have examined clinical variables associated with regional frontal lobe structural abnormalities. The U.K. Maudsley study of 40 early-onset schizophrenia youth with a mean age of 16.1 years, duration of illness of 14.1 months, and age of onset of 14.9 years reported that longer duration of illness was associated with smaller left inferior frontal gyrus volume (Burke, Androutsos, Jogia, Byrne, & Frangou, 2008). In addition, increased cortical thickness in the left orbitofrontal region predicted remission and possible response to treatment within 3 months of psychiatric admission for intractable schizophrenia in 16 of 40 NIMH patients (Greenstein, Wolfe, Gochman, Rapoport, & Gogtay, 2008).

Summary and Conclusions

- The frontal lobe integrates a variety of information relevant to behavior, cognition, language, and social skills due to extensive cortical and subcortical connections.
- In adult schizophrenia regional abnormalities in the orbital frontal, inferior frontal, superior and middle frontal lobe, dorsolateral prefrontal, and anterior cingulate regions are related to psychotic symptoms and cognitive impairment.

- In early-onset schizophrenia duration of illness and treatment response are associated with smaller inferior frontal and orbital frontal gray matter volumes.

Lobar Abnormalities: Temporal Lobe

Temporal Lobe Function. The left superior, middle, and inferior temporal gyri (Figure 21.1) are involved in the processing of language at the level of the word, the sentence, and the paragraph. They integrate language with other incoming sensory information (Friederici, 2011). In concert with their frontal and parietal connections they also participate in the bottom-up and top-down processing of language (see reviews in Friederici, 2011) and (Binney, Parker, & Lambon, 2012). The right temporal lobe plays a role in prosody (Friederici, 2011) coarse semantic coding during metaphor processing (see meta-analysis in Yang, 2012) in contrast to the fine semantic processing in the left language-related areas.

Maturation of children's complex syntactic and semantics skills depends on age-related development of dorsal and ventral white matter tracts that connect the superior temporal gyrus and inferior frontal gyrus (Figure 21.5) (Friederici, 2011). They allow the age-related top-down control of children's complex and abstract linguistic skills.

As part of its function as an association cortex, the temporal lobe is involved in the processing of different types of sensory stimuli and the integration of multimodal visual and auditory stimuli. Posterior to anterior longitudinal connectivity within the temporal lobe and horizontal connectivity across the superior, middle, and inferior temporal gyri play an important role in the complex integration of multimodal sensory functions involving visual and auditory perception (see review in Binney et al., 2012).

The tempero-parietal junction and superior temporal sulcus between the superior temporal gyrus and inferior frontal lobe, premotor cortex and sensory cortex (Figure 21.1) are part of a larger mentalizing network involved in the distinction between self and other and in affective theory of mind or the ability to place oneself in the affective state of another individual (see review in Shamay-Tsoory, 2012). The superior temporal sulcus is also sensitive to the presence of others and the interaction between them (Kujala, Carlson, & Hari, 2012). The anterior temporal lobe represents and retrieves social knowledge by using memory about people, their names and biographies, and more abstract forms of social memory such as memory for traits and social concepts (see review in Olson, McCoy, Klobusicky, & Ross, 2012).

Schizophrenia. Matsumoto et al. (2001) demonstrated significantly reduced right superior temporal gyrus gray matter volume in a stereological MRI study of 40 adolescents with schizophrenia, aged 15.5 years with a mean age of onset of 14.1 years, compared with 40 age, gender, socioeconomically matched healthy controls. Using VBM and tract based spatial statistics on white matter, Douad et al. (2007) also described gray and white matter abnormalities in Heschl's gyrus and in the temporal lobe of 25 adolescent onset schizophrenia patients compared with 25 typically developing adolescents studied at Oxford.

Furthermore, Palaniyappan et al. (2013) found decreased gyrification in the right superior temporal gyrus of these same 25 youth with schizophrenia. In a larger U.K. study Pentila et al. (2008) examined cortical folding in the temporal and collateral sulci (parahippocampal, fusiform, and lingual gyri) of 51 early-onset schizophrenia subjects with a mean age of 16 compared with 50 age and gender-matched healthy youth. The schizophrenia group had significantly lower bilateral global sulcal indices (the ratio between total sulcal area and total outer cortex area) and a lower sulcal index in the left collateral sulcus than the control groups. Bordering on medial temporal lobe structures (the hippocampus, fusiform gyrus, and lingual gyrus) involved in schizophrenia (Honea, Crow, Passingham, & Mackay, 2005), the collateral sulcus probably plays a role in the impaired memory (hippocampus), facial information processing (fusiform gyrus), and learning (lingual gyrus) found in patients with this illness.

Association with Clinical Symptoms and Social Cognition. Since the lateral temporal lobe is central to sensory integration and language, it is not surprising that it is involved in the abnormal auditory and visual perception (hallucinations), form of thought and speech (thought disorder), and thought content (delusions) of schizophrenia. In early-onset schizophrenia, positive signs on the SAPS of 29 youth with first episode psychosis (mean age 16.5 +/– 0.9 years), confirmed six months later as schizophrenia, had smaller left superior temporal gyrus and middle temporal gyrus volume than 34 healthy control subjects (Tang et al., 2012). The severity of both hallucinations and thought disorder were related to smaller right superior temporal gyrus volumes in the 40 adolescent patients described in Matsumoto et al. (2001). Of developmental interest, the youth with earlier onset had significantly smaller bilateral superior temporal gyrus gray matter volumes than those with later onset. Underscoring that onset of schizophrenia in younger

children is related to more severe brain abnormalities, this finding supports the neurodevelopmental theory of schizophrenia.

In terms of illness outcome, cortical thickness in the left superior temporal gyrus and left middle temporal gyrus was significantly higher in the 16 early-onset NIMH patients who remitted 3 months after treatment compared with the 40 patients with continued illness (Greenstein et al., 2008). Thus, youth with schizophrenia who undergo more normal cortical thinning during adolescence might have a better prognosis.

Summary and Conclusions

- The temporal lobe plays an important role in language, integration of multimodal visual and auditory information (relevant to perception and its disturbances), mentalizing, and social cognition (including theory of mind, emotional empathy).
- Youth with schizophrenia have reduced gray matter volume, thickness, and gyrification of the superior temporal gyrus, gray and white matter volumes of the Heschl's gyrus, and sulcal folding in the left collateral sulcus.
- Hallucinations, formal thought disorder, and poor treatment response are associated with these structural abnormalities.

Lobar Abnormalities: Parietal Lobe

Function. The parietal lobe subserves a wide range of functions including working memory, attention (sustained attention, alerting and shifting attention, inhibitory control of attention), retrieval of words and numbers, social cognition (theory of mind), as well as perceptual and motor orienting (see reviews in Cabeza, Ciaramelli, & Moscovitch, 2012; Criaud & Boulinguez, 2013). The mainly right-sided working memory and attention network includes the frontal lobe (dorsolateral prefrontal cortex, inferior frontal gyrus) and inferior parietal gyrus (Figure 21.1). The supramarginal gyrus and the region just behind it, the angular gyrus, are involved in word and number retrieval and the angular gyrus participates in reading.

The close connections of the parietal lobe with the sensory and visual cortex promote its role in perception and motor orienting (see review in Cabeza et al., 2012). The middle longitudinal fascicle is a white matter tract that connects the superior temporal gyrus to the superior and inferior (angular gyrus) parietal lobe (Asami et al., 2013) (Figure 21.5). Given its more ventral connections between the superior temporal gyrus and angular gyrus, this white tract is thought to play a role in language and attention. Its more superior connection between the superior temporal gyrus, superior parietal lobe, and occipital cortex probably participates the integration of visual-spatial audiovisual functions (Makris & Pandya, 2009) (Figure 21.5).

Schizophrenia. A Free Surfer study demonstrated significantly smaller left superior parietal gyrus gray matter volume and surface area in 35 early-onset schizophrenia patients, aged 10–12 years, compared with 51 healthy youth (Kumra et al., 2012). There have been no other studies to date on regional parietal structural abnormalities in early-onset schizophrenia patients compared with control subjects.

Association with Clinical Symptoms and Risk Factors. Among the 40 Maudsley early-onset schizophrenia subjects, aged 16.1 years, those with earlier age of onset (mean age of onset of 14.9 years and duration of illness of 14.1 months) had significantly smaller superior gray matter parietal volumes on the right (Burke et al., 2008). Cortical thickness in the bilateral postcentral and angular gyri was significantly higher in the 16 early-onset NIMH patients who remitted 3 months after treatment compared with the 40 patients with continued illness (Greenstein et al., 2008).

Cannabis use (see Risk Factor section) is related to regional reduction of parietal lobe gray matter volume. Comparison among 16 youth who were nonpsychotic cannabis users, 13 early-onset schizophrenia subjects who were also cannabis users, and 35 youth with schizophrenia revealed significantly smaller left superior parietal lobe gray matter volumes in each of these groups compared with 51 age-matched control subjects (Kumra et al., 2012). But there was no additive effect in the comorbid schizophrenia and cannabis use subgroup. Therefore, the authors of this study concluded that early-onset schizophrenia and cannabis independently increased the likelihood for this parietal lobe gray matter volume abnormality.

Summary and Conclusions

- Despite its role in sensory motor integration, perception, language, cognition, and social cognition, parietal lobe abnormalities in early-onset schizophrenia are understudied.
- Youth with schizophrenia, adolescent nonpsychotic cannabis users, and those with schizophrenia and cannabis use have decreased left superior parietal gyrus gray matter volume.
- Smaller right superior parietal gyrus gray matter volume is related to duration of illness.

- Treatment response is associated with smaller bilateral postcentral and angular gyri.

The Insula

Function. This brain region plays an important role in empathy and in awareness of the body's state (introception) through its perception of emotional, cognitive, and internal physical (i.e., visceral) stimuli (Wylie & Tregellas, 2010) (Figure 21.4). Of relevance to schizophrenia, the insula is involved in how one perceives one's own self-image and differentiates self from non-self and internal from external stimuli.

Schizophrenia. Moran et al. (2013) reported a significant reduction in both left and right insula volume in 98 NIMH early-onset schizophrenia patients compared with 100 healthy controls.

Association with Clinical Symptoms. Smaller right insula volume was significantly related to higher positive psychotic symptom scores and reduced left and right insula volume to poor overall functioning in these early-onset schizophrenia patients (Moran et al., 2013).

Summary and Conclusions

- Reduced bilateral insula volume and its role in differentiation between self and non-self appears to play a role in the positive psychotic symptoms and poor overall functioning of youth with schizophrenia.

Corpus Callosum

Function. The corpus callosum (Figure 21.6) is composed of nerve fibers of variable size that bridge between the hemispheres in a topographic manner so that anterior to posterior callosal fibres connect the left and right frontal, temporal, and parietal lobes and their respective motor, sensory, auditory, language, working memory, attention, and executive functions (see review in van der Knaap & van der Ham, 2011). There is an ongoing debate on whether the corpus callosum inhibits or excites the inter-hemispheric transfer of information because inhibition encourages lateralization whereas excitation leads to integrated bilateral function. Both inhibition and excitation might occur since functions, such as language, are lateralized whereas sensory functions, such as vision, are bilateral.

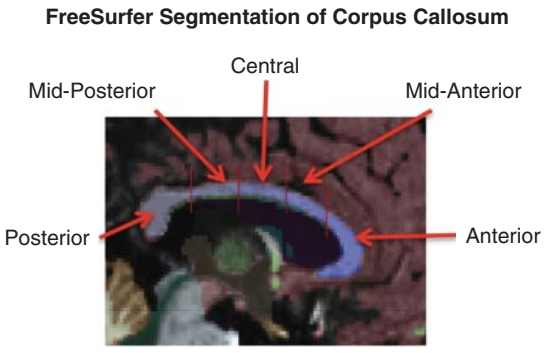

Figure 21.6 Subject MRI scan identifying the sub-regions of the corpus callosum. See footnote 1. *Source:* Reprinted with permission from S. L. M. Johnson, D. Greenstein, L. Clasen, R. Miller, F. Lalonde, J. Rapoport, & N. Gogtay, Absence of anatomic corpus callosal abnormalities in childhood-onset schizophrenia patients and healthy siblings, *Psychiatry Research, 20*(21), 11–16, 2013.

Schizophrenia. A prospective study of the volume of the corpus callosum in the NIMH childhood and adolescent onset schizophrenia patients ($N = 98$) found no significant differences compared with healthy controls ($N = 100$), aged 9–30 years (Johnson, Greenstein, et al., 2013). In contrast, cross sectional DTI studies of tract based spatial statistics on 25 (Douaud et al., 2007), 22 (White, Schmidt, & Karatekin, 2009), 15 (Davenport, Karatekin, White, & Lim, 2010), and 13 early-onset schizophrenia subjects (Henze et al., 2012) report significantly reduced white matter integrity in the genu (Figure 21.6) of the corpus callosum compared with the healthy control subjects. Despite the small sample sizes, similar impaired white matter integrity of the genu (anterior arched part) of the corpus callosum in these four studies might reflect the previously described impaired ongoing normal myelination of the frontal lobe during adolescence (Lenroot & Giedd, 2006).

Association with Clinical Symptoms and Cognition. There have been no studies to date on the relationship of corpus callosal structural abnormalities with symptoms and impaired cognition in early-onset schizophrenia.

Summary and Conclusions

- The corpus callosum, a major interhemisphere commisure, is involved in lateralization and bilateral integration of functions subserved by the frontal, temporal, and parietal lobes.
- There are no abnormalities in the gray matter volume and mid-sagital area of this brain structure in early-onset schizophrenia patients.
- Impaired white matter integrity of the genu that connects the left and right frontal lobes might reflect the impact of the disorder on the development of impaired executive function in youth with schizophrenia.

Hippocampus

Function. The hippocampus participates in remembering the past (memory), imagination (predicting the future), theory of mind (conceiving the viewpoint of others), and navigation (spatial orientation) (see reviews in Buckner & Carroll, 2007 and Mullally & Maguire, 2014). It is part of a core network that includes midline frontal structures, the frontal pole, and the medial temporal and parietal lobes (Buckner & Carroll, 2007). The skills subserved by the hippocampus mature through adolescence in parallel to ongoing development of the brain regions connected to the hippocampus.

Schizophrenia. Eighty-nine of the NIMH early-onset schizophrenia patients, aged 10–29 years, had significantly smaller bilateral hippocampal volumes compared with 79 matched healthy control subjects (Mattai A. et al., 2011). However, there was no significant difference in the longitudinal trajectory of hippocampal development in the patient and control group. A study on 103 NIMH patients and 101 controls identified shape abnormalities involving bilateral inward deformation of the anterior hippocampus (Johnson, Wang, et al., 2013).

Association with Clinical Symptoms. Decreased hippocampal volume in adults with schizophrenia is related to the severity of positive symptoms (Zierhut et al., 2013) but not in youth with this disorder (Mattai et al., 2011). However, bilateral inward deformation was significantly associated with the severity of positive psychotic symptoms and outward deformation with poor overall functioning (Johnson, Wang, et al., 2013).

Summary and Conclusions

- The hippocampus plays a central role in memory, imagination, spatial navigation, and theory of mind.
- Shape abnormalities but not reduced hippocampal volume are related to the clinical manifestations and poor functioning of youth with early-onset schizophrenia.

Thalamus

Function. This brain structure (Figure 21.7) is a relay station for pathways that connect all forms of sensory input, other than olfaction, from the periphery and the subcortical structures with the cortex (see review in Behrens et al., 2003). Table 21.8 and Figure 21.7 present diffusion imaging data based probabilistic tractography algorithm of thalamo-cortical connectivity (Behrens et al., 2003) and related functions (Jakab, Blanc, & Berényi, 2012; Llano, 2013; Watanabe & Funahashi, 2012).

TABLE 21.8 Thalamo-cortical connectivity and functions

Thalamic nuclei (n)	Cortical connectivity	Function
Mediodorsal n. Anterior n.	Prefrontal Temporal	Attention, working memory, verbal intelligence, naming
Lateral and inferior n. Posterior pulvinar	Temporal	Word, sentence generation, naming
Anterior pulvinar Lateral posterior n.	Posterior parietal Extra-striate	Reading
Ventral posterior lateral n.	Somatosensory	Sensations other than smell
Ventra lateral n. Ventral anterior n.	Motor Premotor	Movements

Schizophrenia. Compared with healthy youth, 46 psychotic boys under age 19, of whom 20 were diagnosed with schizophrenia spectrum diagnoses, had significantly smaller bilateral thalamic volumes involving mainly the right mediodorsal and pulvinar areas (Janssen et al., 2012). Two NIMH early-onset schizophrenia samples, one with 20 subjects (Frazier Jean et al., 2008) and one with 44 subjects (Kumra et al., 2000), demonstrated significantly smaller bilateral thalamus volume and reduced mid-sagital thalamic area, respectively, compared with typically developing children.

Association with Clinical Symptoms and Cognition. Although the abnormalities in the mediodorsal and pulvinar regions might contribute to positive psychotic symptoms and to executive function and linguistic deficits, the studies conducted to date in early-onset schizophrenia provide no information on these relationships. However, impaired sensory integration was related to smaller left and right anterior thalamus volumes and to earlier onset of psychosis in 40 first episode psychosis patients (Janssen et al., 2009).

Summary and Conclusions

- Thalamic nuclei participate in sensory integration, language, and cognition.
- Thalamic volumes, mainly mediodorsal nucleus and pulvinar, are reduced in schizophrenia youth.
- These volumetric abnormalities are associated with impaired sensory integration and earlier onset of the disorder.

Basal Ganglia: Caudate, Putamen, and Globus Pallidus

Function. The basal ganglia, together with the substantia nigra and subthalamic nucleus, are involved in movement,

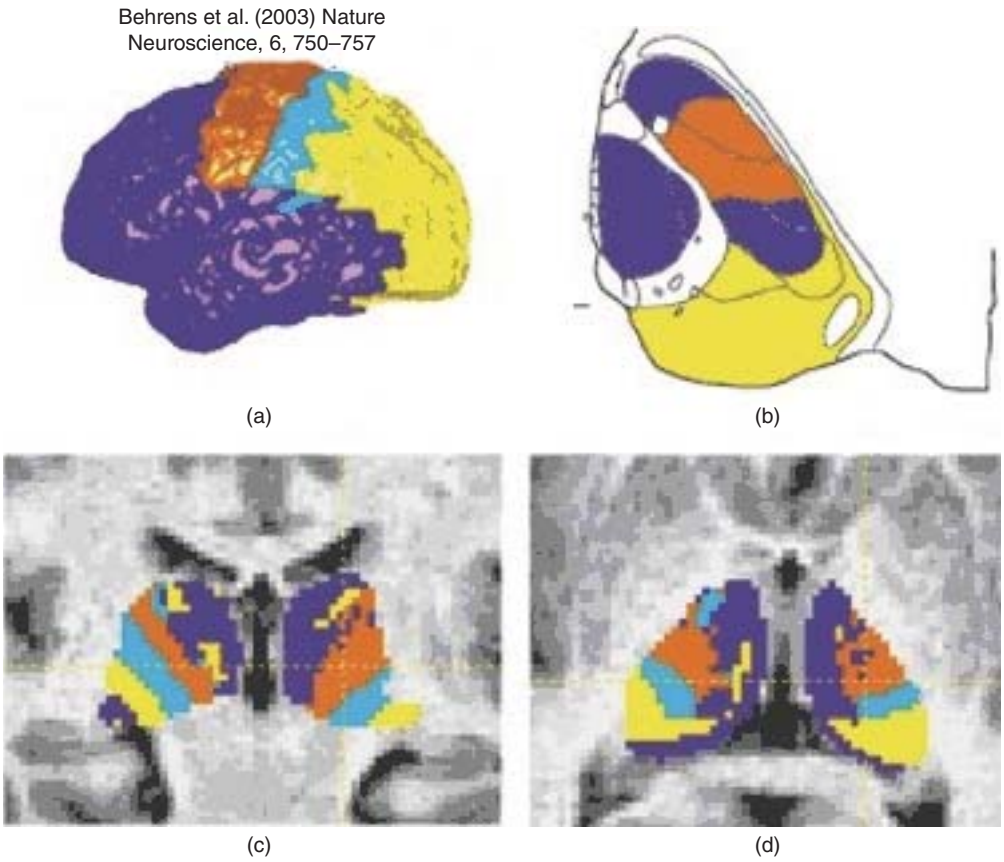

Figure 21.7 Connectivity-based segmentation of the thalamus in a single subject. (a) Division of the cerebral cortex according to anatomical landmarks (see Methods). (b) An axial section based on a histological atlas of the human thalamus with nuclei outlined by black lines. Nuclei have been color-coded according to the cortical zone to which we predict they would show the strongest connections, on the basis of data from nonhuman primates. (c,d) Classifying thalamic voxels based on the zone with the highest probability of connection resulted in clusters of commonly-connected voxels. The clusters correspond to histologically defined locations of major nuclei as in b. The medial, anterior purple area in c and d is thought to include the mediodorsal nucleus and nuclei within the anterior complex, which are connected to prefrontal cortex and the temporal lobe. The more posterior purple area is thought to include parts of the lateral and inferior pulvinar which connect to the temporal lobe. The yellow area is thought to include the anterior pulvinar and the lateral posterior nucleus which project mainly to posterior parietal and extrastriate areas. The blue area is thought to include the ventral posterior lateral nucleus, which projects to somatosensory cortices. The orange area is thought to include the ventral lateral and ventral anterior nuclei, which project to motor and premotor cortices. See footnote 1. *Source:* Reprinted by permission from Behrens, T., Johansen-Berg, H., Woolrich M.W., Smith S.M., Wheeler-Kingshott C.A., Boulby P.A., Barker GJ, Sillery EL, et al. Behrens, T., Johansen-Berg, H., Woolrich M.W., Smith S.M., Wheeler-Kingshott C.A., Boulby P.A., Barker GJ, Sillery EL, et al. Non-invasive mapping of connections between human thalamus and cortex using diffusion imaging, *Nature Neuroscience, 6*(7), 750–757, 2003.

cognition, sensory functions, and behavior (see review in Middleton & Strick, 2000).

Schizophrenia. Only two studies report caudate, putamen, and globus pallidus volumes in early-onset schizophrenia compared with typically developing control subjects. An early NIMH study on 21 patients (of whom 12 had onset before age 12 years) demonstrated significantly larger caudate, putamen, and globus pallidus gray matter volumes than 33 healthy control subjects (Frazier et al., 1996). A two-year follow-up of 18 of these patients treated with clozapine showed normalization of these caudate volumes. Juuhl-Langseth et al. (2012) also reported a bilateral enlargement of caudate volumes in 18 early-onset schizophrenia subjects compared with 33 healthy control subjects. However, these authors examined a large number of subcortical volumes, 29, in a small sample of subjects, and 13 of the 18 patients were on a variety of antipsychotic drugs.

Association with Clinical Symptoms. In light of the small sample size of the above child studies, it remains to be determined if antipsychotic drugs increase caudate volume in early-onset schizophrenia. Tremor, dyskinesias, and

rigidity can occur due to treatment with antipsychotic drugs (see review in Walther & Strik, 2012). However, there is a wide range of motor abnormalities in schizophrenia, including early developmental delay and poor coordination (see Risk Factor section), tremor, chorea, dyskinesia, and slowing that are apparent at diagnosis (Biswas, Malhotra, Malhotra, & Gupta, 2007). These movement abnormalities are also found in children with putative antecedents of schizophrenia (MacManus et al., 2012).

Although these movement symptoms suggest involvement of frontal and striatal dopamine circuits, few studies have examined if they are associated with structural abnormalities in early-onset schizophrenia. Janssen et al.'s 70 adolescents with first episode psychosis and diagnosis of schizophrenia at the 6-month follow-up showed a significant association between smaller right caudate volumes and impaired complex motor sequencing (Janssen et al., 2009).

Summary and Conclusions

- The basal ganglia play a prominent role in movement.
- Youth with schizophrenia have transient enlarged caudate volumes that might represent a medication effect.
- Despite the wide range of motor abnormalities in schizophrenia, few studies have examined the relationship frontostriatal structural abnormalities in these patients.

Cerebellum

Function. Through its connections with the entire brain, the cerebellum (Figure 21.8) plays a role in sensory-motor coordination, sequence learning, attention, processing speed, visual-spatial function, language, and emotions

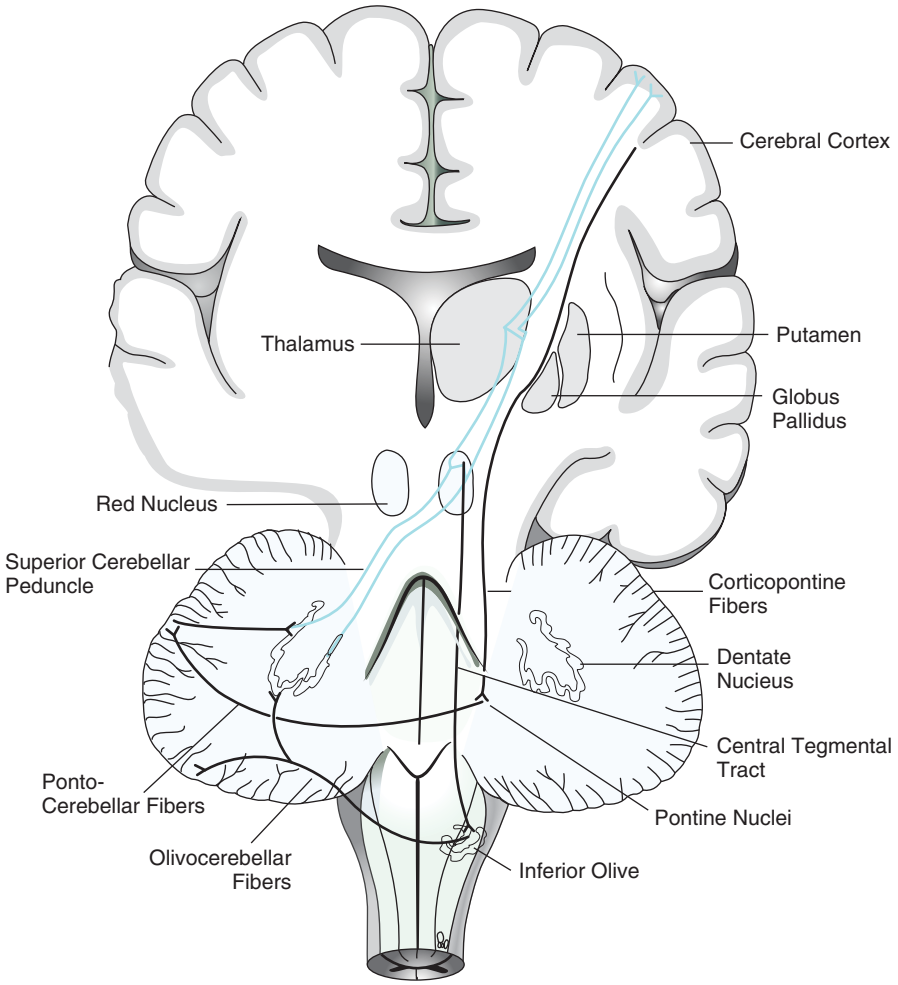

Figure 21.8 Cortico-cerebellar-thalamic-cortical circuit. See footnote 1. *Source:* Reprinted with permission from N. C. Andreasen & R. Pierson, The role of the cerebellum in schizophrenia, *Biological Psychiatry, 64*(2), 81–88, 2008.

(see reviews in D'Angelo & Casali, 2013) and (Andreasen & Pierson, 2008). Cerebellar anatomy is organized to permit it to perform fine-tuned pattern perception, error detection, and rapid online modulation and coordination (Andreasen & Pierson, 2008). D'Angelo and Casali argue that the cerebellum operates as a general-purpose co-processor, whose effects depend on the specific brain centers to which individual modules are connected. They suggest that normal and abnormal functioning in these neural loops could eventually contribute to the broad range of functions subserved by the cerebellum and to the pathogenesis of neuropsychiatric disorders including schizophrenia, dyslexia, autism, and depression.

Schizophrenia. A cross section of 94 early-onset schizophrenia patients from the NIMH sample demonstrated significantly smaller bilateral anterior cerebellar lobe volumes as well as reduced anterior and total vermis volumes compared with 100 control subjects (Greenstein et al., 2011). The patients' developmental trajectory diverged from that of the control group. They continued to have significantly smaller total and left and right hemisphere cerebellar volumes as well as decreased bilateral posterior inferior cerebellar volumes in the control group.

Association with Clinical Symptoms and Cognition. Andreasen (Andreasen & Pierson, 2008) coined the term cognitive dysmetria to capture the broad range of symptoms in schizophrenia (perception, language, concept formation, volition, social behavior, movement, attention, memory, emotion); the difficulty these patients have coordinating the processing, prioritization, retrieval, and expression of information; and the anatomical substrates of dysmetria (the motor cortex and its subcortical connection to the cerebellum via the pons, thalamus, and basal ganglia). For more detail on how this might reflect the specific micro-architecture of the cerebellum, see D'Angelo and Casali (2013) and Andreasen and Pierson (2008).

Andreasen and Pierson suggested that symptoms, such as hallucinations and delusions result when "... pattern and error detection tasks normally performed by the cerebellum are presumed to respond in a flawed manner in patients suffering from schizophrenia. Instead of modulating and coordinating, they misconnect the billions of pieces of information arriving from the cerebral cortex" (Andreasen & Pierson, 2008, p. 82). Nevertheless, most structural MRI researchers on schizophrenia have neglected the humble cerebellum (Andreasen & Pierson, 2008) and cerebellar structural findings are inconsistent (see review in Greenstein et al., 2011).

As found in other neuropsychiatric disorders, the NIMH cross sectional but not the prospective study demonstrated an association between IQ and vermal volume (see review in Greenstein et al., 2011). Reduced volume of the vermis also correlated with poor overall functioning at baseline but not over time. Furthermore, the baseline and developmental trajectory cerebellar abnormalities in these youth were unrelated to psychotic symptoms.

Summary and Conclusions

- The cerebellum acts as a general-purpose co-processor for the fine-tuning of sensory-motor coordination, sequence learning, attention, processing speed, visual-spatial function, language, and emotions.
- When studied cross sectionally, youth with schizophrenia have statistically smaller anterior cerebellar lobes, as well as anterior and total vermal volumes but reduced total, right and left cerebellar hemisphere, and bilateral posterior inferior cerebellar volumes when studied longitudinally.
- The relationship of abnormal vermal volumes with IQ and poor overall functioning is transient in these patients.
- Psychotic symptoms are also unrelated to cerebellar volume abnormalities.

Family and Clinical Risk for Schizophrenia

Family High-Risk

A cross sectional study demonstrated significantly reduced left prefrontal and bilateral temporal gray matter in 52 siblings (aged 8–28 years) of the large NIMH early-onset schizophrenia cohort compared with 52 control subjects (Gogtay et al., 2007). Mattai et al. (2011) replicated these findings in an additional NIMH cohort of 43 siblings, aged 5–26 years, and 86 control subjects. Of note, longitudinal follow-up of gray matter thickness in both sibling samples showed normalization of these findings by age 20 and 17 in the Gogtay et al. and Mattai et al. studies, respectively. Similarly, a 5-year follow-up of white matter growth in 49 siblings of the schizophrenia subjects (mean age 16.1 years) identified slower growth only in the younger group of 7–14 year old siblings (Gogtay et al., 2012).

In contrast to adult sibling and offspring studies (Francis et al., 2011; Palaniyappan, Balain, & Liddle, 2013), the NIMH sibling cohort also did not demonstrate structural abnormalities in the insula (Moran et al., 2013), corpus callosum (Johnson, Greenstein, et al., 2013), hippocampus (Johnson, Wang, et al.; Mattai et al., 2011), and cerebellum

(Greenstein et al., 2011). Developmental, methodological, and illness severity variables in the child and adult studies might underlie these different findings. Among other factors, the methodological differences include the type of morphometric variable studied (volume, cortical thickness), their measurement (MRI scanner and data reduction using manual drawing, VBM, or FreeSurfer), the study design (cross sectional versus prospective studies), heterogeneity of study probands (inclusion of subjects who also have nonpsychotic diagnoses), and lack of matching on demographic variables (ethnicity and socioeconomic status). The NIMH researchers also noted that the normalization of sibling findings might reflect the fact that the brains of a large number of the siblings in their studies were still undergoing development and that many of the siblings were within the age of risk for schizophrenia (Greenstein et al., 2011).

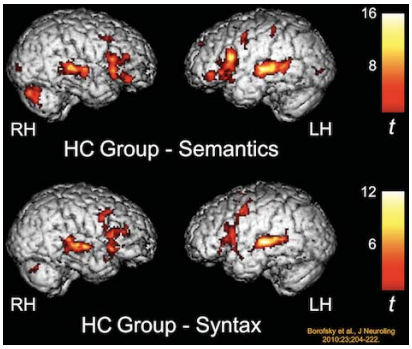
Clinical High-Risk

Among 75 individuals, aged 14–30 years, with prodromal signs of psychosis, the 23 who developed psychosis within 12 months (8 with one of the schizophrenia spectrum diagnoses) had less gray matter at baseline in the right medial temporal, lateral temporal, inferior frontal cortex, and bilateral cingulate cortex than those who did not develop psychosis (Pantelis et al., 2003). Repeat scans at the 12-month follow-up of 21 high-risk subjects demonstrated a significant reduction in gray matter in the left parahippocampal, fusiform, orbitofrontal and cerebellar cortices, as well as the cingulate gyri in the 10 who became psychotic (5 with schizophrenia) (Pantelis et al., 2003). These findings further support the role of frontotemporal regions including the cingulate in the clinical risk and conversion to psychosis.

A comparison of gray and white matter volumes in 20 children with putative signs of psychosis and 20 matched healthy controls, aged 9–12 years, found decreased gray matter volumes in the right middle temporal gyrus, increased gray matter volume in the left superior-middle temporal gyri, and larger white matter volume the left superior temporal gyrus, inferior parietal lobe, and occipital lobe (Cullen et al., 2013). Involvement of the parietal and occipital lobe in the young children in this study might reflect the impact their being at risk for adult onset schizophrenia on the ongoing cortical thinning in posterior brain regions. As previously explained, the NIMH findings for schizophrenia subjects with childhood versus adolescent onset demonstrated reduced gray matter in the parietal lobe only in the childhood onset subjects (Gogtay, 2008).

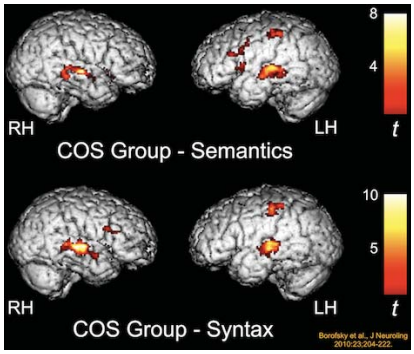
Summary and Conclusions

- Imaging findings in individuals at genetic and clinical risk for schizophrenia provide important information on resilience and risk for the disease.
- Resilience for early-onset schizophrenia in siblings includes normalization by age 17–20 of frontotemporal gray matter reduction and slow white matter growth, as well as no structural abnormalities in the insula, corpus callosum, hippocampus, and cerebellum.
- Resilience among individuals at clinical risk for schizophrenia is related to normal frontotemporal and cingulate gray matter thickness/volume.



Functional Imaging Studies

The few functional imaging studies that have been conducted in early-onset schizophrenia have focused mainly on language (Borofsky et al., 2010), memory (Kyriakopoulos et al., 2012; White, Hongwanishkul, & Schmidt, 2011), and visual processing (White, Moeller, Schmidt, Pardo, & Olman, 2012).



Language and Formal Thought Disorder

Children with schizophrenia (N = 14, mean age: 13.34; IQ: 95) and healthy controls (N = 14, mean age: 12.37; IQ: 104) underwent functional MRI (fMRI) during a semantic judgment task previously shown to differentially engage semantic and syntactic processes (Borofsky et al., 2010). Despite similar performance on the tasks in both groups, the schizophrenia group had increased right lateralization of neural activity during the syntactic condition as found in adults with schizophrenia (see review in Rapp & Steinhäuser, 2013). Different patterns of functional specialization for semantic and syntactic processing in the children with schizophrenia compared with the control group suggested that the patients code semantic and syntactic information differently than the healthy children (see Figure 21.9).

In the patient group formal thought disorder was significantly related to decreased cortical activity during the semantic condition in the left superior temporal gyrus, dorsolateral prefrontal gyrus, dorsomedial frontal gyrus, and inferior frontal gyrus. Formal thought disorder was also associated with reduced neural activity during the syntactic condition in the left inferior frontal gyrus and superior temporal gyrus as well as the insula. These findings corroborate the previously described structural abnormalities in language-related regions in early-onset schizophrenia.

(a)

(b)

Figure 21.9 Cortical activity during semantic and syntactic task in Healthy Control (HC) and Childhood Onset Schizophrenia Groups (COS). a. Several clusters of significant activity in frontotemporal language regions were observed in HC children for both the semantic (top) and syntactic (bottom) conditions as compared with resting baseline. Activation maps are displayed at a threshold of $t > 3.85$, $p < 0.001$ for magnitude, $p < .05$, corrected for spatial extent. b. Children with COS also showed significant task-related activity during the semantic (top) and syntactic (bottom) conditions as compared with resting baseline, albeit to a lesser degree than observed in the HC group. Activation maps are displayed at a threshold of $t > 3.85$, $p < 0.001$ for magnitude, $p < .05$, corrected for spatial extent. See footnote 1. *Source:* Reprinted with permission from L. A. Borofsky, K. McNealy, P. Siddarth, K. N. Wu, M. Dapretto, & R. Caplan, Semantic processing and thought disorder in childhood-onset schizophrenia: Insights from fMRI, *Journal of Neurolinguistics, 23*(3), 204–222, 2010.

Cognitive Processing

Twenty-five youth with schizophrenia, aged 12–19 years and illness onset before age 18, showed significantly reduced activation in the dorsolateral prefrontal cortex, the anterior cingulate, and the frontal operculum during a 2 N back working memory task compared with 20 age-matched control subjects (Kyriakopoulos et al., 2012). The patient group also had reduction in the coupling of the dorsolateral prefrontal cortex, the anterior cingulate, the parietal cortex, and the middle occipital gyrus. Whereas the control group showed an age-related increase in activity in the dorsolateral prefrontal cortex and a decrease in its connectivity with the anterior cingulate cortex during this task, the opposite was found in the patient group. The authors concluded that early-onset schizophrenia is associated with dysfunctional neural engagement of the working memory network and integration of its components.

During a visual spatial working memory task with three different loads, White et al. (2011) reported increased activation in the anterior cingulate, insula, medial temporal lobe, and bilateral lateral temporal lobes in 22 subjects with schizophrenia (mean age was 15.7 years) compared with 24 age-matched controls. With increasing memory load, the patients demonstrated less activation in the parietal lobe compared with the control group. The authors concluded that lack of involvement of the prefrontal cortex function in the working memory task might reflect the developmental impact of the disorder. Their findings support limbic, temporal lobe, and parietal lobe abnormalities during visual spatial working memory.

Multimodal imaging in 11–13 year old children with subclinical symptoms of psychosis ($N = 11$) demonstrated aberrant prefrontal-temporal function in addition to cingulate and insular dysfunctions during a task of response inhibition and error-related processing, respectively, compared with 14 age-matched control subjects (Jacobson et al., 2010). Interestingly, 19 adolescent offspring of parents with schizophrenia also demonstrated dysfunction in frontostriatal pathways and inefficient cognitive processing during a visual working memory task compared with 25 healthy control subjects (Diwadkar et al., 2012). Despite similar performance on the task in both groups, the offspring showed increased activation of the dorsal prefrontal cortex and the caudate during correct compared with incorrect responses. In the control group, however, task proficiency was associated with activation in the caudate.

Summary and Conclusions

- Children with schizophrenia have right lateralization during a semantic task and different activation patterns than healthy control subjects when processing a semantic and a syntactic task.
- Formal thought disorder in children with schizophrenia is associated with decreased activity in language-related regions during a semantic and a syntactic task.
- Decreased cortical activity during working memory tasks identifies dysfunctional neural engagement and integration of the components of the working memory network in youth with schizophrenia.

Connectivity and Graph Theory

One of the main breakthroughs of the imaging studies conducted over the past decade is the identification of connectivity networks, the functions they subserve, and their abnormalities (disconnection) in schizophrenia (see review in Yu et al., 2012). A recent functional connectivity study at rest in 20 healthy adults and 20 age-matched patients who had childhood onset schizophrenia found reduced strength of functional connectivity over short distances localized specifically to connector hubs of multimodal association cortex (Alexander-Bloch et al., 2013). The authors of this study suggest that spatial and topological disturbances of functional network organization could arise from excessive pruning of short-distance functional connections in these patients.

Imaging studies over the past decade have also led to identification of the default mode network or brain regions that are active at rest including the precuneus, anterior and posterior cingulate, medial prefrontal cortex, parahippocampus, and inferior parietal cortices. Tang et al. (2012) described decreased functional connectivity between the medial frontal gyrus and other regions of the default mode network in 32 schizophrenia patients, aged 12–19 years, with recent onset (mean 9.8 months) compared with 38 matched healthy control subjects. They concluded that their findings might reflect abnormal introspective mental activity.

Summary and Conclusions

- Application of graph theory to connectivity studies suggests there is reduced connectivity over short distances in hubs connected to the multimodal association areas in early-onset schizophrenia.
- Impaired connectivity in the default network of youth with schizophrenia might reflect abnormal introspective mental activity.

GENETICS

Genomic studies have shown that schizophrenia is a genetically heterogeneous disorder involving different cytogenetic abnormalities and genetic loci (see review in (McClellan & King, 2010). Rare copy number variants (CNVs) disrupt genes involved in glutamate and neuroreglin pathways and in signaling, synaptic plasticity, and neurodevelopmental processes (McClellan & King, 2010). CNVs that occur de novo are 8 times more common in patients whose illness is not familial (McClellan & King, 2010). But CNVs and other structural genetic abnormalities might also be unique to individual families (McClellan & King, 2010).

Although rare, some CNVs occur at genetic hot spots on chromosomes 1q21.1, 3q29, 15q11.2, 15q13.1, 16p11.2, and 22q11.2 (McClellan & King, 2010). In early-onset schizophrenia they also involve chromosomes 2p16.3 (NRXN1), 15q13.3, 16p13.1, and 17p12 (Ahn et al., 2013). There is a higher rate of rare structural variants and large cytogenetic abnormalities in early-onset compared with adolescent and adult onset schizophrenia (Addington & Rapoport, 2009; Ahn et al., 2013).

Compared with 69 siblings, significantly more childhood onset schizophrenia patients in the NIMH cohort (N = 126) had CNVs with a total of 46 rare CNVs (Ahn et al., 2013). Fifteen patients in this cohort had at least one CNV on chromosomes 22q11, 8q11.2, 10q22.3, 16p11.2 and 17q21.3.

Some of the structural imaging findings found in early-onset schizophrenia are associated with susceptibility genes for schizophrenia. Raznahan et al. (2011) found that among 82 youth with schizophrenia and their 62 siblings (aged 9–22 years), those with the Valline not the Methionine allele of COMT located on chromosome 22 had accelerated dorsolateral prefrontal cortical thinning compared with the attenuated thinning found in the 208 healthy controls. These findings suggest that the reduced cortical thickness found in early-onset patients with schizophrenia might reflect genetic effects. In addition, since the association between accelerated cortical thinning and the Val allele in the siblings normalized over time, Raznahan et al. concluded that the patients' morphometric findings were unrelated to antipsychotic drug treatment.

Most recently in an elegant three stage study of 105 probands with schizophrenia and 84 unaffected siblings, Gulsuner et al. (2013) showed that a network of proteins involved in de novo mutations in probands but not in their siblings is active during fetal development in the dorsolateral prefrontal and ventrolateral frontal lobe. These proteins are "critical to neurogenesis and synaptic integrity, including axon guidance and neuronal migration, signaling, cell proliferation, transport, synaptic transmission, and transcriptional regulation." These findings support the role of the frontal lobe in the neurodevelopmental theory of schizophrenia proposed by Weinberger (Weinberger, 1987).

Among the genetic hot spots for schizophrenia, the microdeletion of 40 genes in and around q11.2 of chromosome 22 is associated with adult onset of a schizophrenia-like psychosis and schizotypal traits in about one-third of youth with this genetic abnormality (Green

et al., 2009). In fact, other than having two parents with schizophrenia, this syndrome is the highest genetic risk factor for schizophrenia (Bassett, Chow, O'Neill, & Brzustowicz, 2001). Additional psychiatric diagnoses found in this syndrome include autism, obsessive-compulsive disorder, phobias, ADHD, generalized anxiety disorder, and depression (see review in Sinderberry et al., 2013). It is also associated with cardiac (De George Syndrome) and palatal abnormalities (velo-cardiac syndrome), as well as impaired cognition (IQ, verbal memory, and executive function).

A large prospective study on brain volumes demonstrated that subjects with 22q11 who exhibited prodromal symptoms at the 3-year follow-up had significantly smaller cranial gray and white matter, prefrontal cortex, mesial temporal lobe, and cerebellar volumes (Kates et al., 2011). The presence of positive symptoms of psychosis was associated with a significant decrease over time in temporal lobe gray matter volume and in verbal IQ. Reduction in temporal lobe gray matter and in verbal IQ also predicts conversion to schizophrenia in youth with clinical risk for schizophrenia (Pantelis et al., 2003; Takahashi et al., 2009), first episode psychosis (Tang et al., 2012), and putative antecedents of schizophrenia (Cullen et al., 2013).

Finally, individuals with autism, intellectual disability, and epilepsy have similar cytogenetic abnormalities similar to patients with schizophrenia that occur on 1q21.1, 15q13.3, 22q11.2, 15q11-q13, and 16q11.2 (McClellan & King, 2010). Mutations disrupting *NRXN1*, *SHANK3*, *CNTNAP2*, and *PRODH* are associated with both schizophrenia and autism (McClellan & King, 2010). Recent clinical evidence for a two-way relationship of epilepsy with schizophrenia (Adelöw, Andersson, Ahlbom, & Tomson, 2012; Hesdorffer et al., 2012; Qin, Xu, Laursen, Vestergaard, & Mortensen, 2005) support these genetic findings. Furthermore, evidence for a critical period during which patients with schizophrenia are more likely to develop epilepsy and epilepsy patients are at increased risk for being diagnosed with schizophrenia (Adelöw et al., 2012; Hesdorffer et al., 2012), underscores the importance of examining the possible role of psychosocial environmental variables.

Finally, although environmental factors play a role in schizophrenia, when and why disruption of the balance between environmental and genetic factors results in the illness remains to be elucidated. In fact, there is a dearth of studies on the role of psychosocial factors in early-onset schizophrenia.

Summary and Conclusions

- Rare copy number variants and de novo mutations occur x8 higher in nonfamilial schizophrenia.
- The offspring of two parents with schizophrenia and probands with chromosome 22q11 mutation have the highest risk for the disorder.
- Childhood onset of schizophrenia is associated with more CNVs than adolescent onset of the disorder.
- Genetic hot spots for the disorder are found on chromosomes 1q21.1, 3q29, 15q11.2, 15q13.1, 16p11.2, and 22q11.2.
- Similar cytogenetic abnormalities are found in schizophrenia, autism, intellectual disability, and epilepsy. Studies are warranted to determine how environmental psychosocial factors trigger the onset of schizophrenia in genetically predisposed youth.

TREATMENT

Antipsychotic Drugs

Typical neuroleptics or first-generation antipsychotic drugs with US Federal Drug Administration (FDA) approval to treat 13–17-year-old schizophrenia youth include haloperidol, chlorpromazine, thioridazine, molindone (now no longer available), and thiothixene (see review in Carlisle & McClellan, 2011). Although effective for positive symptoms of schizophrenia (e.g., hallucinations, delusions, disorganized behavior), lack of efficacy for negative symptoms and induction of extrapyramidal symptoms (EPS) (rigidity, tremor, akathisia), tardive dyskinesia (i.e., involuntary oral-buccal-lingual masticatory movements), and weight gain have limited their use in children.

Based on efficacy and safety findings in double-blind randomized controlled studies, the FDA approved atypical neuroleptics or second-generation antipsychotic drugs including risperidone (1–3mg/d or 4–6mg/d), (Haas et al., 2009), olanzepine (2.5–20.0 mg/d) (Kryzhanovskaya et al., 2009), and aripiprazole (10 or 30mg/d) (Findling et al., 2008) to treat 13–17-year-old patients with schizophrenia. Clozapine (mean dose 176mg/d, SD 149 mg/d) is superior to both haloperidol (mean dose 16mg/d, SD 8 mg/d) (Kumra et al., 1996) and olanzepine (15–20mg/d) (Shaw et al., 2006)), particularly for negative symptoms in early-onset treatment resistant schizophrenia.

Although clinicians now infrequently prescribe typical neuroleptics to treat youth with schizophrenia, the first double-blind multisite randomly assigned trial that compared typical (molindone 10–40 mg/d) to atypical

neuroleptic drugs (risperidone 0.5–6mg/d, olanzepine 2.5–20mg/d) in 116 patients demonstrated no significant differences in response rates and symptom reduction between these medications (Sikich et al., 2008). This multisite study found a minimal effect of these drugs on cognitive function (Frazier et al., 2012). However, response to treatment within 3 weeks was a sensitive measure of clinical outcome in a 6-week randomized double blind trial of 186 youth with schizophrenia, aged 13–17 years treated with aripiprazole versus 96 patients of similar age given placebo (Correll et al., 2013). Nearly 50% of the change in psychotic symptoms occurred within two weeks and 75% of the change was evident within three weeks. The early responders had a significantly better outcome in terms of positive and negative psychotic symptoms, as well as in overall functioning than the nonresponders.

Regarding side effects, molindone alone was associated with akathisia (unpleasant feeing of restlessness and need to be in constant motion). But olanzepine showed the greatest risk for weight gain, as well as significant increases in fasting cholesterol, low-density lipoprotein, insulin, and liver transaminase levels. Double-blind evaluation of the long-term safety and efficacy of these three neuroleptics 44 weeks after the initial 8-week trial confirmed no significant efficacy differences or further symptom reduction following the 8-week initial trial. In contrast to the 8-week trial, in the follow-up study all three drugs were associated with weight gain, risperidone with increased prolactin, and molindone with akathisia. Of note, only 14 subjects (12%) of the original sample completed the study.

Despite the efficacy data, current available safety data highlight the short-term and long-term adverse effects of neuroleptics. The metabolic syndrome occurs with both typical and atypical neuroleptics, and increases the risk for diabetes mellitus and premature coronary artery disease (De Hert et al., 2009). Three of the five following criteria are needed to diagnose this syndrome: Obesity with BMI > 95th percentile, triglycerides > 110 mg/dL, high-density cholesterol < 40 mg/dL, fasting glucose > 100 mg/dL, and blood pressure > 90th percentile (see review in Correll, 2008).

A study of 338 neuroleptic naïve children and adolescents, aged 4–19-years, found significant weight gain (BMI > 95th percentile) in 10%–36% of the subjects with neuroleptic exposure of 7 days or less if treated with olanzepine, risperidone, quetiapine, or aripiprazole for a median of 10.8 weeks (Correll et al., 2009). Although the metabolic risk profiles varied across these drugs, there were more lipid than glucose abnormalities, rare diabetes and metabolic syndrome, and more severe weight gain and lipid abnormalities in olanzepine treated patients. The weight gain of clozapine treated schizophrenia youth falls between that of olanzepine and risperidone (see review in Correll, 2008). In addition to type of neuroleptic, polytherapy increases the likelihood of obesity, dyslipidemia, and type 2 diabetes based in 4140 children and adolescents prescribed 1 of 5 atypical or 2 conventional antipsychotics compared with a random sample of 4500 untreated children (McIntyre & Jerrell, 2008).

Despite the lack of long-term data on weight gain, the metabolic syndrome, and cardiovascular variables in neuroleptic treated youth, the reviewed safety findings justify the need to monitor weight, as well as lipid and glucose abnormalities in these patients. Correll & Kratchovil (Correll, 2008) suggest health screening and monitoring of patients treated with neuroleptics before starting treatment with subsequent repeat testing at 6 weeks, 12 weeks, and annually. They also recommend lifestyle changes in terms of diet and exercise for youth treated with neuroleptics.

Hyperprolactinemia, caused by both typical (haloperidol, pimozide) and atypical neuroleptics (risperidone > olanzepine > ziprasidone), impairs functioning of gonadotropins, estrogen, and testosterone by blocking D2 receptors in the tuberoinfundibular dopamine system of the anterior pituitary (see review in Roke, van Harten, Boot, & Buitelaar, 2009). Hyperprolactinemia occurs within 4–8 weeks of treatment onset and might persist for 1–2 years in patients treated with risperidone (Roke et al., 2009). Youth with a wide range of diagnoses, who are treated with neuroleptics, present mainly with gynecomastia and irregular menses. However, prolactinemia can cause gynecomastia, galactorrhea, sexual dysfunction, reduced fertility, decreased bone density, and osteoporosis. Treatment recommendations in symptomatic youth include neuroleptic dose reduction or crossover to aripiprazole, and use of bromocriptine or amantidine if symptoms continue (Correll, 2008).

Although considered infrequent, extrapyramidal symptoms including tremor, dystonia, akathisia, rigidity, withdrawal dyskinesia, and tardive dyskinesia also occur in youth treated with second-generation antipsychotics (see review in Correll & Kane, 2007). Treatment of these side effects includes anticholinergics (tremor, rigidity, and dystonia), beta blockers or benzodiazepines medications (akathisia), slow cross-titration (withdrawal dyskinesia), as well as dose change or switch to clozapine or preventive use of Vitamin E (tardive dyskinesia) (see review in Correll, 2008).

Neuroleptic malignant syndrome (NMS) is a serious, albeit rare, adverse effect associated with both typical (see review in Silva, Munoz, Alpert, Perlmutter, & Diaz, 1999) and atypical neuroleptics (see review in Neuhut, Lindenmayer, & Silva, 2009). The DSM-IV criteria include rigidity and hyperthermia with at least two of the following symptoms: diaphoresis, dysphagia, tremor, incontinence, tachycardia, tachypnea, hypertension, altering mental states from confusion to coma, and mutism. Laboratory findings include increased serum creatinine phosphokinase (CPK) and leucocytosis.

A case study review of 70 youth treated with typical neuroleptics (Silva et al., 1999) reported death in 9% and serious sequelae in 20% of the cases. However, there were no cases of death in a similar review of 20 youth treated with risperidone, olanzepine, and aripiprazole who had elevated CPK (Neuhut et al., 2009). Only 39% of these children met full NMS diagnostic criteria, while 47.8% presented with fever and rigidity. NMS onset was related to a recent increase in neuroleptic dose, and presented later and lasted less time in children treated with atypical compared with typical neuroleptics. Treatment involves neuroleptic withdrawal, fever reduction, intravenous hydration, and administration of bromocriptine. Use of anticholinergics and ECT in pediatric NMS needs to be further explored.

Finally, the recommendation for treatment of youth with schizophrenia is based on Class I data (see practice parameters in McClellan & Stock, 2013). Nevertheless, 75% of 1745 youth with schizophrenia and related disorders discontinue their medication when treated with aripiprazole, risperidone, quetiapine, olanzapine, or ziprasidone within 18 months (Findling et al., 2010). This is particularly important given evidence that symptoms recur in 77% of first episode patients within a year of stopping medication and in 90% within two years compared with 3% of patients who continue taking their drugs (Zipursky, Menezes, & Streiner, 2013).

