Second, regardless of whether cognitive factors are a cause, correlate, or consequence of psychopathology, *neurodevelopmental* and *neurodegenerative* mechanisms may play a role. Neurodevelopmental processes involve an abnormal unfolding of brain development, while neurodegenerative processes involve loss of neural function over time. While neurodevelopmental processes are posited to play a role in many disorders, the lack of large prospective studies starting early in life has hampered efforts to test these hypotheses and determine the neural processes involved. Neurodevelopmental processes involved in psychopathology are hypothesized to be driven by both genetic and early environmental influences (e.g., prenatal exposure to toxins or infection, postnatal stress) and to

take many forms, including alterations in neurogenesis and apoptosis, the formation and pruning of synaptic connections, and receptor expression (e.g., Rappaport, Giedd, & Gogtay, 2012).

Perturbations in neurodevelopment could take the form of delays in normal developmental processes (e.g., children with ADHD undergo the same sequence of cortical maturation as healthy children, but the timing is delayed; Shaw et al., 2012), or abnormal developmental processes (e.g., atypical patterns of white matter connectivity in neonates at genetic risk for schizophrenia; Shi et al., 2012). While cognitive impairments are presumed to be consequences of neurodevelopmental abnormalities in neurodevelopmental models, links between neurodevelopment and psychopathology are potentially more complex. Early neurodevelopmental abnormalities could be either causes or correlates of psychopathology, while perturbations in neurodevelopment after disorder onset could also conceivably be a consequence of psychopathology, via either direct alterations in neurobiology or indirectly by altering the individual's environment and experiences in a way that changes the course of development (e.g., transactional model).

The most common neurodegenerative model applied to cognitive deficits associated with psychopathology centers around disordered stress and immune responses (e.g., Conrad, 2008). Since chronic stress and elevated cortisol have been linked to many forms of psychopathology (e.g., adult depression; Stetler & Miller, 2011; schizophrenia; Walker, Mittal, & Tessner, 2008), this is a plausible pathway for neurodegeneration and subsequent cognitive deficits associated with psychopathology. Interestingly, abnormally low levels of cortisol (e.g., in PTSD; Morris, Compas, & Garber, 2012) may also lead to neurodegeneration, although the mechanisms need specification (Conrad, 2008).

Neurodegenerative processes could be a consequence of psychopathology (e.g., psychopathology leads to disordered stress response, which leads to neurodegeneration). For example, a meta-analysis found progressive loss of grey matter in the prefrontal cortex and temporal lobe in individuals with schizophrenia, especially during the first episode, suggesting that the onset of schizophrenia triggers a neurodegenerative process (Vita et al., 2012). However, neurodegenerative processes could also be a cause (e.g., chronic stress leads to neurodegeneration which leads to psychopathology) or a correlate (e.g., chronic stress leads independently to both psychopathology and neurodegenerative processes), or the result of a positive feedback loop between these processes (Conrad, 2008). However, in all of these cases cognitive deficits are presumed to be a consequence of the neurodegenerative processes. Since glucocorticoid receptors are highly expressed in the hippocampus and prefrontal cortex, neurodegenerative processes may have the greatest impact on memory and EF (e.g., Hinkelmann et al., 2009), perhaps accounting for their widespread impairment across disorders.

Cognitive Consequences. While not exactly a factor that is contributing as a precursor, per se, to cognitive risk, researchers have hypothesized that experiencing sustained psychopathology may further enhance the development of cognitive products and processes that persist after the peak of symptoms decline (i.e., cognitive scar). From this perspective, a youth's initial psychiatric episode may be caused by factors other than cognitive risks (e.g., a youth's coping abilities are overwhelmed following the experience of a severe stressor). As a consequence of and following the onset of the episode, the individual develops cognitive risks to the recurrence of psychopathology.

This exacerbation of cognitive risk into a more enduring cognitive vulnerability can occur through several (not necessarily exhaustive) pathways. First, youth who develop psychopathology frequently exhibit other noncognitive risk factors, such as poor academic performance and impaired peer relations, and these failures and risks may lead youth to the development of particular cognitive products (e.g., beliefs about low abilities; lack of control over important outcomes) and processes (e.g., greater attention to, encoding of, and memory for such negative experiences). Second and related, experiencing psychopathology symptoms may facilitate access to negative memories and thoughts due to the priming effects of mood on cognition (Bower, 1981). These negative cognitions can be encapsulated and coalesce into enduring products and processes, especially if they persist over an extended period of time and while essential self-concepts and thinking styles are under construction and developing (e.g., middle childhood; early adolescence). Finally, there can be dynamic, transactional relations between the stressful life events that may have triggered the onset of the disorder, and in turn, youth may behave in ways that reinforce the development of the cognitive risks. For example, a child with poor social skills, who consequently encounters rejection, may learn to expect such rejection. Subsequent behavior (e.g., withdrawing from social activity) may contribute to further social rejection, and consequently reinforce and strengthen the developing cognitive products and processes.

A first, necessary step to demonstrate support for these and other potential scar processes is that cognitive products

and processes worsen after experience of psychopathology. Research that examined the cognitive scarring after various forms of psychopathology has been mixed. Consistent with a cognitive scar model, deficits in EF, memory and attention remain in individuals in remission (e.g., euthymic BD, remitted depression, see Cognitive Processes). Findings for cognitive products, such as negative attributional style or rumination, have found mixed evidence for the cognitive scar hypothesis (e.g., remitted depression and BD; see Cognitive Products). However, since this evidence largely comes from cross sectional studies, it is possible that cognitive deficits preceded illness onset, or that there is a transactional positive feedback loop between cognitive deficits and psychopathology. Answering these questions will require more prospective longitudinal studies, starting before disorder onset and following individuals over the course of their illness and into remission.

Longitudinal Measurement Invariance: Stability and Change

Investigating the degree of stability and change in cognitive influences to psychopathology is a fundamental area of inquiry in developmental psychopathology. Yet, surprisingly sparse research has examined this core issue: "the degree of stability of cognitive vulnerability from childhood to adulthood is unknown" (Rutter, Kim-Cohen, & Maughan, 2006, p. 283). Examining the degree of stability and change in cognitive risks, and the likely variance in stability estimates across key developmental periods, can vitally inform mechanisms that may help to explain the strongly chronic, recurrent nature of most forms of psychopathology after initial onset and symptom increases occurring with most child- and adolescent-onset disorders.

Examining *measurement invariance* across development is a first and necessary step when considering both stability and change in cognitive influences to psychopathology, but this is a little researched and frequently ignored topic. In essence, the core question is whether any particular cognitive product or process, at the latent construct level, is the same when assessed with available measures across development. For example, multiple measures exist to assess individuals' negative cognitive style for different ages: young children (Conley et al., 2001), older children (Mezulis et al., 2006), adolescents (Hankin & Abramson, 2002), and adults (Haeffel et al., 2008). It is generally assumed that each of these manifest measures is assessing the latent construct of a negative cognitive style, and the evidence that each of these measures predicts later depressive symptoms, as the theory postulates, is presumed and taken as prima facie evidence to demonstrate that the manifest measures are, indeed, assessing the same core latent construct. However, virtually no research has been conducted to rigorously and properly examine whether the extant manifest measures used presently by investigators are, in fact, assessing the same latent construct over different developmental periods (i.e., measurement invariance; Widaman, Ferrer, & Conger, 2010).