Psychotherapy and Psychoeducation

Although few studies have been conducted on these treatment modalities in early-onset schizophrenia, psychotherapy focused on problem solving and coping with psychotic symptoms, psychoeducation for youth and their families and reintegration into school, and treatment of substance abuse facilitate rehabilitation and treatment adherence (see review in McClellan & Stock, 2013). The treatment approach should be tailored to the level of functioning and deficits experienced by the individual patient and how this affects family functioning.

Summary and Conclusions

- Psychopharmacological treatment is the only treatment modality studied to date for early-onset schizophrenia.
- 1st and 2nd generation antipsychotic drugs effectively treat positive symptoms but are less effective for negative symptoms and impaired cognition.
- Noncompliance is frequent, and most youth stop taking their medication within 18 months, mainly due to drug side effects.
- These include the metabolic syndrome (driven by weight gain), extrapyramidal symptoms, hyperprolactinemia, and the neuroleptic malignant syndrome.
- Supportive psychotherapy, psychoeducation, reintegration to school, cognitive rehabilitation, social skills training, and treatment for comorbid substance abuse where indicated are additional treatment modalities.

FUTURE DIRECTIONS

Since the late 1980s tremendous advances have been made in what we know about early-onset schizophrenia, albeit this has focused mainly on the biology of the disorder. Application of the developmental psychopathology principles (Cicchetti, 2006; Cicchetti & Toth, 2009) to future research on early-onset schizophrenia could pave the way for discovering biological and clinical illness markers needed for early identification of at-risk children. It would enable the development of biopsychosocial treatment modalities that impact the multiple levels of functional impairment found in these children. Incorporation of cultural context to these studies is essential for successful delivery of clinical services and for delineation of the different mechanisms involved in triggering onset of the disorder, its variable manifestations, and response to biological and psychological treatment modalities.

Principle 1: Interrelation Between Adaptive and Maladaptive Development with Special Attention to Resilience Despite Adversities, Genetic Loading, Psychosocial Problems

Despite the progress made on genetic abnormalities in early-onset schizophrenia, we still do not understand the role of psychosocial and demographic environmental variables and their interaction with genetic factors in

determining vulnerability or resilience to development of the disorder, trigger factors for onset and exacerbation of the disease, as well as its course and long-term outcome. In addition to delineating mechanisms underlying early-onset schizophrenia, the findings of prospective developmental studies on the interaction among adversities, genetic loading, and psychosocial problems in children at familial risk for schizophrenia could provide the background needed to develop focused psychosocial treatment studies.

In terms of risk factors and the need for early detection, the information available from birth cohort, offspring, and putative antecedents of schizophrenia studies reviewed in this chapter pertains primarily to adult onset of the disorder. Nevertheless, these studies clearly demonstrate that children with delayed developmental milestones in infancy and the toddler period as well as those with low IQ, impaired language, poor academic performance, and social difficulties during childhood might be at risk for schizophrenia. These variables are also risk factors for a wide range of psychopathology in children and adolescents. Therefore, large-scale prospective studies of children with these nonspecific risk factors could identify the different developmental and clinical profiles associated with the more common childhood and adolescent psychiatric disorders as well as the more rare early-onset schizophrenia.

Principle 2: Multiple Levels of Analysis Approach and an Interdisciplinary Perspective

The impact of early-onset schizophrenia on cognition, language, thinking, social skills, and motivation, the poor efficacy of antipsychotic drugs on these impairments, the adverse effects of these medications, and the high rate of noncompliance underscore the need for targeted rehabilitation studies. Cognitive rehabilitation, speech and language therapy, social skills training, and a positive behavioral approach can help improve the quality of life for children and adolescents with schizophrenia and their families.

As alluded to in the imaging section, cross sectional and longitudinal multidisciplinary, multimodal imaging studies on the broad range of functional impairments involved in youth with schizophrenia compared with their siblings and normal controls would provide important information on the disorder's abnormalities and the compensatory processes in the brains of nonaffected siblings with and without schizophrenia-related genetic findings. The findings of these studies could then be applied to design rehabilitation translational intervention studies (see Principles 3 and 5) focused on the stimulation of compensatory plasticity during ongoing brain development.

Principle 3: Theory and Empirical Research on Basic Biological and Psychological Developmental Processes Informs Prevention and Intervention Initiatives

Epidemiological and outcome studies are also warranted on youth with a wide range of illness severity to determine if, in fact, early-onset schizophrenia is a more severe disorder than the adult onset disorder. If confirmed, these findings would underscore the need for early identification and intervention.

Studies that demonstrate the structural and functional abnormalities of neural networks during ongoing brain development and their relationship with the symptoms and functional impairment of youth with early-onset schizophrenia will identify potential biomarkers of the disorder. These can then be used to identify at risk children and adolescents, to inform epidemiological and genetic studies, and to initiate preventive treatment.

Principle 4: Importance of Cultural Context for Study Designs and Quality Clinical Services

Although schizophrenia is a universal illness, studies are needed to determine the role played by cultural context in the illness's risk factors, triggers, clinical manifestations, dosing, efficacy, and safety of antipsychotic drugs, appropriate psychological treatment approaches, as well as in the imaging and genetic abnormalities. In addition to the theoretical importance of these studies, the relevance of cultural competence to timely detection, quality of care, and destigmatization of the disorder for these children and their families cannot be overstated.

Principle 5: Translational Research

The translation of basic science research findings have increased our knowledge about the pathogenesis of the disorder and its genetic basis, and led to the development of drugs that alleviate the illnesses symptoms. To date, little work has been done on the role of the social environment on brain development and on both behavior and early development in animal models of schizophrenia. Despite the translational limitations involved in animal model studies, they can provide important information on the

interaction of both early and late social environmental factors on the neurochemistry, histopathology, genetic, and imaging components of the disorder and its triggers in young animals.

The opening quote comes from an adolescent boy who, within 2 years of this statement, was diagnosed with schizophrenia. He was experiencing the disturbing perceptions that were the prelude to the clinical onset of this often debilitating disorder. Schizophrenia and other psychotic disorders are among the most devastating of all mental disorders because the clinical symptoms typically arise when the patient is crossing the threshold into adulthood. These illnesses can derail the patient's developmental trajectory and thwart efforts to establish autonomy. In addition, the symptoms can interfere with functioning in critical domains: cognition, emotion, and social relationships.

Scientific advances in the field have led investigators to a clearer, albeit more complex, picture of the etiology of schizophrenia and other psychotic disorders than most would have imagined in the mid-twentieth century. First and foremost, the notion that psychotic disorders can be conceptualized as syndromes with a discrete onset, at either the behavioral or biological level, has given way to neurodevelopmental models of etiology (Cicchetti & Toth, 2009; Walker et al., 2013). While there is variability among contemporary models with respect to the behavioral and biological factors they emphasize, most share in common the assumption that congenital vulnerabilities, normal developmental processes, and environmental factors interact in the etiological process. Thus the onset of clinically defined psychosis is, in most cases, preceded by deviations from normal development in one or more functional domains. But these deviations are not uniform across cases, and the developmental trajectories vary with respect to the nature and severity of the abnormalities. Thus, the notion of equifinality, or multiple pathways to

the same clinical outcome, exemplifies psychotic disorders, as well as most other forms of psychopathology (Cicchetti, 2013; Cicchetti & Toth, 2009).

On the other hand, it has become apparent that the traditional diagnostic boundaries that have been drawn among subtypes of psychotic disorders do not map onto distinct etiologic pathways (Rasic, Hajek, Alda, & Uher, 2013). In fact, exemplifying the concept of multifinality, it has been shown that many risk factors, including genetic and psychosocial factors, are nonspecific and can give rise to multiple forms of psychopathology (Cicchetti & Toth, 2009). Due to the cumulative evidence that the various categories of psychotic disorders have overlapping etiologic pathways, the present chapter refers generally to psychosis or psychosis-spectrum disorders, rather than specifically to schizophrenia.

We begin our discussion with an overview of the symptoms and modal course of psychotic disorders and their associated cognitive deficits. We then turn to a discussion of the origins of vulnerability, an area where there have been the most dramatic changes in our scientific assumptions. This is followed by overviews of epidemiologic factors and postnatal environmental factors, the premorbid and prodromal stages, inflammation and stress, the premorbid and prodromal periods, neurobiological aspects of these illnesses, and treatment/intervention. We then turn to contemporary models of etiology, with an emphasis on the complex interplay among vulnerability, neurodevelopmental processes, and environmental triggers. Finally we examine directions for future research.

THE SYMPTOMS AND MODAL COURSE

By definition, psychosis entails a loss of contact with reality (American Psychiatric Association, 2013). The symptoms that reflect this are hallucinations, delusions, and thought disorder, as manifested in disorganized speech and disorganized behavior. These symptoms are often referred to as *positive symptoms* because they involve perceptions and ideations that are beyond those experienced by most people. Hallucinations are sensory experiences that are not associated with an external stimulus. They can occur in any sensory domain, but are most often auditory or visual. Delusions are false beliefs that are held with conviction despite conflicting evidence. They can range from generalized and relatively mundane notions (e.g., songs played on the radio are intended to have special messages for me) to specific and highly bizarre ideas about the world. Bizarre delusions are clearly implausible and do not derive from ordinary life experiences (e.g., aliens hired by the CIA have implanted transistors in the left hemisphere of my brain). Manifestations of disorganized speech include derailment, characterized by sequences of remotely related or unrelated ideas, and incoherence, such that the organization of the communication is so impaired that it does not convey meaning. Finally, disorganized behavior can be manifested in childlike silliness, unpredictable agitation, or abnormal motor behavior such as stereotypical movements or purposeless and excessive motor activity.

Negative symptoms are another general category of symptoms often associated with psychotic disorders. They reflect the absence or subtraction of elements of the normative experience of reality. Negative symptoms include blunted emotional expression or anhedonia, social withdrawal, alogia (decrease in speech), and avolition (decreased motivation). While negative symptoms are not required for a diagnosis of schizophrenia or any other psychotic disorder, they are present to varying degrees in most patients and contribute to the decline in functioning associated with psychoses.

Unlike previous versions of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), the fifth and most recent revision, the *DSM-5* (American Psychiatric Association, 2013) does not differentiate among subtypes of schizophrenia, but it continues to make distinctions among categories of psychotic disorders based on symptoms. The *DSM-5* lists five disorders in the category of Schizophrenia and other Psychotic Disorders: schizophrenia, schizophreniform, schizoaffective, delusional, brief psychotic disorder, psychosis due to another medical condition, and medication-induced psychotic disorder. The symptom criteria for these disorders are listed in Table 22.1.

As described in Table 22.1, the chief distinction among the categories of schizophrenia, schizophreniform, and brief psychotic disorder concerns the duration of the symptoms; the latter two disorders entail briefer durations. Delusional disorder is the most narrowly defined of the psychotic disorders, as it only requires one psychotic symptom (i.e., delusional belief). The *DSM-5* also makes a distinction based on presumed origins of the psychosis, and includes categories for psychotic symptoms due to a medical condition, such as dementia, and those induced by drugs. Given that the diagnostic criteria of most *DSM-5* psychotic disorders requires only one or two symptoms out of a list of several, two individuals may be diagnosed with the same disorder and not share a single symptom with one another. Thus, patients can vary dramatically in the A criteria for psychotic disorders, with one showing hallucinations

TABLE 22.1 Diagnostic Criteria for Schizophrenia and Other Psychotic Disorders (DSM-V, 2013)

Diagnostic Criteria for Schizophrenia

(A) Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be #1, 2, or 3 below:

1. Delusions.

2. Hallucinations.

3. Disorganized speech (e.g., frequent derailment or incoherence).

4. Grossly disorganized or catatonic behavior.

5. Negative symptoms (i.e., diminished emotional expression or avolition).

(B) For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).

(C) Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

(D) Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

(E) The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

(F) If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, are also present for at least 1 month (or less if successfully treated).

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder and if they are not in contradiction to the diagnostic course criteria.

- First episode, currently in acute episode
- First episode, currently in partial remission
- First episode, currently in full remission
- Multiple episodes, currently in acute episode
- Multiple episodes, currently in partial remission
- Multiple episodes, currently in full remission
- Continuous
- Unspecified

Specify if:

- With catatonia
  - Coding note: Use additional code 293.89 (F06.1) catatonia associated with schizophrenia to indicate the presence of the comorbid catatonia.

(*continued*)

TABLE 22.1 (Continued)

Diagnostic Criteria for Schizophreniform Disorder

(A) Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be (1), (2), or (3):

1. Delusions.

2. Hallucinations.

3. Disorganized speech (e.g., frequent derailment or incoherence).

4. Grossly disorganized or catatonic behavior.

5. Negative symptoms (i.e., diminished emotional expression or avolition).

(B) An episode of the disorder lasts at least 1 month but less than 6 months. When the diagnosis must be made without waiting for recovery, it should be qualified as provisional.

(C) Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either 1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms, or 2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.

(D) The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Diagnostic Criteria for Delusional Disorder

(A) The presence of one (or more) delusions with a duration of 1 month or longer.

(B) Criterion A for schizophrenia has never been met.
- **Note:** Hallucinations, if present, are not prominent and are related to the delusional theme (e.g., the sensation of being infested with insects associated with delusions of infestation).

(C) Apart from the impact of the delusion(s) or its ramifications, functioning is not markedly impaired, and behavior is not obviously bizarre or odd.

(D) If manic or major depressive episodes have occurred, these have been brief relative to the duration of the delusional periods.

The disturbance is not attributable to the physiological effects of a substance or another medical condition and is not better explained by another mental disorder, such as body dysmorphic disorder or obsessive-compulsive disorder.

Specify whether:

- Erotomanic type
- Grandiose type
- Jealous type
- Persecutory type
- Somatic type
- Mixed type
- Unspecified type

Specify if:

- With bizarre content

Specify if:

The following course specifiers are only to be used after a 1-year duration of the disorder:

- First episode, currently in acute episode
- First episode, currently in partial remission:

(*continued*)

TABLE 22.1 (Continued)

- First episode, currently in full remission
- Multiple episodes, currently in acute episode
- Multiple episodes, currently in partial remission
- Multiple episodes, currently in full remission
- Continuous
- Unspecified

Diagnostic Criteria for Brief Psychotic Disorder

(A) Presence of one (or more) of the following symptoms. At least one of these must be (1), (2), or (3):
   1. Delusions.
   2. Hallucinations.
   3. Disorganized speech (e.g., frequent derailment or incoherence).
   4. Grossly disorganized or catatonic behavior.
   - **Note:** Do not include a symptom if it is a culturally sanctioned response.

Duration of an episode of the disturbance is at least 1 day but less than 1 month, with eventual full return to premorbid level of functioning.
The disturbance is not better explained by major depressive or bipolar disorder with psychotic features or another psychotic disorder such as schizophrenia or catatonia, and is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify if:

- With marked stressor(s) (brief reactive psychosis)
- Without marked stressor(s)
- With postpartum onset

Specify if:

- With catatonia
  - Coding note: Use additional code 293.89 (F06.1) catatonia associated with brief psychotic disorder to indicate the presence of the comorbid catatonia.

Diagnostic Criteria for Schizoaffective Disorder

(A) An uninterrupted period of illness during which there is a major mood episode (major depressive or manic) concurrent with Criterion A of schizophrenia.
   - **Note:** The major depressive episode must include Criterion A1: Depressed mood.

(B) Delusions or hallucinations for 2 or more weeks in the absence of a major mood episode (depressive or manic) during the lifetime duration of the illness.

(C) Symptoms that meet criteria for a major mood episode are present for the majority of the total duration of the active and residual portions of the illness.

(D) The disturbance is not attributable to the effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.

Specify whether:

- 295.70 (F25.0) Bipolar type: This subtype applies if a manic episode is part of the presentation. Major depressive episodes may also occur.
- 295.70 (F25.1) Depressive type: This subtype applies if only major depressive episodes are part of the presentation.

(*continued*)

TABLE 22.1 (Continued)

Specify if:

- With catatonia (refer to the criteria for catatonia associated with another mental disorder for definition).

Specify if:
The following course specifiers are only to be used after a 1-year duration of the disorder and if they are not in contradiction to the diagnostic course criteria.

- First episode, currently in acute episode
- First episode, currently in partial remission
- First episode, currently in full remission
- Multiple episodes, currently in acute episode
- Multiple episodes, currently in partial remission
- Multiple episodes, currently in full remission
- Continuous
- Unspecified

Diagnostic Criteria for Psychotic Disorders due to Another Medical Condition

(A) Prominent hallucinations or delusions.

(B) There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct pathophysiological consequence of another medical condition.

(C) The disturbance is not better explained by another mental disorder.

(D) The disturbance does not occur exclusively during the course of a delirium.

(E) The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify whether:
Code based on predominant symptom:

- 293.81 (F06.2) With delusions
- 293.82 (F06.0) With hallucinations

Diagnostic Criteria for Substance/Medication-Induced Psychotic Disorder

(A) Presence of one or both of the following symptoms:
   1. Delusions.
   2. Hallucinations.

(B) There is evidence from the history, physical examination, or laboratory findings of both (1) and (2):
   1. The symptoms in Criterion A developed during or soon after substance intoxication or withdrawal or after exposure to a medication.
   2. The involved substance/medication is capable of producing the symptoms in Criterion A.

(C) The disturbance is not better explained by a psychotic disorder that is not substance/medication-induced. Such evidence of an independent psychotic disorder could include the following:
   - The symptoms preceded the onset of the substance/medication use; the symptoms persist for a substantial period of time (e.g., about 1 month) after the cessation of acute withdrawal or severe intoxication; or there is other evidence of an independent non-substance/medication-induced psychotic disorder (e.g., a history of recurrent non-substance/medication-related episodes).

The disturbance does not occur exclusively during the course of a delirium.
The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

but no delusions, and another with the converse. This variability of symptom presentations within diagnostic categories is not unique to the latest edition of the *DSM* and is present in other categories of mental disorder (e.g., personality disorders). This within-category variability has probably contributed to the difficulty researchers have had in identifying disorder-specific etiologies.

In addition to the disorders listed in Table 22.1, the major mood disorders (i.e., depression and bipolar disorder) can be accompanied by psychotic features. To date, however, there is no strong evidence that these various categories of psychotic illness represent separate disorders with respect to etiology or neurobiological mechanisms. In fact, rapidly accumulating evidence from research on genetic and other etiologic factors indicates that, across the diagnostic boundaries, psychotic and several other mental disorders involve some shared etiologic factors (Craddock, O'Donovan, & Owen, 2009). We will discuss some of this evidence in greater detail.

In prior editions of the *DSM*, there were diagnostic criteria for a catatonic subtype of schizophrenia. In addition to the positive symptom criteria for schizophrenia, this category involved distinct abnormalities in posture and movement, such as motoric immobility, excessive and apparently purposeless motor activity, maintenance of a rigid posture (i.e., waxy immobility), mutism and unusual voluntary movement (e.g., posturing, stereotyped movements, prominent mannerisms, or grimacing). With the elimination of subtypes in the *DSM-5*, there are now separate diagnostic criteria for catatonia, and these are listed in Table 22.2. Thus, individuals can now meet diagnostic criteria for catatonia in addition to, and independent of, any other *DSM-5* diagnosis. This change reflects the increasing evidence that movement abnormalities are associated with a variety of mental illness, especially autism and psychosis spectrum disorders.

All categories of psychotic disorder show certain similarities in developmental course. One of their key epidemiological features is their onset in late adolescence/early adulthood (Carlson et al., 2002; Loranger, 1984). The risk rate for psychosis onset is very low prior to adolescence, then increases steadily with each year of age into the mid-20s. This has alerted researchers to the importance of neuromaturational processes in triggering the expression of psychotic symptoms. Coupled with the burgeoning research on significant brain developmental changes during this same period, most contemporary theories of the etiology of psychosis emphasize the role of adolescent neurodevelopment.

TABLE 22.2 Catatonia Associated with Another Mental Disorder (*DSM-V*, 2013)

The clinical picture is dominated by three (or more) of the following symptoms:

1. Stupor (i.e., no psychomotor activity; not actively relating to environment).
2. Catalepsy (i.e., passive induction of a posture held against gravity).
3. Waxy flexibility (i.e., slight, even resistance to positioning by examiner).
4. Mutism (i.e., no, or very little, verbal response [exclude if known aphasia]).
5. Negativism (i.e., opposition or no response to instructions or external stimuli).
6. Posturing (i.e., spontaneous and active maintenance of a posture against gravity).
7. Mannerism (i.e., odd, circumstantial caricature of normal actions).
8. Stereotypy (i.e., repetitive, abnormally frequent, non-goal-directed movements).
9. Agitation, not influenced by external stimuli.
10. Grimacing.
11. Echolalia (i.e., mimicking another's speech).
12. Echopraxia (i.e., mimicking another's movements).

While a diagnosis of psychosis is rare before the typical age of pubertal onset at about age 13, there is substantial evidence that the vulnerability for psychosis is present before the clinical syndrome emerges. Retrospective studies of diagnosed patients have revealed childhood academic performance deficits (Coi et al., 1993; Watt, 1970), signs of motor dysfunction (Walker et al., 1994), and socioemotional abnormalities (Walker et al., 1993, 2004) relative to their same-aged peers and healthy siblings. Thus behavioral indicators of vulnerability, usually subtle, are apparent long before the manifestation of clinical symptoms of psychosis.

During adolescence, the behavioral signs become more pronounced, and this is often the period when the prodrome emerges (Neumann et al., 1995). As will be described in greater detail, the prodrome is the period of functional decline and gradual emergence of symptoms that precedes the diagnosis of psychosis (Cannon et al., 2008). Lasting from months to years, the prodrome typically entails a decline in social, academic, and/or occupational performance.

The modal course of schizophrenia and other psychotic disorders, with symptoms typically appearing as the individual enters young adulthood, has led investigators to intensify their focus on neurodevelopmental processes in the prodrome that might be playing a role in triggering illness expression. Yet the more subtle signs of dysfunction that are often observed in childhood suggest that earlier developmental periods are also characterized by deviation from normal developmental trajectories.

Cognitive Impairment and Psychosis

In addition to the defining symptoms of psychosis, cognitive performance deficits are among the most common and challenging aspects of psychotic syndromes. Some consider these deficits to be a core feature of psychotic disorders (Barch & Ceaser, 2012). Yet, it is important to note that most patients score within the average range on cognitive tasks, although mean performance for patients is below that of healthy individuals of the same demographic background.

There is a now vast research literature documenting impairments in almost all areas of cognitive performance in patients with schizophrenia and other psychotic disorders (Bora, Yücel, & Pantelis, 2010). These performance deficits are observable on simple perceptual motor tasks, IQ tests, and measures of attention, memory, abstract thinking, and response inhibition. Other areas of deficits that have been the focus of a great deal of research are working memory and executive processes, such as planning and organization (Barch & Ceaser, 2012). Although cognitive deficits are apparent across diagnostic subtypes of psychosis and throughout the course of the illness, they are more pronounced the earlier the onset of illness, with those suffering from childhood onset psychosis having the most debilitating deficits (Frangou, 2013).

As would be expected, these impairments are a significant impediment to occupational functioning and it is unfortunate that they are generally not improved by pharmacologic treatments. Moreover, retrospective and prospective studies indicate that many patients manifest these deficits in childhood, and recent research suggest that they may become more pronounced in the period before the clinical onset of illness (Fusar-Poli et al., 2012; Reichenberg et al. 2010).

Among the cognitive problems associated with psychotic disorders, attentional deficits are among the most well-documented and subjectively distressing to patients (Mirsky et al., 1986; Nuechterlein et al., 2004). Attention deficit-hyperactivity disorder (ADHD) and psychotic diagnoses are highly comorbid (Elman et al., 1998; Kim-Cohen et al., 2003; Rubino et al., 2009). There is also a developmental link, in that a large proportion of those who go on to develop schizophrenia-spectrum disorders were diagnosed with ADHD during childhood. Ross and colleagues (2006) found that 84% of their sample of patients with schizophrenia had a prior childhood diagnosis of ADHD, though this estimate may be inflated due to the early mean age at onset for the sample. Nonetheless, this is a strikingly higher prevalence rate of ADHD as compared with the general population (around 5–6%; Polanczyk et al., 2007). Recently, a prospective study assessing the relative risk of later schizophrenia for those with a childhood diagnosis of ADHD concluded that children with ADHD were at a significantly increased risk for developing schizophrenia (RR = 4.3; Dalsgaard et al., 2013). Further, Rubino and colleagues (2009) showed that ADHD in childhood was even more predictive of schizophrenia than unipolar depression.

Social cognition, the ability to process social information and comprehend and solve interpersonal problems, is also impaired in psychotic patients. Mean performance on tests of facial and nonverbal emotion recognition, social relationship perception, and social problem solving is significantly below that of normative samples (Green et al., 2012). Within the domain of social cognition, an ability that has recently received a great deal of attention is theory of mind (ToM). This refers to the ability to accurately infer the feelings and thoughts of others. In the course of human interactions, ToM serves as the basis for empathy and understanding of the intentions of others. Individuals suffering from psychosis manifest significant deficits in ToM, and this poses problems for establishing and maintaining social relationships (Bora, Yucel & Pantelis, 2009).

There is little debate about the presence of cognitive deficits in psychosis, but their origins and significance remain unclear. The current consensus is that they are one aspect of vulnerability, in that they have been shown to precede the manifestation of clinical symptoms (Bora, Yücel & Pantelis, 2010). This view is consistent with the extensive evidence that vulnerability is typically congenital and arises in fetal brain development. Further, the cognitive impairments linked with schizophrenia and other psychotic disorders tend to persist after pharmacologic and psychotherapeutic treatment, and are associated with poorer prognosis. It has been shown that there are positive correlations among cognitive ability, insight, and social competence in psychosis, and that all of these factors are inversely correlated with clinical symptom severity (Quee et al., 2011). But the relation between cognitive factors and symptoms varies among symptom dimensions. A recent extensive review of the research literature indicates that negative and disorganized symptom dimensions are inversely, but modestly, correlated with cognitive functioning (correlations from –.29 to –.12), but that positive and depressive symptom severity are not associated with cognitive performance in samples of psychotic patients (de Gracia Dominguez et al., 2009). The authors conclude

that this indicates that the neural substrates responsible for disorganized and negative symptoms differ from those of positive and affective symptoms. Thus, cognitive capacity may moderate symptom expression in vulnerable individuals, but it does not appear to be a causal factor in the positive symptoms of psychosis. Researchers are examining the effects of cognitive rehabilitation on patients with psychotic illness, and the results of these efforts will shed further light on the role of cognitive deficit in the manifestation of psychotic symptoms.

THE ORIGINS OF VULNERABILITY TO SCHIZOPHRENIA AND OTHER PSYCHOSES

Over the past few decades, there have been major advances in our scientific understanding of congenital vulnerabilities to a host of human illnesses. Particularly in the realm of genetics, there has been a revolution in our understanding of how both genes and their expression are subject to a host of dynamic processes. Similarly, the prenatal environment has been shown to have pervasive effects on subsequent risk for a range of illnesses. For example, risk for diabetes in children is associated with maternal diet as well as maternal exposure to stress during pregnancy (Tamashiro et al., 2009). These and other findings have led researchers to consider the myriad of ways that developmental programming can occur during the fetal period and set the stage for later risk for morbidity (Gordon et al., 2011; Marques et al., 2013). In the following, we explore the genetic and prenatal environmental factors that give rise to vulnerability to psychosis and the complex interplay among them. These complex processes entail cycles of cross-talk between the environment and biological mechanisms, clearly demonstrating how permeable the boundary is between biology and behavior.

Genetics

Assumptions about the genetics of schizophrenia and other mental disorders have undergone a dramatic change as molecular genetic technologies have advanced. As recently as the 1980s, some investigators in the field of schizophrenia where continuing to debate the existence of a single risk gene for the disorder (Holzman et al., 1988). But as molecular genetic findings have accumulated, it has become clear that (1) there is no single or major risk gene; (2) that the genetic abnormalities that subserve vulnerability to schizophrenia are varied and complex; and (3) that mental disorders that have been viewed as belonging to distinct diagnostic categories actually share many genetic and environmental risk factors.

It now appears that genetic risk factors for schizophrenia and other psychotic disorders, as well as many serious developmental disorders, can be either inherited or acquired. With respect to acquired vulnerabilities, genetic risk sometimes results from aberrant processes that occur very early in the human life span, during the prenatal period, or even *prior to conception*. The evidence supporting these new conceptualizations is largely based on recent advances in our understanding of the genetic mechanisms of disease. Some are now referring to our contemporary view as the postgenomic era because we have moved beyond a focus on static DNA to a greater appreciation of dynamic genetic processes (Charney, 2012).

Beginning in the 1950s, findings from behavioral genetic studies using family, adoption, and twin paradigms all pointed to a significant role for genetic factors in schizophrenia (Gottesman, 1991). Family studies showed that risk for schizophrenia was elevated in biological relatives of patients with the disorder. The elevation in risk varied as a function of genetic similarity to the patient, with first-degree (parents, siblings) relatives having a greater risk than second degree, followed by third degree. Consistent with this, offspring of biological parents with schizophrenia who were reared by healthy adopted parents showed an elevated risk for schizophrenia. Finally, twin studies revealed that monozygotic (MZ) twins were significantly more likely to be concordant for schizophrenia than dizygotic (DZ) twins, with estimated concordance rates across studies varying from about 15–80% for MZ twins versus 5–20% for same-sex DZ pairs. Taken together, these findings were interpreted as providing strong evidence that an inherited genetic predisposition could be the basis of vulnerability. At the same time, with concordance rates for MZ twins being far below 100%, it was obvious that inherited genetic vulnerabilities were not telling the whole story.

There were, in fact, some puzzling aspects in the general pattern of findings. First, the concordance rates reported in MZ twins were highly variable across studies. A meta-analysis of the twin data revealed that several aspects of the study methodology, including the source of the twin samples, contributed to this variance (Walker et al., 1991). Further, the concordance rate for DZ twins, who have been assumed to be as genetically similar as siblings, was substantially higher than the concordance rate for siblings. Finally, the heritability estimates yielded by twin, adoption, and family studies differed, with twin studies being higher than the other methods (Walker et al., 1991).

New findings on the preconception and prenatal factors that influence genes and gene expression are bringing the source of these discrepancies into clearer focus.

Once procedures for genotyping became more widely available in the 1980s, researchers had the opportunity to identify specific risk genes and variants (Owen et al., 2010). By way of background, single nucleotide polymorphisms (SNPs) and copy number variations (CNVs) are often the focus of these studies. A SNP is a DNA sequence that can vary, such that a single nucleotide (i.e., A, T, C or G) in the genome differs among individuals or between chromosome pairs. Thus, there are at least two alternative forms (i.e., alleles) of the gene at the same locus. CNVs are a type of structural variation in the genome, a change in the sequence of nucleotides, in which the DNA in the cell has an abnormal number of copies of one or more sections of the DNA. CNVs can be inherited or can arise through de novo, or spontaneous, mutations.

When considering the role of mutations in illness, it should be emphasized that, although they are essentially errors in the DNA code, they are not always disadvantageous, and in fact are assumed to be the basis for adaptive evolution. Nonetheless, when the mutation results in changes in one or more proteins essential for cellular survival or normal brain function, the consequences are typically negative (Schon, DiMauro, & Hirano, 2012; Veltman & Brunner, 2012). The causes of mutations are not yet fully understood, but it is now assumed that some occur randomly (stochastic processes), whereas others are a function of exposure to mutagens, most notably radiation and chemical exposures. Further, they can originate in germ cells (eggs and sperm) or in somatic cells.

Initially genotyping studies appeared to hold great promise, and investigators reported that alleles of genes, such as DISC1 (disrupted in schizophrenia 1), COM-T (catechol-o-methyltransferase) and NRG-1 (neuregulin 1), were linked with variations in risk for schizophrenia, as well as affective psychosis (Craddock, O'Donovan & Owen, 2005). But the effect sizes for these genes were very small and, although statistically significant with sufficiently large samples, accounted for a very small proportion of the variance. Further, the same genes have been found to confer risk for a variety of psychiatric disorders, as well as biological sensitivity to stress (Walder et al., 2010). Investigators have continued this search over the past three decades, but the results have been disappointing in that individual genes or combinations of genes that had been fairly consistently shown to be linked with schizophrenia ultimately amounted for only a small proportion of risk (Gershon, Alliey-Rodriguez, & Liu, 2011). A recent genome-wide association study (GWAS) revealed 13 new loci associated with risk for schizophrenia, leading the authors to conclude that "8,300 independent, mostly common SNPs (95% credible interval of 6,300–10,200 SNPs) contribute to risk for schizophrenia and that these collectively account for at least 32% of the variance in liability" (Ripke et al., 2013, p. 1150). Taking a somewhat different perspective, researchers reporting another recent GWAS study of both SNPs and CNVs concluded that "rare deleterious variants may be more important in schizophrenia predisposition than common polymorphisms. While our analyses do not suggest that implicated CNVs impinge on particular key pathways, we do support the contribution of specific genomic regions in schizophrenia, presumably due to recurrent mutation. On balance, these data suggest that very few schizophrenia patients share identical genomic causation, potentially complicating efforts to personalize treatment regimens" (Need et al., 2009, p. 1).

At the same time these studies of the genetics of psychosis were under way, new discoveries were revolutionizing perspectives on genetic mechanisms in disease (Charney, 2012). First, it was discovered that genetic mutations, including CNVs, were much more common than had been assumed: some of these originated in germ cells (sperm and ova), and were thus inherited by offspring even though not present in the parent's somatic cells, and others arose spontaneously during embryogenesis, or perhaps later. Second, researchers began to make great strides in understanding the processes whereby gene expression is regulated, giving rise to the field of *epigenetics*. Like mutations, epigenetic changes can be inherited or acquired in the developmental course of the individual. It now appears that both mutations and epigenetics are relevant to our understanding of schizophrenia and other psychotic disorders, and they may explain the puzzling aspects of findings from earlier behavior genetic paradigms.

As noted already, CNVs are one type of mutation. These sometimes entail a deletion in which a part of a chromosome or DNA sequence is missing. Deletions can range from a single base to an entire piece of chromosome, and can be caused by errors in the crossover of chromosomes during meiosis. As early as 1953, Book suggested that mutations might be a source of the genetic abnormalities contributing to schizophrenia. But at the time it was assumed that mutations were not common enough to account for schizophrenia or other common mental illnesses because of the relatively high rate of occurrence of these disorders in the population. But with contemporary techniques for examining genotypes, researchers have discovered that mutations are more common than

had been previously assumed, and they are now able to identify individual and group differences in the proportion of mutations. Studies comparing healthy individuals to patients with schizophrenia and other psychoses have shown that the patients have significantly more CNVs including deletions (Bassett, Scherer, & Brzustowicz, 2010; Rees, Kirov, O'Donovan, & Owen, 2012). In other words, there are more coding errors in their genes. Further, these mutations have been observed on multiple chromosomes and in a range of mental disorders, from autism to adult-onset psychosis (Rapoport, Giedd, & Gogtay, 2012). Thus, to date, there is little evidence of specificity of mutations to schizophrenia or other psychotic disorders, although one trend in the genetic findings is that genes involved in brain development are among those most often linked with mental illness.

The findings of shared genetic abnormalities in autism spectrum and psychosis spectrum disorders are especially challenging to the diagnostic boundaries drawn by current diagnostic taxonomies, including the *DSM-5*. Recent research on genetic deletions has revealed numerous areas of overlap for the two disorder spectra (Adwalla et al., 2010; Burbach & van der Zwaag, 2008; King & Lord, 2010). Examples include the 15q13.3 deletion (Pagnamenta et al., 2009; Stefansson et al., 2008), 16p11.2 deletions and duplications (McCarthy et al., 2009; Weiss et al., 2008), deletions in Neurexin 1 (NRXN1; Ching et al., 2010; Kim et al., 2009; Kirov et al., 2008) and 22q11.2 deletions (Ousley et al., 2013).

The 22q11.2 deletion is one of the most studied in relation to psychosis and autism spectrum disorders (ASD), and it is currently the most predictive genetic risk factor for both. 22q11.2 deletion syndrome (DS) occurs in approximately 1 out of every 4,000 births, and presents variable physical phenotypes, including heart defects, cleft palate, immune deficiencies, skeletal abnormalities, and minor facial anomalies (Esterberg, Ousley, Cubells, & Walker, 2013; Philip & Bassett, 2011; Wilson et al., 1994). Individuals with 22q11.2 DS have been shown to be at a heightened-risk of developing psychosis and ASD, as well as experiencing subclinical symptoms of these disorders. For example, in a sample of adolescents with 22q11.2 DS, 45% experienced attenuated psychotic symptoms, 85% endorsed moderate negative symptoms, 55% experienced disorganized symptoms, and 25% had a diagnosis of ASD (Stoddard, Niendam, Hendren, Carter, & Simon, 2010). When examined for prodromal signs of psychosis, 60% of the 22q11.2 DS individuals met criteria for being at clinical high-risk of developing psychosis (Shapiro, Cubells, Ousley, & Walker, 2011). Given the high percentage of individuals with 22q11.2 DS endorsing psychotic or prodromal signs, it is of no surprise that several studies found that around 30% of individuals with 22q11DS develop psychosis (Antshel et al., 2010; Gothelf et al., 2007; Kates et al., 2011). In some cases, individuals with 22q11.2 DS have comorbid diagnoses of psychosis and ASD (Vorstman et al., 2006). Ousley and colleagues (2013) reported that 40% of their 22q11.2 DS sample that met criteria for ASD also met criteria for a schizophrenia-spectrum disorder, although using more stringent diagnostic criteria for ASD yielded a 20% comorbidity rate.

Clearly, the co-occurring psychotic and autistic symptomology in 22q11.2 DS highlights our need to further investigate the etiological commonalities between psychosis and ASD, as well as the factors that result in such different developmental trajectories. Karayigorgou and colleagues (2010) have suggested that some children with 22q11.2 DS manifest autistic behaviors as part of a prodromal syndrome that precedes the later onset of psychosis. It has also been suggested that the elevated rates of both psychotic disorders and ASD in 22q11.2 DS serve as an example of neuropsychiatric *pleiotropy* (Vorstman et al., 2013). While the term pleiotropy has typically been used to refer to divergent phenotypic manifestations resulting from a single genetic variant, in the case of 22q11.2 DS, there are varied phenotypic manifestations of a specific chromosomal deletion. These varied manifestations are presumably a reflection of gene–gene interactions and gene–environment interactions, as well as individual differences in gene expression profiles, as we will discuss further.

With respect to the origins of mutations, many originate in germ cells of the parents, while others arise in the individual's somatic cells. In the case of germ-line mutations, the parent may acquire a mutation in ova or sperm that is not present in their somatic cells, but is passed on to offspring. The mutation can then be present in the somatic cells of the child. In 2001, Malaspina and colleagues reported evidence that advanced paternal age was associated with heightened risk for schizophrenia in offspring (Malaspina et al., 2001) and this has been replicated by other research groups (Miller et al., 2011). In a recent review of the literature on paternal age, the authors conclude that: "This risk factor increases the risk of schizophrenia as much as any single candidate gene of risk" (Miller et al., 2011, p. 1039). Subsequent studies have found the same link for autism (Hultman et al., 2010; van Balkom et al., 2012) and for intellectual disabilities (Saha et al., 2009). More recently, research has directly verified the genetic mutations mediating these

relations; several studies of large samples have revealed that advanced paternal age is indeed associated with a higher rate of mutations in somatic cells of offspring (Kong et al., 2012). The relation has also been observed for maternal age by some research groups, although the effect is not as great, presumably due to the higher rate of cell divisions in spermatogenesis than in egg production (Kong et al., 2012). Taken together, the previous findings are important, because they demonstrate that genetic abnormalities subserving vulnerability can originate in the *prezygotic period*. In other words, vulnerability can be conferred prior to conception.

Although a plethora of environmental factors can give rise to germ-line mutations, the most well established classes of environmental factors are chemical and radiation exposure (Pacey, 2010; Yauk et al., 2012). Other germ-line mutations result from errors that occur randomly during cell division, especially in spermatogenesis (Kong et al, 2012). As mentioned, mutations can also occur in somatic or body cells (Schon, DiMauro, & Hirano, 2012). These mutations can arise during embryogenesis when cells are rapidly dividing, and may result from environmental factors, such as prenatal or postnatal exposure to drugs and radiation (Veltman & Brunner, 2012).

The adverse effects of mutations result from the protein production abnormalities they can trigger. Thus DNA, whether intact or mutated, affects functioning via gene expression and the production of proteins. But mutations are not the only source of aberrant protein production. There are multiple biological processes that determine gene expression, and DNA code is only one of these. Rapid progress in the understanding of these processes over the past decade has resulted from studies of epigenetics.

Epigenetics is concerned with the processes involved in the expression of genes, and its study has revolutionized perspectives on the causes of mental disorders (Cortessis et al., 2012). Broadly defined, epigenetics refers to the regulation of factors associated with gene expression that are not encoded within the DNA sequence (for reviews, see Gudsnuk & Champagne, 2011; Monk et al., 2012; Szyf, 2012). The two primary epigenetic processes through which genes are expressed or silenced are *DNA methylation* (addition of a methyl group to the cytosine or adenine DNA nucleotides) and remodeling of chromatin structure by chemically modifying *histones* (proteins in cell nuclei that package and order DNA into structural units; Gudsnuk & Champagne, 2011).

DNA methylation entails alterations of the DNA sequence at specific regions of the gene by enzymes known as DNA methyltransferases (DNMTs) (Jaenisch & Bird, 2003). Methylation of DNA generally *decreases* the accessibility of DNA for transcription, resulting in gene silencing. Histone modification involves chemical processes occurring at protein tails (i.e., residues of proteins) that project from histones, but the ways histones can be altered are highly complex—sufficiently complex as to be referred to as the histone code (Jenuwein & Allis, 2001). Changes at histone tails result in the modification of chromatin structure. For instance, histone acetylation opens up the chromatin, allowing the DNA transcription factors to bind and *activate* gene expression. Conversely, histone deacetylation works to condense the chromatin structure, making it much more difficult for transcription factors to access the DNA and thereby *decreasing* gene expression. It is important to note that DNA methylation and histone modification, while representing two distinct epigenetic mechanisms, are not wholly separable processes. Rather, it has been shown that DNA methylation can lead to chemical changes that result in histone deacetylation, and that certain unacetylated histones can attract DNA methyltransferases, both of which further contribute to gene silencing (Rutten & Mill, 2009).

Epigenetic mechanisms are most active early in embryonic development, playing an essential role in cellular differentiation (for review, see Szyf, 2012), but these processes remain dynamic over the course of the life span (Szyf, 2012; Gudsnuk & Champagne, 2011; Monk et al., 2012; Roth & Sweatt, 2011). Further, epigenetic modifications are heritable and reversible (Gudsnuk & Champagne, 2011; Roth et al., 2009; Monk et al., 2012; Pan, Lai, Wu, & Ho, 2013), thus elucidating epigenetic processes in disease is an important area of inquiry for both understanding the etiology of disorders and shedding light on options for preventive intervention.

Several recent reviews have summarized the evidence that adverse early experiences affect epigenetic processes both in animal models and in humans (Monk et al., 2012; Roth et al., 2011; Szyf, 2012). Carefully controlled laboratory studies with animals (primarily rodents), focusing on methylation patterns in a variety of genes implicated in psychiatric disorders, have provided valuable insight into the impact of early life experiences on possible pathogenic processes. For example, adverse early postnatal experiences affect expression of the gene for brain-derived neurotrophic factor (BDNF), a neurotrophic factor that appears to be reduced in schizophrenia, depression, and anxiety disorders (for recent reviews, see Gray et al., 2013; Roth et al., 2011). When compared with controls, infant rats exposed to nonoptimal rearing or maternal stress manifest both hypermethylated prefrontal BDNF DNA

and a reduction in prefrontal BDNF mRNA as adults. Further, Roth and colleagues (2011) demonstrated that the abnormal BDNF methylation and gene expression caused by early maltreatment was reversible when they administered zebularine, a DNA methyltransferase (DNMT) inhibitor. These findings illustrate the dynamic nature of epigenetic processes and how a targeted treatment has the power to undo the deleterious impact of adverse early life experience.

Although research on epigenetic processes in primates is limited, compared with rodent studies, there is increasing evidence of similar relations between environmental factors and gene expression in humans. For example, in a recent study of DNA methylation in the peripheral blood cells of a Canadian community cohort, demographic factors (e.g., sex, age, and ethnicity) and psychosocial factors, such as early life stress and current perceived stress, were significantly associated with methylation levels (Lam et al., 2012). Also of interest for understanding the pathogenic processes of psychiatric illnesses was the finding from this study that cortisol output was associated with variations in DNA methylation. Further research aimed at replicating these results is critical, because they may have significant implications for preventive intervention.

Unlike animal studies, which have analyzed epigenetic profiles directly in brain tissue, the Lam et al. (2012) study used blood samples to ascertain DNA methylation levels,. While brain tissue analysis is typically not feasible with human subjects, there are two postmortem studies that have assessed DNA methylation in human hippocampal tissue (McGowan et al., 2009; Labonté et al., 2012) taken from suicide completers with and without histories of child abuse, as well as non-suicidal controls. McGowan and colleagues (2009) examined both methylation and mRNA levels of the NR3C1 gene, which encodes the glucocorticoid receptor (GR), and found that suicide completers with a history of child abuse exhibited increased methylation at an NR3C1 promoter, as well as reduced expression of GR mRNA. Extending this work, Labonté et al. (2012) conducted a genome-wide analysis of epigenetic markers and mRNA levels in hippocampal tissue from the same sample and found 362 promoters that were differentially methylated (248 hypermethylated and 114 hypomethylated) in suicide completers with a history of abuse versus controls. Genes involved in neuronal plasticity were more strongly differentially methylated. These findings suggest that adverse early life experiences may have an enduring impact on gene expression in the human brain.

Research is recently yielding evidence about epigenetic changes associated with psychosis. Several groups have reported DNA methylation differences between psychotic patients and controls in postmortem studies of brain tissue (for reviews, see Labrie et al., 2012; Syrakic et al., 2013). Perhaps most compelling, comparisons of MZ twins who are discordant for schizophrenia reveal patterns of gene expression in blood cells that differentiate the co-twins. For example, a study comparing MZ twins discordant for schizophrenia or bipolar disorder with psychosis showed numerous loci with illness-associated DNA methylation differences between the co-twins within pairs, as well as between the groups of affected and non-affected twins (Dempster et al., 2011). The epigenetic changes were most pronounced in genes governing the functions of biological networks and pathways that have been hypothesized to be involved in psychiatric disorders and neurodevelopment. The general pattern was significantly hypomethylated regions in affected twins, most notably in the promoter of a gene (ST6GALNAC1—gene-encoding alpha-*N*-acetylgalacto saminide alpha-2,6-sialyltransferase 1) that has been implicated in psychosis. Although some methylation differences were found across all discordant twin pairs for both diagnostic categories, others were specific to one or a couple of pairs. Further, some regions were consistently altered when the combined discordant psychosis group was compared with unaffected co-twins, whereas others were specific to either schizophrenia or bipolar disorder.

Another study examined DNA methylation markers in blood from schizophrenia patients and healthy controls (Lui et al., 2013). After controlling for demographic factors and substance use, the researchers found diagnostic group differences in patterns of hyper- or hypomethylation, and these were validated using an independent data set. There were seven genes with expression levels that were significantly altered in patients (patients showed hypomethylation/upregulation in TCN1, and hypermethylation/downregulation in CD244 and CBFA2T3, and downregulation with hypomethylation in CD244 and CBFA2T3). Within the patient group, the methylation patterns were not associated with disorganized or negative symptoms, but they were correlated with delusions and hallucinations. The pattern of correlations suggested that methylation changes may play a protective role in lessening the severity of delusions and hallucinations in patients. Further analyses showed that the differentially methylated genes are involved in the inflammatory response (i.e., activations of T-cells, B-cells, and natural killer cells or in cytotoxic reaction). Later in this chapter, we discuss other evidence and theories linking immune system dysfunction with psychosis.

In sum, there is no doubt that the study of epigenetics holds tremendous promise for elucidating the determinants of normal and abnormal brain development, as well as the origins of human disease. Yet, methodological challenges must be considered; Epigenetic changes can be a consequence, rather than a cause, of the phenotype of interest. It has been shown, for example, that antipsychotic medications are associated with epigenetic changes (Melas et al., 2012), and all studies to date of epigenetic phenomena in psychosis have primarily included medicated patients. Other environmental exposures linked with epigenetic changes include drug use, stress, and nutritional deficiency, all of which have been shown to be associated with serious mental illness (Holtzman et al., 2013; Kirkbride et al., 2012; Rotter et al., 2012). To disentangle these factors, there is a need for prospective, longitudinal investigations that track epigenetic profiles in individuals at risk for psychosis who have not been exposed to medication and whose environmental exposures across development are documented. As will be described, studies of youth who manifest clinical high-risk syndromes are currently under way and may be the optimal paradigm for tracking epigenetics.

As noted already, the heritability estimates for psychosis based on twin, adoption, and family studies were substantial, yet puzzling in their discrepancies. Moreover, subsequent studies of candidate risk genes, as well as genome wide scans, were not successful in identifying genes that accounted for more than a very small proportion of the phenotypic variance. The findings on mutations and epigenetics, described previously, have shed light on the sources of these discrepancies. In an important paper, Evan Charney (2012) systematically reviewed the potential impact of mutations and epigenetic processes on phenotypic variance in MZ and DZ twins. In particular, he shows how the assumption of equal environments, the basis for the twin study method, does not take these processes into consideration. First, germ-line mutations and germ-line epigenetic profiles resulting from environmental factors are more likely to be shared by MZ than DZ twins. Second, the intrauterine environment is more similar for MZ twins than DZ twins because MZ pairs can share a placenta and chorion (about 2/3 of MZs), as well as an amniotic sac, whereas DZ twins do not. Thus, when shared, placental abnormalities can affect both members of MZ twin pairs. All of these environmental factors contribute to inflated heritability estimates in twin studies. In contrast, in the minority of MZ twin pairs in which the two members have separate placentas, there is greater gene expression discordance at birth (Gordon et al., 2011). Genes previously defined as being involved in response to the external environment showed the most variable expression within pairs, independent of cell type, supporting the idea that even slight differences in intrauterine environment can influence expression profiles.

Further, Charney (2012) reviewed the extensive evidence that the fetal and infant morbidity and mortality rates are highest for MZ twins, intermediate for DZ twins, and lowest for singleton births. The elevated morbidity and mortality rates in twins, especially MZ pairs, are attributed to higher levels of obstetric complications and maternal stress. Phenotypic concordance for developmental disorders and brain morphology shows the same pattern; MZ > DZ > sibling pairs. Thus, twins in general are exposed to a less optimal environment than singletons, and MZ twins have the highest rate of complications, especially when they are monochorionic. The result is greater stress-induced phenotypic concordance in MZ than DZ twins, and in DZ twins compared with singletons. In the next section, we review the evidence that the prenatal environment, including maternal stress exposure, is associated with risk for psychosis.

In summary, the results of research on the genetics of schizophrenia and other psychotic disorders have not revealed any heritable risk alleles of large effect, and those that have been identified confer vulnerability for other disorders, as well as generalized stress sensitivity (Walder et al., 2010). Advances in our understanding of mutations and epigenetics have helped to shed light on other sources of genetic risk, as well as environmental factors that might determine them.

The Prenatal Environment

Against the backdrop of our contemporary understanding of genetics, it is not surprising that there is extensive evidence of greater obstetric complications and adverse prenatal events in individuals who subsequently develop psychosis. The human genome is especially susceptible to mutations during embryonic and fetal development, and epigenetic processes are pivotal in determining the development of the nervous system.

Research has documented a relation between multiple obstetric complications and prenatal events and the subsequent risk of schizophrenia and affective psychosis in offspring (Buka & Fan, 1999; Cannon et al., 2002). Among the prenatal complications that are associated with elevated risk are bleeding, diabetes, rhesus incompatibility, preeclampsia, and maternal viral infection (Brown & Derkits, 2010). Similarly, studies of nutritional deficiency during pregnancy, such as exposure to the Dutch famine, have revealed a higher rate of psychosis in the offspring

(Kirkbride et al., 2012). Delivery complications, especially prolonged labor, are also more common (Buka & Fan, 1999). Finally, the maternal experience of stressful events during pregnancy, such as traumatic personal or natural disasters, heightens the risk for psychosis in offspring (Markham & Koenig, 2011; Van Os et al., 2010).

All of the previous prenatal factors are assumed to heighten risk via their effects on fetal brain development. Although the precise mechanisms are not known, hypoxia is assumed to mediate some of the effects of prenatal and delivery complications (Fineberg et al., 2012), and inflammatory processes have been hypothesized to be involved in the effects of prenatal maternal infection (Miller et al., 2013). Nutritional deficiency is known to compromise fetal brain development, and recent results from animal studies suggest how epigenetic processes might mediate this effect (Kirkbride et al., 2012). With regard to maternal stress, it is assumed that increased maternal cortisol secretion plays a role, partially through inflammatory pathways and also via epigenetic processes that affect the development of brain structure and stress systems in the fetus (Markham & Koenig, 2011; Van Os et al., 2010). In a section to follow, we consider in greater detail the role of brain stress systems in psychosis.

One of the questions raised with regard to the effects of obstetric complications and prenatal events on risk for psychosis is whether they are sufficient to confer vulnerability. Specifically, do they interact with a preexisting genetic liability, or can they give rise to vulnerability independent of genetic risk? There is some evidence of a gene–environment interaction, such that individuals with a family history of schizophrenia may be more susceptible to the adverse effects of prenatal insults (Clarke et al., 2009). Yet there are also findings suggesting the prenatal complications are more common in patients without a family history of psychiatric illness (Cantor-Graae et al., 1994). In fact, in light of our current understanding of epigenetics, the question of whether prenatal complications can confer vulnerability independent of genetic factors should be reconceptualized. It is indeed possible that prezygotic and prenatal factors can cause mutations and epigenetic changes that constitute genetic risk for psychosis. While there are currently no research findings that directly address this issue, it is likely that there will be in the near future.

In summary, initial assumptions about the origins of vulnerability to psychotic disorders were highly simplistic, by contemporary standards, and were limited by the narrow scope of our understanding of genetics and neurodevelopment. The initial focus on single causal genes or small subsets of risk genes has given way to evidence that the processes that give rise to vulnerability are far more complex than assumed and probably entail intricate interactions between environmental and biological factors. In light of the evidence, it appears likely that there are multiple pathways to vulnerability. Thus the etiological processes that confer risk will vary among psychotic patients. Further, environmental risk factors show regional variation, so it is not surprising that there are some national and ethnic differences in risk for schizophrenia.

EPIDEMIOLOGY AND POSTNATAL ENVIRONMENTAL EXPOSURES

Epidemiology

Although there are some national variations, the prevalence and modal age at onset of psychosis, especially schizophrenia, is strikingly consistent across cultures, with lifetime rates of 1.4–4.6 per 1000 across cultures (Jablensky, 2000). This has prompted some theorists to view psychosis as a uniquely human disorder that involves common species-specific genetic factors and brain developmental processes (Crow, 2012).