Equivalently, using the same manifest measure across different developmental periods (e.g., childhood through adolescence and adulthood) still necessitates examination of measurement invariance; utilization of the same measure cannot be assumed to assess the same latent construct across development. Establishing that a particular measure, at the manifest level, is assessing the same theoretical construct and process at the latent level, is a fundamental step. Yet this critically essential work has not been conducted, so research investigating vital developmental psychopathology questions of cognitive influences, including stability, change, and developmental origins, rest on the untested assumption that presently used manifest measures of cognitive products and processes demonstrate a reasonable degree of measurement equivalence over time and across development.

Measurement invariance issues also connect to and raise questions concerning homotypic and heterotypic continuity. For example, is rumination exactly equivalent (homotypic continuity), at both the observed measurement and at the conceptually defined process level, across development (e.g., ages 5, 8, 13, 16, 25, 40, 68), or is rumination similar at the latent process level (e.g., perseverating on negative mood), albeit with some change in its manifestation and form (i.e., heterotypic continuity)? Relatedly, trying to establish the degree of continuity, especially whether the particular cognitive product and process conforms best to homotypic or heterotypic continuity, is further complicated by a lack of established theory and empirical knowledge on the overall hierarchical structure and taxonomy that organizes and connects the different cognitive products and processes together. How does this architecture and structure change across development (e.g., consolidation of cognitive influences) and as a function of psychopathology (e.g., consequence effects)? Issues of structure and consolidation are discussed in greater detail later in the next section, but it's important to highlight here that homotypic and heterotypic continuity concerns directly relate to issues of structure and consolidation across development.

Assuming that observable methods to assess cognitive influences exhibit reasonable measurement invariance, then processes underlying the degree of stability and change in these cognitive risks can be examined. A useful and

rigorous approach to understanding processes in stability and change derives from conceptual and empirical advances in research on basic personality development (Caspi, Roberts, & Shiner, 2005; Fraley & Roberts, 2005), including examination of rank-order stability and mean-level changes over time. Different processes, including (1) a trait-like model, (2) a contextual/autoregressive model, and (3) a combined trait/contextual model, can explain how cognitive risks maintain rank-order, or test–retest, stability over time. Trait models predict that the empirically obtained test–retest correlations will be invariant as the period between test–retest interval increases because there is a stable, enduring force (i.e., the trait cognitive risk) that organizes the manifestation of measured cognitive risks over time. In contrast, contextual models predict that the magnitude of the test–retest correlations for cognitive risk will decrease monotonically as the length of the test–retest interval increases (i.e., an autoregressive simplex pattern; Kenny & Zautra, 2001) because there is no enduring influence that drives the stability over time.

Testing which process (i.e., trait, autoregressive, combination) may best account for the degree of stability in cognitive risk over time requires that multiple waves of data be used. The two-time point study most typically used to demonstrate test–retest reliability is inadequate for formally and rigorously investigating the processes underlying the degree of stability observed over those two time points, regardless of the length of time (Fraley & Roberts, 2005), because it is the pattern of test–retest correlations over time, not the strength of the test–retest correlation, that indicates whether the particular cognitive influence is understood to be organized best from a trait, contextual, or a combined process. With multiple assessments of longitudinal data, the pattern of test–retest correlations can be examined to evaluate whether a trait-like or autoregressive contextual model best explains the rank-order stability of data over time. Moreover, longitudinal analyses can determine the mean levels of stability over time for the participants on average.

To date, little research has examined the degree of stability and change, and the underlying processes that give rise to that stability, in cognitive risks to psychopathology. The first examination of the processes underlying stability of cognitive vulnerability, in any age group, used a diary design with late adolescents who completed daily ratings of the cognitive inferences they made for the most negative event experienced every day for a month (Hankin, Fraley, & Abela, 2005). Findings showed mean-level stability: negative inference scores did not change on average over 35 days. Moreover, moderately stable rank-order stability was observed, and importantly, an enduring, trait-like model best explained the pattern of test–retest stability. Building on this approach and investigating additional cognitive products in younger adolescents (ages 11–16; sixth to tenth grades), Hankin (2008b) examined the degree of stability and change in negative cognitive style, dysfunctional attitudes, and rumination across four time points. A negative cognitive style demonstrated mean-level stability, whereas rumination and dysfunctional attitudes showed some mean-level change. The magnitudes of test–retest reliabilities were moderately high for a negative cognitive style (mean $r = .52$), and more modest for rumination (mean $r =. 28$), and dysfunctional attitudes (mean $r = .26$). The pattern of these test–retest reliabilities over time was best explained by relatively trait-like enduring processes for a negative cognitive style and dysfunctional attitudes, whereas both enduring and contextual dynamics contributed to the moderate stability for rumination. Future research is needed to continue this line of work to younger ages to better establish when these cognitive products begin to coalesce into the enduring, relatively trait-like risks to psychopathology and to expand this approach to understanding the dynamics underlying stability and change to other cognitive products and processes across various developmentally salient age groups.

Taken together, these findings showing that a negative cognitive style, in particular, already demonstrates modestly strong stability, and that enduring dynamic forces underlie this stability, have interesting applications when synthesized with established developmental epidemiological facts. It is intriguing that a negative cognitive style is already relatively trait-like by age 11 when the modal increase in depression rates occurs later in adolescence (especially ages 15–18; Hankin et al., 1998). Moreover, these findings open new questions that convey interesting translational implications for the timing of delivering evidence-based efforts to reduce depression rates. Would it be more effective to implement cognitive-behavioral (CB) depression preventions (Brunwasser, Gillham, & Kim, 2009) before certain cognitive risks, such as a negative cognitive style, have crystallized into relatively trait-like vulnerabilities to depression (i.e., before age 11)? How long do the effects of CB-based preventions last in changing these cognitive vulnerabilities that are believed to be important mechanisms of change in the prevention of depression? Meta-analytic reviews of depression prevention trials indicate that effects are generally short-lived (Horowitz & Garber, 2006; Stice, Shaw, Bohon, Marti, & Rohde, 2009), and similarly, research on CB treatments

of depression and anxiety reveals these psychotherapies exhibit enduring effects (e.g., relatively improved effects lasting up to 5 years), although the psychoactive mediating mechanisms appear to be mainly palliative and do not endure (Hollon, Stewart, & Strunk, 2006). As such, would reductions in core cognitive risks, if changed in late childhood, persist over several years to meaningfully decrease the surge in depression rates that are most likely to occur with modal age of onset in later adolescence?