Nonetheless, there are regional and demographic differences in the risk. For example, across countries, urban and migrant populations have somewhat higher rates of psychosis and other serious mental disorders (McGrath et al., 2004; van Os, Kenis, & Rutten, 2010). Further, within nations, immigrant status, particularly for ethnic minorities, is linked with a significantly higher risk-rate for psychosis (Dealberto, 2010). While the reasons for this are not clear, there is some evidence that perceived discrimination may be a mediating factor (Morgan et al., 2010). Trauma and stress are significantly associated with psychosis risk, and perceived discrimination may be one source of psychosocial stress.

Drug exposures may also contribute to population differences in psychosis risk. Reviews of the research literature on cannabis and psychosis conclude that cannabis use is associated with an increased risk for psychosis (Moore et al., 2007). It also appears to be linked with an earlier age at onset of psychosis (Compton et al., 2009; Large et al., 2011). The tetrahydrocannabinol (THC) content in cannabis, its major psychoactive agent, has similarly been linked with psychosis risk and psychotomimetic effects (van Os, Kenis & Rutten, 2010). Cross-national comparisons have shown that variations in age at onset and risk for psychosis are associated with differences in cannabis use, and higher THC levels are associated with greater risk (Hall & Degenhardt, 2009).

Of course, the correlational nature of these data precludes strong causal inferences. Individuals at risk for psychosis may be drawn to the use of recreational drugs for self-medication or because they are more often in social contexts where drugs are accessible. Alternatively, drug use may actually be increasing the likelihood of psychosis. Two recent reviews of the longitudinal cohort studies (LeBec et al., 2009; McLaren et al., 2010) and one new cohort study with repeated assessments (Kuepper et al., 2011) all concluded that cannabis use can increase risk for psychosis onset and persistence. At the level of neurobiology, findings from experimental research with animals and a few studies of humans suggest that cannabis-induced changes in brain DA activity may be involved in the link with psychosis, but this is considered tentative (Kuepper et al., 2010).

Like cannabis, stimulant use is related with risk for psychosis. This was originally noted in research conducted following widespread increases in methamphetamine use in Japan (Sato, Numachi, & Hamamura, 1992). A recent population-based study showed that all drug use was associated with a higher risk rate for schizophrenia, but that methamphetamine use and cannabis use were linked with higher rates than cocaine, opioid, and alcohol use (Callaghan et al., 2012). The well-established relation of methamphetamine use with psychosis has raised concerns about the increasing rates of prescription stimulant use among youth, particularly given that those who are at risk for psychosis are more likely to be diagnosed with ADHD. Although there is not yet sufficient research to estimate the effect of prescription stimulants on psychosis rates, there are case reports that suggest the presence of prescription stimulant-induced psychosis (Lakhan & Kirchgessner, 2012). This is likely to be a focus of increasing research as large cohorts of youth on prescription stimulants enter the risk period for the onset of psychosis. As is the case for cannabis, the down-stream effects of stimulants, particularly on dopamine (DA) activity, suggest a likely mediating process.

Sex differences in psychosis, particularly schizophrenia, are well-established. Males tend to have an earlier age at onset of psychosis, and the prognosis for males is poorer than for females (Abel, Drake & Goldstein, 2010). In part, this is likely due to the higher rate of substance use, the lower rate of treatment compliance, and the lower levels of social support that characterize male versus female patients (Masand et al., 2009). In addition, it has been suggested that estrogen may have a protective effect for females in that it acts to reduce DA activity (Abel, Drake, & Goldstein, 2010).

Another domain of factors that has been shown to increase vulnerability for psychosis is exposure to brain damage. Both traumatic brain injury (TBI; Molloy, Conroy, Cotter, & Cannon, 2011) and childhood viral infections of the central nervous system elevate the risk of psychosis (Khandaker, Zimbron, Dalman, Lewis, & Jones, 2012). The meta-analysis by Molloy and colleagues (2011) showed an increased risk of schizophrenia following TBI, as well as a more pronounced effect in those with a genetic predisposition to psychosis. The latter suggests a gene–environment interaction.

It has long been established that, in general, patients diagnosed with psychotic disorders have significantly lower rates of marriage and reproduction than the general population, and this is especially pronounced for males (Bundy, Stahl & MacCabe, 2011; Power et al., 2013). The earlier onset and poorer prognosis for psychosis in males may explain the sex difference in both marriage and reproduction. Whatever the origin of this sex difference, it is clear from the data that neither male nor female patients with psychosis and other serious mental disorders reproduce at replacement levels (Power et al., 2013), yet epidemiological studies show stable incidence rates for psychotic disorders across cohorts (Kirkbride et al., 2012) . These findings are inconsistent with the assumption that risk for psychosis is highly heritable and has raised questions about how risk genes for schizophrenia are maintained across generations. The data on reduced fertility are, however, consistent with contemporary findings on the mutations and epigenetic processes that confer vulnerability for psychosis.

The Postnatal Psychosocial Environment: Trauma and Stress

The diathesis–stress model has been a long-standing frame of reference for conceptualizing the etiology of schizophrenia (Walker & Diforio, 1997). It assumes that vulnerability, the diathesis, originates in genetic and prenatal factors, such as those previously discussed. Then, as development ensues, the clinical expression of the diathesis is triggered by environmental factors. We have already seen that maternal stress exposure during pregnancy is related to greater risk for psychosis in offspring. In addition, postnatal trauma and psychosocial stress appear to be important triggering factors.

There is now a large body of retrospective reports demonstrating that childhood exposure to traumatic events is associated with increased risk for psychosis (Holtzman et al., 2012, 2013; Varese et al., 2012). Among the childhood traumas that have shown the most consistent link are physical and sexual abuse. These are elevated in the histories of both diagnosed patients, and individuals who meet

clinical-high-risk criteria for psychosis (Holtzman et al., 2012). One question raised by these findings is whether they reflect causal effects of trauma versus evocative effects of the behavioral syndrome associated with vulnerability; in other words, the likelihood of being in situations that are linked with abuse may be greater for children at-risk for psychosis. Evidence supporting a causal effect comes from a study of patients, their healthy siblings, and unrelated controls (Heins et al., 2011). Discordance in psychotic illness across related individuals was predicted by differential exposure to trauma. The association between trauma and psychosis was apparent in a dose-response fashion across varying levels of illness and vulnerability to psychosis. Along these same lines, using the MZ-twin differences approach, data on childhood adversity and subclinical psychotic experiences were obtained from both twin-pairs members (Alemany et al., 2012). The investigators found that within-pair twin differences in exposure to childhood adversity were associated with corresponding differences in subclinical positive symptoms, suggesting that the relation between childhood adversity and symptoms is not solely attributable to heritable genetic differences in behaviors that evoke more adverse experiences.

Cross sectional studies of general life-event stress and daily stress exposure have not yielded consistent evidence that patients with psychosis or clinical-high-risk individuals are exposed to more stress (Holtzman et al., 2012). But the evidence is more consistent in demonstrating that both psychotic patients and clinical-high-risk individuals do report greater subjective stress in response to events. Further, longitudinal research suggests that the rate of stressful events is higher prior to the onset of psychotic episodes (Collip et al., 2011).

In considering the effects of trauma and stress on subsequent risk for psychosis, it is also relevant to note the evidence for stress sensitization, a phenomena in which exposure to stress enhances latter sensitivity to stress. Using the experience sampling method, one study of psychotic patients revealed that a childhood history of trauma was associated with increased stress reactivity later in life (Lardinois et al., 2011). Research on rodents has elucidated the neurobiological mediators for stress-sensitization. Repeated early stress exposure is associated with later increases in stress hormone and DA secretion in response to stressful events (Hall et al., 1999; Tidey & Miczek, 1996). Similar effects have been observed in humans with previous exposures to stressful events (Laruelle, 2000: Pruessner et al., 2004). The potential neurobiological substrate for stress effects and stress sensitization in psychosis will now be discussed in greater detail.

DEVELOPMENTAL STAGES IN THE EMERGENCE OF PSYCHOSIS

Premorbid Childhood Development

As mentioned previously, it is well documented that, on average, children who later develop a psychotic disorder manifest deficits in cognitive, motor, and social functions. Reviews of the retrospective and prospective research literatures on academic performance indicate that those who later develop schizophrenia performed below their sibling and peers beginning early in elementary school (Watt, Grubb, & Erlenmeyer-Kimling, 1982). Similarly, when compared with peers and siblings with healthy adult outcomes, those who later manifest psychosis show poorer performance on standardized intelligence tests (Aylward et al., 1984; Watt, Grubb, & Erlenmeyer-Kimling, 1982). Thus the cognitive impairment that is so often associated with serious mental illness can be observed long before psychosis onset.

In the domain of social function, there are also significant differences between children who develop psychosis in early adulthood and those who do not. Evidence to support this comes from prospective cohort studies as well as retrospective studies of diagnosed adult patients (Walker et al., 1993; Watt, Grubb, & Erlenmeyer-Kimling, 1982). Among the abnormalities observed by teachers and parents are increased social withdrawal and behavioral noncompliance, and studies of childhood home movies have revealed a lower rate of positive facial expressions of emotion.

Perhaps more than any other indicator, childhood deficits in motor function suggest a neurological basis for premorbid impairment. There is evidence of both abnormalities in movement and delays in motor development during infancy and childhood in individuals who subsequently develop psychotic disorders (Dickson, Laurens, Cullen, & Hodgins, 2012). Several studies have shown that within the first two years of life, individuals who later develop schizophrenia manifest delays and abnormalities in motor development (Fish, Marcus, Hans, & Auerbach, 1993; Walker, Savoie, & Davis, 1994). They are slower to acquire coordinated patterns of crawling, walking, and bimanual manipulation. They also show asymmetries and abnormalities in their movements, such as abnormal postures and involuntary movements of the hands and arms. It is important to note, however, that these early motor signs are not specific to schizophrenia or psychosis in general. Delays and anomalies in motor development are present in children who later manifest a variety of disorders, as well as some who show no subsequent disorder; thus, motor signs are not diagnostic. But the presence of motor deficits in

infants who subsequently manifest schizophrenia suggests that the congenital vulnerability to the disorder can involve brain systems that play a role in movement. In particular, subcortical regions of the brain, especially the striatum, play an important role in motor functions across the life span. The hyperkinetic nature of the motor abnormalities that have been observed in children prior to psychosis onset have been linked with increased dopamine (DA) activity in this region (Walker, 1994). Recent studies have shown that clinical-high-risk individuals and patients with psychosis have heightened DA activity in the striatum (Mizrahi et al., 2012; Wong et al., 1986).

Taken together, the results from research on childhood premorbid development indicate that vulnerability can be subtly expressed long before the onset of clinical psychosis. On the other hand, when considering the research findings it is important to keep in mind that there is variability in premorbid adjustment and it is possible that the variability maps onto differences in etiology (Walker et al., 1996).

The Prodromal Phase and Clinical High Risk

As mentioned already, prior to the onset of the clinical syndrome of schizophrenia and other psychotic disorders, there is typically a period of functional decline and gradual emergence of symptoms (Addington & Heinssen, 2012; Cannon et al., 2008; Holtzman et al., 2013). This *prodromal* period usually appears during adolescence and is the transitional stage from the premorbid state to the point at which the patient meets criteria for clinical psychosis. With respect to functional impairment, there is often a decline in academic and work performance, decreased interest in social and recreational activities, and problems with memory and concentration.

A range of symptoms is associated with the prodromal period, and the symptom pattern and sequence of emergence of symptom subtypes varies among patients (Neumann et al., 1995; Yung & McGorry, 1996). Among the symptoms that begin to manifest themselves earliest in the prodrome are mood changes, and many patients with psychotic disorders are diagnosed with depression before they have psychotic symptoms (Fusar-Poli et al. 2012). Positive symptoms, which are the defining feature of prodromal syndromes using prospective criteria, initially present in an attenuated form (Cannon et al., 2008). For example the individual might report unusual perceptual experiences, such as hearing voices when no one else is around or seeing some an unidentifiable object out of the corner of his eye. In the prodrome, such experiences are attributed by the individual to imagination or error, thus lacking the conviction that is typically shown in patients who meet *DSM* criteria for hallucinations. In fact, these psychotic-like symptoms increase in frequency through the course of normal adolescence and diminish for most by early adulthood (Kelleher & Cannon, 2011). But for those who eventually develop a psychotic disorder, the unusual sensory experiences and ideas become more compelling, and eventually the individual is convinced they are real. When this threshold of conviction is crossed and the symptoms persist, the individual is likely to meet the diagnostic criteria for a psychotic disorder. If there are accompanying symptoms of mood disorder, such as depression or mania, the individual may meet criteria for a diagnosis of schizoaffective disorder or major depression with psychotic features

As mentioned, the prodromal phase has been the subject of increasing research interest because it may be the optimal period for identifying neuropathological processes and, ultimately, for preventive intervention. While the initial research on the prodrome relied on retrospective data obtained from diagnosed patients, investigators are now studying the prodrome prospectively by utilizing assessments aimed at measuring the presence and severity of 'prodromal' signs. Several structured approaches for prospective assessment of prodromal syndromes have been developed and are currently being used in longitudinal studies (Addington & Heinssen, 2012; Correll et al., 2010). These measures focus on *subclinical* manifestations of the perceptual, ideational, and behavioral symptoms of psychosis. In the research literature, individuals who manifest symptoms that meet predetermined severity and duration criteria are designated as clinical-high-risk, ultra-high risk, or prodromal. Because the term prodromal may be taken to imply the inevitability of a subsequent illness, most in the field use the term clinical-high-risk (CHR) to refer to individuals who are manifesting putative prodromal syndromes.

In the United States, the Structured Interview for Prodromal Syndromes (SIPS; Miller et al., 2003) has been the most widely used measure. Like other prodrome assessment tools, it rates the presence and severity of subclinical positive (e g, suspiciousness, unusual ideas and perceptual experiences) and negative (e.g., social withdrawal, decreased emotional expression and role functioning) symptoms, as well as mood and vegetative symptoms. Based on SIPS ratings, individuals who meet CHR criteria can manifest several different syndromes, most often an attenuated positive symptom syndrome or schizotypal personality disorder. Using such measures to identify

CHR samples enhances positive predictive power above the population prevalence rate, as well as the risk rate for first-degree relatives of psychosis patients of about 12% (Sorensen et al., 2009). It has been estimated that 20–40% of CHR individuals will transition or convert (i.e., meet criteria for a psychotic illness) within a roughly 2-year period (McFarlane, 2011), a rate much higher than that of the general population (Eaton, 1999). While the CHR state is sometimes thought of as the 'psychosis prodrome,' conversions to affective illnesses are common, reflecting overlapping developmental trajectories across psychotic illnesses (O'Donovan, Craddock, & Owen, 2009).

The CHR period may be a unique window of opportunity for preventive interventions (Correll, Hauser, Auther, & Cornblatt, 2010). But the opportunities for intervention will be enhanced when current prediction algorithms are refined so that predictive power (sensitivity and specificity) is increased and false positives levels are reduced. Currently ongoing prospective CHR studies are aimed at boosting predictive power (Addington & Heinssen, 2012; Cannon et al., 2008). In addition, these studies are concerned with elucidating neural mechanisms involved in the emergence of psychosis. The North American Prodrome Longitudinal Study (NAPLS) project is the largest investigation of this kind in the United States, and is comprehensively tracking biobehavioral development in CHR individuals (Cannon et al., 2008).

It should be emphasized that, in addition to their elevated risk for psychotic illness, CHR individuals experience significant cognitive dysfunction, distress, and difficulties with social and occupational functioning, and they are often treatment-seeking (Addington & Heinssen, 2012). Cognitive deficits are found in several areas, including attention, planning, and processing speed (Seidman, 2006), and these deficits are most pronounced in those who later transition to psychosis. Similarly, CHR youth score below healthy controls on measures of social-cognitive skills (Fusar-Poli et al., 2012; Thompson, Bartholomeusz, & Yung, 2011). As in the premorbid childhood period, motor abnormalities have also been detected in adolescents who manifest CHR syndromes, including schizotypal personality disorder. Specifically, compared with healthy adolescents, CHR youth show more involuntary movements and coordination problems (Nagy & Szatmari, 1986; Walker et al., 1999). In the area of social functioning, CHR youth often report growing isolation from friends and family, increased conflict with others, the inability to forge new friendships, and a lack of interest in social contact (Cornblatt et al., 2007). Finally, CHR individuals report increasing distress stemming from their inability to think clearly, declining functioning, and attenuated positive symptoms.

To date, longitudinal studies of CHR youth have also yielded a number of behavioral predictors of conversion to psychosis. Among these are greater cognitive impairment, functional deficits, and motor abnormalities (Addington & Heinssen, 2011; Mittal & Walker, 2007; Mittal et al., 2008). More recently, investigators have begun to identify biological markers of risk for transition in CHR populations. These are discussed as we explore the neurochemical and brain abnormalities associated with psychosis.

NEUROBIOLOGICAL MECHANISMS

Inflammatory Processes and Oxidative Stress

As mentioned, there is evidence that risk of subsequent schizophrenia is heightened by fetal exposure to maternal infection. These and other findings have stimulated interest in the potential role of inflammatory processes in psychosis. Recent evidence suggests that neuroinflammation may be involved in both conferring vulnerability and triggering illness expression (Miller et al., 2011). By way of background, the key elements of inflammatory processes will be summarized.

Inflammation, a complex cascade of biological responses, is controlled by immune cells and cytokines. Immune cells (B-cells, T-cells, and phagocytes) act to fight infection. B-cells act via the secretion of antibodies that attack antigens, whereas T-cells act more directly to attack infected cells and also regulate immune responses. Cytokines are immunomodulating substances that are secreted by cells of the immune system. They are proteins, peptides, or glycoproteins that act as signaling molecules in communication among cells. They are secreted in response to immunological challenges, such as exposure to infection. Some cytokines are proinflammatory (interleukin-1 and tumor necrosis factor—alpha [TNF-α]) and serve to initiate an inflammatory response and activate phagocytotic cells to combat infection. However, excessive inflammation can exacerbate or trigger diseases. Thus, other cytokines are anti-inflammatory (e.g., transforming growth factor beta [TGF-β], Interleukin-4, Interleukin-10, Interleukin-11, and) and serve to reduce inflammation and promote healing, and can be neurotrophic. Numerous cytokines are found in the brain, where they play important signaling roles, in addition to their immunological functions. Cytokines have many targets, including immune cells, neurons, and astrocytes. Their actions on neurons are

not completely understood, but they are known to have both neuroprotective and neurotoxic properties.

A substantive body of research supports a role for inflammatory processes and oxidative stress in psychosis. Inflammatory markers are elevated in blood, brain, and CSF in first episode and chronic patients with psychosis (Bechter et al., 2010; Maxeiner et al., 2009; Miller et al., 2011; Potvin et al., 2008). However, several physical and behavioral characteristics that are more common in patients, such as obesity and smoking, affect levels of these cytokines and complicate inferences regarding the role they play in psychosis (Miller, Buckley, Seabolt, Mellor, & Kirkpatrick, 2011). As such, cytokines that are elevated in individuals in their first episode of psychosis and which track with symptom levels are of greatest interest, as they are less likely to be a byproduct of chronic psychosis and related factors: these include IL-6 and transforming growth factor-beta (TGF- β), which is typically anti-inflammatory (Miller et al., 2011)**.** As might be expected, antipsychotics have been shown to normalize cytokine functioning (Zhang et al., 2004), symptoms have been shown track with changes in cytokine levels**,** and some studies have found that cytokines can be used to predict responsivity to antipsychotic treatment (Xiang Yang Zhang, Zhou, Cao, Wu, & Shen, 2005).

A diffusion tensor imaging (DTI) measure of extracellular volume (free water), an indirect index of neuroinflammation, showed that first-episode schizophrenia patients have elevated free water volume, indicating the involvement of regionalized neuroinflammation in early psychosis (Pasternak et al., 2012). In vivo human PET imaging studies find elevations of activated microglia, another hallmark of neuroinflammation, in persons with schizophrenia (Doorduin, de Vries, Willemsen, de Groot, Dierckx & Klein, 2009; van Berckel, et al., 2008). Microglia are now understood to be involved in normal regulation of synaptic plasticity and directly participate in pruning at glutamatergic synapses by phagocytizing less active synapses (Schafer, Lehrman & Stevens, 2012).

Related to this, research also suggests a role for oxidative stress in psychosis. The term *oxidative stress* refers to an imbalance between a biological system's chemically reactive molecules containing oxygen (i.e., reactive oxygen species) and its ability to 'detoxify' the reactive intermediates or to repair the resulting damage. When oxidants and antioxidants are imbalanced in favor of the oxidants, disturbances in the normal redox state of cells can result in toxic effects that damage the cells, including their DNA and signaling capacity. Oxidative stress is elevated during inflammation as part of the host response and can remain elevated under chronic stress (Schiavone, Jaquet, Trabace, & Krause, 2013). Failure of the body's antioxidant defense system to control oxidative stress results in damage to cells that can, in turn, increase the inflammatory response. As with inflammation, markers of oxidative stress are higher in schizophrenia patients (Yao & Keshavan, 2011).

Further evidence that inflammation and oxidative stress are clinically relevant to psychosis is found in several small placebo controlled clinical trials reporting that anti-inflammatory drugs (Laan et al., 2010; Levkovitz et al., 2010; Muller et al., 2002, 2004; Rapaport et al., 2005) and the antioxidant precursor *n-acetyl-cysteine* (Carmeli, Knyazeva, Cuenod, & Do, 2012) used adjunctively with antipsychotic medications ameliorate residual symptoms. Results from a population-based case-control indicated a 60% reduction in psychosis risk in male chronic NSAID (Nonsteroidal anti-inflammatory drugs) users (Laan et al., 2007).

It is well documented that stress and inflammatory processes are inter-related, and that stress exposure can increase susceptibility to infection (Frank, Thompson, Watkins, & Maier, 2012). In the following section we examine biological aspects of stress and evidence that suggests how it might be implicated in psychosis via several pathways, including inflammation.

Stress Biology

As described previously, there is an extensive body of literature documenting the association between stress exposure and risk for psychosis. Investigators are now exploring the neurobiological processes that mediate this association. Among the brain systems that mediate the mammalian response to stress is the hypothalamic-pituitary-adrenal (HPA) axis.

The response of the HPA axis to stress entails a cascade of neurohormonal signaling (Armario et al., 2012; Danese & McEwen, 2012; Hill & Tasker, 2012; Jameison & Dinan, 2001; Stevens & White, 2010). Following stress exposure, cortical input to corticotrophin-releasing hormone (CRH) neurons in the periventricular nucleus (PVN) of the hypothalamus results in the release of CRH from neuronal axon terminals into pituitary circulation. CRH then stimulates secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland into the bloodstream. ACTH, in turn, stimulates adrenal gland production of glucocorticoids (principally cortisol in primates and corticosterone in rodents) via type 2 melanocortin receptors (MC2-R), thereby initiating synthesis of cortisol which is released into circulation. Glucocorticoids act on tissue

throughout the body and cross the blood–brain barrier to act on multiple brain regions via both membrane and intracellular receptors on neurons. Homeostasis in the system is achieved, in part, through negative feedback via receptors for glucocorticoids (GRs) that are located throughout the brain; direct modulatory feedback is provided by hypothalamic and pituitary GRs, while indirect modulation is provided by limbic, thalamic, and frontal cortex GRs. Another receptor that binds glucocorticoids is the mineralocorticoid receptor (MR). Like GRs, MRs are located in many brain regions and also play a role in modulation of the HPA axis.

In the absence of stress, the majority of MRs are occupied, while only about 10% of GRs are bound to glucocorticoids. However, during stress or at the peak of the diurnal cortisol rhythm (i.e., morning), MRs are saturated and higher proportions of GRs become occupied (Silverman & Sternberg, 2012; Stevens & White, 2010). Both animal and human studies suggest that the relative proportion of MR to GR activation may be an important moderating factor in multiple brain processes, with the relation of the ratio of activation to brain function constituting an inverted U such that too much or too little can impair cognitive functions (de Kloet et al., 1999; Lupien et al., 2002).

In response to persistent stress exposure, the HPA axis changes at multiple levels, and while this has primarily been documented in experimental animal research, there is evidence that similar processes occur in humans. For instance, chronic elevations in ACTH can contribute to adrenal hyperplasia in humans, which can result in greater cortisol output in response to the same level of ACTH (Harvey & Sutcliff, 2010; Oitzl et al., 2010). There are also changes at the level of the pituitary that may contribute to alterations in the set point of the HPA axis (Danese & McEwen, 2012; Krishnamurthy et al., 2012; Mondelli et al., 2008). Finally, changes in the negative feedback at multiple levels can result from glucocorticoid-induced compromises to brain structure (Damstead et al., 2011).

Chronic glucocorticoid exposure appears to have adverse effects on numerous brain regions. Sustained corticosterone elevations in rodents, including those due to chronic stress or corticosterone administration, are associated with the regression of synapses and a decrease in dendritic spines in hippocampal and prefrontal neurons (for reviews, see Bennett, 2008; Damstead et al., 2011; McEwen, 2012). Also, elevated glucocorticoids can affect calcium ion channels, structural protein levels in glial cells, and amino acid levels in the hippocampus, and suppress myelination of neuronal processes, an important aspect of adolescent brain development that is related to regional volumetric changes (Belanoff et al., 2001; Damstead et al., 2011). Moreover, in rodent and primate hippocampus, persistent stress and glucocorticoid elevations lead to reduced neuronal excitability (Joels, 2001), impaired synaptic plasticity (McEwen, 2012), and reduced neurogenesis (Schoenfeld & Gould, 2012). The association in humans of increased cortisol levels with decreased hippocampal (Tessner et al., 2007) and cortical gray matter volume (Mainz et al., 2012) is consistent with these findings.

HPA activation is, of course, only one mediator of the biological stress response. Its activation trails the more rapid response by the sympathetic–adrenal–medullary (SAM) axis within the sympathetic nervous system which involves stimulation of catecholamine release (Chrousos, 2009). Prefrontal cortex and limbic structures also contribute to the regulation of SAM function in response to stress.

The present discussion focuses primarily on the role of the HPA axis in mediating the stress response because it has received greater attention in research on psychosis. This is partially a consequence of the ease of measuring secretagogues involved in HPA function, especially cortisol, which can be assayed noninvasively and reliably in saliva (Walker et al., 2008). Further, research has revealed pervasive effects of glucocorticoids on brain structure and function, including hippocampal abnormalities that have been shown to be linked with psychosis (Mondelli et al., 2010). HPA function can, of course, be indexed in secretagogues other than cortisol, including via measurement of ACTH (Stevens & White, 2010). Compared with cortisol, however, ACTH has been relatively neglected in research on psychosis.

In addition to affecting neuronal morphology, glucocorticoids interact with and modulate neurotransmitter systems in the brain, so their effects on brain function and circuitry can be pervasive (McEwen, 2012). For example, HPA axis activation, as indexed by heightened levels of cortisol, leads to the augmentation of DA levels in the human brain (Wand et al., 2007). This is particularly relevant for psychosis because DA, more than any other neurotransmitter system, is implicated in the full spectrum of psychotic disorders (Howes & Kapur, 2009). Animal models indicate that glucocorticoid levels also affect serotonin (Belanoff et al., 2001; Heim & Binder, 2011), norepinephrine (Rastogi & Singhal, 2012), and glutamate in the cortex (Wolf, 2003; Bennett, 2008).

It is important to note the normative developmental augmentation in activation of the HPA axis in humans, as this augmentation parallels the gradual age-related increase in risk for psychotic disorders. Specifically, there is a postpubertal increase in basal and stress-induced cortisol

secretion that occurs in conjunction with advancing stages of puberty and appears to extend into the 3rd decade of life in humans (Adam, 2006; Lupien et al., 2002; Shirtcliff et al., 2011; Walker et al., 2010). This maturational increase in activity has been hypothesized to heighten stress sensitivity in adolescence (Eiland & Romeo, 2012; Walker et al., 2008). To date, we are aware of no published studies on adolescent maturational changes in other indices of HPA function in humans, thus more research is needed to elucidate changes in CRH, ACTH, and other secretagogues. Such investigations are especially important in light of the evidence that HPA activity is involved in the expression of vulnerability for psychosis.

The immune system and stress are intricately interrelated. Activation of the immune system and the HPA axis appear to be mutually mediated and synergistic and, if persistent, are linked with similar neurochemical and neuroanatomical changes (Zunszain et al., 2011) and impaired long-term potentiation (LTP), i.e., the neuronal changes that mediate learning (Kim & Haller, 2007; Yirmiya & Goshen, 2011). Although glucocorticoids have anti-inflammatory effects at low/moderate levels, exposure to persistent stress or glucocorticoid administration can increase the pro-inflammatory response to an immune challenge (Catena-Dell'Osso et al., 2011; Frank MG, Miguel ZD, Watkins LR, Maier, 2010). Glucocorticoids also sensitize the proinflammatory microglia response, thereby priming microglia to respond excessively to immune challenge (Frank, Thompson, Watkins & Maier, 2012). Conversely, activation of the immune response can augment HPA activity, via cytokines (Frank, Miguel, Watkins & Maier, 2009).

There is a burgeoning literature on the relation between the HPA axis and psychosis. In a review, Walker et al. (2008) summarized several trends in the research findings that support the assumption that activation of the HPA axis can trigger the expression of vulnerability for psychosis, and subsequent research findings have converged on the same conclusions (Holtzman et al., 2012, 2013). First, there is evidence that patients with psychosis, especially non-medicated patients, have higher baseline cortisol levels, and studies published subsequent to the review by Walker and colleagues (2008) provided additional support for this conclusion (Borges, Gayer-Anderson, & Mondelli, 2013; Garner et al., 2010; Kale et al., 2010; Venkatasubramanian et al., 2010). Although there are fewer studies of ACTH, largely due to limitations on its assay in saliva and urine, there is also evidence of elevated ACTH in psychotic patients (Brunelin et al., 2008; Ryan et al., 2004). ACTH and the DA metabolite homovanillic acid (HVA) response to metabolic stressors are also elevated in psychotic patients relative to controls (Brunelin et al., 2008). Moreover, a recent postmortem study of pituitary glands from schizophrenia patients and controls revealed that the level of ACTH was elevated (Krishnamurthy et al., 2012).

Second, antipsychotic medications, and many antidepressants, reduce cortisol and ACTH secretion, in addition to decreasing positive symptoms, and findings published subsequent to the aforementioned review support this effect as well (Venkatasubramanian et al., 2010). Similarly, drugs that are direct cortisol antagonists have been shown to decrease psychotic symptomatology in mood disorders and Cushing's disease (Schatzberg & Lindley, 2008).

Third, psychotic patients show HPA axis dysfunction in response to pharmacologic challenge, such as the DEX suppression test (DST). For example, administration of DEX, an exogenous glucocorticoid, typically leads to cortisol suppression due to the HPA axis negative feedback loop. DEX binds to GRs that, in turn, inhibit the secretion of ACTH and cortisol. Thus, cortisol nonsuppression after the DST is an index of HPA axis dysfunction. In the DEX/CRH test, a more sensitive measure of HPA function, DEX is administered, then the following day CRH is administered, and ACTH and cortisol responses are measured. More pronounced ACTH and cortisol secretion in response to CRH reflect reduced glucocorticoid feedback regulation. The previous review by Walker and colleagues (2008) and other reports (Owashi et al., 2008) have found higher post DST and DEX/CRH levels of cortisol and ACTH in patients with schizophrenia and affective psychoses than in healthy and depressed comparison groups. In many patients, this response is reversible with antipsychotic treatment (Ceskova et al., 2006).

Fourth, neuroimaging studies of psychosis patients have consistently revealed volumetric reductions in brain regions that are sensitive to heightened cortisol. It is noteworthy that comparisons of discordant MZ twins suggest that among the most pronounced reductions are those in the hippocampus (Shepherd et al., 2012). Given the role of the hippocampus in modulating HPA activation, these results are also consistent with reports of an inverse correlation between baseline cortisol and hippocampal volume in psychosis (Mondelli et al., 2012).

Fifth, the severity of most symptom dimensions, including positive, negative, and mood symptoms, tend to be positively related to cortisol levels in samples of patients with psychosis. Recent studies of first-episode psychotic patients revealed significant associations of positive and negative symptom severity with cortisol levels (Belvederi Murri et al., 2012; Garner et al., 2012). Further, the

magnitude of symptom severity reduction in response to antipsychotic medications has been linked with the magnitude of cortisol decrease (Mondelli et al., 2012).

Finally, a causal role for HPA activity in triggering or exacerbating psychotic symptoms is supported by research on hypercortisolemia. For example, hypercortisolemia induced by administration of exogenous corticosteroids in high doses can trigger psychotic symptoms (Buchman, 2001; Warrington & Bostwick, 2006). Symptoms of hypercortisolemia-induced psychosis include pressured speech, hallucinations, delusions, and disorganized thought, which are often indistinguishable from the symptoms of psychotic disorders (Ling et al., 1981; Lewis & Smith, 1983; Wada et al., 2001). Indeed, disorders characterized by hypercortisolemia, such as Cushing's syndrome, often involve psychotic symptoms that remit in conjunction with normalization of cortisol levels in response to treatments such as etomidate, an adrenal suppressant (Chan et al., 2011), mifepristone (van der Lely et al., 1991; Chu et al., 2001), and other treatments (Kelly et al., 2003). Interestingly, the risk for psychotic symptoms in Cushing's, though elevated across the life span, is lower in childhood than in young adulthood.

Although there is relatively consistent evidence for elevated baseline cortisol secretion in psychosis, especially in nonmedicated patients, the results of investigations of psychosocial stress-induced cortisol are mixed. Some studies using laboratory psychosocial stressors have found that psychotic patients show no difference or less cortisol increase after stress induction, both on (Jansen et al., 2000; Brenner et al., 2009) and off (van Venrooij et al., 2012) antipsychotic medications. The absence of an enhanced psychosocial stress-induced cortisol increase in psychosis, despite evidence for baseline elevations, may reflect several factors. First, there may be ceiling effects on cortisol increments beyond heightened baseline levels (Crowley et al., 1993). Second, after the onset of psychosis, the stress generated by the symptoms, especially distressing perceptions and ideations, may be more subjectively salient than the effect of any external psychosocial stress. Moreover, the psychosocial events that have the capacity for generating stress may be more idiosyncratic for psychotic patients than for healthy individuals. As discussed earlier, psychosis patients subjectively experience daily events as more distressing than healthy controls, even in the absence of increased stressor frequency.

HPA axis abnormalities, including elevated cortisol levels, have also been found in individuals at increased risk of psychotic illness (Aiello, Horowitz, Hepgul, Pariante, & Mondelli, 2012). In both CHR and genetic high-risk samples, higher cortisol levels are associated with increased risk for psychosis and severity of psychotic symptomatology (Mittal et al., 2013; Walker, Mittal, & Tessner, 2008). A recent report from the NAPLS project on the prodrome to psychosis revealed that CHR youth manifested higher baseline cortisol than matched controls (Walker et al., 2013). Further, among the CHR group, those who transitioned to psychosis showed the highest baseline cortisol level. It is possible that elevated cortisol may be is especially important in the early development of psychotic illness, as it is known to be involved in neurodevelopmental processes, such as synaptic pruning, whose dysregulation is associated with psychotic illness (Cannon, 2008).

Another biological system that is linked with both the inflammatory response and HPA activity is the gut microbiome, the microorganisms that reside in the digestive system. There is recent evidence that psychotic patients manifest abnormalities in the microbiome (Yolken, 2013). Recent experimental research with animals has shown links among HPA activity, cytokines, and the gut microbiome (Cryan & Dinan, 2012). For example, maternal separation in rhesus monkeys results in increased HPA activity (O'Mahony, Hyland, Dinan, & Cryan, 2011) and changes in fecal lactobacilli levels (Bailey & Coe, 1999). Similar effects have been demonstrated in murine models: chronic stress in adult mice has been shown to affect HPA activity, microbiota composition, and inflammatory cytokines (Bailey et al., 2011; O'Mahony et al., 2009). Consistent with the results from animal models, stress exposure in humans is associated with disruption of the intestinal barrier, increases in circulating levels of inflammatory cytokines and HPA activity, and a predisposition toward depression (Maes, Kubera, Leunis, & Berk, 2012). Further, in humans, probiotics have shown promise in the treatment of psychiatric symptoms (Messaoudi et al., 2011; Tillisch et al., 2012).

In summary, there is now extensive evidence at the biological level supporting the validity of the longstanding assumption that stress plays a role in psychotic disorders. Further, the HPA axis and the immune system are closely linked, and both are associated with structural brain characteristics. This raises the possibility that interventions targeting these systems may be effective in the treatment of the neuropathology underlying psychosis (Cohen et al., 2012).

Structural and Functional Brain Abnormalities

Since the inception of neuroimaging, our understanding of the brain abnormalities in psychosis has burgeoned. Structural brain imaging, predominantly magnetic resonance

imaging (MRI), has revealed significant mean reductions in the volume of several brain regions in patients with psychotic disorders when compared with healthy controls. These include gray matter reductions of the anterior cingulate, frontal (particularly medial and inferior) and temporal lobes, hippocampus, amygdala, thalamus, and insula (Shephard et al., 2012). Longitudinal studies indicate that there are also changes over the course of the illness. A meta-analysis showed the greatest volume loss over time is in total cortical gray matter, most notably the left superior temporal gyrus, left anterior gyrus, left Heschl gyrus, left planum temporal, and posterior superior temporal gyrus bilaterally (Vita et al., 2012). The volumetric declines in gray matter appear to be especially pronounced early in the disease process; relative to healthy controls, first-episode patients showed greater progressive decline in cerebral gray matter volume, including frontal, temporal and parietal lobes, and left Heschl gyrus. Although not as pronounced, there is also evidence of white matter volume reductions in both affective and nonaffective psychotic disorders (De Peri et al., 2012).

While the causes of these volumetric decreases are unknown, and they are observed prior to the provision of treatment, there is some evidence from naturalistic studies of patients treated with antipsychotics that declines during the course of illness are partially linked with duration and dosage of antipsychotic medication (Fusar-Poli et al., 2013). The latter evidence is not based on controlled clinical trials; however, Fuser-Poli and colleagues (2013) noted findings from experimental animal studies indicating that antipsychotic exposure is linked with brain volume decline. Clearly further research is needed to address the effects of antipsychotics on brain structure, yet it has become apparent from studies of CHR samples that brain volume decline precedes both the onset of psychosis and the initiation of treatment.

A meta-analysis of research findings from studies of CHR samples compared with matched controls showed significant reductions in gray matter volume in the right superior temporal gyrus, left precuneus, left medial frontal gyrus, right middle frontal gyrus, bilateral parahippocampal/hippocampal regions and bilateral anterior cingulate (Fusar-Poli et al., 2011). The CHR individuals who transitioned to a psychotic episode showed more pronounced baseline gray matter volume reductions in the right inferior frontal gyrus and in the right superior temporal gyrus. These findings have been replicated subsequent to this meta-analysis. In a longitudinal study of 102 CHR participants, 28 of whom developed psychosis (19 schizophrenia, 7 affective psychoses, and 2 other psychoses) subsequent to scanning, those in the CHR sample who developed psychosis (schizophrenia and affective psychosis) showed baseline reductions in the frontal cortex relative to those who did not (Dazzan et al., 2012). The subgroup that transitioned to schizophrenia also showed smaller volumes in the parietal and temporal cortices, and those with affective psychosis had significantly smaller subgenual cingulate volumes. Similar findings have been reported for individuals at genetic high-risk (i.e., first-degree relatives of diagnosed patients) when followed longitudinally; the genetic high-risk group had significantly greater reductions over time than the control group for whole brain volume and left and right prefrontal and temporal lobes (McIntosh et al., 2011). Among the high-risk participants, those who later showed psychotic symptoms manifested greater prefrontal reductions than those who did not. In summary, it appears that brain volumetric reductions precede the onset of psychosis and are not a consequence of the illness.

Inflammatory processes and oxidative stress may be involved in the brain abnormalities observed in patients suffering from psychotic disorder. Inflammation is associated with gray matter volume loss and dysregulated synaptic plasticity. Several studies indicate that chronic neuroinflammation (Frodl & Amico 2013; Mondelli et al., 2011) and reduced endogenous antioxidants (Fraguas et al., 2012) are associated with gray matter loss in schizophrenia and other brain disorders. Interestingly, recent studies in early psychosis patients suggest that anti-inflammatory interventions may attenuate progressive brain changes (Meyer, 2013). It is possible that regionalized excessive synaptic pruning by activated microglia, the hallmark of neuroinflammation, may contribute to gray matter reductions occurring at the onset of psychosis.

Of course, many neurological disorders are associated with reduced brain volume, so the previous findings have not led investigators to implicate a specific brain region in the etiology of psychosis. Instead, it is now generally assumed that these gross anatomical differences are nonspecific indicators of a neuropathological process, and that the critical substrate for psychotic disorders entails an abnormality in neural circuitry (Lisman et al., 2008). Using diffusion tensor imaging (DTI) and functional MRI (fMRI), investigators are beginning to examine circuitry function in psychotic disorders. (Fitzsimmons, Kubicki & Shenton, 2013).

Due to the complexity of the human brain, locating abnormalities in a segment of any one of the many circuits traversing the brain is a challenging task. Not only are there multiple segments in each circuit, but they entail different neuronal subtypes and neurotransmitters. Thus

there are multiple ways the function of any one circuit can be disrupted. A review of the research findings concerning the molecular aspects of circuitry dysfunction in psychosis is beyond the scope of this chapter, but some recent scientific developments are noteworthy. These findings have highlighted the longstanding assumption that DA is involved in psychotic symptom expression.

The notion that DA is involved in the emergence of psychotic symptoms, especially positive symptoms emerged from two established findings (Kuepper, Skinbjerg, & Abi-Dargham, 2013). First, all of the medications that have been found to be effective in the treatment of psychosis share the capacity to antagonize DA activity, primarily by blocking receptors. Second, agents that heighten DA activity in the brain also have the potential to trigger or exacerbate psychotic symptoms in some individuals. For example, amphetamine use can induce psychotic symptoms.

Adding to this evidence, research has demonstrated that brain DA activity, particularly in the striatum, is elevated in schizophrenia (Howes & Kapur, 2009). The striatum is a subcortical area comprised of the caudate, putamen, and nucleus accumbens. DA is a major neurotransmitter in the striatum and it is part of multiple cortico-striatal-thalamic circuits that subserve various cognitive and motor functions. A comprehensive overview of the research literature summarized the following replicated findings: using position emission tomography (PET) and single photon emission tomography (SPECT), investigators have shown there is 1) increased DA synthesis and release in striatal regions in medication-naive psychotic patients; 2) increased amphetamine-induced DA release, and 3) a subgroup of patients manifest increased DA receptors of the D2 subtype in the striatum (Kuepper, Skinbjerg, & Abi-Dargham, 2013).

A structural and functional distinction has been made between the ventral and dorsal striatum, although authors vary in how they make the distinction (Mathews et al., 2013; Voorn et al., 2004). The term ventral striatum is typically used to refer to the nucleus accumbens and the portions of the caudate and putamen below the internal capsule. It receives inputs from, and projects to, anterior cingulate, orbitofrontal, and anterior temporal cortices, as well as to hippocampus, insula, amygdala, and hypothalamus. Thus, it is the area of the striatum with primary connectivity with limbic structures (e.g., the amygdala, hippocampus, and thalamus) and is sometimes referred to as the mesolimbic system. The ventral striatum receives projections via DA fibers from the ventral tegmental area (VTA), known as the mesolimbic DA system. In contrast, the dorsal striatum is the larger area of the caudate and putamen above the internal capsule, and often referred to as the nigrostriatal pathway. Dorsal striatum projections arise from and lead to the frontal eye fields, premotor, supplementary, and primary motor cortices, and dorsolateral prefrontal, somatosensory, and parietal association cortices, regions involved in executive functions. DA input to the dorsal striatum arises primarily from the substantia nigra.

Although past theories had more often implicated the ventral striatum, or mesolimbic system, in psychosis, more recent evidence also implicates the dorsal striatum (Kuepper, Skinbjerg, & Abi-Dargham, 2013). The dorsal striatum plays a major role in motor functions, and it is well established that DA abnormalities in this region are linked with movement abnormalities (Walker et al., 1994). This area is also sometimes referred to as the associative striatum because 1) it appears to play a significant role in stimulus-response habit formation via input from sensorimotor cortex and 2) the dorsomedial area of the striatum, via cortical connections, is involved in the cognitive control of behavior (Liljeholm & O'Doherty, 2012). As discussed earlier, executive functions are among the most impaired in patients with psychotic disorders.

Consistent with the notion of increased DA activity in dorsal striatal circuitry, a recent MRI study examined brain responses to a cognitive task in psychotic patients and controls, and showed greater task-evoked hyperactivity of the substantia nigra of patients (Yoon et al., 2013). This occurred in association with changes in prefrontal and striatal activity in the psychotic group. The general pattern of results indicated that functional connectivity of the prefrontal cortex with these dysfunctional striatal regions was decreased in the patients.

As investigators have intensified their focus on DA function in CHR individuals, the findings converge with those from studies of diagnosed patients and implicate DA function in the dorsal striatum. Two studies found elevated dopamine synthesis in the dorsal striatum of CHR youth compared with healthy controls, and this was most pronounced in CHR youth who transitioned to psychosis (Egerton et al., 2013; Howes et al., 2011). Another PET study showed that higher synaptic DA concentration, measured globally in the striatum, was associated with more severe positive symptoms in CHR patients, and a greater reduction of these symptoms following DA depletion (Bloemen et al., 2013). Finally, providing a link between environmental factors and DA activity, both CHR individuals and schizophrenia patients were found to show greater stress-induced DA release in dorsal regions of the striatum, including the associative striatum (i.e., the predorsal putamen, predorsal and postdorsal

caudate) and the sensorimotor striatum (i.e., postdorsal putamen) when compared with healthy participants (Mizrahi et al., 2012). There was no group difference in DA in the ventral striatum. The emerging evidence of more pronounced DA activity in the dorsal striatum of CHR and psychotic patients is consistent with the findings of motor abnormalities in CHR youth.

In addition to DA, glutamate is another neurotransmitter that has been hypothesized to be linked with psychosis (Javitt, Zukin, Heresco-Levy, & Umbricht, 2012). This is based on evidence that agents that block *N*-methyl-D-aspartate-type (NMDA) glutamate receptors, such as ketamine, increase extracellular glutamate and also induce psychotic symptoms. Conversely, compounds that enhance NMDA receptor function (i.e., agonists) can reduce symptoms and improve cognition in schizophrenia patients. Using proton magnetic resonance spectroscopy ((1)H-MRS), it has been shown that both CHR and first-episode psychosis groups manifest higher levels of glutamate than controls in the dorsal-caudate (de la Fuente-Sandoval et al., 2011). The authors note that this is a DA-rich region implicated in the pathophysiology of psychosis, and that the findings are consistent with evidence that heightened glutamate is associated with an increase in DA release in the striatum. In another PET study of CHR subjects, there was a significant negative relationship between hippocampal glutamate levels and striatal DA synthesis, but this was not observed in controls (Stone et al., 2010). The authors speculate on the potential cascade of interactions among neurotransmitters that can lead to dysfunction of brain circuitry.

Like DA, glutamate activity is also influenced by glucocorticoids. Prolonged stress exposure or administration of glucocorticoids suppresses glutamatergic transmission by reduction of surface glutamate and synaptic NMDA receptors (Timmermans, 2013). This results in a decrease in synaptic plasticity and LTP, thus contributing to cognitive deficits. These and related findings have led to the speculation that prenatal exposure to infection and stress may set the stage for vulnerability to psychosis via sustained activation of immuno-inflammatory pathways and concomitant increases in microglia activation (Anderson & Maes, 2013). During postnatal development stress exposure would constitute a second challenge to inflammatory and oxidative stress pathways, triggering autoimmune and pro-inflammatory responses that lead to a cascade of neurotransmitter abnormalities, especially NMDA receptor hypofunction. At the structural level, the consequences can be neurotoxicity and reduced neurogenesis, myelination and neuroplasticity.

Because there are multiple potential pathways for disrupting any brain circuit, it is not surprising that a variety of brain and neurotransmitter abnormalities have been linked with psychotic disorders. Thus, the efficacy of treatments may vary among patients, and future research may yield findings that enhance our ability to target treatments based on symptom or biological indicators. In the meantime, the available treatments are usually administered without consideration of symptom or biological factors.

TREATMENT AND PREVENTIVE INTERVENTION

Over the past three decades, there have been some modest advances in the treatment of psychotic disorders. Although there are not yet treatments that produce complete remission, the quality of life for patients can be dramatically enhanced by a combination of medication and psychotherapeutic approaches. It is worth noting, however, that many people who suffer from psychotic disorders do not have access to treatment, so many patients do not benefit from the following advances.

For individuals experiencing a first episode of psychosis, stabilization with antipsychotic medication is the initial goal, then maintenance and rehabilitation (Miyamoto, Miyake, Jarskog, Fleischhacker, & Lieberman, 2012). Stabilization of symptoms is considered necessary to set the stage for the psychological interventions and rehabilitation aimed at reducing symptom severity and enhancing functioning. During the maintenance phase, the goal is to reduce residual symptoms and prevent relapse, while rehabilitation programs are directed at enhancing independent living skills.

Antipsychotic Medication

When antipsychotic medication was first introduced in the 1950s, it had a highly beneficial impact on the lives of patients with schizophrenia and other psychotic disorders because, for most, it reduced the severity of positive symptoms. As a result, many were able to leave inpatient care, sometimes after years of hospitalization. Chlorpromazine (Thorazine) was the first in a series of medications that are now referred to as the typical antipsychotics or neuroleptics (Miyamoto, Miyake, Jarskog, Fleischhacker, & Lieberman, 2012). Consistent with the DA hypothesis of psychosis, these medication acted by decreasing, or antagonizing, DA activity especially at the D2 type of DA receptor. But these 'first generation' antipsychotics had significant side effects, especially movement disorders, with tardive dyskinesia being the most severe.

In the late 1980s, a new generation of atypical antipsychotic medications with fewer motor side effects was introduced. These drugs also reduce DA neurotransmission, but in addition have an effect on other neurotransmitters, including serotonin and glutamate. Among the atypical antipsychotics are Risperdal (Risperidone), Zyprexa (Olanzapine), Seroquel (Quetiapine), Geodon (Ziprasidone), Abilify (Aripiprazole), and Clozaril (Clozapine). While still not producing complete symptoms remission, there is some evidence that atypical antipsychotics are more effective than first generation antipsychotics at preventing relapse in first-episode patients (Alvarez-Jimenez et al., 2011a). Clozaril has been found to be one of the most effective of the atypical antipsychotics, especially in treatment-resistant schizophrenia; however, it is not the first line of treatment due to significant side effects (e.g., agranulocytosis and seizures). The atypical antipsychotics are now usually the first approach in the treatment of psychosis, but a recent collaborative national study comparing typical and atypical antipsychotics did not reveal significant differences with regard to their ability to enhance patients' social functioning (Swartz et al., 2007). Thus, the relative advantages of the new generation of antipsychotics are limited in terms of long-term prognosis. Further, they have their own side effects, including increased risk of metabolic syndrome, weight gain/obesity, and new onset or worsening of diabetes mellitus (Newcomer, 2005). As might be expected, medication side effects are significant obstacles to treatment compliance. This is particularly problematic, as 60% of first-episode patients relapse after 1-year if they do not continue antipsychotic treatment, (Alvarez-Jimenez et al., 2011b).One approach to improving compliance is the administration of injectable, long-lasting (depot) antipsychotic medication. This has the advantages of ease of use for the patient and the fact that the clinician can monitor compliance. Injectable antipsychotics, when combined with psychosocial treatments, appear to be very effective in reducing relapse rates (Zhornitsky & Stip, 2012).

Some of the initial trials of preventive intervention with CHR individuals suggested that atypical antipsychotics may have the same preventive potential. In one study, CHR youth were randomly assigned to either low-dose Risperidone with cognitive therapy or to usual care alone (McGorry et al., 2002). After 6 months, the rate of conversion to psychosis was 9.7% for those receiving Risperidone and cognitive treatment, and 35.7% for usual care. For Risperidone-compliant patients, protection against progression extended for, on average, 6 months after cessation of drug treatment. In another randomized, placebo-controlled trial with CHR patients, Olanzapine, an atypical antipsychotic, or placebo was administered for eight weeks (Woods et al., 2003). Although both groups showed a decline in prodromal symptoms, analyses revealed that those on Olanzapine showed fewer and less severe symptoms. There were, however, problems with adverse side effects, and Olanzapine patients gained significantly more weight. Yet, despite these initial promising findings, subsequent follow-up studies have not yielded support for the preventive effects of antipsychotic medications in prodromal samples. Recent systematic reviews of this literature conclude that the severity of prodromal symptoms can be reduced and the onset of the first psychotic episode delayed by combining pharmacologic and psychological therapies, but extended follow-ups of CHR individuals treated with antipsychotics have not shown a significant reduction in transition to psychosis (Addington and Heinssen, 2012).

Given the significant false positive rate of current prospective measures of the prodrome (60–80%), antipsychotics are not considered an appropriate treatment; only a minority of those who meet standard criteria will actually develop a psychotic disorder, and too many would be subjected to side effects unnecessarily (Broome & Fusar-Poli, 2012). Moreover, the prodrome typically emerges in adolescence/early adulthood and we know relatively little about the long-term effects of antipsychotic medication on development. As a result, it is recommended that administering antipsychotic medications to CHR individuals, especially youth, should not be standard treatment (Addington and Heinssen, 2012). As our knowledge of the effects of psychotropic medication on adolescent growth and development increases we will be in a better position to weigh any adverse effects against potential benefits, both short-term and long-term. At the present time, individuals who meet CHR criteria are typically medicated with antidepressants because mood symptoms are so common (Walker et al., 2009). Clearly, there is a need for the development of effective treatments that do not risk significant side effects for CHR individuals (Haroun, Dunn, Haroun, & Cadenhead, 2005).

Psychosocial Treatments

Although antipsychotic medication is typically the first step in the treatment of psychotic disorders, there is now extensive evidence that psychosocial interventions are also beneficial for both the patient and the family. It is generally agreed that the optimal treatment approach is one that combines medication and psychosocial interventions. In

fact, family and patient psychoeducation, which provides information about the nature, origins, and management of psychosis, should begin as early as the initial assessment (Gadelha et al., 2012). Family psychoeducation therapy is an evidence-based practice that is included in the Schizophrenia Patient Outcomes Research Team (PORT) guidelines (Dixon et al., 2010). In addition to improving family members' knowledge of and ability to cope with the symptoms of psychosis, family psychoeducation reduces relapse and hospitalization, in some cases reducing relapse rates by as much as 50% (Lucksted et al., 2012).

Cognitive-behavioral therapy (CBT) for psychotic disorders posits that dysfunctional cognitions can contribute to specific psychotic symptoms (Naeem et al., 2005). CBT for psychosis assumes that the normal cognitive mechanisms are being employed by the patient during periods of nonpsychotic thinking and that these processes can be used to help patients control their symptoms (Naeem et al., 2005). To avoid resistance, psychotic beliefs are not directly challenged; instead, specific symptoms such as hallucinations and delusions are targeted for appraisal of dysfunctional cognitive attributions. Recent reviews of published randomized controlled trials suggest that CBT is effective in reducing the severity of psychotic symptoms (Mueser, Deavers, Penn, & Cassisi, 2013; Rector, Stolar, & Grant, 2011).