Escaping the Silos: Building Integrative Models Across Boundaries

Taxonomy and Stucture of Cognitive Risks: Informing Consolidation in the Interrelation Among Cognitive Risks

As alluded to earlier, there exists no theoretically specified nor empirically determined structure of either cognitive products or processes, separately, nor both cognitive influences together in a hierarchical taxonomy model. The main issue is that numerous cognitive products, in particular, have been postulated and investigated as putative risks to psychopathology. Yet little is known about how these different cognitive products (each of which carries a different name and derives from supposedly relatively unique theoretical underpinnings), relate to each other, and how much they overlap. In other words, do cognitive products demonstrate factorial independence—with other cognitive products as well as possibly conceptually similar individual differences (e.g., neuroticism, as a personality trait, that shares some conceptual and empirical overlap with several cognitive products)?

In contrast and as a shining example of what is needed, considerable research, both theoretical and empirical, has reasonably well established the structure of temperament (e.g., Rothbart & Bates, 2006) and personality traits (e.g., Caspi et al., 2005). A consequence of a well-established personality taxonomy is that existing traits, as well as potentially new ones, can be placed systematically, organized, and understood conceptually within the larger trait taxonomy and structure. Moreover, a fair amount of work has investigated questions of personality development, including stability and change in traits (e.g., Roberts & DelVecchio, 2000) as well as developmental changes in structure and underlying processes contributing to the degree of stability (e.g., Fraley & Roberts, 2005) of these traits over time.

However, the essential theoretical and empirical work has not been conducted on the hierarchical structure of many of the cognitive influences that are the focus of this chapter. This is another concrete example of the general silo approach in much of the scientific inquiry that has taken place with cognitive influences to psychopathology. The factor structure of many cognitive processes has been well defined, at least in healthy individuals (e.g., see Executive Function for a review of the factor structure of EF component processes). However, only a handful of factor analytic studies have examined the factor structure of cognitive products. Those done with young adult samples (e.g., Hankin, Lakdawalla, Carter, Abela, & Adams, 2007) show that each of the cognitive risks (e.g., negative cognitive style, dysfunctional attitudes, rumination) are moderately correlated with each other but factorially independent (i.e., not completely overlapping at the latent level) and are mostly separate from related, but noncognitive, constructs (e.g., low self-esteem, neuroticism, depressed mood). Factor analytic studies of youth are more mixed but tend to suggest that some of these cognitive products overlap and are less distinct at younger ages (e.g., Adams, Abela, & Hankin, 2007). To our knowledge, no other research has examined the factorial structure and latent taxonomy of other cognitive products.

While it is a clear priority to establish a hierarchical structure of both cognitive products and processes to psychopathology across developmental periods, another important, yet under investigated, area is evaluating how the various cognitive risks interrelate with one another and potentially become more consolidated over time. Examining the interrelation among different risks is important because the various forms of cognitive products, for example, may all emerge and stabilize along a similar time-course, but each of these cognitive risks may be relatively independent of each other earlier in development and then begin to become increasingly more interrelated and coalesce. Indeed, this pattern of increasing interrelatedness would be expected based on research in the temperament and personality development literatures (e.g., Caspi et al., 2005), in which many more narrow, lower-order factors are observed early in development, but by middle adolescence and throughout adulthood, the standard personality taxonomy (e.g., Big-5 factors) is routinely obtained. The results from the few factor analytic studies of depressogenic cognitive products suggest that these cognitive risks are more distinct in children than in adolescents and young adults (Hankin et al., 2007). It appears that the various cognitive risks may initially be relatively independent of one another but then become increasingly more interrelated during the transition from childhood to adolescence. As multiple cognitive products potentially coalesce into a consolidated *set* of moderately intercorrelated cognitive risk, youths' degree of vulnerability to psychopathology may

potentiate. An interesting hypothesis in need of empirical examination is that this contamination and consolidation process may occur around the same time that prior researchers (Nolen-Hoeksema et al., 1992; Turner & Cole, 1994) earlier hypothesized that some cognitive risks first emerge.

Given that cognitive risks appear to become more interrelated with one another with progressing age, different approaches toward conceptualizing the relationship among multiple cognitive risks may be optimal for youth at different developmental stages. When youths' cognitive risks are still relatively distinct, knowledge of any particular factor may convey minimal information about overall degree of vulnerability to psychopathology, so a weakest link approach may be the most appropriate conceptualization at this stage: The child's strongest cognitive risk factor may likely be the best indicator of his or her propensity to engage in negative thinking leading to psychopathology. As cognitive risks become more interrelated with one another over time, however, knowledge of a child's level with respect to any given factor provides information about his or her levels with respect to other cognitive risks. At this point in development, an additive or multiplicative model may become more appropriate than a weakest link approach as the presence of multiple vulnerabilities may become an equally, if not more, important indicator of the likelihood the individual engages in negative thought processes contributing to psychopathology (see Abela & Hankin, 2008 for expanded discussion of the strengths and weaknesses of each of these models).

It is axiomatic in developmental psychopathology that there exist multiple developmental pathways (equifinality) and that the various influences leading to these pathways cut across multiple levels of analysis (e.g., from genes to neural circuits to behaviors and cognitions in relevant social contexts in an ecological framework). Given that multiple factors and processes are needed to predict known heterogeneity in causes for prevalent psychopathologies, it is essential to formally organize and consider how the various risk and resilience factors and mechanisms are structured together (i.e., a weakest link, additive, or multiplicative approach), when across development each of these model approaches provides the best fit for organizing cognitive risks, and how these best predict psychopathologies and for whom.

Links Between Cognitive Processes and Products: Still a Bridge Too Far?

In addition to determining the structure within cognitive products and processes, a further challenge is to determine how cognitive products are related to cognitive processes. Cognitive products, such as attributions, biases, and ruminative thoughts must necessarily arise from basic cognitive processes. However, efforts to understand how cognitive processes and products are linked are still in their infancy, akin to the early years of cognitive neuroscience, when scientists knew that neural events must give rise to cognitive processes but had very little idea of how they did so. Just as cognitive neuroscience has made great strides in discovering links between brain and cognitive processes over the past 20 years, the field seems poised to make significant progress in linking cognitive processes and products in coming years.

Indeed, in a few areas progress is already being made toward this goal. For example, two closely related models have recently been proposed, linking EF deficits to cognitive products in depression (Joormann, Levens, & Gotlib, 2011; Joormann, 2010b; Koster, De Lissnyder, Derakshan, & De Raedt, 2011), and aspects of these models have been empirically supported (e.g., Berman et al., 2010; Joormann & Gotlib, 2008; Zetsche, Avanzato, & Joormann, 2012). Specifically, according to these models, the experience of a negative event triggers negative mood and cognitions, which are normally transient, with mood-congruent cognitions quickly being replaced by more positive thoughts that regulate and repair the negative mood. However, depression is associated with deficits in EF, which lead to difficulty shifting attention and updating the contents of working memory to remove negative material and replace it with the more positive material that would normally aid in mood repair. As a result, negative material remains in working memory, leading to increased rumination, decreased reappraisal and impaired problem solving, which in turn reinforce and maintain the negative mood and activate negative cognitions (Joormann et al., 2011; Joormann, 2010b; Koster et al., 2011).

In other areas, there has been speculation regarding how cognitive products and processes may be linked. For example, there are potential parallels between hostile attributional bias and attentional bias toward negative information. However, research on these topics is still nascent, and efforts to understand the mechanisms giving rise to cognitive products are likely to face some significant challenges distinct from those faced by efforts to map cognitive processes onto neural mechanisms. In particular, many cognitive processes rely on brain networks that, while complex, are fairly well defined (e.g., the medial temporal lobe memory system and the frontal-parietal-striatal EF network). Identifying the brain networks involved then provides traction for understanding the component

mechanisms (e.g., unique properties of the hippocampus that support memory). However, cognitive products seem highly unlikely to arise from dedicated brain networks (e.g., there is not likely to be an attribution network). Rather, cognitive products are most likely emergent phenomena of multiple interacting cognitive processes, supported by widely distributed neural activity, making it difficult to gain traction in understanding the mechanisms involved.

How Do We Get There from Here? Bridging Multiple Levels of Analysis

The research reviewed in this chapter spans many levels of analysis, from probing people's accessible thoughts and behaviors through self-report, to assessing their behavioral performance on laboratory tasks, to measuring specific aspects of brain structure and function, and finally connecting these to psychopathological phenotypes. Furthermore, within each of these levels of analysis, there are myriad methodological approaches. Each level of analysis provides valuable information, and each methodological approach has its own strengths and weaknesses. Certainly, there is no one right approach. Rather, like the parable of the blind men and the elephant, each approach provides only partial information, which when taken alone can be misleading.

To give just one example, fMRI provides valuable information about which areas of the brain may be functioning differently in individuals with psychopathology. However, there are limitations to what fMRI can tell us about *how* those brain areas are functioning differently. For example, fMRI signal reflects a mixture of excitatory (e.g., glutamatergic) and inhibitory (e.g., GABAergic) neural activity, with the contributions of each depending on the task, the brain region, and many unknown variables (e.g., Logothetis, 2008). Thus, reduced fMRI signal (hypoactivation) can be the result of reduced activity of excitatory neurons, inhibitory interneurons, or both—the specific neural mechanism underlying the observed change in brain activation cannot be determined by fMRI alone. Thus, while correlational mapping of fMRI brain activation and psychopathology has made important contributions, it must be combined with other methods to move beyond the *where* and *how much activation* questions it can address to specific mechanistic *how* questions it cannot (e.g., Munakata, Chatham, & Snyder, 2012b).

Likewise, deficits on behavioral tasks or differences on self-report measures may arise from a mixture of sources (e.g., deficits in different cognitive processes or use of different strategies may contribute to poor performance on a task, and responses to questions about cognitive products may arise from different streams of biased information processing). Thus, to build more complete cognitive models of developmental psychopathology that can address *how* questions, to construct a picture of the whole elephant as it were, it will be necessary to combine evidence across multiple methods and levels of analysis.

Areas in which progress in generating such integrated models has been made include linking EF deficits in schizophrenia to specific abnormalities in the dopamine system (Barch & Ceaser, 2012), attention biases in depression to specific abnormalities in the serotonin system (Gibb et al., 2013), and connecting cognitive risks to multiple levels of analysis spanning genetics, neurobiology, and physiology (e.g., Hankin, 2012).

An example of an area in which multiple levels of analysis are just beginning to be linked is executive function deficits associated with depression. Here, a more detailed model is slowly emerging that has combined findings across disparate disciplines and methods. People with depression report difficulties with concentration and completing goals (symptom level); behavioral testing indicates deficits on a wide range of EF tasks, suggesting a problem with processes common to all EF tasks, such as maintaining goals in working memory (behavioral level; Snyder, 2013) neuroimaging research finds that individuals with depression have less activation in prefrontal brain areas involved in working memory (neural networks level; e.g., Fitzgerald, Laird, Maller, & Daskalakis, 2008); spectroscopy studies suggest that these lower levels of activation may be due to reduced glutamatergic function (neurotransmitter level; e.g., Yüksel & Ongur, 2010); and finally, computational computer simulations and neural recordings in animals suggest that working memory in prefrontal cortex depends on sustained neural firing triggered by glutamatergic signaling (cellular level; e.g., O'Reilly, Hazy, & Herd, 2013).

Fitting these pieces of evidence together across levels of analysis can generate a hypothesized model—concentration difficulties associated with depression are due to reduced prefrontal glutamatergic functioning leading to impaired ability to maintain goals in working memory through sustained neural firing. This model may prove to be wrong, but it has the virtue of generating specific, testable predictions (e.g., the largest impairments should be found on tasks that most heavily tap active goal maintenance) and implications for treatment (e.g., glutamatergic drugs should improve EF and concentration in individuals with depression; see, e.g., (Hashimoto, 2009) for promising research on novel glutamatergic antidepressants). However, such multilevel integrative models are still relatively rare, and to our knowledge no model has thus far spanned

from cognitive products to specific neural mechanisms. Building such models will undoubtedly be challenging, and will require a major interdisciplinary effort, but we believe they have tremendous potential for understanding the mechanisms involved in the cognitive aspects of psychopathology at a level that will enable the generation of new developmental clinical scientific knowledge and translation to new treatment and prevention approaches.

Transdiagnostic Approaches: Bridging Multiple Forms of Psychopathology

One theoretical approach that has received increasing attention is the study of common processes across seemingly separable constructs. This is known as a *transdiagnostic* approach to examining risk for psychopathology (e.g., McLaughlin & Nolen-Hoeksema, 2011). Our review of cognitive products and processes in relation to multiple prevalent psychopathologies suggests that certain cognitive risks may broadly predict several forms of emotional and behavioral disorders. Here we comment on two issues to consider that require additional future research with respect to a transdiagnostic approach to cognition and development of psychopathology.

The transdiagnostic approach to studying cognitive constructs, in particular, can be illustrated by an examination of rumination, worry, and postevent processing, which are three cognitive constructs hypothesized to fall under the common process of repetitive negative thinking (RNT). It is thought that these three cognitive constructs are similar in that they all involve a repetitive thought process; however they are distinguishable across different forms of psychopathology by their content. Rumination is commonly linked to depression, worry to generalized anxiety disorder, and post-event processing to social phobia (see McEvoy, Mahoney, & Moulds, 2010 for review). For example, in an effort to disentangle the common and unique components of these three cognitive constructs, McEvoy and colleagues (2010) factor analyzed common measures of RNT, including worry, rumination, and post-event processing, and they identified a common RNT factor. This common RNT scale was associated with symptoms of depression, anxiety, general distress, anger, and shame. This study demonstrates that putatively different cognitive products may be more appropriately and parsimoniously conceptualized as a single common process of repetitive negative thinking across various types of psychopathology and emotional states.

On the other hand, cognitive factors that appear transdiagnostic at one level of analysis may not be when more detailed measures at multiple levels of analysis are considered. Just as many problems with a car (e.g., a dead battery, broken starter, or being out of gas) could all lead to the same outcome (the car won't start), the same cognitive endpoint might be reached by many different underlying mechanisms (*equifinality*). For example, at the level of performance on neuropsychological tasks, EF deficits appear to be a transdiagnostic feature of psychopathology. However, as we reviewed, in some cases these shared behavioral deficits may arise from distinct neural mechanisms (e.g., perturbations in different neurotransmitter systems). Thus, determining whether a product or process is truly transdiagnostic requires escaping both diagnostic and methodological silos to consider underlying mechanisms at multiple levels of analysis.