The beneficial effects of CBT may be more pronounced when administered to patients earlier in the course of illness. A meta-analysis examining 14 studies including 1,484 patients concluded that CBT produced significant improvements in patient functioning, especially for acute patients, compared with those individuals suffering from chronic schizophrenia (Zimmermann et al., 2005). However, the investigators acknowledge that many moderating factors still need to be evaluated—including the therapeutic alliance, as well as the extent of cognitive deficits during the pretreatment period.

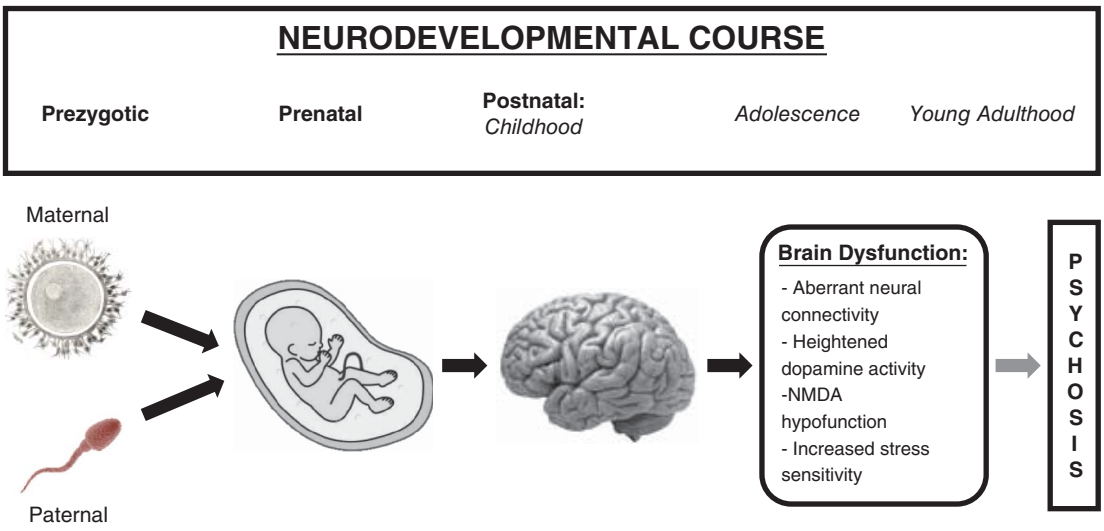
A recent meta-analysis examined the effects of treatment-as-usual (TAU), CBT, and intensive specialized first episode psychosis (FEP) intervention programs that included multidisciplinary teams which provided assertive outreach treatment, evidence-based interventions tailored to patient needs, atypical antipsychotic regimens, manualized CBT strategies, individualized crisis management plans, and family counseling and psychoeducation (Alvarez-Jimenez et al., 2011). The outcome measures were relapse and days of hospitalization. The intense, multimodal intervention provided in the specialized FEP programs was associated with a significantly greater reduction in relapse and days of hospitalization when compared with CBT or TAU alone.

Although research on CBT for preventive intervention has just recently begun, there is also evidence that CBT may be effective in preventing psychosis in CHR youth. A recent meta-analysis of intervention for CHR patients concluded that there was a moderate effect of CBT in reducing symptom severity and transition to psychosis at 12 months (Hutton & Taylor, 2013). To date, this is the most consistent evidence of a preventive intervention effect.

For diagnosed patients, comprehensive programs for supporting the transition back into the community have also been effective in enhancing recovery and reducing relapse. One such program, called Assertive Community Treatment (ACT), was originally developed in the 1970s by researchers in Madison, Wisconsin (Bustillo et al., 2001; Udechuku et al., 2005). ACT is a comprehensive treatment approach for the seriously mentally ill living in the community. Patients are assigned to a multidisciplinary team (nurse, case manager, general physician, and psychiatrist) that has a fixed caseload and a high staff/patient ratio. The team delivers all services to the patient and is available to the patient at all times. Services include home delivery of medication, monitoring of physical and mental health status, in vivo social skills training, and frequent contact with family members. Studies suggest that ACT can reduce time spent in hospital, improve residential stability, and increase patient and family satisfaction (Udechuku et al., 2005).

Social skills training seeks to improve the overall functioning of patients by teaching the skills necessary to improve performance of daily living activities, employment related skills, and interpersonal relationships (Bustillo et al., 2001). Social skills training programs make use of behavioral techniques including modeling, rehearsal, and reinforcement. Recent research indicates that social skills training can improve social competence and treatment compliance (lower social disability and fewer dropouts) compared with structured leisure activities or TAU (Galderisi et al., 2010; Rus-Calafell, Gutiérrez-Maldonado, & Ribas-Sabaté, 2013). However, it remains unclear to what extent this improvement in social competence translates into better functioning in the community. The 2009 PORT guidelines recommend that social skills training be accompanied by strategies to increase real-world use of the skills obtained in therapy (Dixon et al., 2010).

Because the rate of competitive employment for the severely mentally ill is very low, vocational rehabilitation has also been a major focus of many treatment programs. Vocational rehabilitation programs have a positive influence on work-related activities, although they have not yet been shown to have a substantial impact on patients' abilities to obtain employment in the community



(Lehman et al., 2002). Some evidence suggests that supported employment programs produce better results than traditional vocational rehabilitation programs—as measured by patients' ability to obtain competitive, independent employment. Nonetheless, job retention remains a significant problem, and this prevents young, first-episode patients from establishing self-sufficiency (Bustillo et al., 2001; Lehman et al., 2002).

In summary, a multimodal approach to the treatment of psychotic disorders, combining both medication and psychosocial interventions, appears to be the most effective. Such multimodal approaches are, however, very costly, and few patients receive such treatment. Further, for the majority of patients, the aforementioned treatments do not result in complete remission; residual symptoms remain and derail the individual's acquisition of adult social and financial autonomy. To gain leverage in efforts to reduce the burden of serious mental illness, and ultimately provide preventive interventions, we need to refine our understanding of the neural mechanisms that give rise to psychosis during the critical risk period, adolescence/young adulthood.

Neurodevelopmental Models of Etiology

In the previous sections of this chapter, we have documented the dramatic evolution in our understanding of psychotic disorders; the field has shifted from simple models of disorder-specific causal factors to complex models that include influences at multiple levels of analysis. It is apparent that in both normal and abnormal human development, there is interplay between the developing human brain and the environment, both psychosocial and biological. Further, developmental trajectories originate before birth and involve modulating influences through childhood and adolescence.

Figure 22.1 summarizes the risk factors and processes that have been linked with psychotic disorders and the developmental stages at which they initially impinge to potentially alter neurodevelopment. Both the number of potential influences and the role of the physical and psychosocial environmental increase across the prezygotic, prenatal, and postnatal periods. Given our current understanding of the myriad of factors that influence each stage of human brain development, it is to be expected that

Prezygotic Germline Risk Factors	Prenatal Risk Factors	Postnatal Risk Factors
• Risk Alleles • Mutations • Epigenetics	• Mutations • Epigenetics • Maternal infection and inflammation • Maternal Stress • Pregnancy complications • Nutritional deficiency	• Epigenetic processes • Substance use: Cannabis, Amphetamines • Neuroinflammatory processes • Head injury • Psychological trauma and stress • Aberrant neurodevelopmental processes (e.g., heightened endogenous HPA activity, synaptic pruning, myelination)

Figure 22.1 Risk factors and developmental stages psychosis.

the pathways to psychosis-spectrum disorders are varied and complex. Thus a confluence of interacting factors is assumed to contribute to the neurocircuitry dysfunctions that give rise to various psychiatric syndromes, including psychosis.

In this section, we examine some contemporary models of etiology. Although these models differ in their emphases, they share assumptions about the origins of vulnerability, as well as some of the neurobiological mechanisms that give rise to its expression. To set the stage for this discussion, several points about the issues of etiologic specificity and developmental processes should be reiterated.

As stated earlier, we have not, to date, identified biomarkers that are specific to schizophrenia, or even to psychosis in general. At the level of the measurable behavioral phenotypes that we define as syndromes, there is increasing evidence of nonspecificity in the distal (e.g., genetics, prenatal complications) and proximal (e.g., stress, neuroinflammation) risk/etiologic factors. In fact, many risk/etiological factors cross the diagnostic boundaries among psychotic, mood, and autistic-spectrum disorders. This does not mean that there are no diagnosis-specific, downstream neuropathological processes in psychosis, but rather that they can be triggered by a broad range of nonspecific factors.

Indeed, it is the burgeoning evidence of nonspecificity that prompted the recent introduction of the research domain criteria (RDoC) by the National Institute of Mental Health (NIMH; Cuthbert & Insel, 2013). The RDoC is a research classification system for mental disorders that is based upon dimensions and systems of neurobiology and behavior. It was developed by the NIMH in response to concerns that the *DSM-5*, and other diagnostic taxonomies for mental disorders rely solely on presenting signs and symptoms, do not adequately reflect neurobiological and behavioral systems, and draw diagnostic boundaries that are not empirically supported, thereby impeding research on etiology, neuropathology, and intervention. Thus, RDoC is intended to encourage research on fundamental biobehavioral dimensions that cut across current disorder categories.

In addition to encompassing more nonspecific etiologic factors (e.g., stress, neuroinflammatory pathways), contemporary models are also characterized by a greater recognition of developmental processes. Although the assumption that psychosis involves neurodevelopmental processes arose in the 80s, the initial focus was on prenatal development (Lewis and Murray, 1987), whereas more recent etiologic models have shifted their focus to adolescent development and the prodromal period. And, as mentioned, this shift has corresponded with major advances in our understanding of normative postpubertal neurobiological changes, particularly in brain morphology and function.

A comprehensive review of etiologic models of psychosis is beyond the scope of this chapter. Instead, the ensuing discussion highlights some recent models that attempt to encompass new research findings and to account for the modal trajectory in which prodromal symptoms emerge in adolescence. These models share in common the assumption that vulnerability typically originates in genetic and prenatal/perinatal factors that set the stage for psychosis, but that adolescent neurodevelopmental processes are triggering the expression of vulnerability.

Stress has been implicated in the etiology of psychosis for many decades, but theorizing about the biological mechanisms mediating this effect and triggering psychosis only later entered into the discussion. Walker and colleagues (Walker & Diforio, 1997; Walker et al., 2008) proposed a neural diathesis-stress model that posits a congenital abnormality in striatal DA circuitry that is moderated in its expression by the activation of the HPA axis via both external stressors and endogenous neurodevelopmental processes. This model draws upon extensive evidence that measures of HPA activity are elevated in patients with schizophrenia and affective psychoses. It also links HPA activity with a posited downstream neural mechanism in psychosis, in that glucocorticoid release, via activation of the HPA axis, can augment DA activity in the striatum. In addition, it emphasizes the developmental parallels between the normal maturational increase in HPA activity that begins after the onset of puberty and the developmental course of the prodrome to psychosis (Trotman et al., in press).

Since the proposal of the neural–diathesis–stress model, there has been more extensive research on normative adolescent neurodevelopment showing that it is characterized by critical neurobiological changes and appears to be associated with increased biobehavioral sensitivity to stress (Eiland & Romeo, 2012). Postpubertal changes in both gonadal and adrenal hormones, including glucocorticoids, play an important role in epigenetic processes that trigger these processes. In a recent review of the literature on hormones and risk for psychosis, the authors provide an overview of research findings on the relation of steroid hormones with normative changes in brain structure and function and update the neural-diathesis-stress model to incorporate these new findings (Trotman et al., in press). These normative changes include a decline in gray matter during the course of adolescence and into young

adulthood, and this is assumed to subserve the refinement of neural interconnections. Thus, because neurons in many human brain regions have both surface and intracellular receptors for hormones that mediate genomic and nongenomic processes, adolescent hormonal changes are thought to be pivotal for the reorganization of brain structure and circuits.

Consistent with this view, there is now extensive research documenting the adverse effects of elevated glucocorticoids on brain structure/function in animals (Kim & Haller, 2007), and more recent converging evidence of such a relation in humans. For example, a study using fMRI and EEG with administration of synthetic cortisol revealed rapid changes in the functioning and perfusion of the healthy human brain, presumably via nongenomic mechanisms (Strelzyk et al., 2012). At the structural level, studies of healthy and clinical samples have revealed an inverse association between cortisol levels and regional brain volumes in healthy samples (Knoops et al., 2010; Tessner et al., 2007; Walker et al., 2008) and schizophrenia patients (Mondelli et al., 2010). Prospective research has revealed the same relations; baseline cortisol levels were found to be correlated with gray matter volume changes over the course of treatment in youth with anorexia (Mainz et al., 2012). Further, increases in gray matter were associated with decreases in cortisol when measured simultaneously across time in anorexia patients (Castro-Fornieles et al., 2009). Similarly, in youth with trauma exposure, cortisol levels are negatively correlated with volume in the prefrontal cortex and predict longitudinal declines in hippocampal volume (Carrion & Wong, 2012). Conversely, the reduction of cortisol levels in Cushing's patients is associated with an increase in brain volume and a decrease in psychiatric symptoms (Hook et al., 2007). This suggests that some of the adverse effects of heightened glucocorticoids on brain structure may be reversible.

For individuals who are vulnerable to psychosis, elevated cortisol secretion during the course of adolescence may trigger the expression of risk genes or interfere with epigenetic processes in a manner that leads to aberrant brain development, such as the exaggerated postpubertal decreases in gray matter volume and neuronal connectivity observed in CHR youth. When coupled with increased DA activity, as suggested by previously reviewed findings, this would be expected to result in abnormal function of neural circuits that govern perceptual and thought processes.

In contrast to the previous emphasis on stress biology, some recent perspectives on the neurodevelopmental processes in psychotic disorders have incorporated a greater emphasis on the immune system (Anderson & Maes, 2013; Kinney et al., 2010; Meyer, 2013). As described earlier in this chapter, activation of the HPA axis and activation of immune processes are linked with similar neurochemical and neuroanatomical changes, and their effects are mutually mediated and synergistic (Zunszain et al., 2011). Thus, while glucocorticoids have anti-inflammatory effects at low/moderate levels, it has been demonstrated that exposure to persistent stress or the administration of glucocorticoids can increase the pro-inflammatory response to an immune challenge (Catena-Dell'Osso et al., 2011; Frank et al., 2010). Conversely, activation of the immune response can augment HPA activity (Perez, Bottasso, & Savino, 2009). If persistent, both can be associated with neuroregressive and neurodegenerative processes (Zunszain et al., 2011).

In his recent neurodevelopmental model of psychosis, Meyer (2013) suggests how altered prenatal immune function might set the stage for vulnerability and moderate the course of subsequent development. He first reviews the evidence linking psychosis with prenatal exposure to a range of infections (e.g., viral and bacterial), which gave rise to maternal/fetal inflammatory responses (the prenatal cytokine hypotheses), as well as evidence showing increased proinflammatory responses in schizophrenia. He then offers an account of how prenatal exposure to immune challenge can contribute to early pre- and postnatal alterations in inflammatory response systems, and disrupt subsequent neuronal circuit development. Under normal circumstances, homeostatic processes control inflammatory responses; in the brain, microglia and astrocytes play a pivotal role in modulating inflammatory processes, via the production and regulation of cytokines. But these processes, and the associated neurotropic and neurodegenerative effects of cytokines, vary with developmental stage. For example, Meyer (2013) reviews evidence that exposure to prenatal infection and cytokines is linked with abnormal development of the DA system in animal models, as well as structural brain abnormalities (e.g., ventricular enlargement and reduced cortical volume) in human adults. Yet some effects of prenatal infection on brain development only become apparent in postpubescence, when previously dormant neuroinflammatory abnormalities are activated, possibly resulting in derailment of normal adolescent neuromaturational processes, such as myelination, synaptic pruning, and neuronal remodeling. Meyer emphasizes the role that physical and psychological stressors play in this process, and suggests that stress, glucocorticoid elevations, and release of excitotoxic levels of glutamate by activated microglia may contribute to the exaggerated decrease in gray matter volume and heightened glutamate levels

observed in CHR samples, especially in the transition to psychosis. A very similar model is posited by Anderson and Maes (2013), but with a greater emphasis on oxidative stress pathways.

With a greater focus on adolescent developmental processes, Kinney and colleagues (2010) proposed a model that emphasizes how pro-inflammatory cytokines exacerbate risk for psychosis onset in adolescence/young adulthood due to developmental changes in immune function. In addition to the aforementioned findings, they draw on two lines of evidence: (1) alleles associated with increased risk for schizophrenia also affect the activity of pro-inflammatory cytokines; and (2) an excessive inflammatory response can produce an imbalance of glutamatergic and dopaminergic neurotransmission that leads to psychotic symptoms and a progressive loss of brain tissue that contributes to cognitive deficits. Like Meyer (2013), these authors assumed that prenatal factors can confer a latent vulnerability in the immune system that is relatively dormant until puberty. In particular, they note that prenatal exposure to maternal stress, nutritional deficiency, and infection can lead to thymus gland dysfunction in offspring, which is subsequently heightened during adolescence when the thymus gland normally regresses in volume. The thymus gland is important to the immune system because it produces T-cells which play a central role in adaptive immune function. With atrophy of the thymus in adolescence, latent immune vulnerability is manifested, and individuals become more susceptible to infections or immune diseases that can contribute to the onset of psychosis. Further, Kinney and colleagues (2010) emphasized the deleterious effects of stress and glucocorticoids on immune function, as well as the evidence that neuroinflammation and the pro-inflammatory cytokines (e.g., TNF-α) adversely affect neurogenesis, synapse formation, neuronal connectivity, and the survival of neurons. Related to this model, it is relevant to note that a key feature of 22q11.2 deletion syndrome, which is associated with a 20 to 30 fold increase in risk for psychosis, is early loss of the thymus resulting in reduced T-cells, immune deficiency, and reduced resistance to infection (Bassett & Chow, 2008; Shapiro et al., 2011), It is noteworthy that this genetic cause of thymus dysfunction in humans is also linked with a dramatic increase in risk for psychosis.

Some other neurodevelopmental models have focused greater attention on the brain circuitry or connectivity changes associated with psychosis. For example, it has been proposed that genetic and other factors can lead to early developmental disruptions in intra- and interregional connectivity, and thereby give rise to a psychosis vulnerability that is expressed in late adolescence/early adulthood (Karlsgodt et al., 2008; Uhlhaas & Singer, 2011). These models draw on research findings that psychotic disorders are associated with postmortem evidence of reductions in synapse density and dendritic complexity, as well as findings from *in vivo* MRI studies showing white matter changes indicative of deficient connections among cortical regions. The functional expression of abnormal connectivity, in the form of prodromal symptoms, may arise in adolescence because pre-existing abnormalities interact with the normal adolescent process of synaptic pruning or because the pruning process itself is abnormal. At the level of neurotransmitters, one recent model emphasizes the importance of circuits in the prefrontal cortex that involve glutamatergic and gamma-aminobutyric acid (GABA)-ergic transmission and are characterized by heightened sensitivity to environmental perturbation during adolescent development (Hoftman & Lewis, 2011). Again, these connectivity models incorporate stress systems as one of the mechanisms contributing to circuitry abnormalities.

The previously reviewed etiologic models exemplify the variety of plausible neurodevelopmental processes that might give rise to psychosis. It is possible that each provides an accurate account of the etiologic process for a subgroup of individuals who succumb to psychosis. In fact, it is arguable that the search for etiologic subtypes should be a major focus of future research in the field of psychosis.

FUTURE RESEARCH DIRECTIONS

The now overwhelming evidence that there are diverse and complex risk factors and developmental pathways to psychosis should inform our approach to future research. At the level of the measurable behavioral phenotypes that we define as syndromes, there is not yet evidence of specificity in the distal (e.g., genetics, prenatal complications) or proximal (e.g., stress, neuroinflammation) risk/etiologic factors for various psychotic disorders. In fact, there is growing evidence of multifinality, such that many risk/etiological factors cross the diagnostic boundaries among psychotic, mood, and autistic-spectrum disorders. As reflected in RDoC, the primary goal of contemporary psychiatric research should not be to identify *DSM* disorder-specific causal factors, but rather constellations of factors that, a) are linked with one or more psychiatric syndromes or symptom dimensions, and b) suggest modifiable pathways for intervention.

Before turning to a discussion of promising research approaches, it is relevant to consider some of the challenges that confront clinical research on psychosis. First, it is important to consider that the rate of psychotropic prescriptions has increased dramatically in recent decades, and this is especially true of youth. It is considered best practice to promptly initiate antipsychotic medication to patients who meet criteria for a psychotic disorder (Kreyenbuhl, Buchanan, Dickerson, & Dixon, 2010). For ethical reasons, researchers usually do not manipulate medication status, with the exception of clinical trial protocols which typically involve small samples. Instead, most clinical studies of psychotic disorders are naturalistic studies in which medication status is determined by the participant's treatment provider. Because these medications can have significant effects on brain function and structure, they can obscure the natural course of the illness and complicate cross sectional comparisons between clinical and control groups.

One advantage of research on individuals at-risk for psychosis is that they are less likely than diagnosed patients to be on a psychotropic. Nonetheless, most young people (>60%) who manifest clinical signs of risk for psychosis have a history of receiving one or more psychotropic medications (Cadenhead et al., 2010). Further, the prescription of a psychotropic drug, including antipsychotic or antidepressant medication, is presumably determined by the treatment provider's judgment concerning the patient's symptom severity. Thus, if researchers were to exclude prospective participants who have a history of psychotropic medication, the resultant sample would be nonrepresentative of CHR youth. To deal with this problem, investigators often include medication status as a covariate in statistical analyses. But if the prescription of medication is even partially determined by preexisting behavioral or biological factors, this is not the optimal solution. A clear illustration of the challenges posed by psychotropic medication is in the study of biological and behavioral measures of stress. Antipsychotics and antidepressants can dampen both symptom severity and HPA activity. Thus, CHR participants who are on medication may have experienced a medication-induced dampening of symptoms and HPA activity prior to enrollment in the study. This would, of course, reduce the magnitude of any difference in symptom severity and cortisol levels, as well as other biomarkers, between the CHR and control groups. It would also obscure differences in baseline cortisol in cross sectional comparisons of the medicated and nonmedicated CHR subgroups.

Similar challenges are posed by psychosocial treatments. In addition to higher rates of psychotropic medication, it is not surprising that CHR youth also have a higher rate of lifetime psychological treatment, especially individual therapy. In the first phase of the NAPLS study, about 74% had a lifetime history of psychotherapy and almost half were currently in psychotherapy (Cadenhead et al., 2010). Again, it is reasonable to assume that this treatment is not randomly distributed among participants, but is instead correlated with the severity or longevity of their behavioral symptoms. It is also likely that the psychosocial interventions are successful in reducing symptom severity and enhancing coping in many CHR youth.

The research challenges posed by treatment effects have alerted investigators to the benefits of longitudinal over cross sectional research designs. Longitudinal approaches make it possible to examine within-individual changes in biological and behavioral factors while taking baseline conditions into consideration. It is also assumed that the benefits of longitudinal approaches are enhanced when they are applied to critical developmental periods; in the case of psychosis this is primarily the adolescent period. Of course, nonexperimental, longitudinal research does not eliminate problems with the identification of causal pathways to psychosis. It is plausible, for example, that the biomarkers that have been identified in psychotic and CHR samples (e.g., inflammatory processes, oxidative stress, heightened HPA and DA activity, reduced NMDA function, and brain volumetric abnormalities) are the consequence of a latent neuropathological process, rather than mediators in causal pathways. While nonexperimental research cannot unequivocally distinguish among the many alternatives, there is great potential for longitudinal studies that simultaneously and repeatedly measure behavioral functions and biomarkers as they unfold during critical developmental periods. These approaches will yield data that provide firmer bases for inferring causal processes. By obtaining repeated indices over time, and conducting analyses that detect temporally lagged interrelations among them, there is greater opportunity for detecting relations that reflect causal mechanisms.

Moreover, when combined with controlled intervention trials, longitudinal research designs hold great promise for elucidating causal processes (Cicchetti, 2013). There are, for example, numerous interventions, both psychological and biological, that have the potential to modulate stress and neuroinflammatory pathways. Investigations aimed at examining the effects of such interventions in CHR individuals are now ongoing. Combining intervention trials with longitudinal measurement of biomarkers and behavior will likely yield important information about neural mechanisms as well as optimal intervention strategies.

The burgeoning field of research on the prodrome to psychosis is premised on the assumption that preventive intervention is a feasible goal. Indeed, the fact that psychotic disorders typically arise during adolescence/early adulthood suggests that neurohormonal and neurodevelopmental processes taking place during this period are triggering expression. Indeed, the only other periods in the human life span with a significant increase in risk for psychotic illness onset, namely the postpartum and menopausal periods, are also characterized by significant neurohormonal changes. This suggests the possibility that there are neurobiological processes that can be modulated during these periods to prevent illness onset. Lending further support to the notion that neurohormonal and neurotransmitter modulation holds promise for ameliorating positive psychotic symptoms is the fact that, for most patients, including those on antipsychotic medication, psychosis is episodic with intervening periods of higher functioning after the first episode. Thus, research on the neurodevelopmental precursors of psychosis may also yield insights into the prevention of remission after the clinical onset of the first episode of psychosis.

CONSIDERING PERSONALITY PATHOLOGY IN A DEVELOPMENTAL PSYCHOPATHOLOGY FRAMEWORK

A developmental psychopathology framework clarifies many aspects of the scientific approach (Cicchetti & Toth, 2009), several of which will be discussed here as particularly relevant to the *development* of youth *personality disorders (PDs)*, or *personality pathology*. One important tenet of the developmental psychopathology framework is the need to study normal and abnormal development alongside one another and examine the interaction of factors representing both risk and resiliency. That is, a factor may represent risk (or resiliency) in one context but not another. An increasingly nuanced understanding of contextual features is thus required to elucidate the nature of risk/resiliency and better understand the emergence of psychopathology. This tenet is highly relevant to the broader domain of PDs, as PDs reflect diagnostic constructs which have a rich and expansive literature on their normal counterparts (i.e., normal-range personality). In addition, unlike many other diagnostic constructs, theoretical models and assessment tools for PDs have often drawn on and been integrally linked to models and measures of normal-range personality (e.g., Krueger & Tackett, 2003).

This juxtaposition of normal and abnormal constructs is even more fully realized in a move to better understand PDs in early life (Tackett, Balsis, Oltmanns, & Krueger, 2009). Specifically, previous versions of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) have severely restricted diagnosis of PDs prior to age 18 (which we discuss more later on in the current chapter). Restriction of diagnosis inevitably leads to restricted research and, thus, restricted knowledge of how PD constructs manifest in early life. Research on normal-range child personality and temperament, while lagging behind similar work in adults, can thus be especially useful in working toward a better understanding of PDs in early life. In addition, the use of dimensional trait models in temperament and child personality research are particularly amenable to developmental investigations, as they offer an opportunity to follow a more nuanced conceptualization of stability and change, as well as of risk and resiliency, over the life span (Tackett et al., 2009).

Other features of the developmental psychopathology framework, including the emphasis on simultaneously examining multiple levels of analysis in understanding psychopathology development and the importance of concepts such as equifinality (different starting points result in similar developmental outcomes) and multifinality (the

same starting point results in different developmental outcomes) also hold great relevance for the development of PDs, and will be integrated throughout the chapter as appropriate (Cicchetti & Toth, 2009). We tackled the topic of PD development from a number of perspectives in the current chapter. First, we provide a brief overview of normal-range temperament and personality models in children, which have great relevance for the development of pathological personality across the life span. In this section we also summarize research on the development of normal-range personality across the life span. Next, we move to the conceptualization of PDs in *childhood* and *adolescence* and in later life. First, we review research on the development of PDs in childhood and adolescence and in later life. Then, we tackle conceptualization of PDs in the *DSM* and the resultant developmental implications, as well as measurement issues for PDs in both early and later life. Finally, we discuss four core components of PDs: traits, emotions, interpersonal features, and identity; relevant theory and research are reviewed in each of these domains for early life (childhood and adolescence) and for later life. We then review critical developmental periods for PDs: (1) infancy–toddlerhood; (2) middle childhood–early adolescence; (3) late adolescence–early adulthood; and (4) later life. We conclude the chapter with an overarching summary and future directions.

DEFINING NORMAL PERSONALITY

Normal personality is often defined as an individual's characteristic patterns of behaving, feeling, and thinking, which are relatively stable across time and across situations. Researchers studying adult populations typically label these traits as personality, whereas researchers studying child populations have often labeled them as temperament (Shiner & Caspi, 2003; Tackett, 2006). Historical conceptualizations have suggested that temperament traits are distinct in that they are more biologically influenced and present from early in life (Tackett, 2006), although the lines between these two domains has grown increasingly blurred (De Pauw & Mervielde, 2010; Herzhoff & Tackett, 2012; Rothbart & Ahadi, 1994; Rothbart, Ahadi, & Evans, 2000; Shiner, 1998, 2006; Shiner & Caspi, 2003). Despite this growing consensus that temperament and *personality traits* are more alike than different, important differences remain in their conceptualization which has implications for differences in measurement (Tackett, Kushner, De Fruyt, & Mervielde, 2013).

Two common and widely used models of personality and temperament are the Five-Factor model (FFM; see Goldberg, 1993) and Rothbart's biosocial model of temperament (Rothbart, Ahadi, Hershey, & Fisher, 2001), respectively. The FFM encompasses the following five higher order factors of personality: (1) neuroticism—the tendency to experience negative emotions such as anger, fear, and sadness; (2) extraversion—the tendency to experience positive emotions, be active, and social; (3) agreeableness—the tendency to experience affiliation and empathy; (4) conscientiousness—the tendency to experience achievement motivation and be orderly; and (5) openness-to-experience—the tendency to value new experiences, be intellectually curious, and imaginative. In contrast, Rothbart's model encompasses three higher order factors of temperament: (1) negative affectivity (akin to neuroticism); (2) positive emotionality/surgency (akin to extraversion); and (3) effortful control (akin to conscientiousness).

Despite their difference in number of factors, three- and five-factor models of personality have been hierarchically linked in studies with both adults (Markon, Krueger, & Watson, 2005; Tackett, Quilty, Sellbom, Rector, & Bagby, 2008) and children (Tackett, Krueger, Iacono, McGue, 2008). At the highest level, 2-factor models of personality typically include negative affectivity/neuroticism and extraversion/surgency traits (e.g., Digman, 1997; Gray, 1987). Three-factor models, as previously described, typically include a third trait indexing constraint or self-regulatory capacities, which typically breaks off from neuroticism at level 2 (Tellegen, 1985). At level 4, this broad constraint trait splits into intrapersonal constraint (i.e., conscientiousness) and interpersonal constraint (i.e., agreeableness), a distinction in self-regulatory capacities that only begins to appear in temperament measures in adolescence (Ellis & Rothbart, 2001). Finally, at level 5, openness splits off from extraversion, signifying a distinction between nonsocial and social approach-motivated behaviors that are not explicitly found in major temperament models (but see Herzhoff & Tackett, 2012). Therefore, although the temperament and personality literatures have historically developed separately from one another—and important differences remain (Tackett, Kushner, et al., 2013), hierarchical approaches suggest that they may not reflect meaningful developmental differences, but rather, differences in the level of the hierarchy focused on for a particular framework.

At lower levels of the personality hierarchy, more narrowly defined traits—or facets—reside. For example, fear/anxiety is a facet of neuroticism/negative affectivity as measured by both a common personality measure, the revised NEO Personality Inventory (Costa & McCrae, 1992), and a common temperament measure, the Children's

Behavior Questionnaire (Rothbart et al., 2001). Although such lower order traits have been found to have great predictive value for psychopathology (e.g., Reynolds & Clark, 2001), the field of temperament/child personality research is far from a consensus structure of lower order traits across development (Tackett, 2006). More empirical studies are needed to explore both the structural and developmental relationships between temperament and personality at different levels of the hierarchy (Shiner & Caspi, 2003), and as researchers move toward greater agreement regarding the higher order structure of personality in childhood, it is likely that future efforts will begin to demonstrate similar progress in delineating the universe of childhood personality facets.

Although the trait approach dominates empirical research on personality across the life span, other personality constructs also show great relevance to development and psychopathological outcomes. For example, Shiner (2009) has discussed the relevance of McAdams and Pals (2006) multi-level personality framework for the development of PD in youth. Specifically, McAdams and Pals differentiate traits (level 1) from characteristic adaptations (level 2) and personal narratives (level 3). Constructs at all levels are relevant for the development of PDs, not just traits (Shiner, 2009; Shiner & Tackett, 2014). For example, attachment patterns and emotion regulation would fall under level 2 of the McAdams and Pals model as they are not well captured by current personality trait frameworks, yet show enormous import for the development of PDs in youth (Shiner, 2009; Shiner & Tackett, 2014). Similarly, identity development is a key component of personal narratives and is similarly fundamental to an understanding of PD development. Thus, it is important to think broadly when considering the normative personality context within which PD development takes place.

Life Span Development of Normal Personality

Although personality is defined as a relatively stable tendency to behave, think, and feel across situations, studies on the life span development of normal personality reflect robust evidence for both stability and change (Fraley & Roberts, 2005). Long-term longitudinal studies have found that personality/temperament assessed as early as age 3 predicts personality in adulthood as much as 40 years later, suggesting that personality is relatively stable across development (Caspi, 2000; Caspi et al., 2003; Caspi & Silva, 1995; Nave, Sherman, Funder, Hampson, & Goldberg, 2010). This continuity seems to be largely due to genetic and nonshared environmental factors (De Fruyt et al., 2006) and seems to be similar in magnitude across community and clinical samples (De Bolle et al., 2009). Personality psychologists further differentiate between multiple types of stability, or continuity. For example, mean-level stability reflects continuity in absolute levels of personality traits across time, whereas differential continuity (or rank-order stability) refers to continuity in an individual's relative level, or ranking, on a trait relative to a broader population (De Fruyt et al., 2006). Both types of continuity, as well as additional aspects of personality stability, have been studied in populations ranging from childhood to older age. We broadly summarize findings on mean-level and rank-order stability, consider investigations on continuity for personality types which have received substantial attention in childhood and adolescence, and briefly acknowledge additional considerations including measurement issues and individual variability.

Mean-level Stability

The best accounting for life span mean-level stability in personality traits comes from a seminal meta-analysis (Roberts, Walton, & Viechtbauer, 2006). This study found that mean-levels of social dominance, conscientiousness, and emotional stability increased across the life span—especially between ages 20 and 40 years, that social vitality and openness increased in adolescence and then decreased in old age, and that agreeableness increased only in old age (Roberts et al., 2006). Examinations of mean-level stability, in both reviews and independent empirical investigations, have often noted that changes in adult personality tend to happen in the direction of greater maturity, such that most individuals are most likely to increase in their dominance and self-confidence and decrease in their anger and alienation, with more mature individuals changing less than less-mature individuals (Roberts, Caspi, & Moffitt, 2001). More recent investigations of mean-level stability have dedicated focused attention to understanding mean-level changes in childhood and early-mid adolescence. Findings from these studies have not always supported evidence for mean-level stability of personality traits in childhood and adolescence (De Fruyt et al., 2006), and have even hinted that personality traits may progress from more to less maturity between childhood and adolescence, with increased maturity of personality primarily reflecting the later stages of adolescent development and adulthood (Soto, John, Gosling, & Potter, 2011). Such work has been very limited to date in early life, representing an important area for future research.

Rank-order Stability

Roberts and DelVecchio (2000) contributed another seminal study on life span personality development: a meta-analysis on the rank-order stability of personality. These findings suggested that rank-order stability of normal personality traits increased across the life span from childhood to age 50 years, stabilizing until age 70 years (Roberts & DeVecchio, 2000). Importantly, these findings countered previous suggestions that personality did not stabilize until adulthood, such that even in early childhood, evidence for substantial continuity was found as well. In terms of differences in stability across traits, results suggest that stability tends to be highest for extraversion and lowest for neuroticism (Roberts & DelVecchio, 2000). This is true for samples in childhood and adolescence (De Fruyt, et al., 2006; Tackett, et al., 2008) as well as into adulthood (Hampson & Goldberg, 2006).

Personality Types

Other investigations of personality stability have focused on personality types or profiles (e.g., overcontrolled, undercontrolled, and resilient types), rather than traits. Stability of personality types appears to be moderate in adolescence (Akse, Hale, Engels, Raaijmakers, Meeus, 2007; Meeus, Van de Schoot, Klimstra, & Branje, 2011) and to increase with age (Klimstra, Hale, Raaijmakers, Branje, & Meeus, 2009). Of the adolescents who change profiles, most change only once (Meeus et al., 2011) and of the changes that happen, most happen toward greater maturity, e.g., either from undercontrolled to resilient or overcontrolled to resilient (Meeus et al., 2011), or from undercontrolled to overcontrolled (Akse et al., 2007). This change toward greater maturity results in a decreasing percentage of over- and undercontrollers and an increasing percentage of the resilient types from early to late adolescence, consistent with the maturity trends previously noted for personality traits. Interestingly, whether one's profile is similar to other individuals' profiles in any given developmental period (within-time normativeness) has been found to be more predictive of adjustment than whether one's profile at one point in time is similar to one's profile at another point in time (distinctive stability; Klimstra et al., 2009).

Additional Considerations

Studies of normative personality development have been sparse, particularly at earlier ages, and more work in this area is needed. In addition, existing work has pointed toward a number of considerations for future studies in this area. Measurement considerations remain an important concern for understanding and interpreting longitudinal studies of personality development. For example, meta-analyses typically find that the longer the time between assessments, the greater the change in personality, i.e., the lower the rank-order consistency and the greater the mean-level change (Roberts & DelVecchio, 2000; Roberts et al., 2006). Furthermore, meta-analyses (Roberts & DelVecchio, 2000; Roberts et al., 2006) and other studies (e.g., Hampson & Goldberg, 2006) have suggested that the younger the sample, the greater the change in personality, e.g., temperament measures, which are used more frequently in younger samples, typically show lower rank-order consistency and younger samples also tend to show greater mean-level change. These findings are in contrast to studies employing measures of child personality (De Fruyt et al., 2006), and highlight the need to better understand the extent to which measurement problems in the area of child personality confound perceptions of instability (e.g., Tackett et al., 2012). In addition, cross sectional studies offer some insight into potential mean-level changes in childhood and adolescence, but are clearly less desirable than longitudinal studies to pick up on true developmental changes (Klimstra et al., 2009).

Another important measurement consideration is moving beyond broad personality trait domains to investigate facet-level traits (De Fruyt et al., 2006; Soto et al., 2011; Soto & John, 2012). For example, one study found that although the higher order conscientiousness trait increased across age, only its lower order facet Industriousness showed a similar pattern, suggesting that studies on the development of personality across the life span should take into account possibly divergent facet-level changes that might be masked by domain-level changes (Soto et al., 2011; Soto & John, 2012). Soto and John (2012) further found that changes in one domain or facet were not related to changes in another domain or facet, suggesting that mechanisms for personality change operate narrowly on one trait rather than broadly on domains. Such work, of course, also requires more careful attention to delineation and assessment of personality facets in childhood, an area which is severely underdeveloped. Studies relying on personality facets established in adults provide an important contribution to this area, but work focused specifically on personality facets developed for younger populations will be necessary.

A final consideration to note is the issue of individual variability. Despite increasing consistency of personality across development, individual differences in the trajectories of personality also exist, such that some individuals stay relatively stable in their personality, whereas others

decrease or increase in their trait levels over time (e.g., De Fruyt et al., 2006; Mroczek & Spiro, 2003; Vaidya et al., 2008). For example, a study on a large sample of men between the ages of 43 and 91 years found that individual differences in trajectories for extraversion and neuroticism existed across a span of 12 years (Mroczek & Spiro, 2003). Specifically, this study found that although extraversion changed linearly whereas neuroticism declined quadratically *on average*, individual differences in the level and rate of change also emerged. These individual differences were predicted by birth cohort and age-related life events such as marriage, death of a spouse, and memory problems. Age-related life changes with regard to social roles and physical health have also been found to predict personality change in middle-aged women (Helson & Soto, 2005), suggesting that normative changes in personality (e.g., changes toward more maturity) that have been found across different studies (e.g., Akse et al., 2007; Meeus et al., 2011; Roberts et al., 2001; Soto et al., 2011) might be due to normative changes in social roles across life.

In sum, research examining personality continuity has demonstrated evidence for both stability and change across the life span. Previous notions of primary instability in childhood personality, as well as rigid stability from early adulthood onward, are clearly outdated. Modern conceptualizations of normal-range personality development allow room for both stability and change across the life span, and highlight increasingly sophisticated and nuanced approaches to thinking about personality continuity over time.

DEFINING PD ACROSS THE LIFE SPAN

PDs are disturbed characterological patterns of thinking, feeling, behaving, and relating to others. In a broad sense, PDs or pathology defines those instances when normal personality (individual patterns of thoughts, feelings, and behavior) becomes rigid and inflexible, and results in impairment for the individual and others around them. A number of core constructs are thought to define personality pathology, including rigidity (lack of adaptability of one's characteristics to the environment or circumstance), lack of insight and self-awareness, problems in the area of self (e.g., identity), and problems in the area of relationships. In the following section, we review longitudinal investigations of *DSM*-defined PDs, a *DSM*-based discussion of PDs in later life, a specific discussion of the *DSM* approach to PDs in *DSM-IV-TR* (APA, 2000) and *DSM-5* (*APA,* 2013) and measurement issues for PDs in early and later life. Following that, rather than reviewing developmental issues within the existing *DSM* taxonomy (particularly given the lack of validity for the current categorical classification approach and its lack of developmental sensitivity), we discuss developmental issues in both early and later life for core components of personality pathology that undergird PD diagnoses and represent cross-cutting areas of importance across multiple PD categories. Those core components we discuss are traits, emotions, relationships, and identity.

Historical Context: Longitudinal Studies of PDs

Historically, longitudinal studies of PDs have been limited to adult samples; however, more recently, studies have been expanded to include youth samples as well. Similar to longitudinal studies of normal personality, longitudinal studies of PDs have found that abnormal personality is also moderately to strongly stable from six years of age over a time interval as long as 20 years (e.g., Asarnow, 2005; Bornovalova, Hicks, Iacono, & McGue, 2009; Bornovalova, Hicks, Iacono, & McGue, 2012; Chanen, et al., 2004; Cohen, Crawford, Johnson, & Kasen, 2005; Crick, Murray-Close, & Woods, 2005; De Clercq, Van Leeuwen, Van den Noortgate, De Bolle, De Fruyt, 2009; Grilo, Becker, Edell, & McGlashan, 2001; Johnson, et al., 2000; Lenzenweger, 1999; Lynam, et al., 2009; Skodol, et al., 2005; Stepp, Pilkonis, Hipwell, Loeber, & Stouthamer-Loeber, 2010; Winograd, Cohen, & Chen, 2008). Also similar to normal personality, this continuity seems to be largely due to genetic and nonshared environmental factors, at least in the case of borderline PD (Bornovalova et al., 2009). We broadly summarize findings on mean-level and rank-order stability of PD and briefly discuss some potential moderators of PD continuity.

Mean-Level Stability

Across several studies, mean levels of most PDs have been found to decrease across the life span in both those individuals who score above a diagnostic threshold as well as those who score below a diagnostic threshold (Gutiérrez et al., 2012; Lenzenweger, 1999; Paris, 2002, 2003; Paris, Brown, Nowlis, 1987; Sanislow et al., 2009; Shea et al., 2002; Skodol et al., 2005). Exceptions to this downward trend seem to be histrionic and obsessive-compulsive traits—which have been found to stay the same, as well as schizoid traits—which have been found to increase across the life span (Gutiérrez et al., 2012). Developmental changes are also seen across childhood and adolescence,

as PD symptoms peak during early adolescence (Bernstein et al., 1993; Cohen, Crawford et al., 2005; Crawford, Cohen, Johnson, Sneed, & Brook, 2004; Johnson et al., 2000) or immediately preceding puberty in the case of borderline PD symptoms (Crick et al., 2005).

Several factors have been identified as moderators of this mean-level continuity of PDs. For example, although a decrease in mean-levels is evident both in community (e.g., Bornovalova et al., 2009, 2012; Crick et al., 2005; De Clercq, Van Leeuwen et al., 2009) and in inpatient samples (Grilo et al., 2001), mean-levels have been found to decrease more sharply for individuals who show lower initial mean-levels than for those who show higher initial mean-levels (Crawford, Cohen, Johnson, Kasen, First, Gordon, & Brook, 2005; De Clercq, Van Leeuwen et al., 2009). This differential change in trait levels therefore creates an increasing gap between the groups with clinically elevated scores and those with relatively low scores. Another moderator of at least borderline PD continuity is gender. Specifically, contrary to Crick et al.'s (2005) hypothesis that girls' borderline PD traits would increase more greatly than would boys' from 4th to 6th grade, girls' traits marginally decreased whereas boys' did not change. A similar moderating effect of gender was not found later in development (15–18-years; Chanen et al., 2004), however.

Trajectories of abnormal personality have also been found to show substantial individual differences in the level and rate of change of severity (Lenzenweger, Johnson, & Willett, 2004). For example, Lenzenweger and colleagues (2004) found the level of severity to be conditional on group membership (i.e., possibly having a PD versus not having a PD) and sex. Specifically, individuals with a possible PD and males showed elevated scores on 8 of the 15 assessed PDs except for histrionic and dependent PDs. Rate of change of severity was found to be conditional only on an individual's possibility of a PD, with those individuals that possibly had a PD showing a greater decline in severity. Furthermore, although borderline PD traits have been found to generally decrease with age (e.g., Johnson et al., 2000), individual differences in psychosocial histories, such as a history of sexual abuse, trauma, poor parenting, stressful life events as well as parental factors such as low socio-economic status and low IQ affect the trajectory of personality pathology. For example, leaving a stressful relationship has been found to coincide with a decrease in borderline personality symptoms (Gunderson et al., 2003) whereas early maternal separation has been found to predict both an increase in borderline personality symptoms as well as a decrease in the reduction of symptoms over time (Crawford, Cohen, Chen, Anglin, & Ehrensaft, 2009).

Whether and how changes in normal personality or temperament affect changes in abnormal personality is unclear, particularly in early life. For example, Warner and colleagues (2004) found that changes in normal personality affected subsequent changes in PDs, whereas the reverse was not true in an adult sample. Lenzenweger and Willett (2009), on the other hand, found that changes in temperament did not affect changes in schizoid PD, in a sample of college students. Little is also known about the reciprocal effects of Axis I and Axis II disorders, even in adulthood. Specifically, the reciprocal effects of Axis I and Axis II disorders may operate in the direction of improvement in Axis II symptoms preceding improvement in Axis I symptoms, at least in the case of borderline PD and major depressive disorder in a sample of adults (Gunderson et al., 2004); however, further studies examining different disorders in different samples are lacking.

Rank-Order Stability

Despite the historical reluctance to diagnose PDs, before adulthood, the stability of abnormal personality in youth is comparable to that in adults (De Clercq, Van Leeuwen, et al., 2009; Grilo & McGlashan, 2005; Johnson et al., 2000). Specifically, even though PD diagnoses in adults have been found to be more stable than diagnoses of Axis I disorders such as Major Depressive Disorder, PD diagnoses do not seem to be as stable as the *DSM*'s description of PDs suggests (Cohen, Crawford, et al., 2005; Grilo et al., 2004; Grilo & McGlashan, 2005; Johnson, Bromley, Bornstein, & Sneed, 2006; Shea et al., 2002; Skodol et al., 2005; Zanarini, Frankenburg, Hennen, Reich, & Silk, 2005). These findings counter suggestions that personality is too unstable before adulthood for a meaningful diagnosis of PD as well as the idea that a diagnosis of PD is set for life and not likely to change.

Several factors have been identified as moderators of the rank-order continuity of personality pathology. For example, in youth, parent-reports of borderline personality traits (Stepp et al., 2010) have been found to show greater stability than have self- (Bornovalova et al., 2009, 2012; Chanen et al., 2004; Crick et al., 2005; Grilo et al., 2001) or teacher reports (e.g., Stepp et al., 2010). Furthermore, stability for parent reports has also been found to show a linear increasing trend whereas teacher reports show a curvilinear trend with a peak between 8 and 11 years (Stepp et al., 2010). Further moderating the effect of reporters

on the stability of abnormal personality are the pathological traits reported on. For example, teacher reports of internalizing aspects of PDs, such as the depressive aspects of BPD, have been found to be less stable than teacher reports of externalizing aspects of PDs, such as hyperactivity aspects of BPD (Stepp et al., 2010). Self-reports of borderline personality traits have not been found to show such differential stability, rather, both internalizing (e.g., boredom and emptiness) and externalizing (e.g., anger) aspects of borderline PD appear to be stable (Garnet, Levy, Mattanah, Edell, McGlashan., 1994; McGlashan et al., 2005; Zanarini et al., 2005), whereas more severely disturbed aspects such as self-harm and suicidality have been found to be the least stable aspects (McGlashan et al., 2005; Meijer, Goedhart, Treffers, 1998; Zanarini et al., 2005).

Given that differential stability is dependent on the personality aspects being studied, Skodol et al. (2005) suggested that PDs could be best conceptualized as made up of two factors: (1) relatively stable abnormal personality traits and (2) maladaptive behaviors aimed to cope with these abnormal traits (e.g., self-injury to cope with emotional tension). Further supporting this conceptualization is the finding that different PDs become more correlated with one another over time, suggesting that an underlying general personality pathology factor might be at play (Sanislow et al., 2009). Such a conceptualization of PDs might also explain the moderating effect of sample composition on PD stability. For example, borderline personality traits are more stable in community (Bornovalova et al., 2009, 2012; Crick et al., 2005; Stepp et al., 2010) and outpatient (Chanen et al., 2004) than in inpatient samples (Grilo et al., 2001; Meijer et al., 1998; Zanarini et al., 2005) potentially because inpatients receive more intense treatment targeted at the most severe and least stable aspects of personality psychopathology (Grilo et al., 2001). This intervention target might also explain the fact that the diagnostic stability of PDs is comparably lower than are mean-level and rank-order stability of PD symptoms and traits (e.g., Chanen et al., 2004; Black, Baumgard, & Bell, 1995; Lofgren, Bemporad, King, & Lindem, 1991; Mattanah, Becker, Levy, Edell, & McGlashan, 1995; Meijer et al. 1998; Skodol et al., 2005; Skodol, 2008).

In sum, longitudinal studies of PDs have come to some similar conclusions as longitudinal studies of normal personality. Specifically, research has demonstrated evidence for both stability and change in abnormal as well as normal personality across the life span. Future studies are still needed to examine the full range of moderators as well as mediators of such stability and change. In addition, most of this work has been with adults, and that with children and adolescents has often relied on adult-based conceptualizations of PDs. More developmentally sensitive studies should investigate empirically based personality pathology constructs in youth and their developmental trajectories over time. Furthermore, there is still a lack of longitudinal studies covering the extreme ends of the life span that might shed light on important developmental changes during those early and late years that can give rise to changes in personality pathology. Next, we discuss the relevance and importance of examining PDs in later life, an understudied area of research.

PDs in Later Life

Do PDs intensify, remain stable, or burn out with age? At first glance, empirical evidence generally suggests the latter, as a few longitudinal studies of varying samples and time lengths have indicated that PDs decrease over time (i.e., Grilo et al., 2004; Johnson et al., 2000; Lenzenweger et al., 2004). Grilo et al. (2004), for example, found that in a clinical sample of mixed-aged adults, PDs remitted for many individuals and there was a significant decrease in the mean number of criteria met in all four analyzed PDs over a two-year period (p. 773). Johnson et al. (2000) found that in a community sample of young adults, PD traits declined by 28% over an approximately 10-year period. And Lenzenweger et al. (2004) found that in a nonclinical sample of college-aged adults, PDs decreased at a rate of about 1.4 diagnostic criteria per year. In sum, the results from select longitudinal studies of PD suggest that PD traits often decrease over time in adults.

Similarly, the results from many cross sectional studies have indicated that PDs are frequently found to be less prevalent in older adults than younger adults (e.g., Casey & Schrodt, 1989; Cohen et al., 1994; Fogel & Westlake, 1990; Gutiérrez et al., 2012; Samuels et al., 2002; Zimmerman & Coryell, 1989), again suggesting that PDs decline with age. In each of these studies, either PD diagnoses or traits were found to be less frequent or less severe in older adults than a comparison group of relatively younger adults. This finding was most pronounced among the externalizing Cluster B disorders (e.g., Cohen et al., 1994; Ferro, Klein, Schwartz, Kasch, & Leader, 1998; Gutiérrez et al., 2012; Samuels et al., 2002; Segal, Hook, & Coolidge, 2001). Alternate explanations for these cross sectional findings are that the PD diagnostic criteria do not function as intended within an older adult sample (see Mroczek, Hurt,

& Berman, 1999) or are perhaps latent during later adulthood. These are intriguing possibilities that we'll return to later in this chapter. The lower prevalence rates in older adults could also be attributable to the fact that PDs are going undetected, not being adequately captured by the diagnostic criteria, or remaining latent due to the changing contexts of later life.

There is no doubt that PDs are problematic when they exist at any point in a person's life (Segal, Zweig, & Molinari, 2012). They frustrate co-workers, disrupt important relationships, and play key roles in the development of many Axis I disorders (Segal, Coolidge, & Rosowsky, 2006). Our understanding of their implications, however, has been largely limited to their examination in early adulthood. How do PDs rear their heads in later life? What are the late life consequences of having a PD? What are the effects of PDs on individuals, their families, and the healthcare system (see Segal, Hersen, Van Hasselt, Silberman, & Roth, 1996)? Currently, we cannot answer these questions definitively because PDs have not been studied extensively in later life (Agronin & Maletta, 2000). But considering the nature of PDs and how they affect younger adults, one would hypothesize that PDs should have very dire consequences in later life. After all, PDs are long, enduring styles of interacting with others and viewing oneself that lead to key social dysfunctions (APA, 2000).

There is some preliminary data and anecdotal evidence suggesting that PDs may cause severe dysfunction in late life. Consider the Cluster A PDs, such as paranoid PD. One can imagine a young man with a certain amount of paranoia. This young man may not be functionally impaired because he has a healthy body and can engage in some amount of self-protection in public if needed. But consider this same man at a much older age. As an older man, he may be relatively frail and this might lead his paranoia to become dysfunctional—he may find himself trapped in his home, afraid to go out now that he can no longer defend himself against an imagined threat. So it would be in late life that the PD might cross some threshold of dysfunction for the first time in a person's life (see Balsis, Gleason, Woods, & Oltmanns for a discussion of this case example).

Cluster B disorders, such as narcissistic PD, can also lead to increased dysfunction in later life (see Rosowsky & Smyer, 1999 or Siegel & Small, 1986, for relevant case studies). In one case study, an older narcissistic woman continued to experience interpersonal problems that left her vulnerable in later life (Balsis, Eaton, Cooper, & Oltmanns, 2010). She reported an overturn in her social network not seen in regular *aging*. She had difficulty maintaining relationships and found herself facing the challenges of later life with no close family and many broken relationships in the past. As physical illness set in, even the simple tasks of recovering from an illness was somewhat difficult for her because she had no one to rely on for help.