One area where progress has been made in doing so is EF. Here, we discuss in some detail efforts to understand why transdiagnostic impairments in EF occur, as an example of how interdisciplinary research can shed light on transdiagnostic processes more broadly. What gives rise to broad patterns of impairment in core EF processes across most disorders? First, these deficits cannot be easily explained by nonspecific factors such as psychomotor slowing, differences in IQ or education, or medication use (Barch, 2005; Forbes et al., 2009; Snyder et al., 2015; Snyder, 2013). Second, in most cases, effect sizes are similar across the core EF domains, suggesting that psychopathology may be associated with impairment in what is common across EF tasks (common EF, posited to be monitoring for and maintenance of task goals and contextual information; (Miyake & Friedman, 2012), rather than a specific aspect of EF. Future research is needed to refine understanding of how such broad EF deficits arise. One possibility is that impaired function in brain networks involved in EF, including PFC, may lead to broad impairment in EF.

Indeed, extensive neuroimaging evidence indicates that individuals with many forms of psychopathology have structural and functional abnormalities in brain networks involved in EF. Meta-analyses have demonstrated reduced prefrontal grey and/or white matter in individuals with schizophrenia (e.g., Yu et al., 2010), BD (Yu et al., 2010), depression (Liao et al., 2013; Bora, Fornito, Pantelis, & Yucel, 2012), OCD (Menzies et al., 2008), and ADHD (van Ewijk, Heslenfeld, Zwiers, Buitelaar, & Oosterlaan, 2012). Alterations in prefrontal activation during EF tasks are also widespread across disorders. While both decreased (hypoactivation) and increased (hyperactivation) activation relative to healthy controls have been reported, in general reduced activation is found when task performance is impaired, and increased activation is found when task performance is unimpaired, consistent with inefficient processing

(e.g., Cortese et al., 2012; Diener et al., 2012; Hart, Radua, Nakao, Mataix-Cols, & Rubia, 2013; Menzies et al., 2008b; Minzenberg, Laird, Thelen, Carter, & Glahn, 2009; Patel, Spreng, Shin, & Girard, 2012).

Thus, multiple forms of psychopathology all appear to be associated with prefrontal structural abnormalities and functional inefficiency. However, the cellular level abnormalities underlying these broad changes in prefrontal function may vary across disorders. For example, while depression is associated with *reduced* glutamate function (e.g., Luykx et al., 2012), individuals with BD show *increased* glutamate levels in PFC (Gigante et al., 2012). The role of cellular level mechanisms in EF impairments has been most extensively investigated in individuals with schizophrenia. Phasic dopamine bursts, which normally serve to regulate updating of goals and information in working memory, are dysregulated in schizophrenia, leading to a failure to appropriately update relevant information into working memory and lack of stability of representations in the face of interference (Barch, 2005; Eisenberg & Berman, 2010). Thus, altered dopamine function is one key candidate mechanism that may underlie impaired common EF in schizophrenia, leading to impairments across all EF tasks.

In addition, PFC dysfunction may differentially impact different posterior and subcortical areas in different disorders. For example, in the case of PTSD, hypoactivity of the prefrontal–parietal EF network is hypothesized to lead to a loss of top-down control over emotion and memory systems (e.g., the amygdala and hippocampus, (Patel et al., 2012), as well as EF impairments. In addition, the largest deficit for individuals with OCD was for updating, which is believed to depend critically on striatal gating of information into prefrontal cortex (Hazy, Frank, & Reilly, 2007). This suggests that updating may be particularly impaired in people with OCD, since both striatal and prefrontal dysfunction may contribute to deficits on updating tasks. However, there have been few studies of updating in individuals with OCD, so additional research is needed to explore this possibility. Thus, while multiple disorders may be associated with prefrontal dysfunction leading to broad impairment in EF, the underlying neurobiological abnormalities, at the cellular and network level, may be quite distinct.

A further important question is how these prefrontal abnormalities, and thus EF deficits, arise. There is some evidence that PFC abnormalities and impaired EF may be endophenotypes for psychopathology. Significant, though more subtle, impairments in EF and prefrontal abnormalities have been reported in currently healthy individuals with greater genetic risk for schizophrenia (Barch, 2005), BD (Bora et al., 2009), OCD (Menzies et al., 2007) and PTSD (Gilbertson et al., 2006).

These findings suggest that EF deficits may proceed, and potentially be a risk factor for, psychopathology. Although there have been few longitudinal prospective studies which could speak to this issue, there is some evidence that EF deficits may precede illness onset. Specifically, early adolescent EF predicts adult psychosis (Cannon et al., 2006), preschool EF predicts middle-childhood ADHD (even controlling for preschool ADHD symptoms; Campbell & Stauffenberg, 2008), and pre-trauma EF predicts post-trauma PTSD (Parslow & Jorm, 2007). On the resilience side, individuals who have experienced trauma but do not have PTSD have greater PFC activity not only compared with individuals with PTSD, but also compared with healthy controls who have not experienced trauma (Patel et al., 2012). It is thus possible that individual differences in prefrontal function and resulting differences in EF predispose some people to develop psychopathology, while buffering others (Aupperle et al., 2012). These patterns are consistent with neurodevelopmental models of psychopathology, in which disorders are posited to be the behavioral outcome of aberrant neurodevelopment that begins long before the onset of clinical symptoms and is caused by a combination of genetic and environmental factors (Rappaport et al., 2012; Seidman, 2006).

Translational Implications

This section applies what is known about cognitive products and then processes in relation to the treatment and prevention of common psychopathologies. We consider some future directions that can be taken to further reduce mental health burden of individuals across the life span based on theoretical and empirical knowledge covered in this chapter.

Since the initial, groundbreaking clinical work of Beck (1967) and Ellis (1957), cognitive (and cognitive-behavioral, CB) therapies have been developed and rigorously evaluated for many prevalent psychopathologies. While there are important, subtle differences in these CB interventions for different disorders, all of these evidence-based interventions share an emphasis on cognitive products and processes as essential mechanisms that are hypothesized to produce meaningful symptom, emotion, and behavior change. Indeed, perusal of empirically supported treatments (e.g., see Barlow, 2008) for adults (e.g., Division 12 of APA) and youth (e.g., Division 53 of APA) reveals that CB-based interventions are established for depression, general child anxiety, Panic Disorder, PTSD, GAD, SAD,

substance abuse and dependence, binge eating disorder, bulimia nervosa, and disruptive behavioral problems. Other CB-based treatments have shown promise for other disorders, including schizophrenia (Tarrier, 2005) and BD (Miklowitz, 2008). In addition to treatments for diagnosed psychopathologies, several CB-based preventions have been demonstrated to reduce likelihood of future increases in symptoms of and episodes for depression (Horowitz & Garber, 2006; Stice, Rohde, Gau, & Wade, 2010), anxiety (Fisak, Richard, & Mann, 2011), disruptive behavioral problems (Powell et al., 2011), and comorbid internalizing and externalizing problems (e.g., Weiss, Harris, Catron, & Han, 2003).