Cluster C disorders, such as obsessive-compulsive PDs, can reveal similar difficulties in late life (see Segal, et al., 2006, pp. 124–136). Consider a woman with obsessive-compulsive PD who has a high need for control. When this woman with obsessive-compulsive PD enters late life, she may face health changes that are largely out of her control. In an effort to gain a sense of control, the older woman with obsessive-compulsive PD may begin to demonstrate marked dysfunctional behaviors and experience relationship problems. For example, she may squander money and time on excessive physician appointments and take out additional but unnecessary insurance policies. She may also experience more strained relationships with adult children. Her previously acceptable need to control her own children's behaviors, for example, may become dysfunctional after those children have grown up and become independent. These relationships may become particularly strained as the older woman's need for control becomes more inappropriate in late life.

People with avoidant PD (another Cluster C PD, Segal et al., 2006, pp. 104–117), may also experience increased dysfunction in late life. Unlike those with obsessive-compulsive PD, those with avoidant PD may be unlikely to visit the physician even when they should, due to fear or anxiety. Imagine a man with avoidant PD. As a young man, his avoidant PD may not lead to significant health problems or dysfunction. The decision not to go to the doctor might not have had major consequences because, as a young man, he was probably fairly healthy. But, as an older adult with potentially more health needs, the avoidant PD may become dysfunctional for the first time in this man's life. In essence, age becomes the proverbial straw that breaks the camel's back. For this man, his health issues were growing quietly in early life, and it wasn't until later life that those issues became clinically significant. As these anecdotes and case studies illustrate, personality pathology can have unique pathways to dysfunction in later life.

In addition to the anecdotal evidence and case study evidence that PDs cause dysfunction in later life, there is also relevant research demonstrating that poor social relationships are associated with functional impairment, mortality, and disease (Morack, Ram, Fauth, & Gerstorf,

2013; Rosland, Heisler, & Piette, 2012; Tomaka, Thompson, & Palacios, 2006). By definition, people with PDs have poor social relationships, so it is possible that the presence of a PD is a major mediating factor in the link between poor social relationships and disease and between poor social relationships and mortality. For example, a systematic review of dozens of studies revealed that those with relatively poor support had worse disease-related outcomes, including increased mortality (Rosland et al. 2012). It is quite possible that many of the older adults with poor social support across these studies had significant personality pathology and, thus, clear difficulty cultivating and maintaining a strong social support network. These data and other data from the social support literature offer promising leads for PD researchers interested in connecting PDs to some of the most important health outcomes.

In addition to examining disease and mortality as outcomes, we also can examine how PDs contribute to societal burden (cost in terms of money and other resources). We know that older adults are much more likely to have diseases than are younger adults. And we know that people with PDs are more likely to have diseases and to cost the system more than their peers (Gish et al., 2001; Spiessl, Hubner-Liebermann, Binder, & Cording, 2002; Whiteman, Deary, & Fowkes, 2000). Because older adults are the largest users of the healthcare system and represent much of the cost, older adults with PDs likely cost the system disproportionately more. Supporting evidence for the hypothesis that older adults with PDs place an increased burden on society comes from clinical accounts of older adults attempting to use the health care system (see Rosowsky & Smyer, 1999). Indeed, the 'difficult patient' as Rosowsky and Smyer call them, very well may be the patient with a PD, placing unjustifiable demands on staff members that they can't meet, and responding in disruptive ways to staff and other patients. In sum, these patients tend to wreak havoc on the staff and sometimes on the other patients, require special attention, more time, and can disrupt functioning of even a well-run medical unit.

The discussion thus far suggests that PDs can lead to significant problems in later life. Yet, there is little research directly examining the effect of PDs on late life outcomes. One major study is beginning to comprehensively examine the effect of PDs in later life. The St. Louis Personality and Aging Network (SPAN) study (see Oltmanns, et al., 2014) is one such study that may yield important insights into how PDs in late life affect important psychological and health outcomes. The SPAN study is a prospective, longitudinal study designed to examine personality stability and change over time, as well as the impact of personality pathology on later life outcomes. The main goals of the project are to examine the connections between PDs, health, and social adjustment in a representative, community-based sample of 1,600 people between the ages at intake of 55 and 64. This sample is particularly interesting because the participants in the sample are at a critical age—an age when many people begin to meet the challenges of later life. Results from the SPAN study are promising and are revealing ways PDs and PD traits influence older adults' ability to adapt successfully to important life transitions. The study is also revealing ways that PD traits give rise to certain health consequences. For example, forthcoming results indicate that PDs are associated with serious health problems, diseases such as diabetes and heart disease, and life stressors. The results that are beginning to emerge from the SPAN study are ground-breaking and some of the first to demonstrate a link between PDs and late life health outcomes. But, several questions remain. For example, research will need to examine *how* PDs lead to poor health outcomes, which poor health outcomes, how much PDs cost society, how they affect families, and what can be done to treat them.

Clearly, it will be important to study PDs in late life to answer these questions. But there are significant challenges to studying PDs in late life. First, fundamental measurement issues will need to be addressed. These are measurement issues that plague all PD research, but that are particularly marked when researching PDs in late life (see Zweig, 2008). We turn next to the *DSM* classification of PDs, before discussing specific measurement limitations in both early and later life populations.

The *DSM* Diagnostic Approach

A recent version of the *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM-IV-TR* (APA, 2000) described PDs within a categorical system differentiating 10 individual PDs. This classification system for the PDs has suffered much criticism, including concerns regarding excessive comorbidity both within Axis II and across Axis I and II diagnoses, symptom overlap across disorders, a clustering scheme that has not been empirically supported, and within-category diagnostic heterogeneity (e.g., Clark, 2007; Shiner, 2009; Tackett et al., 2009). The general consensus in the field regarding many of these concerns led to a number of innovative proposals for the PD section in preparation for *DSM-5*. For example, members of the work group discussed possible changes

to the *DSM-5* PD section that might have included the primary use of a dimensional PD trait taxonomy for characterizing and classifying individuals (e.g., Hopwood, Thomas, Markon, Wright, & Krueger, 2012) or the use of narrative-based prototypes for capturing existing PD diagnostic categories (e.g., Skodol et al., 2011). These and other provocative and innovative suggestions resulted in great excitement and controversy in the years leading up to the publication of *DSM-5* (Widiger, 2013). Despite the resulting controversy, it came as a great surprise to most of the field to learn that *no* changes would be made to the PD diagnostic criteria between *DSM-IV-TR* and *DSM-5*, 13 years later (Krueger, 2013; Widiger, 2013).

Specifically, an executive decision resulted in rejection of the work group's various suggestions for change and improvement, such that the *DSM-IV-TR* PD categories and criteria were ultimately decided to be reproduced in their entirety in *DSM-5*, and some of the work group's proposals were also included in Section III (areas suggested for future research). Thus, we can anticipate many of the concerns that have plagued the field for decades now to remain, without a clear, practical solution in sight. These consequences are particularly impactful for the area of early PD emergence and development, as previous versions of the *DSM* have played a major role in limiting the capacity for empirical and clinical attention to early life PDs (Shiner, 2009). Furthermore, a dimensional PD model holds much greater promise for a life span developmental perspective on PDs as well as enhanced juxtaposition of normal and abnormal personality development according to a developmental psychopathology perspective (Tackett et al., 2009).

Thus, the review of literature in the current chapter retains the organizational system published in *DSM-IV-TR* and reprinted verbatim in *DSM-5*. Ten PDs are organized into three clusters: Cluster A, Cluster B, and Cluster C. Cluster A disorders include schizoid, schizotypal, and paranoid PDs. Cluster B disorders include borderline, antisocial, narcissistic, and histrionic PDs. Cluster C disorders include avoidant, obsessive-compulsive, and dependent PDs. No specific provisions are made for PDs at younger ages, although diagnoses prior to age 18 are discouraged (and practically, have been treated as largely restricted). We incorporate this existing scheme into the current chapter out of necessity, but instead of reviewing each disorder (or cluster) individually, we instead tackle those core underlying components that are central and cross-cutting to all PDs: traits, emotions, interpersonal relationships, and identity. First, however, we review measurement issues in assessing personality pathology in early and later life.

Measurement Issues in Childhood and Adolescence

Measurement of PD symptoms and characteristics in early life is in a nascent stage relative to PD assessment in adults. This measurement lag is both a cause and consequence of the overall lack of empirical attention historically paid to PD in early life, relative to empirical attention to PDs in adulthood (Tackett, 2010; Tackett et al., 2009). Certainly, empirical research on child and adolescent PD is hindered by lack of proper approaches to measurement, which should be considered a prerequisite to better understanding the etiology, phenomenology, developmental course, and clinical outcomes of early PDs (Tackett, Herzhoff, Reardon, Smack, & Kushner, 2014). With increased attention turning toward early PDs (as seen in multiple recent special issues devoted to this topic: e.g., Paris, 2013; Cicchetti & Crick, 2009; Stepp, 2012; Tackett, 2010; Tackett & Sharp, 2014), we can and should anticipate more sophisticated, thoughtful, and comprehensive approaches to measuring PD characteristics in children and adolescents, as well.

As with many areas of youth psychopathology, assessment of youth PD has traditionally relied on methods most commonly used in adult populations—specifically, structured diagnostic interviews and questionnaires completed by the parent, self, or clinician (Tackett, Herzhoff, Reardon, Smack, et al., 2014). Questionnaires include broadly based measures that cover a wide variety of personality disordered traits as well as more specific questionnaires designed to assess a narrowly defined domain (e.g., borderline: Crick et al., 2005, or narcissistic: Barry, Frick, & Killian, 2003, characteristics). Among broad, omnibus measure of PD traits, most involve adaptations of adult PD measures, with a recent focus on developing empirically based measures derived specifically for younger populations.

Omnibus questionnaire measures of PD characteristics have been frequently used in adult populations. Such measures possess a number of advantages, including their ability to measure multiple domains of PD characteristics simultaneously, efficiency, and low-cost of administration, and strong psychometric properties. A number of notable examples exist of adult PD questionnaires that have been modified in some way (e.g., for language and developmental appropriateness) to be used in younger age groups: the adolescent version of the Minnesota Multiphasic Personality Inventory, or MMPI-A (Butcher

et al., 1992; Sellbom & Jarrett, 2013), the adolescent version of the Dimensional Assessment of Personality Pathology, or DAPP-BQ-A (Tromp & Koot, 2008), and the youth version of the Schedule for Nonadaptive and Adaptive Personality, or SNAP-Y (Linde, Stringer, Simms, & Clark, 2013). Although—from a developmental standpoint—measures adapted down from adult use may not be ideal, these measures have served important functions in rapidly accelerating empirical research on early PD characteristics and facilitating continuity of findings across youth and adult samples. However, it remains important for measurement approaches for early PD to retain developmental sensitivity as well: those constructs relevant for adult PD may not all be relevant for youth and, likewise, some constructs relevant for youth PD may go unnoticed by researchers and clinicians working with adult PD.

Developmentally derived bottom-up measures highlight the need to examine empirically based PD constructs using different age groups as the *starting* rather than *ending* point. This approach allows developmentally relevant constructs to emerge, and less developmentally relevant constructs to recede, in the process of scale construction. The most prominent current example of such a measure is the Dimensional Symptom Itempool or DIPSI (De Clercq, De Fruyt, Van Leeuwen, & Mervielde, 2006). The DIPSI was constructed from raw data on child and adolescent populations, using items that emerged from the developmental literature as well as work on adult PDs. The higher order structure of the DIPSI comprises 4 domains: Disagreeableness, Introversion, Emotional Instability, and Compulsivity. Not only do these domains appear largely analogous to higher order factors from adult measures (e.g., the DAPP-BQ and the SNAP), but recent research suggests that these domains are hierarchically related to the SNAP-Y in meaningful ways and evidence both convergence and divergence with SNAP-Y scales (Kushner, Tackett, & De Clercq, 2013).

An issue that is not new to child psychologists of any domain is the conflict that emerges between a desire to collect multi-source, multi-informant data on our constructs of interest and the inevitable discrepancies that ultimately arise from different sources and different informants (Achenbach, McConaughy, & Howell, 1987). The area of youth PD is not immune to these broader concerns (Tackett, Herzhoff, Reardon, Smack, et al., 2014), as various informants and sources often correlate moderately, at best (Sharp, Mosko, Chang, & Ha, 2010; Tackett, Herzhoff, Reardon, Smack, et al., 2014). Furthermore, concerns over adult self-reports regarding PDs have previously resulted in researchers cautioning against sole reliance on self-report of PD, even at older ages (Klonsky, Oltmanns, Turkheimer, 2002; Oltmanns & Turkheimer, 2009). Indeed, recent empirical research using both parent and youth self-report have pushed back against the idea that self-report may serve as a gold standard for PD measurement: in one study, parent reports of youth PD traits moderated hormonal associations with psychopathology, but youth self-reports of PD traits did not (Tackett, Herzhoff, Josephs, Harden, & Page-Gould, 2014). More explicit efforts to disentangle informant discrepancies for youth PD are beginning to emerge (Tackett, Herzhoff, Reardon, Smack, et al., 2014), but much more work is needed to fully understand how best to integrate information from multiple sources and multiple informants in the assessment of youth PD. In the meantime, we encourage researchers and clinicians to collect multi-method, multi-informant data when possible but retain a more nuanced approach to integrating information as opposed to reductionist methods of aggregation (e.g., creating averages across informants). Not only does each method and source potentially contain valuable information, but the discrepancies among them may also be useful and predictive of later outcomes (e.g., De Los Reyes, 2011; Tackett, Herzhoff, Reardon, Smack, et al., 2014).

Measurement Issues in Later Life

Turning to measurement issues for PDs at older ages, it is important to consider those fundamental measurement issues in the assessment of PDs which exist across all age groups—not just later life. These measurement problems impede our understanding of PDs and personality pathology in general. One problem is that the diagnostic thresholds—the number of criteria needed to meet diagnosis of a PD—are imperfect markers of personality pathology and somewhat arbitrary (Clark, 1992; Hyman, 2002; Livesley, Schroeder, Jackson, & Jang, 1994; Oldham, 2007). Why are patients eligible for a diagnosis of avoidant PD when they meet 4 of 7 criteria but not 3 of 7? Another fundamental measurement issue that limits our understanding of PDs in general has to do with the general approach that is used to assess PDs. Currently, much of the field uses a categorical approach to identifying the PD—one is either categorized as having or not having a PD based partly on the number of criteria they meet (Krueger, Skodol, Livesley, Shrout, & Huang, 2007). However, there is good evidence to suggest that personality pathology might be best described dimensionally (a person has degrees of PD pathology), rather than

categorically (the person either does or does not have a PD). We will return to these two fundamental assessment issues—the issues of thresholds and a categorical vs. dimensional approach— later in the chapter and describe how they are particularly problematic for studying PD in late life. Next, we describe additional measurement issues in assessing PDs. We comment on how each of these measurement issues make difficult the assessment of PDs across all age groups, and how some of these measurement issues are particularly marked for assessing PDs in later life.

We briefly noted that there are conceptual problems with using thresholds to categorize people as either having a PD or not, but there are additional problems with the criteria themselves that are particularly troublesome when applied to individuals entering later life. The criteria for meeting each PD were created with a younger adult in mind (Mroczek et al., 1999; Segal et al., 2012). When applied to older adults, the items have relatively poor face validity. Several of the problematic items have been described elsewhere (Rosowsky, Abrams, & Zweig, 1999), but one example comes from the criteria for avoidant PD. One criterion for meeting avoidant PD is that the person, "*avoids occupational activities*. . . " (APA, 2000, p. 721). This item may work well enough to identify avoidance in a younger adult, but in an older, retired adult it does not work as well. A younger adult with severe avoidant PD pathology might endorse this item for reasons having to do with the person's PD. In contrast, an older adult with a similar level of avoidant PD pathology might not endorse the item because the older adult is retired. This means that an older adult could respond negatively to all probes like this one that are designed to assess the PD pathology, simply because of the context of the probe—having to do with occupational activities—that no longer applies to the older adult. Because of problems with this and other items, one could gain an inaccurate picture of an older adult's level of PD pathology. In larger research studies of many older adults, one might incorrectly infer that avoidant PD pathology decreases in older adults, simply because they are less likely to endorse some items because of their age (Balsis, Woods, Gleason, & Oltmanns, 2007).

The problems with face validity do not solely reveal themselves for the diagnosis of avoidant PD, but they are pervasive across many of the 79 diagnostic items (Segal et al., 2006). Items such as the one for schizoid PD, "has little . . . interest in . . . sexual experiences with another person" (APA, 2000, p. 697), may also fail to capture PD pathology in older adults. Whereas this item might be strongly related to schizoid PD pathology in younger adults, it might be less strongly related to schizoid pathology in older adults. A younger adult who endorses this item might have high levels of schizoid PD pathology. Because there are not many obvious alternative explanations for why the person might endorse this item (that would not apply to all other age groups), the relationship between the construct of interest and endorsement of this item in this age group is strong. For older adults, however, the relationship might be more tenuous. An endorsement might represent side effects of medications, physiological changes that prevent certain sexual capacities, different hormonal levels, or even lack of partner availability. So for older adults, an endorsement of this item might be related to schizoid PD, but it also might be related to a number of other age associated factors.

In addition to these specific examples, a recent study revealed that approximately half of the PD criteria may contain measurement bias across younger and older age groups (Balsis, Gleason, et al., 2007). A follow-up study revealed that the measurement bias may actually lead to problems diagnosing similar levels of PD severity across individuals from different age groups (Balsis, Woods, et al., 2007). Thus, problems with poor face validity can lead to failures to diagnose personality pathology in older adults (Zweig & Parchi, 2010). Poor face validity can also lead to other measurement errors. For example, having items with poor face validity means that a measure will have poor internal consistency as indicated by alpha reliability. If the PD criteria have high face validity for younger adults, then the ratings across items will likely reflect the core dimension of interest and alpha reliability may be relatively high. However, if the PD criteria have relatively poor face validity, as is the case for older adults, then ratings across items will be less likely to reflect the core dimension of interest. If this is the case, then the alpha reliability of the measure will be lower. Similar problems arise with inter-rater reliability and different aspects of validity.

A recent study examined all 79 diagnostic criteria (plus criteria for provisional PDs) across the adult life span, and reported changes for those criteria between approximate ages 20 and 50 (Gutiérrez et al., 2012), suggesting that PDs change with age. The table in the article (p. 769) shows the items ranked in order from the ones that showed the greatest decrease across progressive age groups to the ones that showed the greatest increase across progressive age groups. While these data have been taken as evidence that PD

features change with age, an examination of the extreme items (the greatest decreasing items and greatest increasing items) suggests that these items are likely picking up on changes in age rather than changes in PD pathology. For example, three of the five items with greatest increase in endorsement with age are schizoid items. The two with the greatest increases are "No close friends" (p. 769) and "No interest in sex" (p. 769), an increase in these endorsements probably do not reflect an increase in people becoming more schizoid in middle age, but simply a reflection of that context of middle adult life relative to the context of early adult life. The other items among the top five that increased with age were for obsessive-compulsive PD. These items were workaholism (p. 769) and stinginess (p. 769). Here again an increase in the likelihood of endorsing these items with age seems to reflect more about that person's life circumstance during middle age rather than an increase in obsessive-compulsive PD pathology. Increases in these items then drive the increase in diagnosis of these two disorders (schizoid and obsessive-compulsive PD), making it appear as though people are changing in terms of their PD pathology along these dimensions. Instead, it is likely the case that endorsement of these items (and the apparent increase in pathology) along these two dimensions merely reflects changes in life stage.

On the other end of the spectrum are the items that were endorsed less frequently with age. Five of the first six are items for antisocial PD, which corresponds with the dramatic decrease in antisocial PD diagnoses into middle adulthood and later life. For example, the item about having reckless disregard for one's safety is endorsed less often as people age, but here again one might consider the possibility that people with antisocial PD adopt different strategies as they age to express their antisocial personality pathology (see Oltmanns & Balsis, 2011 for a relevant case study). The PD item with the biggest change is the one for narcissistic PD, Fantasizes about unlimited success. People who are older are less likely to endorse this item, but here again, this decreased endorsement might not represent a change in baseline narcissism, but rather a reconstitution of it. Older narcissists might be less likely to *look forward* and fantasize about *future* successes than younger narcissists simply because of their advanced age. Instead, older narcissists may reinterpret their current life's circumstance (regardless of how rosy it is) as evidence of success. The overall findings from this paper (Gutiérrez et al., 2012) showed an overall decrease in PD pathology. However, we suggest that this overall trend may simply reflect a problem with the criteria. Unfortunately, data that appear to show a mellowing or a decrease in PDs in late life create the perception that PDs aren't important in later life, which may have the unfortunate consequence of keeping researchers from examining PDs disorders in later life.

Thus, we have seen how many of the criteria may not work well for measuring PDs in later life. One solution is to rewrite the items for older adults. This would mean that younger adults would have one set of diagnostic criteria and older adults would have a different set. At a certain age, which would be difficult to define, a clinician would opt to use the later life diagnostic criteria. Having two different sets of criteria is a tempting proposition, but introduces multiple problems such as meaningful longitudinal comparison, determining the age at which criteria sets would switch, and the need to recognize that older adults are but one example of special populations and creating alternative item sets for multiple groups is not feasible.

Another solution is to retain the individual items but weight them differently across age groups. This means that one would apply the same items to younger adults and older adults, but weight the responses according to the ability of those items to differentially identify the latent trait across the age groups. Clinicians could enter into a computer or a personal digital assistant (PDA) the age of the participant (and other demographic variables for more sophisticated weights that take into consideration different demographic influences on item function) as well as the pattern or symptoms for that individual, and the software could instantly reference the literature and report to the clinician where the client stood along the given dimension of interest. The dimension could potentially be calibrated to be identical across members of different age groups, ethnicities, genders, or other variables (for example, inpatient vs. outpatient). This is a potentially viable solution that would ameliorate measurement problems for older adults and bring a certain degree of consistency to PD measurement that has not been observed previously.

A third solution is to consider PDs at another level of analysis. The *DSM* criteria operate at a very contextually rich behavioral level; "avoids occupational activities," "has recurrent suspicions . . . regarding fidelity of spouse or sexual partner," and " . . . aggressiveness, as indicated by repeated physical fights or assaults" are such examples. Each of these items describes a personality style or response that reflects a personality trait in action in a particular context. As we described earlier,

many of the *DSM* items lack face validity for use with older adults because they tend to include a younger adult context in their wording. Therefore, one may be able to circumvent this problem by using items that do not contain any context. The item, "avoids occupational activities" would simply become, "is avoidant." Similarly, the item, "has recurrent suspicions . . . regarding fidelity of spouse or sexual partner," could become "is suspicious," and " . . . aggressiveness, as indicated by repeated physical fights or assaults" could become, "aggressive (broadly defined)." A likely consequence of such a change would be decreased reliability of symptom-level measurement, but it remains an important alternative to consider.

A trait approach to understanding PDs might be the right level of analysis, as traits tend not to be linked as strongly to any particular context and have more advantages in developmental research, as previously discussed in this chapter. Researchers have argued that existing measures designed to assess personality traits are sample invariant across age—that they measure the traits equally well in younger and older adults (see Allemand, Zimprich, & Hendriks, 2008). While this possibility of using existing trait measures to examine personality pathology across the life span seems appealing, a close look at some of the extant literature reveals at least relatively small measurement imprecision. With that small caveat in mind, the broader trait measures clearly show many fewer measurement problems across age groups and over time (Allemand, Zimprich, & Martin, 2008). Items on an ideal measure would be vetted for invariance *before* the measure becomes available to the community of researchers. We next turn to discussing core cross-cutting components of PDs—traits, emotions, relationships, and identity—in early and later life.

Components of PD

Traits: Early Life

As mentioned earlier, both abnormal and normal personality traits can be reliably assessed during childhood (e.g., Paris, 2003; Rothbart & Bates, 2006), are moderately stable during this early developmental period (e.g., Roberts & DelVecchio, 2000; Stepp et al., 2010), and their stability is largely heritable (e.g., Bornovalova et al., 2009; De Fruyt et al., 2006). These similarities, along with the finding that abnormal personality changes *follow* changes in normal personality in adults (Warner et al., 2004), underline the important role that traits play in the early development of PDs. In fact, PD preventions targeting youth based on their normal personality traits have already shown great utility in diminishing the development and severity of adolescent PDs (e.g., Chanen et al., 2008). PD counts based on the FFM of normal personality have also shown discriminant validity in screening PDs and psychopathy in youth (Decuyper, De Clercq, De Bolle, & De Fruyt, 2009). Despite their key role in defining PDs, abnormal personality traits have been distinguished from PDs by emphasizing two additional components needed to conceptualize PDs beyond abnormal traits (Livesley & Jang, 2000; Verheul et al., 2008). Specifically, PDs involve dysfunctional cognitions about the self and others (Fonagy & Bateman, 2008) as well as interpersonal dysfunctions, both of which we discuss later, and which are not typically well-represented in trait models (normal or abnormal). Here, we broadly summarize findings on relationships between traits and PDs in youth by considering contributions from normal personality traits, omnibus abnormal personality trait models (e.g., DAPP-BQ, DIPSI), and additional narrowly defined traits that have been connected to youth PD (e.g., callous/unemotional traits).

A limited number of studies have investigated the relationship between normal personality traits and Cluster A features. Of the studies that have investigated correlates of Cluster A features, most have found that Cluster A features are associated with characteristics such as odd speech (Carlson & Fish, 2005), having unusual fantasies (Wolff, 1991), showing unconventional verbal responses (Caplan, 1994), and holding paranormal beliefs (Hergovich, Schott, & Arendasy, 2008). In FFM terms, these characteristics could arguably be summarized under the personality trait openness to experience. Other studies have also found youth Cluster A features to be associated with an absence of close friends, suspiciousness (Carlson & Fish, 2005), being described as loners (Wolff, 1991), and experiencing paranoia (Rutter, Kim-Cohen, & Maughan, 2006), potentially suggesting lower scores on the FFM trait extraversion or agreeableness. In fact, in a sample of adolescents, at the higher order personality trait level, Cluster A PD symptoms have been most consistently linked with low agreeableness and low extraversion (De Clercq & De Fruyt, 2003; De Clercq, De Fruyt, & Van Leeuwen, 2004). Interestingly, only schizotypal PD symptoms were found to show positive relationships with the higher order openness factor (De Clercq & De Fruyt, 2003; De Clercq et al., 2004) whereas schizoid PD symptoms were negatively associated with openness and paranoid PD symptoms showed no associations (De Clercq & De Fruyt, 2003), suggesting divergent associations among Cluster A PDs.

More studies have investigated the relationship between normal personality traits and Cluster B personality disorders; therefore, we will summarize findings separately for psychopathy, narcissism, and borderline PDs. With regard to psychopathy, studies have found that personality correlates of psychopathy in early life mirror those in later life (De Clercq & De Fruyt, 2003; De Clercq et al., 2004; Lynam et al., 2005; Salekin, Leistico, Trobst, Schrum, & Lochman, 2005). Specifically, at the higher order personality trait level, psychopathy is associated with low agreeableness and conscientiousness as well as high neuroticism in adolescence. Furthermore, at the lower order trait level, psychopathy is also associated with low inhibition—indicating low conscientiousness—as well as high activity, dominance and sociality—indicating high extraversion—and high coldness and low compliance—indicating low agreeableness—(e.g., Glenn, Raine, Venables, & Mednick, 2007; Le Corff & Toupin, 2010). Furthermore, in contrast to adults, associations between psychopathy and anxiety or fearfulness seem to be more fluid in early years, with psychopathy characteristics being longitudinally associated with low fearfulness in early childhood (Glenn et al., 2007) but with high anxiety in adolescence (Salekin, Rosenbaum, & Less, 2008), and overall questions remaining regarding the nature of youth psychopathic traits in the context of anxiety.

With regard to narcissism, studies have found that—like other Cluster B disorders—it is associated with high aggression (Barry, Grafeman, Adler, Pickard, 2007)—indicating low levels of agreeableness. At the lower order personality trait level, narcissism is negatively associated with all agreeableness facets but positively associated with achievement striving yet negatively with concentration and perseverance—indicating diverse connections with conscientiousness facets (De Clercq & De Fruyt, 2003; De Clercq et al., 2004). More variability has been found in the association with self-esteem—indicating neuroticism—with some studies finding associations with low self-esteem and others finding no association (Barry et al., 2003; Barry, Thompson, et al., 2007; Thomaes, Stegge, Bushman, Olthof, & Denissen, 2008). These differences have led to suggestions that the association might change over time to the positive association typically found in adulthood (Barry, Grafeman, et al., 2007). In addition, associations between self-consciousness and narcissism may change depending on the extent to which comorbidity is accounted for. Specifically, when relevant personality facets were entered simultaneously to predict narcissism without partialling out comorbid psychopathology, self-consciousness was a positive predictor; however, when general psychopathology was partialed out, self-consciousness was a negative predictor, suggesting that low self-consciousness has a unique relationship with specific variance in narcissism (De Clercq & De Fruyt, 2003).

Most studies investigating the relationship between normal personality traits and PDs in youth have focused on borderline PD. All dysfunctional aspects of borderline PDs (i.e., relationship difficulties, identity disturbance, impulsivity, and affective instability) have been associated with normal personality traits although with different levels of coverage. Specifically, at the higher order personality trait level, relationship difficulties can be captured by low agreeableness, identity disturbance can be captured by low self-confidence and high Egocentrism, and impulsivity can be captured by low conscientiousness, whereas affective instability can be captured by high neuroticism (Tackett & Kushner, 2014). In fact, low agreeableness, conscientiousness, and extraversion, as well as high neuroticisms have been most consistently associated with borderline PD (e.g., De Clercq et al., 2004; Saulsman & Page, 2004). Overall, of the borderline PD dysfunctions, impulsivity seems to be best captured by normal personality traits whereas identity disturbance seems to be captured most poorly. At the lower order personality trait level, depression, impulsiveness, vulnerability, anxiety, and low self-confidence (indicating neuroticism), low trust, irritability, and low compliance (indicating agreeableness), and low persistence (indicating conscientiousness) have been found to predict borderline PD symptoms in youth over and above comorbid psychopathology (De Clercq, De Fruyt, & Mervielde, 2003; De Clercq et al., 2004). Furthermore, sensation seeking in childhood has also been related to borderline PD (Gratz et al., 2009), potentially explaining the increased risk of sexually transmitted diseases and other health issues that have been associated with the disorder (Chanen, Jovev, & Jackson, 2007). In terms of early temperament, both high activity—indicating extraversion—and high emotionality have been related to borderline PD (Carlson, Egeland, & Sroufe, 2009).

Many fewer studies have investigated the relationship between normal personality traits and Cluster C PDs. In fact, controversy exists over whether avoidant PD can even be clearly differentiated from social phobia in adolescence (Rettew, 2000). Of the studies that have investigated correlates of Cluster C PDs, most have found that adult avoidant PD is associated with diminished involvement in extracurricular activities, including athletics and other hobbies, as

well as diminished popularity, including a smaller number of positive relationships with adults, in childhood and adolescence—indicating low extraversion (Rettew et al., 2003; Skodol et al., 2002). In fact, at the higher order personality trait level, Cluster C PDs have been found to be most consistently associated with low extraversion and high neuroticism as well as with low Openness to Actions at the lower order personality trait level (De Clercq & De Fruyt, 2003). In addition, obsessive-compulsive PD shows strong associations with conscientiousness and its maladaptive variant Compulsivity even after partialling out comorbid psychopathology (Aelterman, Decuyper, De Fruyt, 2010). In terms of early temperament, increasing withdrawal, a possible predictor of avoidant PD, has been found to be most consistently associated with low resiliency, i.e., the inability to quickly adapt to changes in the environment (Eggum et al., 2009).

Normal personality traits can also be affected by maltreatment in childhood to take on pathological profiles. Specifically, childhood abuse has been linked with personality profiles that were lower in openness, conscientiousness, and agreeableness and higher in neuroticism and this maladaptive profile was relatively stable over a three-year period (Rogosch & Cicchetti, 2004). More generally, childhood maltreatment—including abuse of physical, sexual, and verbal nature, as well as neglect—has been linked with higher rates of PDs (Cohen, Crawford, et al., 2005; Guzder, Paris, Zelkowitz, & Marchessault, 1996; Johnson et al., 2001; Raine, 2006; Skodol et al., 2005; Zanarini et al., 2005). The mechanism by which this link operates seems to be maladaptive parenting succeeding the maltreatment in combination with other endogenous risk factors (Fonagy & Bateman, 2008).

Many PD measures assess a broad range of abnormal personality traits (Widiger & Simonsen, 2005), as previously described in this chapter. Similar to omnibus models of normal personality traits, these omnibus models of abnormal personality traits typically converge on analogous factor structures (e.g., Clark, 1993; De Clercq et al., 2003; Livesley & Jackson, 2009). Specifically, at the higher order trait level, omnibus models of abnormal personality traits usually include the four factors Emotional Instability, pathological Introversion, Antagonism, and Compulsivity and sometimes a fifth factor labeled Peculiarity or Psychoticism that captures Cluster A characteristics (Harkness & McNulty, 1994; Tackett, Silberschmidt, Krueger, & Sponheim, 2008). Studies using the Dimensional Assessment of Personality Pathology-Basic Questionnaire for Adolescents (DAPP-BG-A; Tromp & Koot, 2008) have found that the model's higher and lower order traits are related to *DSM-IV* PD symptoms in hypothesized directions. Specifically, referred adolescents with PDs scored higher on 11 of the 7 lower order scales and two of the four higher order scales compared with nonreferred adolescents, with the facets self-harm, identity problems, and emotional dysregulation showing the greatest effect. In terms of distinguishing between classes of adolescents referred for PDs and those referred for other problems, the scales self-harm, emotion dysregulation, suspiciousness, conduct problems, and dissocial behavior performed particularly well. Furthermore, similar to the incremental validity that normal personality trait facets show in the prediction of PDs (e.g., Reynolds & Clark, 2001), abnormal personality trait facets also showed incremental validity in predicting all PD symptoms, except for schizoid, schizotypal, and passive-aggressive PD symptoms.

Specific PD traits, such as callous-unemotional traits, have been conceptualized as a key component of psychopathy in youth alongside egocentricity and impulsivity (Barry et al., 2000; Salekin & Frick, 2005) and have been found to discriminate between youths scoring below or above clinical psychopathy cutoffs based on the FFM (Decuyper et al., 2009). Callous-unemotional traits in early life also predict psychopathy in adulthood (Burke, Loeber, & Lahey, 2007). Associations between callous-unemotional traits and omnibus models of abnormal as well as normal personality are similar to those associations with adult psychopathy, supporting the key role that those traits play in youth psychopathy (Decuyper, De Bolle, De Fruyt, & De Clercq, 2011; Latzman, Lilienfeld, Latzman, & Clark, 2013). Specifically, callous-unemotional traits are most consistently associated with low agreeableness/high Antagonism, and low conscientiousness/Compulsivity. Associations with neuroticism/Emotional Instability differed across studies, with a boys-only sample showing high neuroticism/Emotional Instability in relation to callous-unemotional traits (Latzman et al., 2013) and the mixed-gender sample showing low neuroticism/Emotional Instability in relation to callous-unemotional traits (Decuyper et al., 2011). In addition to associations with psychopathy, callous-unemotional traits have also been associated with high borderline and low sadistic traits, with self-serving cognitive distortions such as blaming others (e.g., Chabrol, van Leeuwen, Rodgers, & Gibbs, 2011), and with low reward and punishment responsivity (Marini &

Stickle, 2010). Additionally, although both normal and abnormal personality traits predict unique variance in callous-unemotional traits, callous-unemotional traits showed incremental prediction of general psychopathology symptoms in a large community sample (Moran et al., 2009). Thus, normal and abnormal personality traits clearly play a critical role in the manifestation, development, and outcomes associated with personality pathology in early life.

Traits: Later Life

Numerous studies suggest that significant relationships exist between the five-factor model of personality (i.e., neuroticism, extraversion, openness, agreeableness, and conscientiousness) and the *DSM-IV-TR* PDs in adults. Specifically, in a meta-analysis, Saulsman and Page (2004) found that neuroticism was positively related and agreeableness was negatively related to many PDs, with the neuroticism factor showing the highest mean correlation with PD categories. As stated elsewhere in this chapter, self-reported neuroticism/negative affect may decrease across the life span (Roberts et al., 2006; Mrozcek & Kolarz, 1998), but there is evidence that those who score high on neuroticism follow a different trajectory. Rather than decrease with age, high-scorers in neuroticism are less likely to experience the positive changes that frequently accompany the aging process (see Charles & Carstensen, 2009). In other words, individuals who score high on neuroticism likely remain high on neuroticism, even into old age, which could have implications for later PD stability and impairment.

It could also be that the age-related decline of neuroticism and negative affect is simply an artifact of the aging process. As individuals age, their life contexts change, such that they likely spend more time alone due to retirement, the empty nest, the potential death of spouses, and declines in physical abilities which prevent mobility. In this lower activity context, an older individual may not feel particularly neurotic or disagreeable, and therefore not report it. In social situations or engagement with the healthcare system, however, these latent personality attributes will likely reemerge. So, it may not be that individuals actually decrease in neuroticism and increase in agreeableness, as the observed data suggests, but that the context of older adulthood changes to make the experiences of these traits less frequent and less salient for older adults, and when life events present themselves, their latent pathology will reemerge. Thus, traits remain a critical component of PD development across the life span.

Emotions: Early Life

Another component that plays an important role in the early development of PDs is emotion and emotion regulation. Emotion dysregulation can be described as a person's inability to modulate the duration, intensity, or timing of their emotions. That is, rather than referring to the content of emotion, emotion dysregulation describes a person's response to their emotions (e.g., Gratz et al., 2009). Different PDs in youth have been hypothesized to be associated with different forms of dysregulated emotions. Specifically, Cluster B PDs have been hypothesized to be characterized by underregulated emotions, Cluster C PDs by overregulated emotions, and Cluster A PDs by a general lack of emotional responses (Shiner & Tackett, 2014). Empirically, for instance, the Cluster B borderline PD has been linked with rage and a tendency to feel overwhelmed by emotions (Reich & Zanarini, 2001) whereas the Cluster A schizophrenia spectrum has been characterized by constricted affect in childhood and adolescence (Carlson & Fish, 2005). Despite these hypothesized links between emotions and PDs across clusters, most empirical research on youth emotions has focused on links with borderline PD, with fewer studies focusing on psychopathy and almost none on other PDs in childhood and adolescence. Therefore, we focus here mainly on summarizing findings on the relationship between emotions and borderline PD, as well as psychopathy.

Borderline PD has been most strongly linked with emotion dysregulation in childhood and adolescence. In fact, structural models of borderline PD in youth include affective instability as one of the disorder's defining components (Becker, McGlashan, & Grilo, 2006) and Linehan (1993) postulates that most borderline PD symptoms are caused either directly or indirectly by dysregulated emotions or maladaptive attempts to modulate emotional reactions. Empirically, moodiness in infancy, emotionality and emotional sensitivity in early childhood, and emotional instability in middle childhood and adolescence have all been associated with later borderline PD symptoms in adulthood (e.g., Carlson et al., 2009; Crick et al., 2005; Goodman et al., 2010). Retrospective reports suggest that adults with borderline PD had greater difficulties with emotion regulation in their early years than did adults with other PDs (Reich & Zanarini, 2001). Compared with adults, children experience emotions such as anger and moodiness (that have been associated with borderline PD) more frequently (Zanarini et al., 2011).

Despite self-reported greater emotional sensitivity in childhood, adolescents with borderline personality pathology appear to be no more accurate at identifying emotions than are healthy controls (Jovev et al., 2011). In fact, alexithymia—the tendency to have difficulty identifying and describing emotions (e.g., Taylor, Bagby, & Parker, 1997)—has been found to mediate the link between early attachment disruptions and the development of borderline PD in adolescence (Deborde et al., 2012). Such early attachment disruptions may provide children with inadequate opportunities for the development of emotion regulation (including accurately identifying emotion), which in turn increases a child's likelihood of developing borderline PD later in life (Fonagy & Bateman, 2008). Emotion dysregulation also partially mediates the effects of affective dysfunction in girls (but not in boys; Gratz et al., 2009) and theory of mind (Sharp et al., 2011) on borderline PD symptoms in youth. Interestingly, despite the important mediating role of emotion dysregulation for links between borderline PD features and symptoms, youth with borderline PD regulate their emotions no differently than healthy controls after a mild interpersonal rejection (Lawrence, Chanen, & Allen, 2011). Compared with healthy controls, though, youth with borderline PD reported more intense mood states across a range of negative and positive mood states, which suggests higher risk for experiencing emotions that are too intense to be effectively regulated (Lawrence et al. 2011).

Borderline PD and Cluster C PDs are linked with attention biases toward negative emotional words in adulthood (Arntz, Appels, & Sieswerda, 2000), suggesting that a hypersensitivity to negative emotion stimuli might be a cross-cutting factor underlying multiple PDs. In contrast, in adolescence, borderline PD has been associated with attention biases to negative emotional faces only when adolescents were in a negative mood, whereas it was associated with the reverse bias when the same adolescents were in a positive mood (von Ceumern-Lindenstjerna et al., 2010), underlining the importance of taking into account those individuals' current emotional state. At a neurological level, a smaller anterior cingulate gyrus—a brain area involved in gauging the importance of emotional stimuli as well as regulating emotions—has been associated with borderline PD in adults (Hazlett et al., 2005; Tebartz van Elst et al., 2003) as well as borderline PD and major depressive disorder comorbidity in adolescents (Goodman et al., 2011). Thus, emotions and emotion regulation clearly play a critical role in the development of borderline PD in early life, although more research is needed to fully understand the relations between these domains.

Compared with borderline PD, fewer studies have investigated the link between emotion and emotion dysregulation with youth psychopathy, although emotion has long been considered a core component in theoretical approaches to early psychopathy. Psychopathy is conceptualized as reflecting decreased emotional responses (Blair, Peschardt, Budhani, Mitchell, & Pine, 2006) and, as mentioned earlier, callous-unemotional traits have been conceptualized as a defining feature of psychopathy in children and adolescents (Frick & White, 2008). In a more recent study, however, researchers found that decreased response was specific to fearful emotions and did not generalize to other types of emotions, which is in line with links between psychopathy and impoverished fear learning, physiological responses to fearful stimuli, and identification of fear in peers (Marsh et al., 2011). For example, psychopathy has been associated with decreased electrodermal activity in response to distressing and threatening visual stimuli in children (Blair, 1999) and distressing white-noise bursts in adolescents (Fung et al., 2005).

Emotions: Later Life

Although results have sometimes been mixed, research has generally supported the conclusion that reported experiences of positive affect slightly increase across the adult life span and reported experiences of negative affect generally decrease across the adult life span (Carstensen, Pasupathi, Mayr, & Nesselroade, 2000; Mrozcek & Kolarz, 1998). Research also suggests that positive emotional experiences last longer and negative emotional experiences last for a shorter duration for older adults than younger adults (Carstensen et al., 2000). Additionally, John and Gross (2004) suggest that emotion regulation strategies generally improve with age, with older adults using more adaptive strategies (see also Carstensen, Fung, & Charles, 2003) and fewer maladaptive strategies to regulate their emotions. Like with personality traits, therefore, for the population in general it appears that the emotional lives of adults improve with age (e.g., Carstensen & Charles, 1998; Gross et al., 1997).

Contrary to this somewhat rosy picture, those with PDs likely experience as much or more negative emotions in later life and have more difficulty regulating their emotions than their normal counterparts. Charles and Carstensen (2009), for example, report that individuals who are high on neuroticism "do not experience age-related benefits in emotional functioning" that are frequently found to be characteristic of older adults (p. 399). As many PDs

are associated with neuroticism (Saulsman & Page, 2004), individuals with PDs are perhaps among the ones who do not experience the aforementioned age-related emotional benefits. This finding makes intuitive sense, as one might expect those with PDs to have a relatively difficult time learning from their previous socio-emotional experiences. Such individuals may not be able to optimize their emotional experiences like people with adaptive personality structures.

Interpersonal Relationships: Early Life

The third core component that plays an important role in the early development of PDs is interpersonal relationships. Indeed, the interpersonal context in which behavior arises has been proposed as one element (in addition to identity disturbances) that clarifies the difference between normal personality traits and PDs (Livesley & Jang, 2000; Verheul et al., 2008). Research on interpersonal relationships in PDs has focused primarily on two interrelated but distinct constructs: attachment and social cognition. Therefore, we focus here mainly on summarizing findings on links between attachment, social cognition and PDs. More recent research has also pointed to the importance of relational aggression in early personality pathology, so we will briefly discuss this here as well.

Attachment to a primary caregiver has been conceptualized as a mental representation of the child's relationship, environment, experience, and self (Shiner, 2010), that predicts adaptive and maladaptive trajectories and might explain later personality disordered behavior (Shiner & Tackett, 2014). Specifically, the representation of the child's early relationship with their primary caregiver is hypothesized to serve as a template for the child's future relationships and responses to their environment (Hazen & Shaver, 1987; Mikulincer & Shaver, 2007; Shiner & Tackett, 2014). Two dimensions of attachment have been identified by contemporary attachment theorists: (1) a person's preference for affiliation versus independence and (2) a person's tendency to feel secure or worried about a partner's availability (Fraley & Shaver, 2008). Adaptive attachment typically develops in infancy and early childhood, when children form patterns of insecurity and security based on their relationship with their primary caregiver (Mikulincer & Shaver, 2007). Consequently, infancy and early childhood are critical developmental periods for PDs (Tackett et al., 2009), consistent with the notion that PDs emerge early in life (Paris, 2003).

Although disrupted attachment is likely an important component in the development of many different kinds of PDs, theory and research has focused especially on its importance for the development of borderline PD (Levy, 2005; Westen, Nakash, Thomas, & Bradley, 2006). For example, adolescents with borderline PD have a higher prevalence of maladaptive attachment styles that include rejection and abandonment fears (Westen et al., 2006). Similarly, young children of mothers who have borderline PD represent the attachment with their parents in a more maladaptive way (Macfie & Swan, 2009). Specifically, these children narrate stories that include more negative expectations about the relationships with their parents, more abandonment fears, and more reversed roles between parents and children, than do children with mothers without borderline PD. In addition, attachment disorganization and maternal hostility in early childhood predict borderline PD symptoms later in adulthood (Carlson et al., 2009). More specifically, this association may be mediated by disturbances in youth's self-representation (Carlson et al., 2009) as well as alexithymia, the inability to identify emotions, in adolescents (Deborde et al., 2012). Maternal separation in early childhood also predicts both increases in borderline PD symptoms throughout adolescence and adulthood, as well as slower decreases in these symptoms over time, and this effect occurred over and above other risk factors such as abuse, risky parenting, and maternal problems (Crawford et al., 2009). Thus, theory and research converge on the importance of attachment for PD development in early life, although more empirical research is needed, especially research exploring other manifestations of early PDs beyond borderline PD.

In addition to the importance of attachment in the development of PD, researchers have also broadened their focus of self-other cognitions that affect the development of PDs. Examples of such self-other cognitions that affect children's interpersonal adjustment or maladjustment include beliefs around how flexible their own behavior is, perceptions of others' intentions, perceptions of their self-competence, and experiences of alienation from their peers (Shiner, 2009; Tackett et al., 2009). Specifically, interpersonal problems for people with PDs often arise because they misperceive others' motives and emotions (Tackett et al., 2009). In other words, they have difficulty empathizing with others and using the knowledge gained from empathy to guide their behavioral responses. Examples of misperceptions of others' motives might include unreasonable abandonment fears in dependent PD or paranoid beliefs about other people in paranoid PD. Interpersonal problems for people with PDs also often arise because they misperceive the nature of their relationships with other

people and consequently misjudge the appropriateness or inappropriateness of their own behavior (Tackett et al., 2009). For example, individuals with PDs might maintain too much or too little distance from other people, for instance, in relationships with romantic partners. In addition, their rigidity and inflexibility can often worsen their interpersonal problems because people with PD have difficulty adapting to social challenges (Westen & Heim, 2003).

Especially relevant for the development of a diverse variety of personality pathology in youth are the following three components of social cognition: (1) trust, (2) theory of mind (or mentalizing), and (3) emotion recognition (Sharp, 2012a). For example, in youth, hypomentalizing has been associated with antisocial PD, whereas hypermentalizing has been associated with borderline PD (Sharp, 2012b). In an adolescent sample, the relationship between borderline personality traits and hypermentalizing (i.e., over-interpreting others thoughts and motives) was mediated by emotion regulation (Sharp et al., 2011). Deficits in social cognition, such as differentiating and integrating one's self perspective with others', is also associated with borderline PD in adolescence and early adulthood, over and above attachment disturbance (Jennings, Hulbert, Jackson, & Chanen, 2012). These deficits generalized across social situations and were not specific to those that are most relevant to borderline PD, such as situations of abuse, deprivation, or abandonment.

Apart from borderline PD, deficits in self-other cognitions are also relevant to the development of other PDs. For example, although some studies have found that children with psychopathic traits have a normative number of friends, they have also found that those children perceived conflict in their friendships more so than their partner did, suggesting that children with psychopathic traits might be biased in their social-cognitive processes (Muñoz, Kerr, & Bešic, 2008). Despite these biases, friendships were still found to be protective against delinquent behavior in children with psychopathic features. Furthermore, in the case of narcissistic tendencies, differences in children's motives have distinguished between adaptation and maladaptation, where children with communal motives (e.g., motivations toward affiliation and altruism) tend to have adaptive self-esteem whereas children with agentic motives (e.g., motivations toward power and autonomy) tend to have high self-esteem marked by maladaptive narcissistic tendencies (Thomaes et al., 2008). Finally, positive schizotypy has been negatively associated with theory of mind performance, but persecutory delusions and impulsivity were positively associated with theory of mind performance in adolescence (Barragan, Laurens, Navarro, & Obiols, 2011). The role of social cognitive processes remains an important area for future research in early PD development.

Relational aggression (also referred to as social or indirect aggression) is aggressive behavior intended to damage one's social status or interpersonal relationships (Crick & Grotpeter, 1996). The role of both perpetrator and victim in the context of relational aggression appears to be important in the development of PDs, most notably borderline PD. In fact, relational aggression has been conceptualized as an early indicator of borderline PD (Crick et al., 2005; Rogosch & Cicchetti, 2005), although recent research suggests it may be more central to externalizing PDs broadly conceived and show some specific links to narcissistic tendencies (Tackett, Herzhoff, Reardon, De Clercq, & Sharp, 2014). Engagement in social and physical aggression in middle childhood predicts borderline (and narcissistic) personality features in adolescence, regardless of whether these forms of aggression generally decreased with age (Underwood, Beron, Rosen, 2011). Beyond typical externalizing PDs, adolescents with paranoid PD increase faster in their use of peer bullying from childhood to adolescence, suggesting that relational aggression plays an important role in the development of that disorder as well (Natsuaki, Cicchetti, & Rogosch, 2009). Furthermore, those adolescents were also rated as likely to initiate fights, unlikely to be leaders, and likely to be viewed as uncooperative by their peers.

On the other hand, being a victim of peer bullying via both relational and physical aggression in childhood appears to increase risk for the development of borderline PD symptoms (Wolke, Schreier, Zanarini, & Winsper, 2012). Peer victimization (via relational and physical aggression, verbal aggression, and aggression against property) is also a risk factor for the development of schizotypal personality characteristics in schoolchildren between 8 and 16 (Fung & Raine, 2012). In the case of schizotypal personality, the relationship between peer victimization and the increased risk of schizotypal personality was mediated by increased social anxiety, paranoid ideation, and a dearth of close friends. Together, these findings suggest that relational aggression might be an important future research direction in furthering our understanding of the development of a variety of PDs.

As is evident from our previous discussion, interpersonal problems play an important role in the early development of many types of PDs. In fact, a lack of meaningful interpersonal relationships is a feature cutting across the many types of PDs. For example, a lack of close friends or being described as loners are some of the most common early schizophrenia spectrum (Cluster A)

symptoms (Carlson & Fish, 2005; Wolff, 1991). Furthermore, schizotypal traits in adolescents have been associated with deficits in social functioning, including hobbies, leisure activities, intellectual interests, and family relationships (Fonseca-Pedrero, Lemos-Giráldez, Paíno-Piñero, Villazón-García, & Muñiz, 2010). In contrast to children with Asperger disorder, a disorder which manifests commonalities in social impairment with Cluster A PDs (Cohen, Crawford, et al., 2005;Weston & Riolo, 2007), children with Cluster A PD symptoms might still feel the social isolation whereas children with Asperger Disorder feel indifferent about social interactions (Carlson & Fish, 2005).

In the case of Cluster B disorders, interpersonal maladaptation (such as interpersonal instability) has been conceptualized as a defining feature of borderline PD (Becker et al., 2006; Reich & Zanarini, 2001). Mothers have reported that their daughters with borderline PD began experiencing interpersonal problems in toddlerhood and childhood (Goodman et al., 2010). Interpersonal problems also appear to play an important role in the severity of borderline PD symptoms. Specifically, among adolescents with borderline PD, unstable interpersonal relationships were uniquely associated with nonsuicidal self-injury and suicide (Muehlenkamp, Ertelt, Miller, & Claes, 2011). This link was also found in a sample of Chinese adolescents, such that disturbances in interpersonal relationships were predictive of nonsuicidal self-injury (You, Leung, Lai, & Fu, 2012).

Finally, in the case of Cluster C PDs, adults with avoidant PD retrospectively reported less popularity in childhood and adolescence, having fewer meaningful relationships with adults, and less involvement in hobbies and athletics than did adults with no or other PDs (Rettew et al., 2003). Interestingly, they also reported that their caregivers showed more impaired social skills than did adults with other PDs. Taken together, these findings underline the defining role that interpersonal difficulties play in the development of multiple PDs even from a very young age.

Interpersonal Relationships: Later Life

Research suggests that as adults age, they prune their social networks, systematically removing negative or unimportant social contacts and strengthening their positive or important relationships (e.g., Carstensen, 1992). As a result, adults tend to have progressively smaller, but more meaningful social networks. This finding is consistent with the theory of selective optimization with compensation, a theory of adaption which states that as individuals age, they increasingly focus their attention on areas of high priority (selection) that offer meaningful benefits (optimization), while finding new ways to cope with aging-related losses and to maintain functionality (compensation; Baltes & Baltes, 1990). Specifically, the pruning of social relationships represents one instance of how individuals selectively optimize their meaningful relationships and cut their losses with their unimportant relationships.

Although we are unaware of any large-scale studies which specifically analyzed the relationships of older adults with PDs, informed speculation from various sources is possible. For example, in a case study of an older adult with narcissistic PD, the participant had drastically changing social networks from one time point to the next (Balsis et al., 2010). Individuals who she rated as being in her innermost circle at one point were later not reported at all or were relegated to a lesser circle. As this example suggests, individuals with PDs likely have marked impairment in the interpersonal realm, which would lead to fewer functional relationships as they age (e.g., because of burned bridges or avoidance of close relationships). Further, for the healthy individuals who are in the process of trimming their social networks as they age, individuals with PDs are likely candidates to be pruned because of their potentially difficult interpersonal style.

Relationships are also important because they provide a network of social support that can offer important services. Relationships provide the emotional and instrumental support that, while important for all individuals, may be especially important for older adults because of their increased dependence. Due in part to declines in their physical capabilities, older adults may need instrumental support for tasks that were once routine, such as driving, grocery shopping, personal hygiene care, and housecleaning. Without a system of social support, older individuals would also lack emotional support during potentially difficult transitions, such as the empty nest, retirement, and the deaths of one's parents and peers. In short, disrupted relationships due to PDs might leave one isolated during a time of increased need for social support. Rather than have a rich, supportive network of individuals on which one could rely, individuals with PDs may have to face the challenges of later life alone.