Cognitive Products as Mediating Mechanisms and Moderators in CB-based Interventions

In addition to CB-approaches as evidence-based interventions to treat and prevent psychopathology, research has also examined various cognitive risks as mediating mechanisms of intervention effects. Despite the central importance of cognitive products and processes as putative mediators of change in CB-approaches, it is surprising that relatively few studies have empirically examined cognitive influences as mechanisms (Hundt et al., 2013 with adults; Webb, Auerbach, & Derubeis, 2012 with youth). It is worth noting that this relative paucity of cognitive mediation research is not unique to investigation in CB-based interventions, but rather applies broadly to general lack of understanding of how and why psychotherapy is efficacious and leads to change (e.g., Kazdin, 2009). Such research on mediating mechanisms is important also because it can provide evidence regarding cognitive risks as a possible causal risk factor in developmental psychopathology (Kazdin et al., 1997; Kraemer et al., 2001).

Much of the research on cognitive mechanisms of change in psychotherapy has focused on depression (e.g., Kazdin, 2007), and most of that has used adult samples (see Garratt, Ingram, Rand, & Sawalani, 2007 for review). As such, the following studies reflect this knowledge base to provide the most evidence-based examples of how cognition may explain how psychotherapies work. Generally a number of studies have shown that CBT for depression in adults (Garratt et al., 2007) and adolescents (Weersing, Rozenman, & Gonzalez, 2009) is related to reductions in cognitive products, but not all have formally examined mediation to link change in negative cognitions to subsequent change in symptoms. Among youth, CBT for anxiety produced moderate to large effects in various theoretically specified mechanisms, whereas CBT for depression yielded small effects for change (Chu & Harrison, 2007).

Some individual studies suggest that particular cognitive risks may mediate CB-based intervention effects. A negative attributional style has been shown to mediate the efficacy of CBT for depression (e.g., Barber & DeRubeis, 2001). Dysfunctional attitudes (or automatic thoughts, depending on the study) mediated effects of CBT for adult depression (e.g., Beevers, Keitner, Ryan, & Miller, 2003; Warmerdam, van Straten, Jongsma, Twisk, & Cuijpers, 2010) and adolescent depression (e.g., Jacobs et al., 2009). Moreover, mediation through dysfunctional attitudes has been shown in CBT for adult alcoholism comorbid with depressive symptoms (Ramsey, Brown, Stuart, Burgess, & Miller, 2002), and preliminary mediation of effects for CBT were found in an open trial for schizophrenia (Morrison et al., 2012). There have been demonstrations of specific mediation for dysfunctional attitudes in CBT versus interpersonal psychotherapy for adult depression (Quilty, McBride, & Bagby, 2008) and versus pharmacotherapy (Dozois et al., 2009; Garratt et al., 2007). Indeed, the preponderance of data suggest that antidepressants modify many of the cognitive biases in depression (e.g., Roiser, Elliott, & Sahakian, 2012). Moreover, several brain areas and cognitively mediated neural circuits implicated in depression etiology show change resulting from CBT as well as pharmacotherapy (Roiser et al., 2012). Anxiety schema change (Teachman, Marker, & Smith-Janik, 2008) and panic appraisals (Cho, Smits, Powers, & Telch, 2006) in Panic Disorder mediated effects of CBT for panic. Dysfunctional trauma-related appraisals demonstrated temporal precedence in mediation for Trauma-Focused CBT in treatment for PTSD (Kleim et al., 2012). Self-efficacy beliefs mediated efficacy in CBT, specifically in contrast to IPT, for bulimia among adults (Wilson, Fairburn, Agras, Walsh, & Kraemer, 2002).

Regarding rumination as a putative mechanism, research has shown that reductions in rumination mediated effects in mindfulness based CBT for adult depression (Van Aalderen et al., 2012). It has been suggested that addressing repetitive negative thinking, broadly defined, represents an efficient way to target the cognitive risk and maintenance factors that are transdiagnostically present across multiple psychopathologies (McLaughlin & Nolen-Hoeksema, 2011). Mindfulness-based interventions, in which clients are taught to emotionally disengage from recurrent negative thoughts (e.g., rumination) instead of letting them adversely affect one's mood, may be another therapeutic approach to reducing repetitive negative thinking and psychopathology (Rood et al., 2010).

While this review is consistent with the view that cognitive products mediate effects of CB-based interventions,

it is noteworthy that few studies have rigorously examined essential mechanism questions and have properly examined mediation (Kazdin, 2009). Most study designs do not go beyond showing that CBT is associated with reductions in cognitive products and symptoms and that these two variables are correlated, so the temporal precedence in the vast majority of cognitive mechanism studies of therapy is unknown. Indeed, results from a CB-based prevention trial of adolescents at-risk for depression highlight that cognitive risks may be changed by the intervention, but the temporal precedence of change in cognition prior to change in symptoms is not guaranteed (Stice et al., 2010) and still needs to be established.

In addition to examination of mediation, a few studies have investigated whether cognitive products moderate treatment outcome in depression. In a review of adult CBT for depression studies, dysfunctional attitudes were reported to moderate CBT response (Hamilton & Dobson, 2002). The available studies with depressed adolescents suggest likewise. Cognitive distortion predicted depression in treatment (Brent et al., 1998). High cognitive distortions helped depressed adolescents receiving combined pharmacotherapy and CBT (Curry et al., 2006), although dysfunctional attitudes did not predict adolescent treatment response across intervention modalities in contrast to the adult research (Jacobs et al., 2010).

Cognitive Products as Mediators and Moderators in Prevention Work

With respect to preventive interventions, selective and indicated programs, such as those focused on youth with enhanced cognitive risk (e.g., negative cognitive style), have been demonstrated to be more effective than universal preventions for youth depression (Horowitz & Garber, 2006), although definitive tests of moderation have not been examined (Garber, Korelitz, & Samanez-Larkin, 2012). A negative cognitive style partially mediated the effects of a CB-based prevention, the Penn Resiliency Program, on depressive symptoms (Brunwasser et al., 2009).

Cognitive Processes as Mediators in Interventions

Regarding translation implications for the cognitive processes that comprised the focus of this chapter, pretreatment cognition has been shown to predict treatment response. In particular, EF and episodic memory task performance predict pharmacotherapy response in individuals with depression (McLennan & Mathias, 2010), schizophrenia (Kim et al., 2008), OCD (e.g., D'Alcante et al., 2012), and BD (e.g., Gruber, Rosso, & Yurgelun-Todd, 2008). Although the precise reasons are unclear (e.g., there could be neurobiological explanations), poor medication compliance is the most likely and parsimonious explanation because these findings hold across several different types of psychiatric medications. Moreover, over-general autobiographical memory predicts poor clinical outcomes after treatment, over and above what is predicted by initial symptoms (Sumner et al., 2010). Finally, Cognitive Bias Modification training, which redirects attentional biases from negative emotional stimuli (e.g., threat) to more neutral stimuli, has been shown to reduce symptoms of anxiety and depression (e.g., see MacLeod & Mathews, 2012 for review). Redirecting subtle perceptual cognitive biases in emotion recognition toward happy faces, and away from angry faces, can reduce anger and aggression, consistent with Dodge's model via mediating hostile attribution bias (Penton-Voak et al., 2013). It is important to note that despite these individual studies finding positive, preliminary evidence, to date none of these interventions focused on changing cognitive processes has been established as fully evidence-based according to rigorous EST criteria (e.g., Chambless & Hollon, 1998).