Identity: Early Life

Finally, the fourth component that plays an important role in the early development of PDs is identity disturbance (Fonagy & Bateman, 2008). Identity disturbances can be described as self-conceptualizations that are extreme, inflexible, and change unpredictably. For example, rather

than thinking about themselves and others in a nuanced way, individuals with identity disturbances might think of themselves and others as being all good or all bad (Tackett et al., 2009). Identity disturbances have also been conceptualized as made up of different factors, such as (1) lack of normative commitment—the difficulty in committing to stable values and perspectives about the future, (2) role absorption—the tendency to identify with a single role, which can change dramatically across time and situations, (3) painful incoherence—experiences of distress about feeling incoherent, and (4) lack of consistency—tendency to lack consistency in behavior and sense of self over time, all of which have emerged in both adult and adolescent samples (Westen, Betan, & Defife, 2011). This multidimensional identity disturbance construct has been associated with numerous PDs, but especially with borderline PD.

Distorted mental images about the self are one of the defining distinctions between normal personality traits and PDs (Tackett et al., 2009). Specifically, distortions in the cognitive perspectives of the self prevent people with PDs from adapting successfully to the social world that we live in, thereby influencing the interpersonal component of PDs. For example, identity disturbances can be associated with maladaptive interpersonal relationships given that, with an extreme and inflexible self-image, it is difficult for a person to successfully negotiate relationships with others. Similarly, identity disturbances can be associated with impaired emotion regulation, given that self-images that change unpredictably from a positive extreme to a negative extreme increase the likelihood for similarly extreme changes in emotions, thereby influencing risk for the emotional component of PDs. Furthermore, when adopting an extremely negative view of themselves that is inferior to others, individuals with PDs might rely excessively on others to bolster their self-esteem. A disrupted sense of self has been identified as one of five indicators in childhood that reflects the unsuccessful negotiation of developmental tasks (Geiger & Crick, 2001). Particularly in adolescence, consolidating one's identity is an extremely salient developmental task (Crawford et al., 2004).

In terms of the development of PDs, Shiner (2009) has described two maladaptive pathways in the normal development of identity that might be particularly relevant. Specifically, the first pathway involves difficulties with constructing a coherent life narrative, whereas the second pathway involves difficulties with integrating negative experiences into one's narrative. Adolescents on the first maladaptive pathway might have problems committing to a single coherent and integrated life narrative. They might also experience challenges in remembering distinct past events and instead concentrate on general and vague memories. Both problems can put those adolescents at risk for maladaptive psychological functioning. Adolescents on the second maladaptive pathway, on the other hand, might have specific weaknesses in employing adaptive ways of integrating negative experiences into their narrative, for example through coping strategies such as using positive explanatory frameworks (Pals, 2006). Furthermore, these adolescents might engage in maladaptive behavior such as incorporating a negative experience in such a way that it spoils a preceding positive experience, also called a contamination sequence (McAdams, 2009). Finally, these adolescents might struggle with meaning-making, i.e., creating positive meaning out of a negative event (McLean & Pasupathi, 2012). Taken together, a lack of adaptive coping strategies and use of maladaptive behaviors can have negative psychological consequences for youth identity development.

Identity disturbances are particularly relevant to Cluster B PDs that are associated with diffusion or fragmentation of identities (Fonagy & Bateman, 2008). Therefore, we focus here on summarizing findings for Cluster B PDs, such as borderline PDs, psychopathy, and narcissism. Of the Cluster B PDs, borderline PD has been most strongly linked with identity disturbances. Even in early childhood, children of mothers with borderline PD have self-representations that are more incongruent and shameful than those of their peers who have mothers without borderline PD, and these disturbances in self-representation have been related to maternal self-harm (Macfie & Swan, 2009). Furthermore, within borderline PD, the symptom of confusion about self appears to differentiate between nonsuicidal and suicidal self-injury (Muehlenkamp et al., 2011). This relationship between identity disturbances and nonsuicidal self-injury does not seem to be specific to borderline PD, either. Specifically, in late adolescence, self-esteem may partially to fully mediate the relationship between nonsuicidal self-injury and several PDs, including borderline, antisocial, dependent, depressive, avoidant, and negativistic PDs (Cawood & Huprich, 2011).

Among other Cluster B PDs, both psychopathy and narcissistic PD have been linked with identity disturbances. For example, self-serving cognitive distortions interact with psychopathic traits to predict antisocial behavior in adolescent boys and girls (Chabrol et al., 2011). Specifically, self-serving cognitive distortions predicted antisocial behavior only in adolescents who scored high on psychopathy. Furthermore, in early adolescence,

narcissism is related to an inflated view of the self (Bukowkski, Schwartzman, Santo, Bagwell, & Adams, 2009). In summary, identity disturbances play an important role in the development of a range of PDs, especially Cluster B PDs, and predict important outcomes of youth PD such as nonsuicidal or suicidal self-injury. These findings highlight the need for further research on the role that identity disturbances play in the full range of PDs, and the need to understand how pathways might be altered toward a more successful negotiation of the developmental task of identity consolidation.

A concept that is highly relevant for identity development is that of personal narratives, or life stories (McAdams & Pals, 2006; McLean & Pasupathi, 2012). Life narratives are especially critical during the developmental period of adolescence, when youth become more competent to narrate their complex life story coherently (Habermas & de Silveira, 2008; Shiner, 2010). The creation of adolescents' personal narratives is deeply rooted in their social context (McLean & Pasupathi, 2012; Shiner, 2009). For example, from an early age, children begin constructing their stories with the help of other adults, usually their caregivers, which then affects their narrative complexity (e.g., Fivush, Haden, & Reese, 2006). Later in adolescence, the youth's peer group is the most important social context that actively shapes their stories. Therefore, given the importance of interpersonal relationships in the development of PDs, it becomes clear that personal narratives hold special relevance for the development of these disorders, as well. Although previous editions of the *DSM* have considered identity disturbances particularly important in their conceptualization of BPD, the field now recognizes such disturbances as important in the conceptualization of many PDs. Therefore, additional attention to the development and assessment of life narratives will be especially relevant for the study of youth PDs.

Identity: Later Life

Less is known about the process of identity formation in later life, let alone the pathological aspects of identity in later life. Erikson's (1950) influential model of sequential developmental conflicts offers the perspective that individuals are tasked with the process of identity formation during adolescence, but the development and maintenance of identity is surely a life-long process. There is evidence suggesting that individuals' narrative identities become more complex and sophisticated with age (see McAdams & Olson, 2010). In older adulthood, a shift may occur from developing one's identity to reflecting on one's identity (Waterman & Archer, 1990). Consistent with Erikson's (1950) stage of ego integrity versus despair and the life review (Butler, 1963), older adults may begin to reminisce and reanalyze their lives.

Rather than approach late life with integrity as Erikson (1950) envisioned the healthy person to do, individuals with PDs may react to later life with despair over a life fraught with negative affect, disrupted social relationships, and a potentially unclear sense of self. However, for individuals who have successfully internalized (or defended) their personality pathology, they may die how they lived. That is, for a severe narcissist, for example, he or she might die believing in the delusions of grandeur that supported his or her ego throughout life. But for individuals who are aware or who become aware of how their life is lacking, later life could be a difficult period, indeed; one fraught with sadness and regret over what could have otherwise been. We now turn to critical developmental periods for PDs across the life span.

CRITICAL DEVELOPMENTAL PERIODS FOR PDs

Given recent support for both stability and change in PDs over time (Tyrer, 2005), identifying critical developmental periods in the development of PDs might help elucidate periods of life when PDs are most conducive to intervention and prevention. Identifying such periods requires attention to both normal and abnormal developmental processes to identify maladaptive changes that deviate from the norm (Tackett, et al., 2009). We will focus our discussion on four critical developmental periods that appear to be important for the development of personality pathology. Specifically, we focus on early life (including infancy and early childhood), the transition from middle childhood to early adolescence, the transition from late adolescence to early adulthood, and the period of later life.

Infancy–Toddlerhood

Despite current *DSM* conceptualizations of PDs as having an adult onset (Crawford, Cohen, & Brook, 2001a), historically, PD characteristics have been conceptualized as originating early in life (Paris, 2003; Tyrer, 2007). Factors such as hostile parents, disorganized attachment styles, and temperament in early childhood have been related to PD symptoms in adulthood, with borderline PD symptoms receiving the most research attention (Carlson et al., 2009). We review these constructs in more detail and briefly review biological findings as well.

As previously discussed, one construct that is critical for the development of PDs in early life is attachment (Crawford et al., 2006; Raine, 2006; Weston & Riolo, 2007). Specifically, disrupted attachment with a caregiver during early life sets a pattern for disrupted interpersonal relationships in later life (Sroufe, Carlson, Levy, & Egeland, 1999) whereas beneficial parenting behaviors might be a protective factor against the development of maladaptive personality traits (Johnson, Liu, & Cohen, 2011). The infant years from birth until age 2 have been identified as particularly critical for the formation of attachment. For example, for children characterized by an angry temperament, prolonged separation from their mother predicted later schizotypal PD symptoms, but only if the separation took place during infancy and not later in childhood (Anglin, Cohen, & Chen, 2008).

As previously discussed, the development of borderline BD has been most closely linked to attachment theory (see Bradley & Westen, 2005; Levy, 2005). For example, although the findings have been mixed, separation from parents during the early years has also been associated with borderline PD development (Levy, 2005; Reich & Zanarini, 2001). A number of research findings speak to this. Children with borderline PD symptoms were more likely to have mothers who exhibited disrupted communication patterns (Levy, 2005). Adolescent girls with borderline PD were more likely to have had disrupted attachment than did adolescent girls with other mental health problems (Ludolph, Westen, Misle, & Jackson, 1990). Furthermore, increases in borderline PD symptoms from early adolescence to middle adulthood have been associated with maternal separation in early childhood (Crawford et al., 2009). For men, separation from caregivers in early childhood, especially before the age of 5, has been associated with a range of Cluster B PDs (not only borderline PD; Lahti et al., 2012). Given that interpersonal relationships are at the core of both attachment theory and PD conceptualizations, it is not surprising that the early years can leave a lasting impact on the development of PDs (Crick et al., 2005).

More extreme parental neglect during the childhood years has also been implicated in the development of a range of PDs. For example, maltreatment in the form of both emotional and sexual abuse during childhood has been associated with borderline PD in adulthood, at least in women, (Hernandez, Arntz, Gaviria, Labad, & Gutiérrez-Zotes, 2012), hyperbolic temperament, which is thought to underlie borderline pathology (Hopwood & Zanarini, 2012), and general personality pathology in incarcerated adolescent boys (Nederlof, Van der Ham, Dingemans, & Oel, 2010). A study conducted in a Chinese sample found childhood abuse to be more prevalent in patients with borderline PD than in patients with other Axis II or Axis I disorders (Huang et al., 2012).

Another construct that is critical for the development of PDs in early life is emotion- and self-regulation (Crick et al., 2005). For example, early disrupted attachment may deprive the child of opportunities to develop adaptive emotion regulation, which then increases their likelihood to develop borderline PD (Fonagy & Bateman, 2008). In contrast, dysregulated temperament—characterized by high stress reactivity—may increase a child's likelihood for disrupted attachment with their caregiver, which, in combination, increases the child's likelihood to develop borderline PD (Gunderson & Lyons-Ruth, 2008). Furthermore, the child's temperament may interact with the caregiver's temperament in increasing negative parenting, which then interferes with the development of adaptive emotion regulation and interpersonal relationships (Gunderson & Lyons-Ruth, 2008; Levy, 2005). Adult individuals with borderline PD retrospectively reported more difficulties with emotion regulation during childhood than did individuals with other PDs (Reich & Zanarini, 2001).

Other individual factors in infancy–toddlerhood may also increase risk for later PDs. Increased emotional and behavioral problems, impulsivity, and decreased cognitive functioning in early childhood have also been associated with borderline personality features in middle childhood (Belsky et al., 2012). Maternal reports of moodiness in infancy differentiate adults with borderline PD from their siblings without the disorder (Goodman et al., 2010). In addition, fearful emotions also seem to play an important role in the development of some PDs, such that increasing withdrawal has been identified as a possible early predictor of avoidant PD (Eggum et al., 2009) whereas low fearfulness in early childhood has been associated with psychopathy characteristics (Glenn et al., 2007). Together, these findings underline the importance of a range of individual differences during the early years for the development of PDs.

In addition to disrupted attachment and individual difference factors, stress and trauma during early life have effects on the development of PDs. Such effects may be mediated by functional and structural brain abnormalities (Raine, 2006; Skodol et al., 2002). For example, asphyxia, delivery complications, and prematurity have all been associated with PDs in a forensic population, suggesting that abnormal brain development might underlie those disorders (Fazel et al., 2012). Other early biological indicators, such as body growth, have also been associated

with the development of PDs. For example, low weight at age 6 months and 11 years was associated with later PDs in men in one study (Lahti et al., 2011). Another study found that longer skin-conductance half-recovery times to negative stimuli in early childhood were associated with higher psychopathy scores in adulthood (Glenn et al., 2007). Together, these findings suggest that certain biological factors in the early years may also predispose youth to the development of multiple PDs later in adulthood.

Middle Childhood–Early Adolescence

By early adolescence, the stability of PD symptoms begins to reach levels comparable to those in adulthood (Bukowski et al., 2009; Cohen, Crawford et al., 2005; Johnson et al., 2000; Raine, 2006; Salekin et al., 2008), highlighting this as another potential critical period for PD development. In fact, across adolescence, Cluster B PD symptoms were found to show greater stability than even internalizing or externalizing symptoms (Crawford et al., 2001a). The stability of Cluster B personality traits appears to be highly heritable (Bornovalova et al., 2009; Forsman, Lichtenstein, Andershed, & Larsson, 2008). Furthermore, the association between psychopathic personality in adolescence and antisocial behavior in adulthood appears to be mediated by genetic factors (Forsman, Lichtenstein, Andershed, & Larsson, 2010). Among Cluster A symptoms, paranoid PD symptoms showed the greatest stability between the ages of 13 to 16 (Cohen, Crawford, et al., 2005). Although PD symptoms reach adult-levels of stability by early adolescence, important differences still exist in their manifestation. For example, Speranza et al. (2012) found that affective stability was particularly central to BPD in adolescence, which is not necessarily the case later on in life. Zanarini and colleagues (2011) found that BPD in childhood was more characterized by anger and moodiness than in adulthood, whereas BPD in adulthood was more characterized by impulsivity, identity disturbances, and paranoia. In addition, in the case of schizotypal traits, Fonseca-Pedrero and colleagues (2012) found that younger adolescents were characterized by lower scores in social anxiety and disorganization and higher scores in odd thinking, language, and lack of friends compared with older adolescents.

Multiple domains highly relevant to adolescents appear to play a critical role in the development of PD symptoms: Identity consolidation, peer relationships, and socio-economic factors and risky behaviors. During adolescence, identity consolidation is one of the most important tasks (Crawford et al., 2004), as previously described in this chapter. In the case of narcissistic traits specifically, preadolescence has been identified as a critical period to measure the development of such traits given that more normative exaggeration of self-competence decreases around age 10 years (Thomaes, Bushman, Stegge, & Olthof, 2008) and by early adolescence, narcissistic traits have been associated with an inflated self-view (Bukowski et al., 2009). The same period has also been identified as critical for interventions given the greater malleability of children's self-views during preadolescence than during late adolescence (Thomaes, Bushman, et al., 2008; Washburn, MacMahon, King, Reinecke, & Silver, 2004).

In addition to the task of identity consolidation, navigating social relationships is an important developmental task that can introduce normative stress during early adolescence. In the case of narcissistic traits, the possible increase in shame from childhood to adolescence due to youth's greater self-consciousness could moderate the effect of narcissistic traits to predict aggressive behavior, such that children high in narcissistic traits are likely to aggress only if they feel ashamed (Thomaes, Bushman, et al., 2008). Narcissistic traits in early adolescence have been associated with reactive and relational aggression as well as a diminished stress response (Bukowski et al., 2009). Poor peer relations have been linked to PD symptoms in middle childhood–early adolescence across a range of PD domains (Fung & Raine, 2012; Natsuaki, Cicchetti, & Rogosch, 2009; Wolke et al., 2012). Furthermore, an absence of meaningful relationships in childhood may play a cascading role in the development of schizoid PD (Lenzenweger, 2010). Physical and social aggression in middle childhood predicts adolescent borderline and narcissistic features in adolescence (Goodman et al., 2010; Underwood et al., 2011). Taken together, these findings suggest that disrupted interpersonal peer relationships, especially those characterized by aggression, likely have both a moderating as well as a direct effect on the development and maintenance of PDs during this developmental period, as the salience of the peer group increases.

The greater social environment that youth spend most of their time in, namely schools, has also been found to have a profound impact on the development of PD symptoms. Specifically, schools with climates high in learning focus and student autonomy were associated with decreases in Cluster B and A symptoms, respectively (Kasen, Cohen, Chen, Johnson, & Crawford, 2009). In contrast, schools with climates high in conflicts or informality among students and teachers were associated with increases in Cluster A and C symptoms, underlining both

the positive and negative influences of school climates on youth PD symptoms. Communication more generally becomes increasingly important during middle childhood. For example, communication patterns show a significant decrease in loose associations and illogical thinking after age 7, suggesting that prior to middle childhood, these communication styles are more normative. Consequently, middle childhood has been implicated as a critical developmental period for the disrupted communication that characterizes schizotypal PD (Caplan, 1994). Furthermore, theory of mind deficits have also been associated with positive schizotypy symptoms in adolescents (Barragan, Laurens, Navarro, & Obiols, 2011). In summary, both the social environments of peers and of schools have been shown to have a strong influence on the development of a range of PDs during the early adolescent period. In addition, in the case of Cluster PDs, communication that is necessary for adaptive functioning in any of the social environments is especially crucial and may become more impaired by middle childhood.

In the case of antisocial PD, the timing of conduct disorder symptoms has been implicated as especially important. Specifically, early onset of severe conduct disorder may increase the likelihood for later development of antisocial PD (Moffitt, Caspi, Harrington, & Milne, 2002; Paris, 2008). This prediction of Axis I disorders to antisocial PD seems to be unique to conduct problems and does not generalize to internalizing or substance use problems in adolescence (Diamantopoulou, Verhulst, & van der Ende, 2010). Furthermore, this unique association between conduct disorder and antisocial PD may be at least partially mediated by early-onset alcohol abuse (Khalifa, Duggan, Howard, & Lumsden, 2012). In fact, some researchers have argued that stable conduct disorder during childhood might be categorized as a PD (Cohen, Crawford, et al., 2005). Furthermore, violent conduct disorder symptoms increase youth's risk for the development of antisocial PD (Gelhorn, Sakai, Price, & Crowley, 2007) and adults with antisocial PD who have a history of conduct disorder have been found to be more antisocial than have adults without such a history (Walters & Knight, 2010). Thus, antisocial PD often appears to originate with early onset and severe conduct problems, including alcohol use and violence, and these early problems seem to have a lasting and worsening effect on the presentation of antisocial PD.

Early antisocial behavior may result in multiple outcomes, however, such that individuals who stay on the path of antisociality can be differentiated from those who change to a path of avoidance and social isolation (Rutter et al., 2006). In addition, these paths may vary by gender. One study found that only girls who showed disruptive behavior symptoms in midadolescence exhibited Cluster B symptoms by early adulthood (Crawford, Cohen, & Brook, 2001b). Furthermore, (incarcerated) girls might show a unique relationship between adolescent attention deficit hyperactivity disorder and psychopathy that boys do not show (Sevecke, Kosson, & Krischer, 2009). Specifically, Sevecke and colleagues found that the relationship between attention deficit hyperactivity disorder and psychopathy in boys was explained mostly by the association between attention-deficit/hyperactivity disorder and conduct disorder, whereas the relationship in girls explained unique variance over and above conduct disorder. These multifinality effects across gender are particularly interesting given the low prevalence of antisocial behavior in adult women (Guzder et al., 1996). In contrast, attention deficit hyperactivity disorder and oppositional defiant disorder symptoms prospectively predicted borderline PD symptoms in a clinical sample of adult men (Burke & Stepp, 2012) as well as a sample of adolescent girls (Stepp, Burke, Hipwell, & Loeber, 2011). Overall then, these findings suggest that gender is an especially crucial moderating factor in the development of antisocial PD during adolescence that requires further study to fully understand the developmental path of the disorder.

Socioeconomic factors have also been implicated in the development of antisocial behavior in adolescence. Specifically, although these risk factors might not influence the emergence of psychopathic traits, they might nevertheless motivate children characterized by psychopathic traits to utilize more antisocial strategies to achieve their goals (Blair et al., 2006). However, one empirical study found that the development of psychopathic traits from early adolescence to early adulthood in boys was influenced by low socioeconomic status, a delinquent peer group, and the experience of corporal punishment (Lynam, Loeber, & Stouthamer-Loeber, 2008). In addition, one study found the association between psychopathic traits and risky decision-making in preadolescence to be moderated by the child's social class, such that the association was significant only for children from high social classes (Gao, Baker, Raine, Wu, & Bezdjian, 2009). So far, the exact influence of socioeconomic factors on the development of psychopathic traits is unclear. Specifically, future studies are needed to further clarify whether socio-economic factors have a direct or moderating effect (or both) on the development of these maladaptive traits.

Finally, given the increase of general risk taking during adolescence, it is not surprising that risk taking behaviors

have also been found to have an important effect on the development of PDs. Sensation seeking in childhood has also been related to borderline PD, potentially explaining the increased risk of sexually transmitted diseases and other health issues that have been associated with the disorder (Chanen et al., 2007). Other risky behaviors such as early substance abuse have also been implicated in the development of PD symptoms. For example, early cannabis use in adolescence has been found to predict schizotypal PD symptoms in middle adulthood over and above other risk factors such as adolescent schizotypal PD symptoms or comorbid Axis I disorders, suggesting that the mechanism regarding this link are an important future research direction (Anglin et al., 2012) whereas early-onset alcohol abuse has been found to mediate the link between early conduct disorder and later antisociality in incarcerated males (Khalifa et al., 2012). Overall, these findings again suggest that risk-taking behaviors may be related to the development of a range of PDs in multiple ways (e.g., directly, as a moderator, or as a mediator), underlining the importance of further study on the topic.

Late Adolescence–Early Adulthood

The transition to adulthood is another potential critical period in the development of PDs for several reasons. During this period, people with personality pathology tend to increasingly deviate from the norm (for a review, see Clark, 2005) and life quality of individuals with personality pathology during this transition is similarly low to that of adults with the same pathology (Feenstra et al., 2012). Furthermore, borderline PD traits increase in their heritability from adolescence to adulthood (Bornovalova et al., 2009), which may reflect a loosening of environmental constraints on borderline symptomatology during this developmental transition. Whereas the co-occurrence between borderline PD traits and substance use is primarily due to shared environmental factors in adolescence, it is increasingly due to genetic factors in early adulthood (Bornovalova et al., 2012), again suggesting a developmental shift in the relative impact of environmental influences. In the case of psychopathic traits, both affective-interpersonal features and social deviance have been found to be similarly heritable at age 17 and genetic factors seemed to mediate the association between social deviance and environmental risk factors (Hicks, Carlson, Blonigen, Patrick, Iacono, & McGue, 2012).

One of the most important developmental tasks during this period is becoming an independent adult outside of the home of one's family of origin, which can be impeded by the maladaptive interpersonal patterns associated with PDs (Cohen, Chen, et al., 2005; Johnson, Chen, & Cohen, 2004). Another important developmental task in this period is developing one's own intimate relationships, which may also be impeded by certain PDs. For example, for girls, the negative association between intimacy and Cluster B PD symptoms is stronger in late than in early adolescence (Crawford et al., 2004), suggesting that—as intimate relationships become the focus of developmental tasks—they also start to have a stronger effect on Cluster B characteristics.

Among individuals with PD characteristics, those with high levels of Cluster A PD symptoms in adolescence show the greatest impairment during the transition to young adulthood (Cohen, Crawford, et al., 2005). This pattern fits well with the rising prevalence of severe psychosis during early adulthood. An example of deviation from social norms is that individuals with Cluster A PDs are more likely to be early parents during this developmental period (Cohen, Chen, et al., 2005). Heavy use of cannabis during this transition, but not later in adulthood, appears to predict schizophrenia diagnoses later in life (Rutter et al., 2006), suggesting that this might be a critical developmental period for the brain during which it is particularly susceptible to the heavy use of drugs. Findings regarding other PD characteristics further support the role of neurodevelopmental factors during this transitional period. For example, in the case of borderline PD, neurological abnormalities (i.e., reduced volume in the anterior cingulate gyrus) appear as early as adolescence (Goodman et al., 2011) as they do in adulthood (Hazlett et al., 2005; Tebartz van Elst et al., 2003). In the case of schizotypal symptoms, interpersonal symptoms were associated with executive functioning deficits, fine motor dyscoordination, and some physical anomalies in adolescence and, for a smaller subsample of these individuals, these neurodevelopmental factors were already present in middle childhood (Hans et al., 2009). Taken together, these findings suggest that genetic and neurophysiological factors may be present by adolescence and affect PD development during the transition to adulthood.

Later Adulthood

Later adulthood is also a critical time to measure PDs and associated outcomes. Do PDs develop for the first time in later adulthood? This is an important question that, when analyzed carefully, reveals fundamental issues about PDs that remain to be addressed. PDs, by their very definitions,

are of a long duration, and can be traced back to early adolescence. By this definition, it would seem unlikely that a person would enter later life and then develop a PD. Yet there is evidence that PDs can emerge in later adulthood or become functionally problematic for the first time in later adulthood (see Oltmanns & Balsis, 2011). Here we return to the two fundamental PD measurement problems mentioned at the outset—the arbitrariness of diagnostic thresholds and the categorical approach to measuring PDs.

How can we understand the development of a PD in late life? To do so, it is helpful to again consider the issue of thresholds and the somewhat arbitrary marking of them. Likely, there is not something qualitatively different between a person who meets four items verses five items of the borderline PD diagnostic set, for example. Both people are potentially having problems in their lives. Why the threshold for this PD was set at five items to meet diagnosis is not entirely reasoned. Indeed, a handful of the makers of *DSM* have indicated that the thresholds are at least somewhat arbitrary (Oldham, 2007). Given the somewhat arbitrary nature of the PD thresholds, it becomes easy to imagine a person who has subthreshold levels of a particular PD at time 1 who later rises above threshold due to some stressor. Consider a person who at the age of 20 met 4 of the 8 criteria for histrionic PD. Imagine that the person meets the same number of criteria at age 40 and 60. But, then, imagine that this person at the age of 65 experiences the death of her husband, who acted as an influence on dampening some of her natural tendencies for eroticization. Upon his death and the end of his influence, she may become especially exhibitionistic, for example, and now meets 5 of the 8 criteria, thus qualifying her for a diagnosis. From a distance, the data would appear as though the PD had emerged in later adulthood for the first time. However, as this example suggests, the apparent emergence of the PD at the age of 65 could result in part because the threshold system that is currently used is somewhat arbitrary and there is little difference between someone who meets four versus five criteria. In this example, the latent PD propensity was always present and was revealed when the woman's husband died. In this way, later life brings with it many contextual changes, like the death of a spouse, that present problems for our measurement systems. But these contextual changes can also be seen in another light. These later life changes can be the very things that allow for the emergence of an officially diagnosable PD.

Another critical context change that occurs around later life that might lead to the emergence of latent PD pathology is retirement. Retirement can lead to a major role change, financial change, as well as a challenge to one's identity. For certain individuals, such as a younger man with latent narcissistic PD, a career can fulfill many of their narcissistic needs (e.g., the need for power, ego confirmation) through socially acceptable means, such as occupational successes. When older, and without these types of career outlets and reinforcers, this older adult might resort to seeking reinforcement through other means, perhaps by denigrating others within the confines of his small social circle. So what was just below threshold, and may be socially enabling at a younger age, could become social disabling in later life. Here again, the disorder might be diagnosed for the first time in later life.

One can easily imagine other major critical periods in later life that could give rise to PD onset. For example, in late life, a person's health often begins to change. A younger person with a certain amount of paranoia might not show functional impairment associated with paranoid PD because he has a healthy body and reasons that he can engage in certain degrees of self-protection in public if needed, as described previously in this chapter. That same individual, now old, frail, and vulnerable, might find himself trapped in his home, still paranoid about others but now afraid to leave the house. In this example, the PD might interact with changes in health to cross some threshold of dysfunction for the first time in later life.

The bottom line is that later life is a dynamic time with lots of changes that can give rise to previously unseen PD pathology. The extent to which these late life changes reveal PD pathology is not well understood because we do not currently have good data upon which to base such observations. Clearly, though, examining PD pathology in later life would allow us to understand the stability and changeability of PD pathology across the life span and help us to understand how context affects the presentation of PD pathology even into later life.

CONCLUSIONS AND FUTURE DIRECTIONS

The current chapter had multiple goals, with one overarching theme: a desire to understand PD development across the life span within a developmental psychopathology framework. PDs lend themselves especially well to a developmental psychopathology perspective, as the rich and growing literature on normal-range personality measurement and development has much to offer a better understanding of measurement and development of personality pathology. We reviewed literature on the

longitudinal course for both normal and pathological personality, which show numerous similarities to one another. Importantly, such studies point to converging evidence for both stability and change in the development of normal and abnormal personality across the life span. Such evidence supports the need to examine the emergence and impact of PDs in early life, while also emphasizing their potential for change and the need to better understand the moderating roles of context and developmental stage.

Although we largely confined ourselves to language codified in the *DSM-IV* and *DSM-5* approach to PD conceptualization (which are virtually identical), we organized the literature using a different framework. Specifically, we examined core, cross-cutting components for PDs (traits, emotions, relationships, and identity), as well as critical developmental periods for PDs (infancy–toddlerhood, middle childhood–early adolescence, later adolescence–early adulthood, and later adulthood) to organize the empirical literature reviewed here. The decisions to explore common underlying components within a developmental context are resonant with a developmental psychopathology perspective as well. This approach speaks more directly to etiology, developmental pathways, multiple levels of analysis, and potential targets for intervention than would a strictly diagnostic framework. As a result, we hope that the information contained in the current chapter will apply more broadly across various types of personality pathology and will extend to other forms of mental disorder and other potential developmental outcomes. Personality is surely connected with virtually any form of psychopathology, thus holds much greater import than a disorder-specific perspective would convey.

Translational Implications

There are a number of translational implications that follow from the present chapter. In particular, the organization of the current chapter focused on cross-cutting components for PDs (traits, emotions, relationships, and identity) and critical developmental periods for PDs (infancy–toddlerhood, middle childhood/early adolescence, later adolescence/early adulthood, and later adulthood) both of which point to potential targets for intervention and prevention. Cross-cutting, core components of PDs are consistent with the developmental psychopathology emphasis on multiple levels of analysis, and further offer highly relevant targets for preventive interventions. Research suggesting that personality trait change is more likely to lead to PD change than the reverse (Warner et al., 2004), for example, suggests that core traits may be a more meaningful and effective target of intervention than PDs themselves. Increasing research is pointing to evidence for systematic personality change across the life span, which further highlights the translational value of core components of PDs, such as personality traits. Indeed, youth traits have already shown early success as targets for preventive interventions of early PD (Chanen et al., 2008).

Similarly, a better understanding of critical developmental periods point to sensitive periods in the development of personality pathology that may also be highly amenable to preventive intervention efforts. Importantly, critical developmental periods for PD development emerge well before PDs are typically diagnosed in late adolescence or adulthood. Thus, it is critical that educators, researchers, parents, and clinicians, begin attending to core components of PDs long before the potential emergence of full-blown personality pathology. Adaptive development of early attachment, constructive emotion regulation skills, and productive interpersonal relationships may all be critical to developmental success, including decreased risk for later personality pathology. Such developmental milestones can be nurtured prior to those developmental periods in which they are most salient. In addition, children identified as higher risk based on such developmental milestones may represent key targets for preventive interventions, particularly if deficits in core components of personality pathology (e.g., the presence of high-risk personality traits) are also identified.

In addition, there are major impediments to understanding how PDs present themselves in early and in later life because the current measurement tools simply don't work as well for children, adolescents, and older adults as they do for younger adults (who generally reflect the dominant population in research and practice). Developing accurate measures to assess personality and personality pathology in children, adolescents, and older adults is of great practical importance. Once accurate measures are available, clinicians will be able to better identify and treat these populations with PDs, and thereby enhance the well-being of both younger and older people, and their families.

Future Directions

The future is bright for an increasingly nuanced perspective on personality pathology across the life span. As this chapter highlights, however, there is much work to be done. Optimism comes from recent advances in child personality and PD research, which suggest a growing interest in measuring and investigating personality pathology in early

life. It will be essential for PD researchers interested in children and adolescents to take the existing measurement crisis seriously. Assessments based on those created for adults will remain critically valuable to advancing the field, yet they do not offer a comprehensive developmental perspective on early personality pathology. Further work examining those early PD constructs most relevant at different ages (which may or may not match those often studied in adults), developing empirically based bottom-up measurement tools, and examining issues of informant discrepancy and integration represent key contributions for the field to realize in coming years.

Furthermore, although our knowledge regarding PD stability and flexibility is steadily advancing, our understanding of the moderators and mediators of this stability and flexibility is still limited. Thus, we think that the moderating roles of context, including cultural, socioeconomic, and gender variations in contexts, need to be better understood. Identification of mechanisms behind the development of personality pathology across the life span will be especially important in advancing the translational implications of this research given that these mechanisms could present potential treatment targets. In addition, after reviewing the literature with a focus on critical developmental periods for PDs, it became clear that future studies need to focus on more circumscribed developmental periods to uncover factors that are relevant in one developmental period but not in another that would be missed if data were aggregated across developmental periods. Finally, more long-term studies at the extreme ends of development (early childhood and late adulthood) as well as on a range of PDs or personality pathology traits will also move the field forward in its quest to understand PD developmental across the life span to best help individuals at all stages of their life.

Additional future directions can be identified from a life span perspective of PD development. For example, personality and PDs need to be linked more clearly to the most important outcomes for older adults, such as disease and mortality. What role does personality play in causing these outcomes? To answer this question, it will be necessary to follow individuals longitudinally across the life span to examine how personality contributes to these important outcomes, which tend to occur in later life. In addition, research will need to show the differential impact of personality and PDs across the life span on other key variables. How do PDs disrupt natural social and emotional development in later life? And what are the consequences of this disruption for the individual with the PD, their intimate relationships, families, and the health care system? Later life is a unique time with unique challenges. Individuals are transitioning to retirement, facing diminishing health and vitality, changing roles from provider to dependent, and needing to lean on others for care and support. How exactly does personality and PDs affect these transitions and situations? These and other fundamental questions about personality and PDs can be answered by considering their consequences in later life. Finally, when we consider later life, we are required to reexamine basic theories and assumptions about PDs. We see that in later life, PDs can emerge for the first time, challenging the notion that PDs mellow with age. Across all of these questions and perspectives, it becomes clear that studying PDs within the context of personality traits might provide us with the best avenue for future improvement. And indeed, as articulated throughout this chapter, studying these important constructs in later life—when many important outcomes occur—will benefit PD research, help us reach more valid interpretations and understandings of these debilitating disorders, and ultimately help us discover effective ways to treat those affected by PDs.

Taken together, attention to developmental issues will likely represent important contributions to the broader field of PD theory and research in the coming years. Although studying younger and older ages than is the norm presents numerous challenges, such challenges must be embraced by the field. Doing so should lead us all to a better understanding of the phenomena we study and, ultimately, the best approaches to preventing and treating the problems that emerge.

BACKGROUND AND CONTEXT FOR A DEVELOPMENTAL MODEL OF PERSONALITY DISTURBANCE

Personality disorders have long held the fascination of clinicians actively engaged in the diagnosis and treatment of psychopathology. For most of the past 100 years, the psychiatric, clinical psychological, and psychoanalytic perspectives have viewed personality disorders (PDs), which affect about 10% of the population (Lenzenweger, 2008), as (1) relatively enduring and trait-like disorders, (2) largely psychological in nature, (3) fixed firmly within the person over time, and (4) likely the result of dyshygienic childrearing practices. The primary models of the etiology of personality disturbance hailed largely from the psychoanalytic realm, had little connection to what was known empirically about normal personality or temperament, and contained virtually no representation of neurobiology processes or genetic influences with respect to etiology or development. Moreover, for much of last century the prevalence of personality pathology in the general population was essentially unknown (with guesstimates varying widely, even wildly), but clinicians caring for patients observed such pathology frequently in their patients. Finally, many clinicians and theoreticians pondered the possibility that certain personality disorders such as the psychopath or the borderline were *qualitatively* (a difference by kind or type, not degree) demarcated from the range of diversity seen for normal personality (Cleckley, 1964; Frosch, 1970; Hare, 1993; Kernberg, 1968; Rado, 1960; Reich, 1933/1949). Indeed, generations of clinicians and researchers have been taught that personality disorders (1) are relatively discrete entities that diverge from

This work was supported in part by Research Grants MH55347 to R. A. Depue and MH45448 to M. F. Lenzenweger.

normal personality in an implicitly qualitative manner (not unlike the way a broken leg or viral infection demarcates a qualitatively different health status); (2) are to be regarded as minimally responsive to treatments; (3) set like plaster in terms of their longitudinal consistency across the life course; (4) are the result of unifactorial psychological processes (e.g., single traits, single process models, such as excessive aggression leads to personality pathology); (5) are relatively common in the population (as suggested in the *DSM* nomenclature since 1980); and (6) are often the result of poor parenting practices (e.g., severe discipline, childhood sexual abuse).

Scientific inquiry into the nature of personality disorders was relatively somnolent prior to 1980, with most energy directed toward theory (without concomitant empirical research) and clinical treatment issues. A sea change occurred with the advent of explicit diagnostic criteria for the personality disorders in the *DSM-III* (American Psychiatric Association, 1980). While the diagnostic criteria for personality disorders in the *DSM-III* were not formally operational as has been asserted by some, they were clearly articulated and provided a rubric for the identification of clinically significant deviations in personality functioning. Scientific inquiry into the definition, classification, and nature of personality disorders really began in earnest in the era ushered in by the *DSM-III*. By the mid-1980s the personality disorder research area found itself largely concerned with debates regarding the proper definition of PDs (e.g., categories vs. dimensions?) as well as the refinement and continued development of diagnostic instruments for the assessment of PDs. This was so because the PDs had only recently been defined explicitly (i.e., *DSM-III,* APA, 1980) and instrumentation for reliable assessment had only just begun to emerge (forerunners of the *IPDE*, *SCID-II*, and *SIDP*). At that time, there was also a growing scientific interest related to factors impacting the diagnosis of personality pathology, for example, (1) the comorbidity of PDs with Axis I disorders; (2) the challenging reality of multiple personality disorders in the same individual; (3) the utility of interview versus self-report assessment instruments (Zimmerman, 1994); and (4) possible sex/gender bias in the definition/diagnosis of PD's (see Lenzenweger & Clarkin, 2005, for review). Many of these issues continue to be of concern even today and were, indeed, taken up in the attempted revision of the personality disorders section of the recently published *DSM-5* (American Psychiatric Association, 2013).

Basic definitional and assessment issues were rightfully the focus of PD research in the 1980s. However, by the end of the 1980s, more substantive and methodological questions had begun to loom large for the PD research area. Many investigators began to seek answers to fundamental questions that lacked empirical illumination or adequate development, such as:

1. Does mental state impact the assessment of personality disorders, which are putatively more enduring (i.e., a state–trait issue)?
2. Could one develop a screening instrument for personality disorders that would be reasonably efficient (i.e., generate few false negative cases) for application in epidemiologic studies?
3. What is the epidemiology of personality disorders in *nonclinical* community populations?
4. Can one find *DSM*-defined personality disorders in other countries (cultures)?
5. Are there diagnostic approaches to personality disorders that might supplement traditional methods and incorporate information from observers other than clinicians?
6. What would a theory of PDs look like that incorporates contemporary neural science, affective neuroscience, genomics, temperament, personality, and so on?
7. What is the precise nature of the natural history and course of personality psychopathology when studied in longitudinal perspective?

PRIOR ATTEMPTS TO UNDERSTAND PERSONALITY DISORDER: LEXICAL TRAITS, HYBRID CONSTRUCTS, AND AXIS I DISORDERS EXTENDED

Our focus in this chapter is on the development of a model of personality disturbance that incorporates contemporary neural science, affective neuroscience, genomics, epigenetics, and personality. However, before presenting our perspective on this problem, it is important to briefly review other prior approaches seeking to link personality to pathology to either personality or Axis I psychopathology. In short, most other models connecting personality factors to personality disorder have argued that personality disorders represent (1) subsyndromal or preclinical extensions of Axis I disorder liabilities; (2) the result of the impact of moderating factors acting upon personality systems; or (3) simple noninteractive extremes of normally occurring personality dimensions (i.e., very low or very high values on a measured personality dimension). In discussing these models we illustrate the proposed

relevance to personality disorder specifically with illustrations based on borderline personality disorder. Let us consider the last of these possibilities first. Consider the popular five-factor (or BIG-5) approach to characterizing personality. It is an approach that hails from academic personality psychology efforts to distill personality dimensions from language-based trait descriptors and describes normal personality in terms of five continuous dimensions, namely, extraversion, neuroticism, openness, agreeableness, and conscientiousness (see Saulsman & Page, 2004; Widiger, 2005; and Widiger & Costa, 2012 for reviews). In the five-factor approach, PDs are viewed as reflecting simple extremes on naturally occurring normal personality dimensions, most often neuroticism or agreeableness. For example, in the five-factor approach, borderline personality disorder is associated principally with low levels on the agreeableness dimension. The empirical basis for linking the five-factor model of normal personality to personality disorder is to be found in correlational studies that have reported associations between the five-factors (typically measured with popular self-report inventories) and scores on the various personality disorders (defined in the DSM system) measured by any of a myriad of personality disorder assessment devices. Not only has the entire five-factor approach been subjected to trenchant methodological and substantive criticism (see Block, 1995, 2001, 2010; Franić, Borsboom, Dolan, & Boomsma, 2013; Shedler & Westen, 2004; Westen, 1996;), but the conceptualization of personality pathology as simply an extreme form of disagreeableness or neuroticism fails to capture to richness of these disorders, a richness well known to the experienced clinician and astute observers of this broad class of psychopathology.

A second model that sought to link personality factors to personality disorder was proposed by Cloninger et al. (1993). In this model, Cloninger and colleagues (Cloninger et al., 1993) proposed a model of normal personality thought to consist of two broad subsets of multidimensional domains. The first domain is made up of what are referred to as temperament dimensions and the second is referred to as character dimensions. Temperament consists of harm avoidance, novelty seeking, reward dependence, and persistence. The character domain is argued to consist of self-directedness, self-transcendence, and cooperativeness. According to this model, PD is thought to be reflective largely of low levels of self-directedness, a so-called character dimension (Cloninger et al., 1993). Specifically regarding BPD (and all other forms of personality disorder), Cloninger's framework asserts the disorder is reflective of low levels of self-directedness (a character feature) and high levels of both novelty seeking and harm avoidance. The Cloninger model and its associated measurement strategy suffer from a variety of marked conceptual and technical flaws, but these are beyond the scope of this discussion (see Depue & Lenzenweger, 2005; Farmer & Goldberg, 2008a, 2008b; Stallings et al., 1996; Waller et al., 1991). Research on BPD features in relation to the Cloninger temperament and character dimensions—specifically, the predicted correlations between BPD and low self-directedness, high novelty seeking and high harm avoidance—reveals only modest inconsistent support for the model (see Barnow et al., 2007, for review).

Finally, the third model under consideration is one that that has viewed personality disorder largely in terms of subsyndromal or preclinical expressions of liabilities for major forms of psychopathology (i.e., psychotic illness, affective disorders, and so on). Continuing with our illustrations using BPD, Siever and Davis (1991; see also Siever & Weinstein, 2009) proposed that BPD and the other Cluster B PDs (histrionic, antisocial, narcissistic) are variants of affective disorder. BPD, in this approach, is viewed essentially as a subsyndromal variant of affective illness marked by affective instability as a central criterion as well as high levels of impulse dyscontrol and aggression. This position regarding borderline pathology—positing a connection between BPD and major affective illness processes—has received only mixed support in the literature (cf., Gunderson & Phillips, 1991 vs. New, Triebwasser, & Charney, 2008). The critical clinical and conceptual point with respect to the Siever and Davis (1991; Siever & Weinstein, 2009) position is that BPD is not really considered as a disorder of personality, rather, it is viewed as functionally a variant of Axis I psychopathology. This particular model fails to capture the interactive nature of the underlying neurobiological processes that set the stage for BPD, rather pathology is viewed in terms of deviations on separate psychological dimensions thought to be related to underlying neurobiologically mediated processes. The other personality disorders are also essentially explained in the Siever/Davis (Siever & Davis, 1991) approach as variants of underlying Axis I disorder liabilities. For example, the Cluster A (schizotypal, paranoid, schizoid) disorders are viewed as related to schizophrenia-liability via cognitive disorganization and the Cluster C (avoidant, compulsive, dependent) disorders are viewed as derivative of anxiety and anxiety threshold dysfunction. This model was originally proposed in 1991 and remains largely the same currently (see Siever & Weinstein, 2009).

A detailed consideration of the limits of the five-factor, Cloninger et al., and Siever/Davis approaches to personality pathology can be found in Depue and Lenzenweger (2001, 2005). What has been generally lacking from most models of personality disorder can be summed up in a straightforward manner: (1) conceptualization of PD as a complex emergent end product of interacting processes; (2) clear instantiation of the personality systems underpinning PD in neurobehavioral systems; (3) thorough consideration of the impact of both genetic and epigenetic factors on the development of PD; and (4) thoughtful inclusion of environmental inputs (e.g., severe trauma) in interaction with the liability/predisposition to PD defined by the underlying neurobehavioral systems. We present an alternative model in this context for consideration in understanding BPD specifically as well as all PDs, more generally (Depue & Lenzenweger, 2001, 2005, 2006).

Brief Overview of the Attempted Redefinition of Personality Disorder in the *DSM-5*

There have been many discussions of the manner in which the American Psychiatric Association's Task Force on Personality Disorders labored to redefine the nature of personality pathology and the manner in which it should be diagnosed in the recently released *DSM-5*. The various professional perspectives as well as the theoretical, clinical, and political concerns that attended these discussions will not be repeated here as they are readily available in the published literature across many journals. An excellent overview summary of the entire attempted revision process of the personality disorders section of the DSM can be found in Krueger (2013; see also Lenzenweger, 2012). What is worth noting is that the system that was proposed as an alternative to the long-standing description of individual personality disorders contained in the various *DSM* systems (*DSM-III, DSM-III-R, DSM-IV, DSM-IV-TR*) was rejected by both the Scientific Committee of the *DSM-5* Task Force, as well as the American Psychiatric Association's Board of Trustees. Thus, what one sees in the *DSM-5* in terms of personality disorders definitions and the manner in which diagnosis of PD is to be done are simply the exact same as those contained in the *DSM-IV-TR*. The core of the proposed PD model for the *DSM-5*, which was subsequently rejected by the APA, focused on (1) the degree of distortion present in self and other relations (an interpersonal conception that emphasizes both agency and communion as important dimensions of personality); and (2) a system of five broad domains of pathological personality specifiers (or traits). Personality disorder in the proposed model for the *DSM-5* used both of these elements to serve as the basis for describing and diagnosing PD (see Krueger, 2013, for excellent overview). The proposed revision also retained six personality disorder types defined by relatively unique patterns of impairments and traits—all readily recognizable from prior *DSM* systems—borderline, obsessive-compulsive, avoidant, schizotypal, antisocial, and narcissistic personality disorders. The revised approach represented what has been termed a *hybrid dimensional categorical model* and can be found in the appendix (also known as Section III) of the *DSM-5*. What is striking, from our theoretical perspective, is that the proposed (but not adopted) model for defining and diagnosing PD in *DSM-5* still largely viewed personality descriptors as simply associated traits of PD, rather than defining PD explicitly in terms of those underlying neurobehavioral systems giving rise to personality descriptors or traits. That said, the proposed system for *DSM-5* showed an increased awareness of the centrality of interpersonal dysfunction for personality pathology (see Krueger, 2013), which echoes not only our long-standing view regarding the centrality of the affiliation system in personality pathology (see below and Depue & Lenzenweger, 2001, 2005) but also a similar sentiment proposed by others (e.g., Gunderson & Lyons-Ruth, 2008; Hopwood, Wright, Ansell, & Pincus, 2013).

A Dimensional, Multivariate Framework of Personality Disturbance

As we argued recently (Depue & Lenzenweger, 2005), with the exception of schizotypal and paranoid disorders, it is no longer possible to accept the notion that personality disorders (PDs) represent distinct, categorical diagnostic entities. The behavioral features of PDs are not organized into discrete diagnostic entities, and multivariate studies of behavioral criteria fail to identify factors that resemble existing diagnostic constructs (Livesley, 2001). Indeed, just the opposite is observed: the behavioral features of PDs merge imperceptibly in a continuous fashion across diagnostic categories, resulting in a) significant overlap of behavioral features across categories and hence diagnostic comorbidity within individuals, and b) symptom heterogeneity within categories and hence frequent (and most common in some studies) application of the ambiguous diagnosis of personality disorders not otherwise specified (Livesley, 2001; Saulsman & Page 2004; see also Lenzenweger, 2008). Moreover, aside from schizotypy/schizotypic disorders (Lenzenweger, 2010), the existing latent class and taxometric analysis literature on PDs generally does

not provide support for distinct entities in the PD realm, and some provisional taxonic findings for borderline and antisocial PDs are open to doubt. It is, accordingly, not surprising that diagnostic membership is not significantly associated with predictive validity as to prognosis nor psychological or pharmacological treatments (Livesley, 2001).

Such a state of affairs supports proponents of a dimensional approach to PDs, who note that (1) the behavioral features of PDs not only overlap diagnostic categories, but also merge imperceptibly with normality (Livesley, 2001; Saulsman & Page, 2004); and (2) the factorial structure of behavioral traits associated with PDs is similar in clinical and nonclinical samples (Reynolds & Clark, 2001). Furthermore, the higher order structure of PD traits resembles four of the five major traits identified in the higher order structure of normal personality (Reynolds & Clark, 2001). These findings suggest that PDs may be better understood as emerging (*in an interactive manner*) at the extremes of personality dimensions that define the structure of behavior in the normal population (Depue & Lenzenweger, 2005).

The realization that personality dimensions should be related to conceptualizations of personality disorder or disturbance has led to innumerable attempts to illustrate the association of personality traits to PD diagnostic categories. Most of these prior studies, as noted above, have relied on the five-factor model of personality, which defines a structure characterized by the higher order traits of extraversion, neuroticism, agreeableness, conscientiousness, and openness to experience. A recent meta-analysis demonstrated the limitation of the approach of correlating the first four traits with PDs (Openness was uncorrelated with any category; Saulsman & Page, 2004). The meta-analysis showed: (1) the correlation of these four traits with PD categories is moderate to weak; (2) the complex entity of a PD category is defined by as little as one trait but never by four traits in a significant way; and (3) single traits (especially neuroticism) characterize more than one, sometimes several, putatively distinct PDs. How helpful is it to know that Histrionic PD is characterized by moderately high extraversion but by no other trait; or, similarly, that Dependent PD is associated with moderately high neuroticism but with no other trait. Furthermore, the problem in this approach does not appear to be explained simply by use of a small number of broad traits. When the 30 facet scales of the NEO-PI were correlated with PD categories, only modest gains were achieved relative to the use of the four major traits (mean difference in $R^2 \sim 0.04$) (Reynolds & Clark 2001). What the meta-analysis did reveal is that most PDs manifest, in common, higher trait levels of neuroticism and lower trait levels of agreeableness, meaning that most individuals with PDs are subject to negative emotionality, heightened stress reactivity, and impaired interpersonal behavior. Thus, *when PD categories serve as the outcome variable*, personality traits provide little in the way of power to discriminate between such categories or to inform the issue of dimensional continuity from personality traits to states of disorder.

On the basis of the above discussion, we have argued that personality *disorders* as discrete disease entities do not exist per se (Depue & Lenzenweger, 2005). As an alternative, we proposed a new perspective, where personality disturbance represents emergent phenotypes that arise from the interaction of extreme values on critical subsets of major personality traits. That is, each individual's personality represents the interaction of all major traits. (In this context we note that the term *emergent* is used to describe personality disorders as configurations of disturbance that emerge or arise from the novel combination of constituent components, but such configurations of disturbance cannot be reduced readily to these contributing components. For example, one might think of the experience of consciousness or visual imagery as emergent properties of the brain (or, more specifically, neural circuits and structures within the brain) (cf., Rumelhart, 1984). Where individuals lie at the extreme (low or high) ends of interacting trait dimensions on subsets of the major traits, emotional behavior emerges that generates social or occupational impairment, rendering disturbance in the individual's life resulting from personality factors. This model follows from the position that higher order traits of personality reflect the activities of neurobehavioral systems (Depue, 2006; Depue & Collins, 1999; Depue & Morrone-Strupinsky, 2005). Though genetically speaking it may be possible to conceive of the neurobiological variables associated with neurobehavioral systems as subject to independent influences, it is impossible to imagine that these systems are independent at a functional level. Neurobehavioral systems, and the personality traits that reflect their influence, interact to produce complex behavior patterns—personality as a whole—in a multivariate fashion. Although this model is dimensional in nature, where personality disturbance lies at the extreme of normal, interacting personality dimensions, no assumption is made herein that phenotypic dimensions of personality are genetically continuous. The phenotypic continuity could well represent several underlying *distinct* genotypic distributions, as may be the case even within the normal range of variation of some personality traits (Depue, 2006).

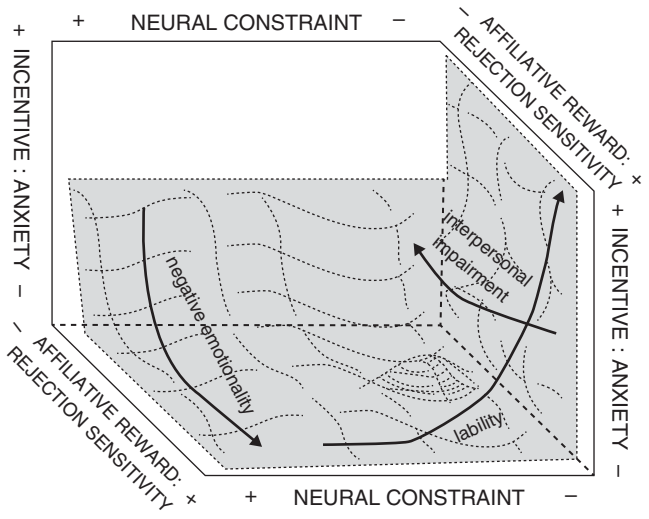

Figure 24.1 A multidimensional model of personality disturbance.