In addition to cognitive processes predicting later treatment response, the opposite direction, in which interventions affect cognitive processes, has also been investigated. The majority, but not all, studies find that stimulant medications improve cognitive performance in individuals with ADHD, and more studies have found positive effects on EF and attention than memory (see Pietrzak, Mollica, Maruff, & Snyder, 2006 for review). Cognitive rehabilitation interventions, which are aimed at teaching compensatory strategies (e.g., use of lists and memory cues, dividing tasks into smaller steps, etc.), can improve functional outcomes (e.g., occupational/academic functioning) in individuals with schizophrenia (e.g., see Kluwe-Schiavon, Sanvicente-Vieira, Kristensen, & Grassi-Oliveira, 2013 for review), BD (e.g., Deckersbach et al., 2010), and ADHD (e.g., Hahn-Markowitz, Manor, & Maeir, 2011). There is less research on cognitive remediation in individuals with depression or anxiety disorders, although it is interesting that some therapies (e.g., behavioral activation; e.g., Dimidjian, Barrera, Martell, Muñoz, & Lewinsohn, 2011) incorporate compensatory strategies (e.g., memory cues to engage in an activity, like putting walking shoes by the door). There are interesting suggestions that certain medications (e.g., Modafinil, a cognitive enhancer) have potential for improving EF in individuals with depression (e.g., improved response to antidepressant treatment with Modafinil (Abolfazli et al., 2011), but these effects are not yet well established with cognitive

control (Murrough, Iacoviello, Neumeister, Charney, & Iosifescu, 2011).

Finally, it is notable that there is less evidence in support of direct training of cognitive processes (i.e., targeting the weakness rather than compensatory strategies). In general, while task performance improves, there is little evidence that training effects generalize to real-world function or improve clinical symptoms (e.g., Rabipour & Raz, 2012). Two possible exceptions are Cognitive Bias Modification, as reviewed earlier, and EF training in children with ADHD, which may decrease symptoms and increase academic function (Rabipour & Raz, 2012). However, a recent meta-analysis found evidence for only very small and nonsignificant effects EF and attention training programs on academic performance and blinded subjective ratings of children with ADHD, although there were very small but significant improvements on nontrained cognitive tasks (Rapport, Orban, Kofler, & Friedman, 2013). It is not clear to what extent these findings reflect genuine limitations of cognitive training in general, versus problems with the specific training programs (many of them commercial products); for example, many of the programs focus on training the least impaired aspect of EF in children with ADHD, simple working memory maintenance (Rapport et al., 2013). This leaves open the possibility that types of training that better target areas of weakness might provide better transfer. Intriguing findings suggest that certain types of EF training may change the underlying neural mechanisms to be more efficient rather than changing strategy use only (Owens, Koster, & Derakshan, 2013), suggesting that such training might transfer more broadly to processes involving the same neural mechanisms, although this has not yet been tested.

Future of Translational Directions for Cognitive Risk Research in Developmental Psychopathology

We focus on five future directions for translation of the basic theoretical and empirical work on cognitive influence into enhancement of current therapies as well as development and testing of novel intervention approaches. First, there are considerable promise and gains to be made by applying developmentally sensitive knowledge about cognitive products and processes to the personalization of treatments and preventions (Insel, 2009), especially to answer the questions of what works for whom (i.e., moderation) and why (i.e., mediation), and for which forms of psychopathology (i.e., transdiagnostically across several disorders or specifically to one). Second, novel areas for investigation include the optimal timing of when it may be best to implement evidence-based preventions to forestall the development of psychopathology, based on accumulating knowledge of the emergence, stabilization, and consolidation of cognitive influences (as discussed earlier) and for how long interventions can reduce cognitive risks in an enduring manner (whether for relapse prevention in treatments or for onset reduction via preventions). Third, a continued emphasis on investigating mediating mechanisms that underlie demonstrated efficacy of treatments is a must. While CB-based approaches are all grounded in the underlying theory of change that underscores identification and reduction of negative cognitions, which, in turn, are hypothesized to ameliorate symptoms and problematic behaviors, this does not have to be the case (Stice et al., 2010).

Also, the fundamental processes at play may change across development. In particular, incorporating capitalization versus compensation approaches to therapy change (Cheavens, Strunk, Lazarus, & Goldstein, 2012) can be an important, but relatively under-investigated, individualized approach to understanding how changes in cognition may lead to improved mental health. For example, it is not clear whether various therapies are reducing cognitive risks (e.g., dysfunctional attitudes), enhancing cognitive strengths (e.g., improved EF), or both. Fourth, this review revealed a paucity of research focusing on cognitive influences as potential moderators of treatments, especially, and preventions more formally. There likely are individual differences in cognitive products and processes that moderate intervention efficacy, and this knowledge would be very helpful for adapting and enhancing personalized treatment approaches. For example, the efficacy of CBT is believed to partly depend on individuals' EF ability, yet only one pilot study has examined this theory-based moderating hypothesis: older adults with poor EF did not respond as well to CBT for anxiety (Mohlman & Gorman, 2005). Last, tailoring interventions to make them more developmentally appropriate, based on the cognitive skills, strengths and weaknesses, as informed by the basic knowledge reviewed in this chapter, may improve efficacy when CB-interventions are designed, tested, and delivered at a level commensurate with the individual's cognitive abilities (both products and processes).

Conclusions

In closing, this chapter is the first to have reviewed several of the most prominent cognitive products and processes in relation to the development of multiple common, prevalent psychopathologies. There is a considerable corpus of evidence using cross sectional designs, predominantly

with adult samples, demonstrating that both products and processes are associated with several psychopathologies, although there are gaps in coverage. Studies that have spanned different developmental periods, from childhood into adolescence and adulthood, suggest that cognitive influences are related to psychopathologies across the life span, at least in the ages studied to date. In many cases, longitudinal studies indicate that cognitive factors, especially products, predict prospective elevations of psychopathological symptoms and disorder. Still, the evidence basis at this point is not sufficiently advanced to make definitive conclusions regarding which of several logical models may best account for these associations. Last, this review generally revealed a silo approach in the many studies that have examined isolated cognitive influences separately from other cognitive risks, and usually in relation to a single psychopathological outcome. We urge future research efforts to take a more interdisciplinary, integrative approach that seeks to synthesize conceptual and empirical knowledge across cognitive products and processes, with assessment and analysis of multiple forms of psychopathologies, across multiple levels of analysis using prospective longitudinal designs with carefully considered, developmentally appropriate samples. In summary, this chapter demonstrates that the field investigating cognitive risks to developmental psychopathology is a vibrant, active area that has produced numerous, impressive, and important findings that are critical for a comprehensive understanding of the development of psychopathology across the life span and possess clear translational import for enhancing many evidence-based, CB interventions. We are excited about the future of inquiry in cognitive influences in developmental psychopathology that can build upon the currently strong theoretical and empirical foundation and then rapidly, significantly propel knowledge forward.