This multidimensional model of personality disturbance is illustrated in Figure 24.1. In the model, the axes are defined by neurobehavioral systems (which we will explicate later) rather than by personality traits, because traits are only approximate, fallible estimates of these systems. In Figure 24.1, behavioral approach based on positive incentive motivation (thought to underlie extraversion and positive emotionality, Depue & Collins, 1999) and anxiety/stress reactivity (thought to underlie neuroticism and negative emotionality, Canli, 2008; Depue & Lenzenweger, 2005) are modeled as a ratio of their relative strength, because the opposing nature of their eliciting stimuli affects behavior in a reciprocal manner, such that the *elicitation* or *expression* of one system is influenced by the strength of the other. The affiliative reward dimension (representing the capacity to experience consummatory reward from social and soft-touch stimulation, and thought to underlie the trait of social closeness or agreeableness, Depue & Morrone-Stupinsky, 2005) is placed in ratio with rejection sensitivity in the model, because they both largely influence the interpersonal domain, but can have opposite effects on social bonding. Moreover, a dimension of rejection sensitivity likely provides a novel contribution to dependent-, avoidant-, and borderline-like disturbance (all high on this dimension). The neural constraint dimension (thought to underlie the trait of constraint or conscientiousness) modulates the expressive features (especially the threshold of stimulus elicitation) of the other systems (Carver & Miller, 2006; Depue & Lenzenweger, 2005; Spoont 1992). Due to the limitation of graphing more than three dimensions, it should be noted that the model includes one additional system/trait that we suggest influences the manifestation of personality disturbance: the ratio of affective aggression:fear is necessary to account for the full range of antisocial (high aggression:low fear) behavior. Taken together, then, the model proposes that the interaction of at least six neurobehavioral systems underlying dimensional personality traits are necessary to account for the emergent phenotypes observed in personality disturbance.

Two significant features of the model are worth emphasizing. First, the phenotypic expression of personality disturbance, represented by the gray-shaded *reaction* surface in the figure (accounting for ~10% of the population; Livesley, 2001), is continuous in nature, changing in character gradually but seamlessly across the surface in a manner that reflects the changing product of the multidimensional interactions. It may be that certain areas of the surface (i.e., certain system/trait interactions) are associated with increased probability (risk) of certain features of personality disturbance (perhaps having led to clinical theories of PDs based on prototypic phenotypes), and this is represented in the right-back area of the figure as an elevation in the surface that is continuous rather than distinct in contour. This representation, however, is not meant to imply that a distinct disorder exists in that particular area of the surface.

Second, the extent and positioning of the gray reaction surface is weighted most heavily by *increasing* anxiety/stress reactivity, *decreasing* neural constraint, and *decreasing* affiliative reward:*increasing* rejection sensitivity. This weighting is also reflected in the lines with directional arrows overlaying the gray surface in the figure, which illustrate increasing phenotypic negative emotionality, emotional lability, and interpersonal impairment. These three factors were found to be the most common characteristics of all PDs in the meta-analysis of Saulsman and Page (2004), and a recent study showed independent genetic contributions to these factors (Kendler et al., 2008), thereby empirically supporting their emphasis in the model.

Implications of the model are discussed in detail elsewhere (Depue & Lenzenweger, 2005), but one seems important in the consideration of the *development* of personality disturbance: sex differences in some forms of personality disturbance may imply differential risk (neurobiologic or environmental) based on gender. The increased prevalence of males with antisocial behavior may reflect the higher mean of males in the population on the ratio of traits of aggression:fear and a lower mean on constraint (Spoont, 1992). Additionally, the increased prevalence of females with borderline- and dependent-like personality disturbance may reflect a combination of

(1) their higher mean on both trait anxiety; (2) their higher mean on social closeness, thereby increasing the need for social relationships whose loss is feared; (3) their higher mean on rejection sensitivity, thereby increasing their vacillation between dependence and rejection of others; (4) their lower mean on extraversion, particularly social dominance, hence enhancing the predominance of high levels of trait anxiety; and (5) their lower mean on the ratio of aggression:fear, hence decreasing the prevalence of antisocial behavior (Depue & Collins, 1999; Depue & Morrone-Strupinsky, 2005; Tellegen & Waller, 1997).

Developmental Implications of the Model

Viewing the phenotypic expression of personality disturbance within the concept of a *reaction surface* in Figure 24.1 implies that an individual's expression of disturbance is variable across time, waxing and waning with fluctuations in environmental circumstances, stressors, and interpersonal disruptions. Indeed, Lenzenweger demonstrated in a longitudinal assessment of the stability of formally defined personality disorders that phenotypic intensity varied markedly over time, thereby affecting the presence/absence of diagnostic status as well as level of symptomatology (Lenzenweger et al., 2004). This implies that one's multivariate value on the reaction surface represents a risk or potential for personality disturbance whose full expression is dependent on current life circumstances. Furthermore, that risk or potential is accordingly variable over time as well. An individual's mean level on personality traits is a function of multiple genetic and environmental variables, in keeping with recent models of the development of psychopathology (Cicchetti, 2007), and the interaction of these variables over the life span may modify the extremity of an individual's level in enduring ways. In this way, *developmental* experience can substantially modify an individual's level on personality traits, and may contribute to an individual's position with respect to the reaction surface.

In our subsequent discussion of these experiential effects on the neurobehavioral systems underlying personality traits, it is helpful to first define a framework of how experiential factors interact with neurobiological variables to determine personality trait levels. In so doing, we will use neuroticism—defined as anxiety, stress reactivity, and negative emotionality—as an example. As shown in Figure 24.2, an individual's trait level of expressed anxiety and negative emotion is dependent on the individual's characteristic minimum threshold of stimulus elicitation of a neurobiological variable associated with anxiety/stress reactivity. This minimum threshold represents a central

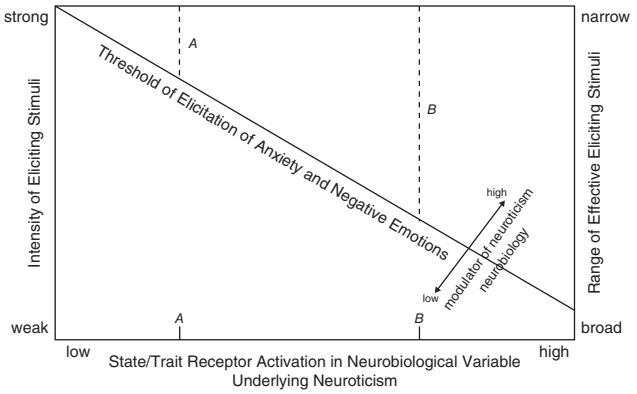

Figure 24.2 A minimum threshold for elicitation of anxiety and negative emotions is illustrated as a trade-off function between eliciting stimulus magnitude (left vertical axis) and postsynaptic receptor activation of a neurobiological variable underlying the personality trait of neuroticism (horizontal axis). Range of effective (eliciting) stimuli is illustrated on the right vertical axis as a function of level of receptor activation. Two hypothetical individuals with low and high *trait* postsynaptic receptor activation (demarcated on the horizontal axis as *A* and *B*, respectively) are shown to have narrow (*A*) and broad (*B*) ranges of effective stimuli, respectively. Threshold effects due to a modulator of neuroticism neurobiology are illustrated as well.

nervous system weighting of the external and internal factors that contribute to initiation of the processes associated with anxiety (Depue & Collins, 1999). Generally, the threshold is weighted most strongly by the joint function of two main variables: (1) magnitude of anxiety-inducing stimulation; and (2) level of postsynaptic receptor activation by the neurotransmitters or neuropeptides that mediate the effects of the stimulus in facilitating anxiety. The relation between these two variables is represented in Figure 24.2 as a trade-off function, where pairs of values (of stimulus magnitude and receptor activation) specify a diagonal representing the minimum threshold value for activation of a behavioral or emotional process, in this case anxiety and negative emotions. Because the two input variables are interactive, independent variation in either one not only modifies the probability of behavior, but it also simultaneously modifies the value of the other variable that is required to reach a minimum threshold. Finally, individual variation in variables that significantly interact with the functioning of the anxiety-facilitating neurotransmitter would serve as a source of modulation of the threshold. We discuss this further under the section on constraint.

A *trait* dimension of postsynaptic receptor activation by an anxiety-facilitating neurobiological variable is represented on the horizontal axis of Figure 24.2, where two

individuals with divergent trait levels are demarcated: *A* (low trait level) and *B* (high trait level). Trait levels would be determined by genetic factors that affect the functional activity of the neurobiolgoical variable, as well as by developmental experiences that modify gene expression (e.g., by affecting receptor availability). These two divergent individuals may be used to illustrate the effects of trait differences in both acquisition and maintenance of anxiety, stress reactivity, and negative emotionality.

As Figure 24.2 indicates, for any given stimulus, the degree of *state* (contemporaneous, stimulus-induced) neural response (receptor activation) will on average be larger in individual *B* versus *A*. Our proposal is that this differential responsivity is a major source of the neurobiological basis of the *temperamental* (i.e., nonexperiential) component of anxiety and, hence, of variation in the acquisition of stimulus control and levels of anxiety. Because the degree of state neural activity is correlated with the magnitude of *subjective emotional experiences* that are naturally elicited by stimuli, negative emotionality is also predicted to be more enhanced in *B* vs *A*.

This difference between individuals *A* and *B* in magnitude of stimulus-induced neural activation and accompanying subjective emotional experience may contribute to two important sources of variation in the *development* of anxious, stress reactive behavior. First, as noted above, independent variation in either of the two interactive variables that determine threshold (neural activation and magnitude of the stimulus) also simultaneously modifies the value of the other variable that is required to reach a minimum threshold. This suggests that the enhanced negative emotion induced by stimuli in individual *B* will result in an equally enhanced negative encoding in memory of that anxiety-inducing stimulus relative to individual *A*.

Second, if individual differences in emotional encoding apply across the full range of magnitudes of stimuli, trait differences in neural activation may have marked effects on the range of effective (i.e., anxiety-inducing) stimuli. This is illustrated in Figure 24.2, where the right vertical axis represents the range of effective stimuli. Increasing trait levels of neural activation (horizontal axis) are associated with an increasing efficacy of weaker stimuli and, thus, with an increasing range of effective stimuli. In Figure 24.2 individuals *A* and *B* are shown to have a narrow vs broad range, respectively. Significantly, the broader range for individual *B* suggests that on average *B* will experience more frequent stimulus elicitation of anxiety, stress, and negative emotions. This means that the probability at any point in time of being in an anxious, stressed state for individual *B* is higher than for *A*. Therefore, when subsequent stimuli are encountered, their subjectively evaluated emotional magnitude will show a stronger negative bias for *B* than *A*. Thus, trait differences in thresholds may *proactively* influence the evaluation and encoding of stimuli, and may not be restricted to *reactive* emotional processes.

Such a perceptual/attentional bias for negative, anxiety-eliciting cues may be mediated by the basolateral nuclei of the amygdala. Crude representations of anxiety-associated cues can reach the basolateral nuclei via monosynaptic projections from the thalamus within ~10 msec without awareness. This input then activates a dense network of backprojections from the basolateral nuclei to many regions of the brain, including those that process sensory representations, thereby facilitating the processing specifically of anxiety-producing cues. The enhanced negative encoding in memory in the basolateral amygdala of such cues by individual B throughout development would lead to frequent, rapid activation of the amygdala when such cues were reexperienced, and in turn a perceptual/attentional biasing of anxiety cues of even weak magnitude via the amygdala's backprojections.

The overall manifestation of these various processes is likely to be more frequent negative emotional experience for individual *B* relative to *A*. A broader range of effective, anxiety-producing stimuli, each with enhanced negative emotional encoding, is expected to produce more robust neural reactivity to stimuli in individual *B*. Accordingly, an enhanced acquisition of a broader array of conditioned stimuli that become associated with anxiety-producing contexts can be expected for individual *B*. Thus, variation in neural activation by stimuli may not only influence the level of negative emotion, but also may lead to variation in the strength of associative processes that link neutral stimuli with negative emotional contexts. *The outcome of these interactions may be the acquisition of a more elaborate associative network of negative emotional environmental contexts in individual B, leading to* different *developmental trajectories* in anxiety and stress reactivity for individuals *A* and *B*.

In the discussion that follows, we will briefly review the neurobehavioral systems that underlie the major personality traits, and focus more substantially on the evidence that they are subject to experience-dependent modification that can be enduring through the effects of experience on genetic expression, mainly through processes known as epigenetics. It is through such processes that risk for personality disturbance may be modified by experience at any point in development, but perhaps especially during early critical periods of development. Due to the fact that this research

has been inordinately focused on anxiety and stress reactivity, the *neuroticism* section will be most extensive relative to other traits. This seems appropriate, however, since the trait of neuroticism is the strongest associate of most PDs.

NEUROBEHAVIORAL SYSTEMS UNDERLYING HIGHER ORDER PERSONALITY TRAITS AND THEIR MODIFICATION BY EXPERIENCE

We focus on the five major traits in Figure 24.1 which are robustly identified in the psychometric literature: *neuroticism*, *extraversion*, s*ocial closeness* or *agreeableness*, *rejection sensitivity*, and *constraint or conscientiousness*. We will define below coherent neurobehavioral systems for each of these traits, and evidence indicating that they are significantly modified by experience.

Neuroticism

Fear versus Anxiety

Adaptation to aversive environmental conditions is crucial for species survival, and at least two distinct behavioral systems have evolved to promote such adaptation. One system is fear (often labeled harm avoidance in the trait literature), which is a specific behavioral system that evolved as a means of escaping unconditioned aversive stimuli that are inherently dangerous to survival, such as tactile pain, injury contexts, snakes, spiders, heights, and sudden sounds. These stimuli are specific, discrete, and explicit, and in turn elicit specific, short-latency, high-magnitude phasic responses of autonomic arousal, subjective feelings of panic, and behavioral escape. Specific, discrete neutral stimuli associated with these unconditioned events elicit conditioned fear.

There are, however, many situations in which specific aversive cues do not exist, but rather the stimulus conditions are associated with an elevated *potential* risk of danger or aversive consequences. In such cases, no explicit aversive stimuli are present to inherently activate fear circuitries. Nevertheless, the stimuli can be unconditioned in nature, as in darkness, open spaces, unfamiliarity, strangers, and predator odors, or they can be conditioned contextual cues (general textures, colors, relative spatial locations, sounds) that have been associated with previous exposure to specific aversive stimuli. Conceptually, these stimuli are characterized in common by unpredictability, uncontrollability, unavoidability, unfamiliarity—or, more simply, *uncertainty*, which are the same stimulus features that characterize what is referred to as stress.

To reduce the risk of danger in such circumstances, a second behavioral system evolved, *anxiety*. Anxiety is characterized by negative emotions (anxiety, depression, hostility, suspiciousness, distress) that serve the purpose of informing the individual that, though no explicit, specific aversive stimuli are present, conditions are potentially threatening (White & Depue, 1999). This affective state, and the physiological arousal that accompanies it, continues or reverberates until the uncertainty is resolved. It is this prolonged negative state of anxiety that distinguishes its subjective character from the rapid, brief state of panic and fear associated with the presence of a specific fear stimulus. Associated responses that may functionally help to resolve the uncertainty are heightened attentional scanning of the uncertain environment and cognitive worrying and rumination over possible response–outcome scenarios. Thus, anxiety represents a general behavioral system that is activated by a broad *class* of stimulus (uncertainty), whereas fear represents a more specific behavioral system that evolved to respond to specific stimuli critical for survival. The trait literature supports the *independence* of anxiety and fear, which as personality traits are completely uncorrelated and are subject to distinct sources of genetic variation (Tellegen et al., 1988; White & Depue, 1999).

Neurobiology of Anxiety and Stress Reactivity

The neurobehavioral system of anxiety is represented in the higher order traits of personality by *neuroticism*, which is characterized by negative emotions, a heightened and persistent state of stress reactivity, and interpersonal alienation. Animal and human research have identified three neurobiological pathways that are associated with anxiety, stress reactivity, and neuroticism, which is consistent with the systems theory concept of multifinality (Cicchetti & Dawson, 2002): a genetic polymorphism in the gene that codes for the serotonin transporter, the central corticotrophin-releasing hormone (CRH) system, and the peripheral glucocorticoid system. Furthermore, all three are subject to modification by adverse events in early development.

1. Serotonin Transporter

Serotonin Transporter and Neural Circuitries Following release serotonin (5-HT) is deactivated by being taken back up into the presynaptic terminal and is then restored in vesicles. This uptake process requires active transport across the presynaptic membrane by the 5-HT transporter (5-HTT) residing in that membrane. As shown in Figure 24.3, there is a polymorphism in the promotor region of the gene (SLC6A4) that codes for 5-HTT that

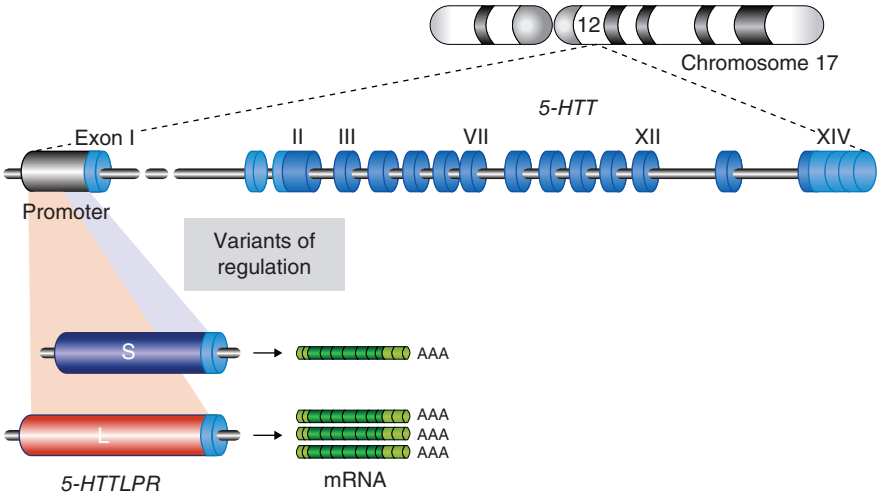

Figure 24.3 Illustration of the components of the gene (SLC6A4) that codes for the serotonin transporter (5-HTT). Polymorphism of the promotor region yields two common alleles (S and L) that differ in length of nucleotide number. See footnote 1.

results in two common alleles, referred to as long (l) and short (s) alleles since their respective promotor regions differ in number of nucleotides (Lesch & Canli, 2006). Due to the facilitatory effects of the promotor region on gene production, the l-allele codes for more RNA and therefore produces more transporter protein than the s-allele. The s-allele is characterized by reduced 5-HTT promotor activity and 5-HTT expression, resulting in a reduced rate of removing 5-HT from the synaptic cleft and increased extracellular levels of 5-HT.

At the behavioral level, 5-HTT knockout mice exhibit increased anxiety and reduced exploration, and primates and humans with the s-allele (or the homolog of it in primates) express increased behavioral anxiety, increased scores on neuroticism scales, increased risk of depression, less effective responses to SSRI treatment, and reduced social closeness (Hariri, 2006). At the neural level, the s-allele has been associated with both neural function and structure. The s-allele has been consistently found to be associated in both males and females with enhanced amygdala reactivity to many forms of emotional stimuli, including fear and angry faces, and negative scenes and words (Canli & Lesch, 2007; Hariri, 2006). In addition, the s-allele is associated with reduced gray matter volume in the amygdala, suggesting reduced dendritic branching and axonal arborization (Hariri, 2006). Thus, there is a link between gene variation and basic brain mechanisms involved in processing negative emotion.

The reduced gray matter volume and increased reactivity of the amygdala in s-allele carriers (both S/S and L/S) raises the possibility that the amygdala's neural circuitry interactions may be influenced (i.e., its projections to and

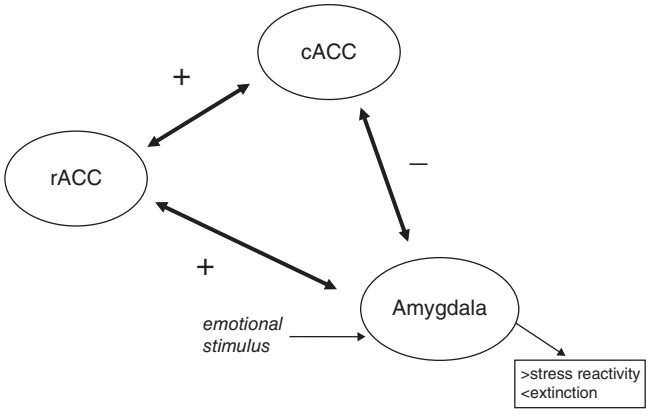

Figure 24.4 Anterior cingulate–amygdala circuitry that provides negative feedback to modulate activity of the amygdala.

efferents from other brain regions). Indeed, recent research on the anterior cingulate cortex (ACC)–amygdala circuitry confirms this possibility. Specifically, the perigenual portion of the ACC, which surrounds the genua of the corpus collosum, is composed of the subgenual, rostral rACC and the supragenual, caudal cACC. As shown in Figure 24.4, the rACC receives the densest projections from the amygdala, conveys that information to the cACC, which in turn sends efferents back to the amygdala. This circuitry is critical to modulating amygdala reactivity via inhibitory feedback from cACC to the amygdala during times of emotional stress.

Pezawas et al. (2005) found psychiatrically normal s-allele carriers to have reduced gray matter volume of both the perigenual ACC and the amygdala, with the most pronounced reduction in the rACC region, and a

reduced covariance of pACC (especially rACC)–amygdala volumes. Furthermore, during the processing of fear and angry faces, there was greatly reduced positive covariance between rACC–amygdala activation, and reduced negative covariance between cACC–amygdala activation, suggesting a reduced negative feedback of the cACC on amygdala reactivity to stressful stimuli. Covariance between rACC–amygdala activation accounted for ~30% of the vairance in neuroticism scores in the entire sample, whereas no single region was significantly related to neuroticism. Thus, it is the reduced coherence of activity across brain regions associated with the s-allele that most markedly affects enhanced reactivity to stress.

The implications of amygdala overreactivity are consistent with the phenotypic features of neuroticism. One can expect the persistent increased arousal being conveyed by amygdala efferents to other brain regions to be associated with anxiety and feelings of distress, persistent enhancement of vigilance for threat, increased rumination of negative thoughts, increased acquisition of negative emotional memories, and decreased extinction of anxiety elicited by environmental contexts. The s-allele creates a reduced threshold for stimulus-induced arousal in the amygdala that is dependent on less coherent activity within its interactions with perigenual ACC circuitry. This state of persistent overreactivity apparently creates an enhanced risk for anxiety and depressive disorders in s-allele carriers, but only under conditions of stressful life events or early adverse experience such as childhood maltreatment (Caspi et al., 2003).

Serotonin and Development of Neural Connections The altered coherence in gray matter volume and functional activity in the pACC–amygdala circuitry, implying reduced dendritic branching and axonal arborization, suggests the possibility that the s-allele modifies connections between brain regions. Significantly, 5-HT plays a critical role in the development and plasticity of the brain (Gaspar et al., 2003). 5-HT neurons are among the earliest neurons to be generated prenatally, appearing in the first embryonic month in primates. Knockout of the 5-HT system prenatally results in no gross wiring or structural effects, but 5-HT is used as a later developmental signal, which modulates construction and plasticity of brain circuits. Major pre- and postnatal developmental effects of 5-HT include modulation of dendritic length and number of spines, and axon arborization: that is, the development of selected brain circuits.

Pre- and postnatal developmental effects of 5-HT arise from two sources. First, there is direct release of 5-HT from brainstem raphe (where 5-HT synthesizing neurons are localized) projections to cortical target regions. Second, glutamate neurons, which comprise the main excitatory neurons that interconnect brain regions, in the process of developing thalamic–limbic and cortico-cortical efferents capture 5-HT via transient axonal expression of the 5-HT transporter. 5-HT is then released at thalamocortical and cortico-cortical synapses to enhance presynaptic axon arborization and postsynaptic dendritic processes, again enhancing neural circuitries. This represents, then, one of the means by which l- and s-allele variation could make a significant difference in interconnections between brain regions.

The effects of 5-HT during development are dependent on which 5-HT receptors are activated. There are 4 groupings of these receptors. 5-HT1A autoreceptors, localized to soma and dendrites of raphe nuclei, and 5-HT2A receptors, one of the most widely expressed in the brain, are expressed late in development and enhance dendritic processes. 5-HT2A receptors also modulate the expression of the Bdnf (brain-derived neurotrophic factor) gene in neocortex and hippocampus. Bdnf secretion from postsynaptic neurons in response to neurotransmitter activation of postsynaptic receptors sculpts glutamate innervation patterns of dendrites and axons, increases synaptic efficacy of glutamate, and modulates LTP in the hippocampus. Thus, 5-HT2A receptor activation can in this indirect way modulate dendritic and axonal processes. On the other hand, 5-HT1B and 5-HT2C receptors are mainly localized to axons and axon terminals, enhancing synaptic strength via axon arborization of glutamate axonal connections through enhanced release of glutamate.

This 5-HT modulation has its strongest effects during development as opposed to later in life (Ansorge et al., 2004; Gaspar et al., 2003; Gross & Hen 2004; Leonardo & Hen 2006). In rodents, the forebrain has an experience-expectant period of dramatic synaptogenesis and dendritic growth 3–4 weeks postnatally, and hippocampal maturation of dendritic branches occurs during 2–4 weeks postnatally. In primates, this period corresponds to early postnatal months. The 5-HT1A receptor also appears in week 2 postnatally in hippocampus, amygdala, and ACC, and, if knocked out or blocked in the first 4 weeks in the early postnatal period, there is a strong enhancement of adult anxiety which first appears in week 3—but no anxiety enhancement occurs when the receptor is blocked in adulthood (Lesch & Canli, 2006; Tsetsenis et al., 2007). 5-HT1A autoreceptors enhance dendritic maturation, and thus their blockade could affect neural circuitry; whereas 5-HT1A postsynaptic receptors induce hyperpolarization and reduce neuronal excitability

in postsynaptic neurons—thus increasing the threshold for firing the postsynaptic neuron. Blockade of this latter effect could contribute to amygdala overreactivity. These findings suggest that 5-HT mediation by 5HT1A receptors is essential to the establishment of normal anxiety-modulating circuits in the brain during early postnatal development. Knockout of monoamine oxidase A (MAOA), which provides the main degradation of 5-HT after reuptake, increases 5-HT inordinately, and has many developmental effects, but only when it is knocked out in the early postnatal period (Gaspar et al., 2003). Consistent with these biochemical findings is that adverse rearing environments in monkeys (Champoux et al., 2002) and in humans (Taylor et al., 2006) interact with the 5-HTT polymorphism, where the effects of the s-allele on anxiety and depression is enhanced by environment.

In sum, then, it is hypothesized that the 5-HTT polymorphism affects 5-HT–modulated development of dendritic and axonal development and fine-tuning of connectivity patterns in the forebrain. Variation in the connectivity of the pACC–amygdala circuits manifests neurally as amygdala hyperreactivity to stress, and behaviorally as anxiety, stress reactivity, negative emotionality, and an increased risk for anxiety and depressive disorders in the context of accumulating environmental adversity. Risk factors that interact with 5-HT effects may be a polymorphic variation in the Bdnf gene (val Bdnf) that results in reduced Bdnf postsynaptic secretion and hence reduced synaptic connectivity; low levels of MAOA activity, increasing 5-HT presynaptic levels and release; and early environmental diversity.

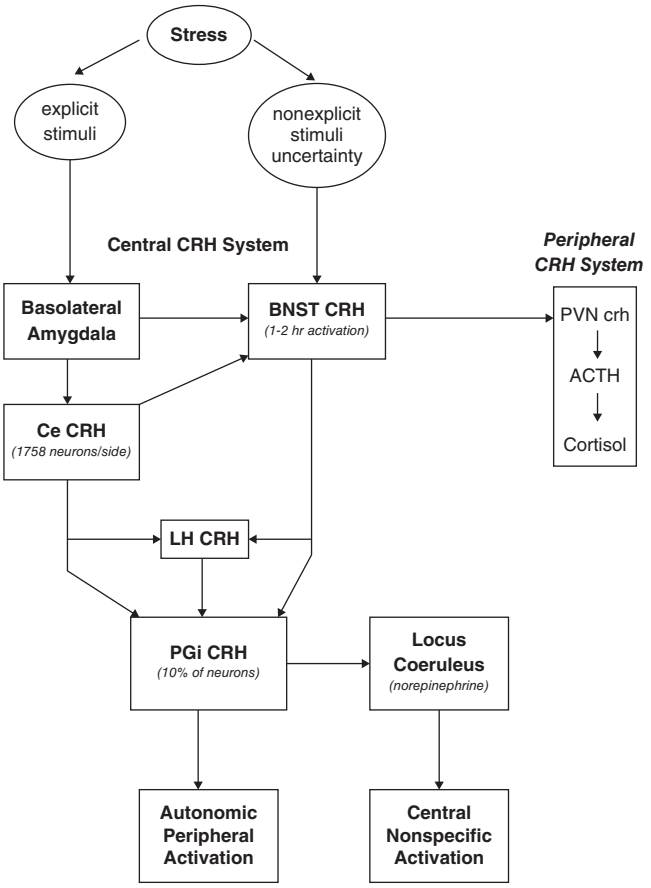

Figure 24.5 Components of the central and peripheral corticotrophin releasing-hormone (CRH) systems. Abbreviations: Ce (central amygdala nucleus), BNST (bed nucleus of the stria terminalis), LH (lateral hypothalamus), PGi (paragiganticocellularis), PVN (paraventricular nucleus of the hypothalamus), ACTH (corticotropic hormone from the anterior pituitary).

2. Central CRH Functioning

Central CRH and Anxiety As illustrated in Figure 24.5, the effects of stress are mediated by a central system of CRH neurons. Stressful contexts can include both explicit, discrete stimuli that generate fear and nonexplicit stimuli associated with uncertainty that generate anxiety. It is now well established that association of discrete, explicit neutral stimuli (fear CS) with an aversive UCS occurs via cortical uni- and polymodal sensory efferents that converge on the basolateral complex of the amygdala (Davis & Shi, 1999; Kalin et al., 2004; LeDoux, 1998). Fear CSs elicit a host of behavioral, neuropeptide, and autonomic responses via output from the basolateral amygdala to the central amygdala (Ce), which in turn sends functionally *separable* efferents to many hypothalamic and brainstem targets (LeDoux et al., 1998).

In contrast, the enduring potentiating effects of nondiscrete, contextually related aversive stimuli on anxiety (but not fear) is dependent on a group of structures collectively referred to as the *extended amygdala*, which receives massive projections from basolateral and olfactory amygdala complexes, and which represents a macrostructure that is characterized by two divisions, central and medial (Heimer 2003; Kalin et al., 2001). These two divisions originate from the central and medial nuclei of the amygdala, and consist of cell groups that are distributed throughout the sublenticular area, bed nucleus of the stria terminalis (BNST), around striatal and pallidal structures, and back to merge specifically with the caudomedial region of the nucleus accumbens.

The central division of the extended amygdala appears to associate *general contextual features and nonexplicit, nondiscrete* conditioned and unconditioned stimuli with reward or punishment (e.g., light conditions, physical features, spatial relations) (Davis & Shi 1999; McDonald

et al., 1999). Similar to the outputs from the Ce, most structures of the central division of the extended amygdala can transmit this motivationally relevant information to some or all hypothalamic and brainstem structures related to emotional expression (Heimer, 2003). This output coordinates activation of (1) the negative affective state of anxiety to inform the individual that the current context is uncertain and potentially dangerous; (2) autonomic arousal to mobilize energy for potential action; (3) selective attention to maximize sensory input at specified locations in the visual field; and (4) cognition to derive a response strategy. Thus, two emotional learning systems may have evolved: the basolateral amygdala to associate reinforcement with explicit, specific characteristics of objects (i.e., for fear), and the BNST to associate reinforcement with nonexplicit spatial and contextual stimulus aspects (i.e., for anxiety).

As indicated in Figure 24.5, the basolateral and central amygdala and the BNST provide integration of behavioral, neuroendocrine, and autonomic responses to stressful circumstances (Leri et al., 2002). This integration is accomplished by the activity of both the peripheral and central CRH systems. The *peripheral* system involves CRH neurons located in the paraventricular nucleus of the hypothalamus (PVN), which when activated initiates the series of events that ends in the release of cortisol from the adrenal cortex. Cortisol then circulates in the bloodstream and increases energy reserves (gluconeogenesis) and, if not excessive in quantity, can enhance neurotransmitters involved in modulating emotion and memory (Kim & Diamond, 2002).

In contrast, the *central* CRH system is composed of CRH neurons located in many different subcortical brain regions that modulate emotion, memory, and central nervous system arousal. Whereas the majority of CRH neurons in the CNS do not mediate the effects of stress, some of the CRH-containing regions that are important in mediating stress effects are illustrated in Figure 24.5. For instance, the basolateral amygdala detects discrete aversive stimuli associated with stressful circumstances and activates the extensive array of CRH neurons located in the Ce (~1750 neurons per hemisphere) (Merali et al., 2003). These CRH neurons project to many brain regions that modulate emotion, memory, and arousal, including the BNST and the peripheral CRH neurons in the PVN. Stress variables associated with context and uncertainty activate CRH neurons in the BNST, which have similar projection targets as the Ce (Macey et al., 2003). Both the Ce and the BNST can activate CRH neurons in the lateral hypothalamus (LH), a region that integrates CNS arousal as a means of modulating changes in the ANS. In turn, the LH CRH projections modulate ANS activity. Importantly, as illustrated in Figure 24.5, all three sources of CRH projections—the Ce, BNST, and LH—innervate CRH neurons in the paragiganticocellularis (PGi) (Aston-Jones, 1996), which is located in the rostral ventrolateral area of the medulla in the brainstem. The PGi is a massive nucleus that provides major integration of central and autonomic arousal and, in turn, coordinates and triggers arousal responses to urgent stimuli via two main pathways eminating from its own population of CRH neurons, which make up 10% of PGi neurons (Aston-Jones, 1996). One CRH pathway modulates the ANS via projections to the intermediolateral cell column of the spinal cord, activating sympathetic preganglionic autonomic neurons.

The other CRH pathway modulates central arousal effects via activation of the locus coeruleus (LC), where PGi CRH innervation of the LC in humans and monkeys is dense (Aston-Jones, 1996). The LC, which is composed of ~20,000 neurons that provide the major source of norepinephrine (NE) in the brain, innervates the entire brain. LC neurons that release NE onto *B*-adrenergic receptors are responsible for producing a nonspecific emotional activation via broadly collateralizing axons to the central nervous system (Aston-Jones, 1996), and this NE release to chronic stress is increased in inbred rat strains with high anxiety (Blizzard, 1988) and in posttraumatic stress disorder patients (Charney et al., 1998). This nonspecific emotional activation pattern comprises a global urgent response system that responds to unpredicted events and hence facilitates behavioral readiness, alerting (enhanced sensory processing), and attention (enhanced selection of stimuli) (Aston-Jones, 1996), which are all characteristic of states of anxiety in highly stress-reactive rodents and monkeys (Blizzard, 1988; Redmond, 1987). And this central arousal can be enduring: PGi CRH activation of LC neurons endures and peaks 40 minutes after stimulation of the PGi (Aston-Jones, 1996). This persistent activation of spontaneous activity in the LC renders the effects of short-lived, nonsalient stimuli of little effect on the LC, such that salient stimuli have an inordinate effect on LC activity and hence, in turn, on central activation. Thus, taken together, the central CRH neuron system is capable of activating a vast array of behaviorally relevant neural and hormonal processes during stressful conditions, including activation of the peripheral CRH system.

Early research demonstrated that CRH in the BNST rather than in the Ce mediates anxiety as opposed to fear, whereas the Ce expresses fear but not anxiety. Thus, injection of CRH into the BNST of rats potentiates startle (an index of anxiety) in a dose-dependent manner for up to

two hours duration (Davis & Shi 1999). Subsequent work has confirmed a specific role for CRH in the BNST in the mediation of anxiogenic effects. Intense inescapable stressors induce a persistent anxious state in rats characterized by increased sensory reactivity and enhanced associative learning with aversive UCSs. This is accompanied by elevated levels of CRH in the BNST. Marked anxiety effects lasting longer than 24 hours are produced after administration of three doses of CRH over 1.5 hours, despite no lasting effect on peripheral release of corticosterone (Servatius et al., 2005). The source of naturally occurring CRH in the BNST is from the Ce's population of CRH neurons: CRH release from the Ce after a psychogenic stressor causes long-term anxiety effects in rats, which correlates with CSF CRH concentrations (Merali et al., 2003).

The anxiogenic effects of CRH are specific to the lateral region of the BNST. Intra-lateral BNST (but not intra-Ce) administration of CRH in rats elicits dose-dependent anxiogenic effects via CRH-R1 receptors, including reduced exploration of an unfamiliar cage and an elevated T-maze (which are both aversive UCSs); reduced sleep, food intake, and sexual activity; and increased sympathetic and behavioral signs of anxiety (shaking, crouching, cautious approach) (Nie et al., 2004). Furthermore, intra-lateral BNST (but not intra-Ce) administration of CRH in rats provides a dose-dependent aversion to the CRH-paired environment via CRH-R1 receptors, indicating that the lateral BNST is a critical site for associative conditioning of context and aversive signals mediated by CRH (Sahuque et al., 2006). The CRH-R1 receptors in the forebrain mediate these anxiogenic effects. Transgenic mice with elevated CRH-R1 (but not with elevated R2) receptors in the central forebrain (but with no elevation peripherally in the hypothalamus or pituitary) show extreme indications of anxiety; whereas mice with knockout of the CRH-R1 (but not R2) receptor gene in the central forebrain (but not peripherally) show little anxiety in the elevated-T maze or in the light-dark test (both being aversive UCSs) (Deussing & Wurst, 2005). Moreover, conditional activation of CRH-R1 gene expression centrally (but not peripherally) produces *anxiogenic* effects, whereas conditional inhibition of CRH-R1 gene expression centrally (but not peripherally) produces *anxiolytic* effects. And finally, a CRH-R1 antagonist administered orally to male monkeys impaired development and expression of contextual anxiety conditioning, and blocked social stress-induced (two unfamiliar male monkeys placed in attached plexiglass cages) increases in anxiety behaviors, cortisol, CSF CRH concentrations, and locus coeruleus neuronal firing (Habib et al., 2000).

These findings taken together suggest that anxiety is essentially a stress response system that relies on a central network of CRH neuron populations acting via CRH-R1 receptors that provide integrated responses (hormonal, behavioral, autonomic and central arousal) to the stressor. CRH especially in the lateral BNST mediates what is a defining characteristic of anxiety as opposed to fear: *anxiogenic* effects, which last as long as uncertainty is unresolved, and aversive *contextual* conditioning. These CRH-induced psychological effects appear to strongly match the content of trait neuroticism measures, where the strongest primary or facet scale in the higher order factor of neuroticism in Tellegen's personality questionnaire is termed *stress reactivity* due to the persistent negative emotional responses reported to stress-related events in items loading on the scale (Tellegen & Waller, 1997).

Finally, although trait levels of neuroticism are very stable over as many as 20 years, it is less stable up to adolescence. This suggests that neural factors that contribute to neuroticism may be more influenced by experience earlier in life. In support of this notion, a recent study found that early postnatal separations from mother rats daily for three hours caused in pups later in life enhanced reactivity to brief stressors in anxiety behaviors and corticosterone secretion but also in CRH mRNA expression in the Ce (Gillespie & Nemeroff, 2007). The latter implies that early adverse experience may result in a persistent Ce-induced enhanced reactivity via its CRH efferents throughout stress-related neural pathways shown in Figure 24.5, including in the lateral BNST.

3. Peripheral Glucocorticoid System

Peripheral Pathways As shown on the far right side of Figure 24.5, the BNST via CRH efferents activates CRH neurons in the PVN under stressful conditions. CRH is then released from the hypothalamic CRH neurons and is transported via a portal system to the anterior pituitary, where adrenocorticotropic hormone (ACTH) is released into the blood stream, activates the adrenal cortex, which then secretes cortisol (mainly corticosterone in rodents). Cortisol travels through the blood stream and has a diverse set of effects on energy metabolism and neural functioning. In humans and rodents, there are two types of stress-induced cortisol receptors. Type I or mineralocorticoid receptors (MRs) have a high affinity for cortisol and thereby mediate the acute stress-induced effects of cortisol on bodily responses. Type II or glucocorticoid receptors (GRs) have a low affinity for cortisol, and thereby become bound to cortisol only at high levels of cortisol concentration. Such high levels of cortisol in the

hippocampus, acting via GRs, activate inhibitory output from the hippocampus to the hypothalamic CRH secretory neurons, thereby reducing the activity of the CRH-cortisol stress response system. This pathway represents the major negative feedback system for controlling stress-induced CRH-cortisol responses.

Peripheral Glucocorticoid System and Early Adversity Noting that the relations between early adversity and environmental poverty with adulthood health (including stress disorders later in life) appear to be mediated by parental influences, researchers have begun to explore whether these parental influences operate via effects on the development of neural systems that underlie the expression of behavioral and endocrine responses to stress (Gross & Hen, 2004; Meaney, 2001; Sapolsky, 2004). Postnatal handling studies in rats provided early support for this notion. Postnatal handling of 3–15 minutes/day resulted in reduced stress reactivity and fearfulness, and increased exploration; decreased hippocampal aging and more intact cognitive functioning in old age; increased GRs in the hippocampus; and increased GABA A receptors (the activation of which reduces anxiety behavior in rats) in the amygdala, locus coeruleus, and hippocampus. In contrast, maternal separation of rat pups had the opposite effects of postnatal handling. For instance, pups separated from their mothers for 180 minutes/day for 2–14 days (which simulates a scarce environment in which the mother leaves the nest for days at a time to forage for food) show significant increases in CRH mRNA expression in the Ce and PVN; decreased GR mRNA and reduced 5-HT1A responses in the hippocampus; and reduced GR binding in the hippocampus, hypothalamus, and frontal cortex, all of which blunts the CRH negative feedback system. Importantly, these pups also manifested a lifetime hyperresponsivity to unfamiliar stressors.

A series of studies of individual differences in rat maternal behavior toward pups has also supported these findings (Champagne et al., 2008; Leonardo & Hen, 2006; Meaney, 2001; Weaver et al., 2004). Rat mothers naturally differ in their levels of licking/grooming and arched-back nursing (which is less stressful for pups than being compressed by the mother's body during nursing), creating two groups of mothers: high vs low LG-ABN. These different maternal patterns are stable over litters, so they appear to be trait-like under normal conditions. Behaviorally, pups of high LG-ABN mothers show reduced startle responses, increased open-field exploration, and reduced latencies to eat food in a novel environment. Neurobiologically, these pups show reduced plasma ACTH and corticosterone responses to acute stress; increased hippocampal GR mRNA expression and hence increased glucocorticoid negative feedback sensitivity; decreased CRH mRNA levels in the hypothalamus; increased affinity for GABA at its A receptor in the amygdala and locus coeruleus; and an increased 5-HT tone in the hippocampus. Moreover, as pups and adults, offspring of high LG-ABN mothers also show less cell death and increased glutamate receptor levels (resulting in enhanced synaptogenesis) in the hippocampus and enhanced memory on hippocampal-dependent tasks.

Thus, the behavior of the mother toward offspring can apparently program behavioral and endocrine responses to stress that endure the entire life span. Moreover, as illustrated in Figure 24.6, individual differences in stress reactivity mediated by maternal care are transmitted across generations (Gross & Hen 2004). Indeed, though adult mothers must overcome initial neophobia to pups, female offspring of high LG mothers are initially less averse to pups. And when offspring of low LG mothers are raised

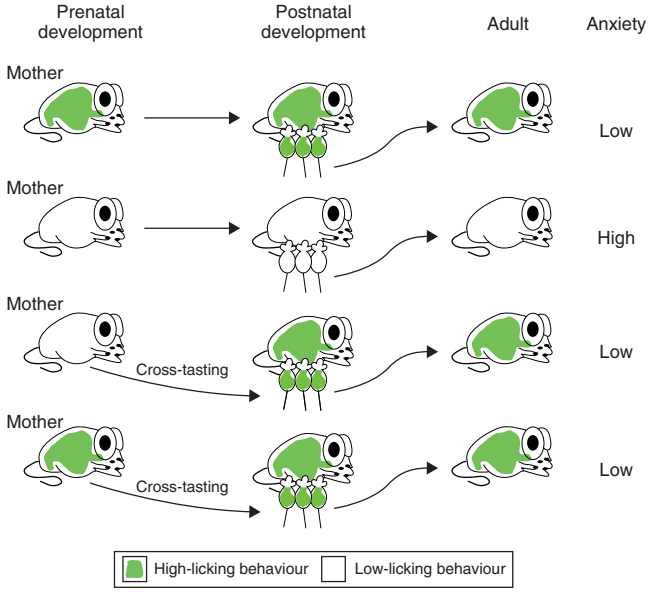

Figure 24.6 Rats raised by mothers that display low licking-and-grooming behavior exhibit more anxiety-related behavior than rats raised by high licking-and-grooming mothers. Cross-fostering studies show that the offspring of low licking-and-grooming mothers raised by high licking-and-grooming mothers are less prone to anxiety-related behavior as adults. This indicates that the effect is mediated by postnatal maternal environment. However, offspring of high licking-and-grooming mothers raised by low licking-and-grooming mothers do not have an increased tendency to develop anxiety-related behavior in adulthood, indicating that specific factors inherited by the high licking-and-grooming offspring protect them from the effects of being mothered by low licking-and-grooming females. See footnote 1. *Source:* Adapted from Gross and Hen (2004).

from birth by high LG mothers (i.e., cross-fostering), these offspring manifest low stress reactivity and anxiety as pups and adults. Importantly, however, although Meaney (2001) reported that raising offspring of high LG mothers with low LG mothers produced stress reactive offspring, this has not been replicated: others have found that these offspring show adult stress phenotypes that are more similar to their high LG biological mother (Figure 24.6; Gross & Hen, 2004). We return to this issue later. But what is clear is that variation in maternal care can affect development of neural systems that mediate stress reactivity, which subsequently influences offsprings' maternal behavior.

It is important to note that there is a convergence between the roles of 5-HT and CRH in these studies that may be significant with respect to the above discussion of the serotonin transporter and CRH in anxiety and stress reactivity. Recall that high LG mothers and their offspring showed increased 5-HT tone in the hippocampus, and that maternal separation reduced 5-HT1A responses in hippocampus.

Stress-induced CRH release onto CRH-R1 receptors in the dorsal raphe nucleus (a major brainstem site of 5-HT neurons) elevates 5-HT concentrations in the hippocampus by 350%. 5-HT activity in the hippocampus activates GR gene expression, providing increased negative feedback to the PVN and Ce CRH neurons. In turn, GR activation enhances postsynaptic effects of 5-HT1A activation, which increases inhibition of excitation in the postsynaptic neuron. Furthermore, 5-HT activation of postsynaptic glutamate neurons in the hippocampus activates Bdnf secretion into the synapse, increasing synaptic processes and decreased aging effects in the hippocampus. Therefore, variation in the functional properties of the 5-HT or the CRH-R1 systems could influence the efficacy of the GR-induced negative feedback system for controlling stress-induced cortisol secretion.

Early Experience and Epigenetic Processes

The critical question concerning the early handling, separation, and maternal care findings is how these influences on stress reactivity and anxiety become long-lasting. Research thus far has supported the role of two mechanisms: epigenetic effects and DNA methylation, both of which involve an alteration of gene expression by experience. In terms of epigenetic effects, as shown in Figure 24.7, DNA is wrapped around proteins called histones, with the DNA and histones collectively comprising chromatin (Tsankova et al., 2007). The functional unit of chromatin is the nucleosome, which is composed of 147 base pairs of DNA wrapped around a core histone group, where there are two copies of each of the four histones (Figure 24.7a). The compactness (openness vs. closedness) of histones in a particular region of chromatin determines how readily transcription factors can access promoters in the DNA (Figure 24.7a). A wide variety of regulators can alter chromatin structure (i.e., its openness), and hence the access to genes. Neurotransmitter (e.g., 5-HT) or hormone (e.g., cortisol) action at receptors can elicit activity in postsynaptic regulators of chromatin structure, and hence access to genes. For instance, activation of MRs and GRs alters the expression of 70–100 genes, 50% of which are upregulated. As we shall see, experience, via neurotransmitter and hormone effects, can permanently alter chromatin regulators and openness to gene transcription, and hence behavior.

Alternatively, in terms of DNA methylation, genes can be stably silenced for substantial periods of time (a lifetime in the case of the second X chromosome in females) when a methyl group is attached to nucleotides in a gene's promotor or exon regions, where the methyl group then tightly binds a repressor protein (Figure 24.7b, Inactive and Repressed sections). Demethylation of a gene leads to enhanced expression of its protein product.

Changes in both chromatin remodeling and DNA methylation state are implicated strongly in the effects of handling and maternal style. Acetylation of histones decreases their binding to DNA (increases chromatin openness), thereby increasing access of transcription factors to promoters and exons. Histones surrounding the GR gene were more acetylated in high LG mothers and their offspring. As illustrated in Figure 24.8, an hypothesized chain of events (Champagne et al., 2008; Sapolsky, 2004; Tsankova et al., 2007) is that high LG rearing results in increased 5-HT neurotransmission in the hippocampus of pups (Point 1 in the figure). The resulting increased 5-HT activation of postsynaptic neurons in the hippocampus leads to strong activation of cAMP, protein kinase A (PKA), and its cascade of events within the postsynaptic neuron. In turn, an increased acetylation of histones and opening of chromatin occurs (Point 2). Also, increased expression of the transcription factor nerve growth factor-inducible protein A (NGFI-A) occurs, which results in increased NFGI-A binding to its binding site located on the first exon of the GR gene (Point 3). Such binding enhances the expression of GRs in the hippocampus, providing enhanced negative feedback effects on central and peripheral CRH release. 5-HT via its postsynaptic effects activates the BDNF gene, which increases synaptogenesis in the hippocampus when released into the synaptic cleft (Point 5).

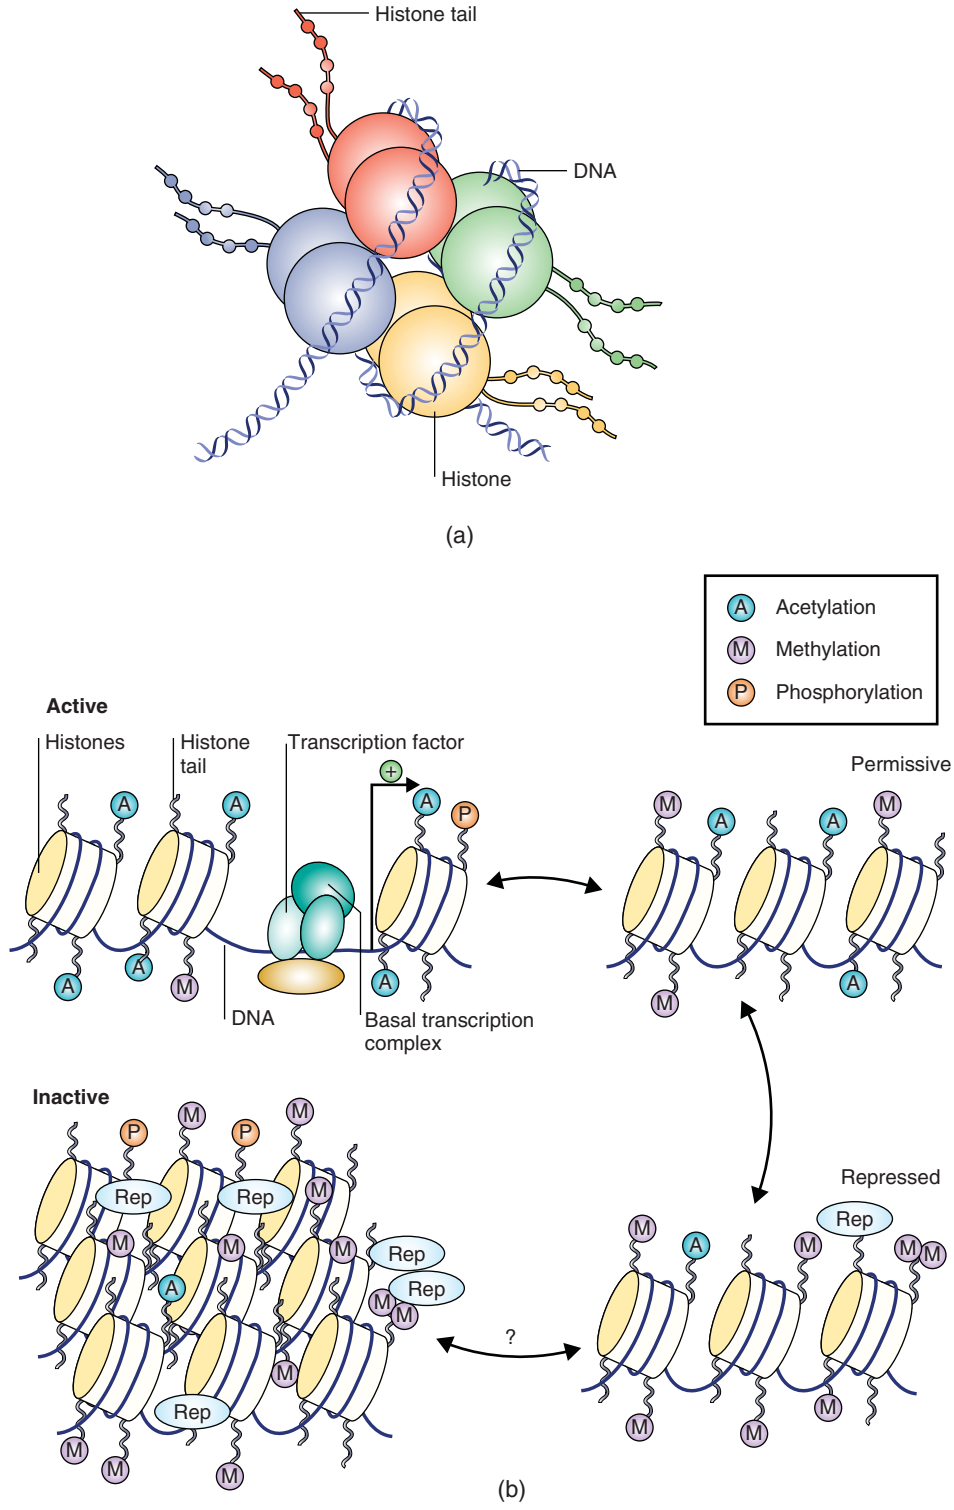

Figure 24.7 General scheme of chromatin remodeling. a) Picture of a nucleosome showing a DNA strand wrapped around a histone octamer composed of two copies each of the histones. b) Chromatin can be conceptualized as existing in two primary structural states: as active or open (top left) in which histone acetylation (a) is associated with opening the nucleosome to allow binding of the basal transcriptional complex and other activators of transcription; or as condensed or closed where all gene activity is permanently silenced (bottom left). In reality, chromatin exists in a continuum of several functional states (active; permissive (top right); repressed (bottom right; and inactive). See footnote 1. *Source:* Adapted from Tsankova et al., 2007.

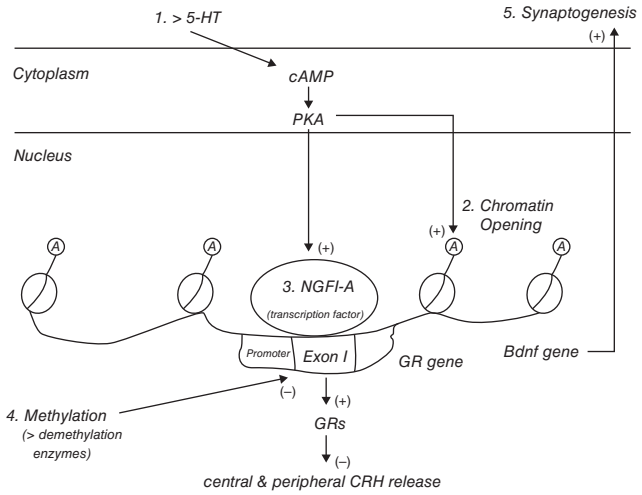

Figure 24.8 Five effects of high LG maternal care in the hippocampus on gene expression.

In terms of DNA methylation, it has been found that the methylation state of the NGFI-A binding site on the first exon of the GR gene is plastic around the time of birth. The site is then methylated the first day after birth, decreasing transcription of the hippocampal GR gene. Over the next week, exposure to high LG mothering (by biological or cross-fostering females) caused the binding site to be demethylated, increasing transcription of the GR gene and hence hippocampal GRs (Point 4). Recent evidence supports a causative role for the above histone actylation and methylation effects. A pharmacological inhibitor of histone deacetylation opens up chromatin and facilitates access of demethylating enzymes, shifting the balance in chromatin toward acetylation. Administration of this inhibitor to adult rats raised in a low LG environment transformed them into a high LG adult in terms of stress reactivity. This behavioral effect was accompanied by an increase in NGFI-A access to the now demethylated promotor and exon 1 of the GR gene, and by reduced levels of circulating glucocorticoids.

Significantly, most of the effects of handling and maternal style occur only within a critical developmental period (Champagne et al., 2008; Gross & Hen, 2004; Leonardo & Hen, 2006; Meaney, 2001). Handling, maternal style, and methylation status all must be present in the first week of life to have an effect in rodents. This is consistent with the findings discussed above, where the first three weeks in rodents are critical in the developmental effects of 5-HT, the effects of knocking out 5-HT1A receptors and MAOA, and in CRH reactivity. Similarly, SSRIs (which result in enhanced 5-HT availability) administered during weeks 1–3 (but not during weeks 6–8) normalize the glucocorticoid response in parentally stressed mice, indicating that this critical developmental period may have a relatively narrow window. Thus, as summarized in Figure 24.9, experience during early postnatal weeks in rodents, and perhaps early months in primates, appear to interact with genetic polymorphisms in 5-HT, Bdnf, and MAOA functioning, creating a critical period for establishing effective synaptic development in the forebrain structures that mediate anxiety in response to experience-dependent signals.

Extraversion

Dopamine Contributions to Extraversion. Through empirical studies and integrative reviews, we have demonstrated that extraversion reflects the activity of a mammalian

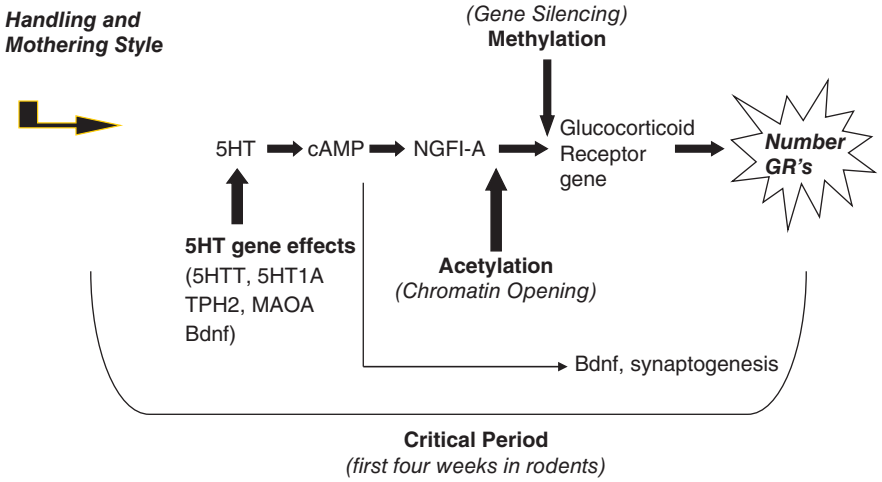

Figure 24.9 A summary of the effects of maternal experience and genetic polymorphisms on gene expression of glucocorticoid receptors during an early postnatal period. See footnote 1.

behavioral approach system based on positive incentive motivation (Depue, 2006; Depue & Collins, 1999; Depue & Morrone-Strupinsky, 2005). This system is activated by, and serves to bring an animal in contact with, unconditioned and conditioned rewarding incentive stimuli. Incentives are inherently evaluated as positive in valence, and activate incentive motivation, increased energy through sympathetic nervous system activity, and forward locomotion as a means of bringing individuals into close proximity to rewards. The incentive state is clearly evident in the phenotypic features of extraversion, and is associated with subjective feelings of desire, wanting, excitement, elation, enthusiasm, potency, and self-efficacy that are distinct from, but typically co-occur with, feelings of pleasure and liking.

Animal research demonstrates that the positive incentive motivation and experience of reward that underlies a behavioral system of approach is dependent on the functional properties of the midbrain ventral tegmental area (VTA) dopamine (DA) projection system. DA agonists or antagonists in the VTA or nucleus accumbens (NAS), which is a major terminal site of VTA DA projections, in rats and monkeys facilitate or markedly impair, respectively, a broad array of incentive motivated behaviors. Furthermore, dose-dependent DA receptor activation in the VTA-NAS pathway facilitates the acute rewarding effects of stimulants, and the NAS is a particularly strong site for intracranial self-administration of DA agonists. DA agonists injected in the NAS also modulate behavioral responses to *conditioned* incentive stimuli in a dose-dependent fashion. In single-unit recording studies, VTA DA neurons are activated preferentially by appetitive incentive stimuli, and DA cells, most numerously in the VTA, respond vigorously to and in proportion to the magnitude of both conditioned and unconditioned incentive stimuli and in anticipation of reward (Schultz, 2007). Similarly, in human neuroimaging studies, increased activation in the VTA and NAS correlates with the amount of reward anticipated, and with ratings of excitement preceding the reward (Canli, 2006; Knutson & Bhanji, 2006). Morevover, during acute administration the intensity of a subject's subjective euphoria increased in a dose-dependent manner in proportion to cocaine binding to the DA uptake transporter (and hence to DA levels) in the striatum (Drevets et al., 2001; Volkow et al., 1997). Hence, taken together, the animal and human evidence demonstrates that the VTA DA–NAS pathway is a primary neural circuit for incentive motivation and its accompanying subjective state of reward.

Consistent with these findings are results with a polymorphism of the dopamine D4 receptor gene on chromosome 11 (Munafo et al., 2003). The D4 receptor is part of the D2 family of DA receptors, which are generally inhibitory in nature. The D4 polymorphism is characterized by variation in the number of repeats of a 48-base-pair unit in exon 3. The most common repeats in the population are 4 and 7 repeats, where the 7-repeat allele is characterized by a two-fold reduction in inhibitory effects on postsynaptic second messenger cAMP relative to the 4-repeat allele. Several small studies have found the 7-repeat allele to be associated with increased extraversion levels relative to the 4-repeat allele, and this was also found using behavioral features of positive emotion in a study of 8–12 month old infants (Lakatos et al., 2003). When this polymorphism is taken in interaction with a polymorphism of the DA transporter (DAT) (one allele being associated with reduced DA uptake and hence increased time of DA in the synapse to activate postsynaptic receptors), impulsivity was significantly increased in terms of number of comission errors in a go/no-go task.

In the discussion above of a threshold model of behavioral responding, it was argued that higher levels of neurobiological traits underlying personality would enhance the association of neutral cues with emotional state. We found that high extraverts more readily associate specific and general contextual cues to DA-agonist induced subjective reward than low extraverts, who showed no associative conditioning at the dose level of methylphenidate used in the studies (Depue, 2006). These findings are consistent with an enhanced reward encoding of positive cues, and are consistent with the fact that extraversion is correlated with increased amygdala activation to happy versus neutral and negative faces. Moreover, the latter finding implies early detection of the enhanced weighted positive stimuli in the amygdala, which through back-projections to many areas of the brain, including sensory processing regions, can bias perceptual processing and attention to positive cues in the environment. Several studies support just such a bias in extraversion (Canli, 2006).

Early Adversity and Dopamine Functioning Early adverse experience in animals has a marked effect on DA functioning, as summarized in Figure 24.10. Single intense stressors or repeated, prolonged stressors, including maternal separations in neonatal rats and monkeys, lead to a sensitization of NAS DA release to repetition of the same stressor or to novel stressors and DA-agonists later in life (Point 6 in the figure; Depue & Collins, 1999; Meaney et al., 2002). There is also an increase in the acquisition of self-administration, and a reduced threshold in terms of

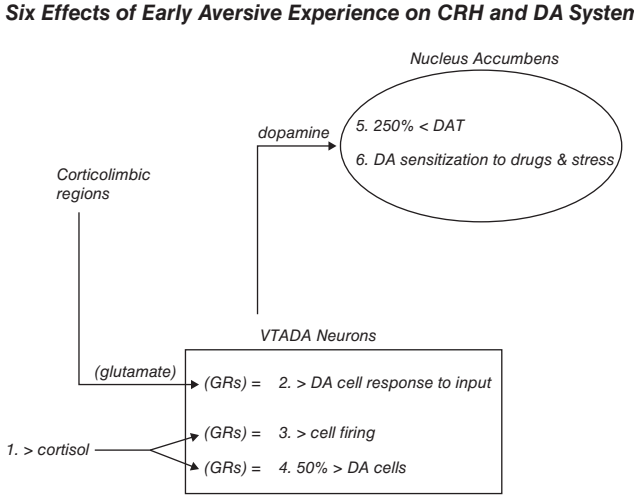

Figure 24.10 Six effects of early aversive experience on glucocorticoid and DA systems in the VTA and NAS.

effective dosage of psychostimulants, alcohol, and opiates, and an increased intensity of effort (craving?) to obtain these drugs (Meaney et al., 2002). Furthermore, rat pups exposed to maternal separations have a 250% reduction in DA transporters in the NAS as adults, which increases time of DA availability at postsynaptic receptors, whereas rats with a history of handling show reduced DA release in the NAS to stress and DA-agonist drugs (Point 5; Meaney et al., 2002).

These effects appear to be enhanced by an interaction of glucocorticoid activation of GRs with DA. Amphetamine and stress both increase corticosterone secretion and NAS DA release. Administration of dexamethasone (synthetic cortisol) prenatally and during the first seven postnatal days in rats results in a 50% increase in VTA DA neurons (Point 4), and increased corticosterone and NAS DA release to stress and DA-agonist drugs in adulthood (McArthur et al., 2005). Even adult humans who report poor maternal care as children have stress-induced increased cortisol levels that correlate ($r = 0.78$) with increased NAS DA release (Pruessner et al., 2004). This effect is enhanced by stressor-induced prolonged oversecretion of cortisol (Point 1) that activates GRs located on VTA DA neurons (Oswald et al., 2005). Such activation has the effect of increasing DA cell responses to input from corticolimbic regions (Point 2), possibly from an enhancement of glutamate release mediated by GRs on glutamate terminals that synapse on VTA DA neurons. In addition, cortisol activation of GRs on VTA DA neurons also enhances the frequency of DA cell firing (Point 3).

Thus, prolonged stressors, such as poor, conflictual, violent, or inconsistent familial environments or physical or sexual abuse early in life, can sensitize the VTA-NAS DA system in an enduring manner. This may have significance for personality disturbance. High levels of extraversion are often associated with histrionic-impulsive behavioral features that can lead to both occupational and interpersonal impairment. In addition, if *extreme* levels of extraversion reflect a sensitized DA system due to early adverse conditions, the risk for increased acquisition of addiction to even low doses of DA-agonist drugs (psychostimulants, alcohol and opiates) later in life may be significantly increased. Also, the increased associative conditioning of context to reward found in high extraverts by us may contribute to rapid conditioning of drug-associated contexts that enhance drug craving and maintenance of addiction. All of these effects would aggravate personality disturbance that is created in combination with other subsets of critical traits, such as neuroticism.

Social Closeness/Agreeableness

In contrast to the highly motivating incentive state associated with extraversion, the core content of social closeness and agreeableness scales reflects the operation of neural processes that create a warm, affectionate, gratifying subjective emotional state elicited by affiliative stimuli, such as soft touch (kissing, caressing, stroking, play); sexual touch; hair grooming; psychological and physical warmth; a caring, smiling, friendly face; soft, caring vocalizations; and shared intimacy (symbolic touching). Our hypothesis is that the subjective emotional experience of warmth and affection reflects the *capacity to experience consummatory* ***reward*** *that is elicited by a broad array of affiliative stimuli* (Depue & Morrone-Strupinsky, 2005). This reward capacity is viewed as providing the key element utilized in associative conditioning processes that permit the development and maintenance of longer-term affective bonds that are characteristic of social organization in human and other primate societies.

A broad range of evidence suggests a role for the endogenous opiate neuropeptide in reward that is exerted by opiate neurons in the hypothalamic arcuate nucleus that project to many brain regions. Most relevant to affiliative reward is the mu (μ) opiate receptor (OR) family, which is the main site of exogenously administered opiate drugs (e.g., morphine) and of endogenous endorphins (particularly, *B*-endorphin) (Depue & Morrone-Strupinsky, 2005). Rewarding properties of μOR agonists are directly indicated by the fact that animals will work for the prototypical μ-agonists morphine and heroin, and that they are dose-dependently self-administered in animals

and humans. *B*-endorphin release on μOR receptors is increased in rats, monkeys, and humans by lactation and nursing, sexual activity, vaginocervical stimulation, maternal social interaction, brief social isolation, and grooming and other nonsexual tactile stimulation (Depue & Morrone-Strupinsky, 2005).

In monkeys and rodents, social bonding is not possible without soft tactile stimulation from the mother (Fleming et al., 1994), and this may involve activation of the μ-opiate system. Mammals, and especially primates, have evolved particular receptors on the skin and a sensory pathway for soft touch (Liu et al., 2007; Olausson et al., 2002) that projects to the anterior insular cortex, a structure that mediates awareness of the subjective experience of emotions (Craig 2009). Via projections to the rostral ACC, the anterior insula can activate *B*-endorphin neurons in the arcuate nucleus which activate reward and physiological quiescence via projections to the VTA-NAS and brainstem regions.

The rewarding effect of opiates may be especially mediated by μORs located in the NAS and VTA, both of which support self-administration of μOR agonists that is attenuated by intracranially administered μOR antagonists. Destruction of DA terminals in the NAS also showed that opiate self-administration is independent of DA function, at least at the level of the NAS (Laviolette et al., 2004). Rewarding effects of opiates are also directly indicated by the fact that a range of μOR agonists, when injected intracerebroventricularly or directly into the NAS, serve as unconditioned rewarding stimuli in a dose-dependent manner in producing a conditioned place preference, a behavioral measure of reward. VTA-localized μORs particularly in the rostral zone of the VTA mediate (1) rewarding effects such as self-administration behavior and conditioned place preference; (2) increased sexual activity and maternal behaviors; and (3) the persistently increased play behavior, social grooming, and social approach of rats subjected to morphine in utero. Transgenic mice lacking the μOR gene show no morphine-induced place preferences nor physical dependence from morphine consumption. And significantly, opiate but not oxytocin antagonists block the development of partner preference that is induced specifically by *repeated* exposure and *repeated* sexual activity in rodents (Carter et al., 1997).

Individual differences in social closeness are subject to strong genetic influence (Tellegen et al., 1988). If personality disturbance occurs in the region located at the extreme tails of individual difference distributions in the trait of social closeness, it is important to show that the neuromodulators associated with the trait are sources of individual differences in these behavioral systems. Individual differences in humans and rodents have been demonstrated in levels of μOR expression and binding that are associated with a preference for uOR-agonists such as morphine (Uhl et al., 1999; Zubieta et al., 2001). In humans, individual differences in CNS μOR densities show a range of up to 75% between lower and upper thirds of the distribution (Uhl et al., 1999), differences that appear to be related to variation in the rewarding effects of alcohol in humans and rodents.

One source of this individual variation is different single nucleotide polymorphisms (SNPs) in the μOR gene, OPRM1 (Bond et al., 1998; Gelernter et al., 1999). The most prevalent of these is A118G, with an allelic frequency of ~10%. This SNP bound *B*-endorphin three times more tightly than the most common allelic form of the receptor. Furthermore, *B*-endorphin is three times more effective in agonist-induced activation of G-protein–coupled potassium channels at the A118G variant receptor compared with the most common allelic form. Importantly, this genetic variation in μOR properties is related to response to rewarding drugs, such as morphine, alcohol, and cocaine, and to opiate self-administration behavior in animals (Zhang et al., 2007). Taken together, these studies suggest that genetic variation in μOR properties in humans and rodents is (1) substantial; (2) an essential element in the variation in the rewarding value of opiate agonists; and (3) critical in accounting for variation in the Pavlovian learning that underlies the association between contextual cues and reward, as occurs in partner and place preferences (Van den Oever et al., 2008).

Two recent studies have found that μORs are critical in modulating the strength of attachment behaviors in animals. Transgenic mice lacking the μOR gene showed markedly *reduced* (1) opiate self-administration reward; (2) acquisition of place and mate/pup preferences; (3) maternal behaviors (pup tactile stimulation, pup retrieval, nursing); (4) play and social grooming; and (5) NAS DA release to ethanol and amphetamine (Moles et al., 2004). Also, juvenile monkeys having the homolog of the μOR gene polymorphism that is characterized by enhanced *B*-endorphin functioning showed greatly enhanced distress and a lack of attachment behavior as a function of a series of maternal separations (Barr et al., 2008). And, finally, we have shown that a μOR antagonist in subjects with high trait levels of social closeness *reversed* their heightened ratings of affection to film scenes and their greater tolerance to heat (mediated by μORs) such that they now expressed levels not different from low trait social closeness subjects (Depue, 2006).

In terms of effects of experience on social closeness, it is the only higher order trait that shows significant within-family experience effects (Tellegen et al., 1988), indicating that both familial and nonfamilial relationships have a marked effect on trait levels. Of course, there is an immense animal and human literature that demonstrates that level of attachment is affected by interpersonal experience starting in the postnatal period (Fleming et al., 1999). Unfortunately, no studies of experience-dependent modulations of the μOR system have been reported, so it is unclear whether experience operates on social bonding via this system. There is emerging evidence, however, that social interactions during the neonatal period organize the subsequent expression of affiliative behavior by altering sensitivity to neuropeptides (Cushing & Kramer, 2005). What is clear is that low trait levels of social closeness/agreeableness accompany neuroticism as being the strongest personality associates of a range of personality disturbances. Whether these low trait levels are due to adverse early experience or an interaction of genetic and experiential factors needs empirical attention.

Social Rejection Sensitivity

Items covering the nature of social rejection sensitivity (SRS) have not been included in personality questionnaires. We view this as a serious oversight, since close interpersonal relationships are modulated by at least two very strong emotional systems: social closeness and bonding, drawing people together, and SRS, which either pulls people closer to avoid separation anxiety or pushes people away. SRS is also a central feature in personality disturbance, appearing in classical PD categories as borderline, dependent, and avoidant.

SRS is elicited by social separation due to group exclusion and whenever social relationships are threatened, damaged, or lost. It is also elicited by more symbolic forms of withdrawal of love or acceptance, including negative feedback about the self; verbal devaluation; disapproving, frowning faces; averted gazes; and expressions of the social emotions of contempt, indignation, and disgust by others. In response, people experience hurt, pain, anxiety and agitation, sadness, and the social emotions of guilt, shame, and embarrassment. Such a neurobehavioral system allows others to control social transgressions, and the rejected person avoids social ostracization that would follow if no anxiety or guilt were experienced—which in monkeys leads to death within weeks. From an evolutionary standpoint, SRS may have developed to maintain closeness of long-developing toddlers to nourishment- and safety-providing caregivers (Eisenberger & Lieberman 2004). Thus, SRS may be based on social pain—the distressing experience arising from the perception or potential psychological distance from close others or a social group (Eisenberger & Lieberman, 2004).

The description of the distress associated with social rejection is dominated by the terms pain and hurt, terms that are not ordinarily associated with other negative emotions. Physical pain has two components: physical sensory experience, and affective experience of unpleasantness and psychological pain and hurt. The latter component is associated with activation in the dorsal region of the ACC (dACC). This region is also the location of neurons that provide an aversive, punishment signal to the basolateral amygdala, where that aversive signal is paired with neutral cues in emotional associative learning (Johansen & Fields 2004). Thus, the dACC may provide the foundation for affectively aversive signals during the experience of harm—either physical harm or social harm. Indeed, recent studies have found that during the experience of social rejection, humans show intense activation of the dACC, which presumably activates the amygdala to generate the bodily responses that create the unpleasant emotional experience (Eisenberger & Lieberman, 2004; Somerville et al., 2006).

Though we are not aware of any research on the effects of experience on SRS levels or dACC activation levels, it is clear that familial and nonfamilial experiences of social rejection affect social trust and security of attachments. The entire area of SRS is understudied in psychology and neuroscience.

Constraint/Conscientiousness

The Nature of Constraint

Constraint represents a broad trait of impulsivity that modulates the expression of many domains of behavior, including emotional, motor, cognitive, and sensory reactivity (Carver, 2006; Depue & Collins, 1999; Depue & Lenzenweger, 2005; Depue & Spoont, 1986; Spoont, 1992; Zald & Depue, 2001). Whereas the four traits described above all reflect the activity of neurobehavioral systems, constraint lacks ties to any specific motivational-emotional system (Carver, 2006; Depue & Collins, 1999; Spoont, 1992). Thus, we have proposed that constraint is the personality trait that reflects the greatest CNS weight on the construct of a minimum response threshold (Depue & Collins 19999; Depue & Lenzenweger, 2005; Depue & Spoont, 1986). This can be visualized in Figure 24.2, where the trait of constraint would be the major modulator of the

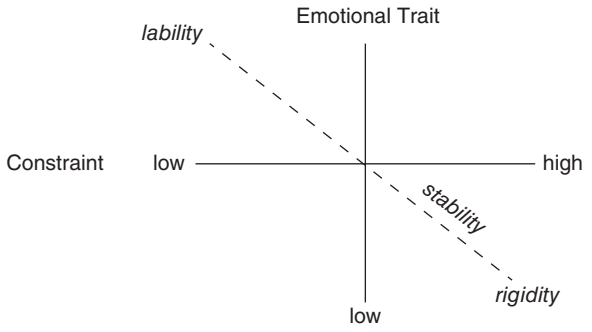

Figure 24.11 The interaction of an emotional trait with the higher order trait of constraint, forming a diagonal of behavioral stability extending from labile to rigid.

threshold for behavioral manifestation. In this model, emotional higher order personality traits reflect the influence of neurobiological variables that strongly contribute to the threshold for responding, such as DA in the facilitation of incentive motivated behavior, μ-opiates in the experience of affiliative reward, and CRH in the potentiation of anxiety. Constraint modulates the probability of elicitation of all of those variables.

Significantly, as shown in Figure 24.11, constraint in its modulatory interaction with an emotional personality trait creates a diagonal of stability of emotional behavior. This diagonal extends from lability where the emotional trait's level is high and constraint is low (i.e., increasingly easy stimulus elicitation of behavior due to a low threshold created by the interaction as in Figure 24.2) to rigidity when the emotional trait's level is low and constraint is high (i.e., increasingly difficult stimulus elicitation of behavior due to a high threshold created by the interaction).

Constraint and Serotonin Functioning

Functional levels of neurotransmitters that provide a strong, relatively generalized *tonic inhibitory* influence on behavioral responding would be good candidates as significant modulators of a response elicitation threshold, and hence would likely account for a large proportion of the variance in the trait of constraint. We and others previously (Carver, 2006; Coccaro & Siever, 1991; Depue, 1995; Depue & Spoont, 1986; Lesch & Canli, 2006; Panksepp, 1998; Spoont, 1992; Zald & Depue, 2001; Zuckerman 1994) suggested that 5-HT, acting at multiple receptor sites in most brain regions, is such a modulator. 5-HT modulates a diverse set of functions—including emotion, motivation, motor, affiliation, cognition, food intake, sleep, sexual activity, and sensory reactivity (Carver, 2006; Depue & Spoont, 1986; Lesch & Canli, 2006; Spoont, 1992). Furthermore, *reduced* 5-HT functioning in animals (Depue & Spoont, 1986; Spoont, 1992) and humans (Coccaro & Siever, 1991) is also accompanied by *irritability* and *hypersensitivity* to stimulation in most sensory modalities (Spoont, 1992). Thus, 5-HT plays a substantial modulatory role in general neurobiological functioning that affects many forms of motivated behavior. In this sense, constraint might be viewed as reflecting the influence of the CNS variable of 5-HT, which we refer to as *neural constraint* in Figure 24.11. In support of this notion, we found that 5-HT agonist-induced increases in serum prolactin secretion were correlated significantly and specifically only with the Constraint/Impulsivity (control) scale (-0.44, $p < .01$) from Tellegen's personality questionnaire of 13 primary scales (Depue, 1995).

Constraint, Instability, and Personality Disturbance

Along with neuroticism and low social closeness, constraint is well correlated with personality disturbance, particularly of the type related to unstable behavior (as in the classical unstable group of PDs of histrionic, antisocial, and borderline). A vast body of animal and human evidence consistently associates *reduced* functioning of 5-HT neurotransmission with *behavioral instability*. In addition, recent research on two polymorphisms of the gene for tryptophan hydroxylase (TPH2, which is localized in brain rather than the periphery), the rate limiting enzyme in the synthesis of 5-HT, indicates marked behavioral instability (particularly in affective aggression and impulsive suicide) and increased amygdala reactivity to positive and negative emotional slides in any one of the alleles that reduces brain 5-HT by 50% (Hennig et al., 2005; Manuck et al., 1999; Rujescu et al., 2002). Furthermore, reduced levels of 5-HT are associated with many clinical conditions, including impulsive, violent suicide across several types of disorder, obsessive-compulsive disorder, disorders of impulse control, aggression and irritability, depression, anxiety and enhanced stress reactivity, arson, unconstrained sexual behavior, and substance abuse (Carver, 2006; Coccaro & Siever, 1991; Depue & Spoont, 1986; Winstanley, 2005).

The nature of this instability depends on the neurobehavioral system being elicited. An example of the interaction of neurobiological variables associated with constraint (5-HT) and extraversion (DA) helps to illustrate this point (see Depue & Lenzenweger, 2005, for a discussion of the behavioral consequences of an interaction of each of the higher order traits with constraint). 5-HT is an inhibitory modulator of a host of DA-facilitated behaviors, including the reinforcing properties of psychostimulants, novelty-induced locomotor activity, the acquisition of self-administration of cocaine, and DA

utilization in the NAS (Depue & Collins, 1999; Depue & Spoont, 1986; Spoont, 1992). This modulatory influence arises in large part from the dense dorsal raphe 5-HT efferents to the VTA and NAS, connections that are known to modulate DA activity (Spoont 1992). A 5-HT–related reduction in the threshold of DA facilitation of behavior results in an exaggerated response to incentive stimuli, which is most apparent in reward–punishment conflict situations. In such situations, exaggerated responding to incentives results in (1) a greater weighting of immediate versus delayed future rewards; (2) increased reactivity to the reward of safety or relief associated with active avoidance (e.g., suicidal behavior); (3) impulsive behavior, i.e., a propensity to respond to reward when withholding or delaying a response may produce a more favorable long-term outcome; and (4) various attempts to experience the increased magnitude and frequency of incentive reward (e.g., self-administration of DA-active substances; Coccaro & Siever, 1991; Depue & Iacono, 1989; Lesch & Canli, 2006; Winstanley et al., 2005). All of these effects impair the ability to sustain long-term goal-directed behavior programs (such as obtaining a college degree) by mental representations of expected rewards that can be repeatedly accessed, held online in prefrontal cortex, and thereby symbolically motivate behavior (Depue & Collins, 1999).

This discussion suggests an important role for 5-HT in the model of personality disturbance shown in Figure 24.1. Reduced levels of 5-HT create a highly reactive individual in terms of hyperactivity of the ANS to stress, hyperirritability to sensory overload and life frustrations, enhanced affective aggression to even minor provocations, unplanned suicidal attempts when stressors become unbearable, instability of attachment to others (vacillating between approach and avoidance), and labile positive and anxious moods. This behavioral instability may reflect the effect of 5-HT's reduced neural constraint over many CNS variables (Spoont, 1992), which might explain how alterations of 5-HT functioning are found in so many different clinical disorders. Such weak constraint over CNS variables might render the effects of stress as markedly increased on biology and hence behavior. In other words, 5-HT–constraint may serve as a general modulator of expression on the reaction surface, increasing expression of personality disturbance during times of life stress and interpersonal chaos. At the same time, stress may increase the probability that 5-HT constraint will disinhibit the elicitation of the neurobehavioral systems of other emotional traits: animal research has shown that stressors of many types, but especially perceived or actual social aggression and social isolation (both of which are common in the life of individuals with personality disturbance), further decrease 5-HT functioning. Thus, 5-HT constraint may serve as a strong modulator of the extremity of an individual's position on a trait and, in turn, the *course* of intensity of personality disturbance over the life span.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The above discussion has suggested a number of variables that contribute to the development of a position within the reaction surface (gray area in Figure 24.1) of personality disturbance. In our view, the sine qua non of being within that reaction surface, being susceptible to personality disturbance, is extremity on the neurobiological variables underlying a critical subset of emotional traits. The reason for this is that being at the extreme has marked effects on the threshold for eliciting those traits under stimulus conditions. Depending on the phenotypic features of personality disturbance (which is dependent not just on extremity but on the subset of interacting major traits, as outlined in Figure 24.1), the *impairing* threshold value may be *low*, as in the case of neuroticism, social rejection sensitivity, affective aggression, fear, and extraversion (in terms of histrionic, impulsive behavior), or *high*, as in the case of affiliative bonding and extraversion (in terms of depressive behavior). As noted in the discussion of Figure 24.2, extreme threshold values lead to variation in the range of stimuli that are subject to negative or positive associative conditioning and to subsequent biasing of perceptual and attentional processes to stimuli that elicit a certain trait. Both of these latter effects likely help to maintain and increase the extremity of trait values over time.

A second important contributor to being within the reaction surface is the functioning of 5-HT, which as shown in Figure 24.2 modulates the value of the threshold required for trait elicitation. As shown in Figure 24.11, especially *reduced* functioning of 5-HT creates instability when interacting with extreme levels of an emotional trait. It is important to note that 5-HT–induced instability is manifested at two different levels: (1) at the phenotypic level as in Figure 24.11; but also (2) at the neurobiological level. Recall the discussion of 5-HT x DA interactions: reduced 5-HT functioning in the NAS results in a very low threshold for eliciting DA facilitation of behavior by incentive stimuli. *This illustrates that the impact of environmental stimulation on neurobiological variables underlying emotional traits is modulated by 5-HT functioning*.

Both the extremity of neurobiological variables underlying emotional traits and 5-HT functioning are modified by genetic polymorphisms, with substantial effects noted so far for the genes of the DAD4 receptor, DAT, the μOR, MAOA, Bdnf, 5-HTT, 5-HT1A receptor, and TPH2. Thus, genetic contributions to position within the reaction surface are likely to be significant.

There is a growing literature that indicates that stressful environmental experiences have a robust effect on the functioning of neurobiological variables underlying personality traits. The stressors may derive from environmental conditions that are external (e.g., poverty, dangerous neighborhoods), within the family (e.g., conflict, violence, sexual abuse, caregiver separation or neglect), or within the caregiver (e.g., maternal style). The exciting aspect of this area of research is the beginning of an understanding of how these environmental influences affect neurobiological functioning and hence behavioral variation in enduring ways. This was discussed in terms of sensitization in extraversion, and a variety of other epigenetic effects in neuroticism. Thus, this raises the possibility that environmental history may strongly affect an individual's extremity on critical personality traits, and hence position within the reaction surface of personality disturbance.

Both genetic and environmental stress variables appear to be most profound and enduring when they exert their effects during early developmental periods. This may be due to the fact that brain development has critical developmental windows in postnatal, childhood, and adolescent periods. Thus, the s-allele, other genetic variations in 5-HT functioning, and MAOA activity have substantial effects on the development of neural circuitry in the postnatal period when the forebrain is undergoing exuberant experience-expectant dendritic and axonal growth. These early effects endure life long, but are not significant when introduced in adulthood. There are other periods of experience-expectant brain growth in childhood, and robust growth in cortico–cortical connections between prefrontal and posterior regions in adolescence (Blakemore 2008). It is perhaps for this reason that the well-documented stability of most higher order personality traits is valid mainly *after* adolescence.

The Role of Individual Differences in the Interaction of Genes and Environment

In consideration of these genetic and environmental effects, the role of individual differences in trait neurobiological functioning is often neglected. However, as indicated in the discussion of Figure 24.2, the effects of experience on neural functioning are dependent on preexisting trait levels of genetically influenced neural functioning. This dependency has been demonstrated recently several times (Caspi et al., 2002, 2003), but the influence of individual differences is often neglected in discussions of the effects of experience on neural systems (e.g., Meaney, 2001). A dramatic example of this dependency is illustrated in Figure 24.12, which is based on a body of research with rats who differ in DA functioning in the NAS, the site of DA's facilitation of incentive reward (Depue & Collins 1999). In this example, the stimulus is not environmental but rather a direct activation of DA receptors by amphetamine (a DA agonist), and its effect on the acquisition of self-administration of amphetamine is plotted in two groups of rats differing markedly in trait DA functioning. Whereas the high DA group readily acquires self-administration behavior, the low DA group is unaffected by the stimulus (amphetamine). Apparently the amphetamine has too weak an effect on the rats with low DA reactivity to reach the threshold of experiencing a subjective sense of reward. Thus, these two groups of rats will encode their surrounding context in opposite ways (as rewarding vs. neutral), such that the subsequent efficacy of the context will only be enhanced for the high DA group. These findings also mean that stress-induced epigenetic effects on the DA system (e.g., sensitization) will be much greater in the high versus low DA group. One can imagine dramatic differences in the developmental trajectories of these two groups in terms of (1) the elaborateness of their associative networks of positive emotional

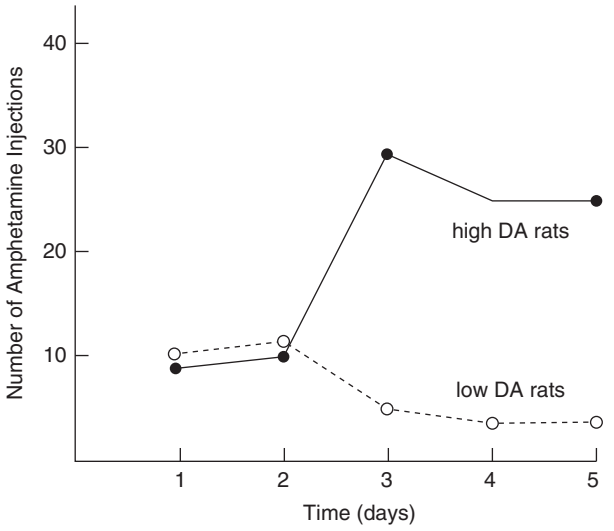

Figure 24.12 Rats differing in dopamine (DA) functioning show a different course of acquisition of self-administration of amphetamine over days.

environmental contexts; and (2) the capacity of these contexts to elicit epigenetic effects and (positive incentive motivated behavior.

The same point can be made from the findings illustrated in the last two rows of Figure 24.6. The cross-fostered offspring of low LG mothers raised by high LG mothers are less prone to anxiety-related behavior as adults. This indicates that the effect is mediated by postnatal maternal environment. However, offspring of high LG mothers raised by low LG mothers do not have an increased tendency to develop anxiety-related behavior in adulthood, indicating that specific factors inherited by the high LG offspring modify or protect them from the effects of being mothered by low LG females.

Similarly, from the results in Figure 24.13, it was concluded that the genotypic variation in MAOA activity was only expressed as significant antisocial behavior with experience of severe childhood maltreatment: the genotype's effects on behavior are dependent on level of environmental adversity. An alternative perspective suggests that, since there is a dimension of childhood maltreatment from none to severe and the level of antisocial behavior is correlated with that dimension, the extent of environmental influence on antisocial behavior is dependent on genetically influenced neurobiological trait levels (i.e., those created by variation in MAOA activity levels)—once environmental adversity rises above none.

Both MAOA groups show increasing behavioral responses to increasing stress; it is just that stress activates

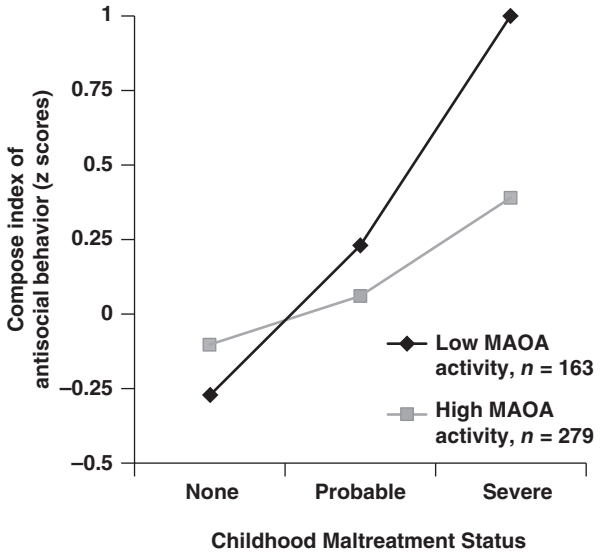

Figure 24.13 Effects of increasing levels of childhood maltreatment on antisocial behavior as a function of a genetic polymorphism in MAOA. *Source:* Adapted from Caspi et al. (2002).

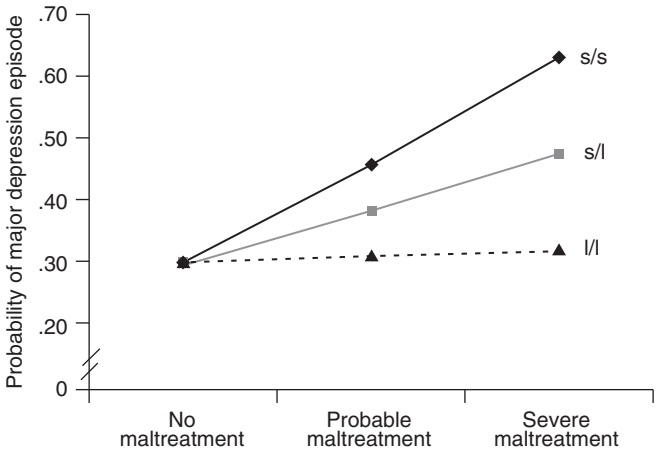

Figure 24.14 Effects of increasing levels of childhood maltreatment on depression as a function of a genetic polymorphism in 5-HTT (s- vs l-alleles). *Source:* Adapted from Caspi et al. (2003).

a greater response in the neurobiology created by low MAOA conditions and hence in behavior. A similar case can be made in Figure 24.14: the effect of maltreatment on depression is dependent on the interaction of stress with different neurobiological trait levels created by genetic variation in 5-HTT (s- vs l-alleles).

Finally, these various considerations can be modeled more formally as in Figure 24.15, where the risk of lying within the reaction surface of personality disturbance is a function of three variables. First, extremity of the trait values of neurobiological variables underlying a critical subset of emotional traits (such as a combination of high neuroticism and social rejection sensitivity, and low affiliative reward) is on the horizontal axis. Again, this

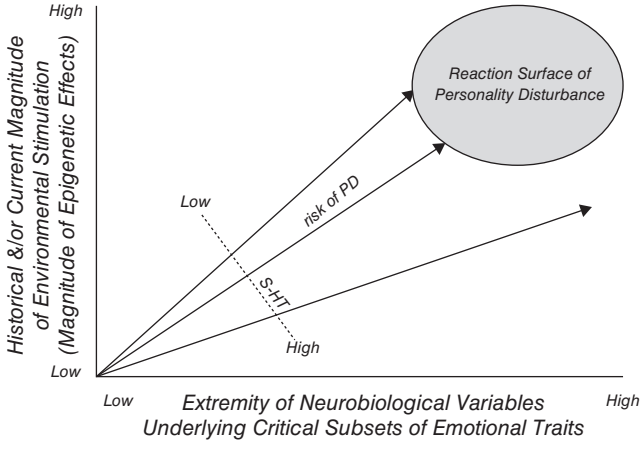

Figure 24.15 Nature of the interaction between environmental and neurobiological variables in the development of personality disturbance.

serves as the foundation of risk, the sine qua non for the development of personality disturbance. This foundation is set by genetic factors (but of course later reflects a history of gene–environment interaction), which may have their greatest impact on neural development during critical early life periods up to adolescence. Second, an individual's magnitude of historical or current environmental stress is a substantial contributor to development of personality disturbance. But as shown in the figure, the environmental effect varies in its magnitude as a function of neurobiological trait levels on the horizontal axis. This implies that the magnitude of epigenetic effects is dependent on neurobiological trait levels, being greatest at extreme neurobiological levels. At low neurobiological trait levels, environmental impact via epigenetic effects are hypothesized, as illustrated in Figures 24.6 (bottom row), 24.12, 24.13, and 24.14, to be limited. Lastly, level of 5-HT functioning is expected to modify risk for lying within the reaction surface of personality disturbance, particularly by its effect on neurobiological reactivity to stimulus provocation (i.e., the magnitude of epigenetic effects induced by environmental provocation). *Reduced* 5-HT functioning is hypothesized to (1) enhance the reactivity of neurobiological variables to stress, thereby (2) increasing enduring epigenetic effects and thus extremity of trait neurobiological functioning of variables on the horizontal axis, and (3) risk of lying within the reaction surface for personality disturbance, where reduced intensities of environmental stress are required to induce epigenetic effects in the neurobiological variables on the horizontal axis—an effect represented by elevation of the upper diagonal in the figure. Thus, in this model of personality disturbance, both genetic and environmental factors play key roles, the relative influence of which probably varies as a function of type of genes, cumulative environments, developmental period, and behavioral patterns.

Translational Implications

The stated goal of translational research, particularly as advocated by the National Institute of Mental Health (National Advisory Mental Health Council, 2000), is twofold. First, in both the childhood and adult psychopathology domains, the explicit goal of developmental and experimental psychopathology research is the illumination of those factors responsible for the pathophysiology of mental illness. The second aspect of the goal—the translational element—is the explicit interest in the translation of behavioral science and neuroscience research discoveries into innovations in the clinical care for those suffering from the many forms of psychopathology. Given that what we have termed *personality disturbance* (more typically termed *personality disorder*) affects approximately 10% of the population (Lenzenweger, 2008), the public health implications of this type of psychopathology for the population are clearly quite striking. Personality disturbance is well-known to be associated with considerable direct-care costs and after-care costs as well as foregone earnings that are appreciable. Moreover, personality disturbance causes considerable impacts not only on the person who suffers from a form of personality disorder but also relations with family members, friends, and coworkers. Finally, personality disturbance in parents will likely impact their ability to provide an optimal environment for the psychological and psychosocial development of their children, thus representing a factor that will enhance risk of disorder in the children (in addition, obviously, to the contributions made toward pathology via genetic and epigenetic inputs from the same parents). Thus, the translational emphasis in relation to personality disturbance is extraordinarily relevant as we move forward in our understanding of the basic mechanisms and processes involved in the etiology and development of personality disturbance. In our model we have sought to articulate the manner in which basic neurobehavioral systems, impacted by environmental factors, can create a matrix from which personality disturbance can arise as an emergent product. However, this model is not only useful as a theoretical exercise and a heuristic for research, but rather the primary neurobehavioral systems we have identified (incentive motivation/agentic extraversion; social closeness/affiliative extraversion; anxiety; fear; neural constraint) all represent targets for the development of treatments. Each of these primary neurobehavioral systems could easily be the focus for the development of novel psychopharmacological interventions (cf. Nunes, Carroll, & Bickel, 2002). The implications of our model, moreover, extend beyond the development of pharmacological interventions for personality disturbance in the translational paradigm, but they also strike us as consistent with the development of psychotherapy strategies that might impact the psychological and social processes we discuss (Tashiro & Mortensen, 2006). For example, further refinement of psychotherapeutic strategies explicitly directed at enhancing constraint, facilitating social closeness, altering cognitions related to the meaning of rewards (or accessibility of reward), or moderating anxiety, fear, and rejection sensitivity strike us as viable and, more importantly, substantively guided translational efforts.

Subject Index

Page numbers followed by f and t refer to figures and tables, respectively.

AA. *See* Accelerated aging
AAI. *See* Adult Attachment Interview
AAMR. *See* American Association on Mental Retardation
ABC. *See* Attachment and BioBehavioral Catch-Up; Attachment and biobehavioral catch-up
Abduction of disorder by psychiatry, 395
Abnormality, PAPA defining approach, 157
Abnormal personality, trajectories, 1044
Abuse, term (usage), 458
Abusive/nonabusive mothers, facial/vocal emotional expressions, 468
Academic adjustment, foster care (impact), 519–520
Academic functioning, ER (relationship), 215–219
Academic success, cognitive/behavioral skills (requirement), 529
ACC. *See* Anterior cingulate cortex
Accelerated aging (AA) theory, 922
ACE. *See* Adverse childhood experiences
ACES. *See* Adverse Childhood Experiences Survey
Acetaldehyde dehydrogenase (ALDH), impact, 866
Acetylcholine receptor subtype, impact, 866
ACT. *See* Assertive Community Treatment
ACTH. *See* Adrenocorticotrophic hormone
Activation, 619
Active effects model, 247
Active rGE, 844
Active vision, joint attention PDPM (relationship), 130–131
Activity-dependent genes, impact, 137–138
Acute stress response, 433
Adaptive facet, perspective (narcissism), 715–716
Adaptive tipping point, perspective (narcissism), 715
Adderall, misuse, 836
Addiction
  core neural model, 818
  medications, 871
  model, 695–696
  narcissism, parallel, 706
  temporal discounting hypothetical curve, 622f
  understanding, 868–869
ADHD. *See* Attention deficit/hyperactivity disorder
Adolescence (adolescents)
  adolescent onset schizophrenia, differential diagnosis (developmental approach), 956t
  ADU dependence, self-organized peer groups/progressions, 663f
  animals, mesolimbic dopamine pathway, 821
  antisocial behavior
    rehabilitation, 670f
    study, 671
  assessment, structural MRI (usage), 928
  behavioral problem history, treatment, 672
  binge drinking, growth curve trajectories, 809f
  bipolar disorder
    assessment, 903–904
    diagnosis, 901–903
    onset/course, 904–906
    phenomenology, 903–906
    prevalence, 904
    prodromes/precursors, 906–907
    treatment, 907
Borderline Personality Disorder (BPD), relationship, 759–761
coercive joining, violence (relationship), 665–668
course, dynamic changes, 820–822
development, 220–221
developmental histories, challenges, 760
developmental processes, focus, 1026
early adolescence, personality development (developmental period), 1063–1065
ER cognitively based strategies, 199–200
Fostering Healthy Futures (FHF), 543
friendship influence
  ADU progression, 664f
  violence progression, 666f
friendships, microsocial dynamics, 667
gray matter loss, average rates, 970f
The Incredible Years, 543
late-adolescence dependence, ADU mediator (peer clustering), 663f
late adolescence, personality dependence (developmental period), 1065
limited model, 295–296
maladaptive pathway, 1060
Middle School Success (MSS), 543
narcissism
  assessment, 691–694
  manifestations, 687–691
  measures, 694
  questions/concerns, 691–692
  self-report measures, 692–694
Narcissistic Personality Disorder (NPD), diagnosis pros/cons, 707–708
narcissistic traits, 1063
peer influence
  developmental pathway, 661–662
  life history perspective, 661f
peers, sexual selection, 659–662
personality disorder (PD), measurement issues, 1048–1049
problem behavior, 659–668
  self-organized peer groups, relationship, 661f
schizophrenia
  gyrification index, alterations, 971f
  risk, elevated level, 960
substance use
  epidemiological trends, 836–837
  etiology, media exposure (impact), 875
  progression, friendship (dyadic coregulation moderator), 665f

Adolescence (adolescents) *(Continued)*
relationship, 849–850
transition, 849
Treatment Foster Care Oregon for Adolescents (TFCO-A), 542
violence
prognosis, longitudinal studies, 666
trauma, contributions, 667f
youth narcissism, 684
ADOS. *See* Autism Diagnostic Observation Schedule
Adrenal steroid hormones, regulation, 487
Adrenocorticotrophic hormone (ACTH), 202, 521
release, 565, 1092
responses, elevation, 858
stimulation, 401
ADU. *See* Alcohol and drug use
Adult Attachment Interview (AAI), 251, 732
Reflective Functioning (RF) Scale, 742
Adulthood
binge drinking, growth curve trajectories, 809f
early adulthood, personality disorder (developmental period), 1065
late middle adulthood, longitudinal subtype typology/prospective trajectory class studies (parallelisms), 811f
later adulthood, personality development (developmental period), 1065–1066
Adult narcissism, 683–684
clinical observations, 686
diagnostic approaches, 685–686
empirical research, 686
manifestations, 685–687
social-personality research, 686–687
Adult-onset bipolar disorder, 905
Adult onset schizophrenia
academic performance/cognition, quality (problem), 964
antecedents, childhood trial, 960t
development, abnormality, 964
perinatal factors, 962–963
risk factors, 963
Adults
attachment styles, studies, 733
bipolar disorder, diagnosis, 901
depression
childhood trauma, relationship, 564
child maltreatment, effects (moderation), 479
depression, interpersonal theories, 293
narcissism, intrapersonal/interpersonal manifestations, 684
neurofunctional organization, observation, 126
OCD, meta-analyses, 329, 331
Adverse childhood experiences (ACE), factors, 482–483
Adverse Childhood Experiences Survey (ACES), 458
impact, 524
Adversity. *See* Early adversity
childhood adversity
Borderline Personality Disorder (BPD), relationship, 738–744
childhood schizophrenia, relationship, 964–965
effects, developmental psychopathology model, 557t
developmental adversity, 769–770
exposure, 283
genetic research, 525

  stress responsive neurohormonal systems, alterations, 407
  term, usage, 391
Trauma-spectrum model, 389
  usefulness/relevance, 390
Traumatic brain injury (TBI), 1010
Traumatic events
  child maltreatment victims, memory, 576–577
  cognitive risks, associations (occurrence), 355
  knowledge, 433
  maltreated child memory, 577
  memory, 574–576
Traumatic experiences
  dissociation/repression, impact, 569
  impaired memory theories, 569–571
  orienting, defensive responses (contrast), 569–570
  overinterpretation theory, 570
  robust memory theories, 568–569
  survival processing, 569
Traumatic reminder exposure, studies, 406
Traumatic stress
  analysis, multiple levels, 386
  effects, mediation, 409
  multilevel developmental psychopathology perspective, 386
  multilevel developmental psychopathology perspective, translational implications, 411
Traumatic stress, model, 401f
Traumatized children
  associative memory, psychopathology (relationship), 573
  attention/encoding, 571–573
  memory, empirical studies, 571–582
  neutral/positive events, memory, 573–574
  stressful/traumatic events, memory (impact), 574–576
  translational issues, 580
Treatment as usual (TAU), 764–765
  effects, 1022
Treatment decision making, dimensional continuum (development), 175–176
Treatment Foster Care Oregon for Adolescents (TFCO-A), 542
Triangulation, process, 282–283
Trier social stress test (TSST), 575–576
Truth, impact, 876
Tryptophan hydroxylase 1 (TPH1), 916
Tryptophan hydroxylase (TPH) gene, 734
Tryptophan hydroxylase (TPH2) gene, polymorphisms, 1101
TSST. *See* Trier social stress test
Tumor necrosis factor-alpha (TNF-?), 1013
Two-process model, 605–607
  summary comments, 608
Type 1 attention, laboratory tests, 611–613
Type 1 processes, impulsivity (relationship), 621–623
Type 2 attention, laboratory tests, 613–615
Type 2 melanocortin receptors (MC2-R), 1014
Type 2 processes, impulsivity (relationship), 623–626
Type-of-stimulus dimension, 556

UBE3C, 856
UCLA Family Study, 960
UCSs, associative learning, 1092
Updating, EF component, 316–322

Val66Met
  BDNF Met carriers, 965
  genotype, 435
  polymorphism, 435
Val homozygotes, 965
VBM. *See* Voxel based morphometry
Ventral attention network, 609f
Ventral medial prefrontal NAA, nonremitters (comparison), 931–932
Ventral tegmental area (VTA), 1096
  DA fibers, projections, 1019
  dopamine projection system, 1097
  glucocorticoid/DA systems, 1098f
  mediation, 1099
  VTA DA neurons, 1098
  VTA-NAS DA, 1098
Ventrolateral prefrontal cortex (VLPFC), 929
Ventromedial PFC (vmPFC), 745
Verbal abilities, development, 192–193
Verbal fluency, deficits, 322–323
Verbal fluency/planning, 322–323
Verbal Selective Reminding Test (vSRT), 404
Verbosity, presence, 31
Violence
  coercive joining, relationship, 665–668
  development
    microsocial coercion, 659, 668f
    questions, 668
  progression, adolescent friendship influence, 666f
VIPR2, 856
Visual attention control, 138
Vitamin E, preventive use, 985
VLPFC. *See* Ventrolateral prefrontal cortex
vmPFC. *See* Ventromedial PFC
Volumetric decreases, causes, 1018
Voxel based morphometry (VBM), 967, 981
vSRT. *See* Verbal Selective Reminding Test
VTA. *See* Ventral tegmental area
Vulnerability
  domains, 818–819
  factors, 460–461
  models, 248, 602
  narcissistic vulnerability, 684

origins, 1003–1009
reaction time vulnerability, 616
susceptibility models, contrast, 602f
Vulnerability-stress model, 263
Vulnerable narcissism, 689–691
clinical observations, 689–690
empirical evidence, 690–691
manifestations, 689–690

Waist-hip ratio, 483
Water diffusion displacement, DTI measures, 968
Wechsler Intelligence Scale for Children, 539, 964
Wechsler Memory Scale (WMS), 404
Wechsler Preschool and Primary Scale of Intelligence, 539
Well-being, neglect (impact), 527–529
White House Conference on Children, 515
White matter
childhood schizophrenia, 968
microstructure, 612f
neuroimaging assessment, 926–927
schizophrenia, 971–981
tracts
abnormalities, 972–976
SLF II/III, 973f
volume, increase, 968
Whole person
involvement, 9
social-emotional well-being, 22–23
study, 21–35
Whole, properties, 768–769
Williams syndrome, 14, 19, 23
face processing, 51–54
facial expression profiling, 51–54
hypersociability, 29
language development, 31
neuroscience, usage, 50–54
social competence, 26–28
verbosity, 31
Willowbrook State School, conditions (exposure), 22
Windle Very High Heavy Drinking trajectory group, 810
Within-group differences, 2
WM. *See* Working memory
WMS. *See* Wechsler Memory Scale
Women, Infants, and Children (WIC) program, family enrollment, 657
Working memory (WM), 322
central executive component, 322
Worry
repetitive negative thought, 345
rumination, similarity, 345

Youth narcissism, 684
aggressiveness, 689
assessment
ethics, 681, 691–692
impact, 692
increase, evidence, 713–714
measure, necessity, 692
Youth personality disorders, development, 1039
Youth Risk Behavior Survey (YRBSS), 834
Youths
access policies, 877
behavioral difficulties/marginalization, 667–668
depression, 248f
long-term trajectories, 265
popularity, 267
social networks, theories, 265