TRAUMATIC STRESS FROM MULTIPLE LEVELS OF ANALYSIS: AN INTRODUCTION

Society is increasingly preoccupied with and overwhelmed by traumatic stress. Whether it is school shootings, terrorist attacks, or multiple car pile-ups on the freeway, we cannot escape from its effects. The passage of time only sees an increase in the impact of traumatic stress on society. Advances in technology make it possible to learn instantly about traumatic events happening far away, that 100 years ago we may never had heard about at all. With smartphones beeping out tornado warnings and Amber alerts, and 24-hour cable news urging us to stay tuned to the latest bombing attack or hurricane, there is no place left to hide.

Our bodies are equipped with stress response systems that are better suited for the savannah than the office complex. Neurohormonal and neural circuit response systems allow us to respond quickly, run fast, or fight back with strength. In today's society, stress is more likely to come in the form of failing an exam or getting a virus on your computer than it is from an attack by a predator. Evolution, however, is naturally conservative. Our stress response systems are preserved through the generations, even if we don't need them as much as we used to, and in some cases they do more harm than good. When adaptation and coping are not able to keep the balance, the outcome can be extreme, with the development of mental disorders like posttraumatic stress disorder (PTSD) and depression.

How trauma affects the individual depends on a number of factors. Its impact depends on the developmental period when it occurred, social and environmental factors, physiology, prior history of stress, and individual psychological factors. This represents only a portion of all of the possible influences that are brought to bear. An understanding of the impact of traumatic stress thus requires a multilevel approach, inclusive of psychology, biology, genetics, social and cultural factors, spirituality, family and community, and existential questions about the meaning of being human. This chapter reviews the effects of trauma on the individual from a multilevel analysis approach.

The work presented in this review was supported by grants from the NIMH (MH56120), R01 MH056120, R01 HL088726, K24 MH076955, and P01 HL101398, and the Department of Veterans Affairs.

A RANGE OF PSYCHOPATHOLOGIES FOLLOWING EARLY TRAUMA: TRAUMA-SPECTRUM DISORDERS AND THE MULTILEVEL APPROACH TO THE ASSESSMENT OF THE TRAUMA RESPONSE

Bremner argued for a concept of *trauma-spectrum disorders* (Bremner, 1999, 2002a), as a group of mental disorders that all have their links in trauma, usually occurring in childhood. These disorders include PTSD, some cases of depression related to early trauma or abuse, dissociative identify disorder (DID), and borderline personality disorder (BPD). The model also acknowledges that substance abuse, psychosomatic disorders, and the increased risk for disorders like heart disease are part of the spectrum of outcomes related to psychological trauma. As such the model permits an assessment of the full range of effects on trauma on the individual, and is not limited by, for example, an emphasis on a single psychiatric disorder as defined by specific criteria as outlined in sources such as the Diagnostic and Statistical Manual (APA, 2000).

The trauma spectrum model illustrates the principle of multifinality, in which one cause leads to multiple outcomes (Cicchetti & Rogosch, 1996). For instance, DID is characterized by alterations and distortions in personal identity, and is associated with symptoms of depersonalization (feeling out of body), derealization (feeling like you are in a dream) and amnesia (gaps in memory). BPD involves intense feelings of emptiness and fears of abandonment with associated disruptive relationships and self-destruction. Both are closely linked with early trauma and are more common in women, as is depression, which in about half of patients is linked to early trauma (Zanarini, 1997). Therefore, one event can have multiple outcomes. In other words, if two individuals are exposed to the same trauma, one might develop DID, another BPD, or BID with comorbid depression. There are multiple factors that go into determining the outcomes following trauma.

The trauma-spectrum disorders model predicts that early trauma results in specific changes in brain and neurobiology that underlie the symptoms of PTSD, BPD, DID and depression in women with early childhood abuse. Additionally, PTSD is considered to be more appropriately grouped with these disorders related to trauma, rather than the current classification with other anxiety disorders, like panic disorder, generalized anxiety disorder (GAD), and obsessive-compulsive disorder (OCD). In addition, the trauma-spectrum model represents a multilevel approach to nosology, in that biological (i.e., fear circuits), environmental (trauma), and social aspects (social support or the lack thereof) are including in the analysis. This is in contrast to current commonly utilized approaches, which involves a prima facie approach to patients with trauma-related symptoms. This leads to outcomes like the conclusion that all disorders in which anxiety is present should be classified as anxiety disorders.

On the other hand, the multilevel approach does not attempt to create false classifications based on a single factor, like neurobiology. This is in contrast to approaches that, for example, assume that only inherent neurobiological factors influence the development of mental disorders, and attempts to force groups of symptoms into discrete entities that are presented as only related to specific brain pathologies. The deliberations around the formation of the Diagnostic and Statistical Manual-V (*DSM-V*) often took the tack of trotting out brain biologies as a scientific foundation for the classification of mental disorders. This approach often points out that Psychiatry (the *DSM* is a publication of the American Psychiatric Association) is one of community of medical specialties, and psychiatric illnesses should be approached in the same way that, for instance, diabetes is approached by endocrinologists. According to this approach, an illness (diabetes) is caused by a specific defect in physiology (shortage of insulin, or resistance of the tissues to the effects of insulin), and is treated by repairing the defect (giving insulin injections). Thus, the body is able to transport glucose (sugar) into the tissues of the body, which need it as energy and to function. Through the treatments, symptoms of mental confusion, increased urination, and weakness are avoided, and the long-term consequences of poor glucose control, like hypertension and eye and kidney disease, are reduced or eliminated. The patient sees the doctor on regular occasions, where he undergoes laboratory testing and physical examination, and the doctor makes adjustments to the treatment, and writes a prescription for more medication, which the patient gets filled at the pharmacy. In a similar manner, the psychiatrist would treat a patient for a disease (depression) that is related to a physiological defect (shortage of serotonin in the brain) with a medication to correct the deficiency (selective serotonin reuptake inhibitors, or SSRIs). These medications work by increasing serotonin in the brain, relieving symptoms of depression, and avoiding the long-term consequences of depression, like suicide, or disruptions in work or family life. The patient visits the doctor on a regular basis, where he or she is assessed for symptoms, adjustments in the medication are made, or perhaps the medication is substituted for another if the response to the treatment is poor, the doctor writes a prescription for more medication, and the patient gets it

filled at the pharmacy. This fits with a rational or medical approach to mental illness, reassures the doctor, and possibly the patient, is not too expensive and therefore endorsed by the insurance industry, and fuels a profitable health-care industry in pharmaceuticals, laboratory testing, and outpatient psychiatry.

The only problem with the medical model approach to mental illness is that it doesn't really work. For one thing, the serotonin deficiency model of depression is not accurate. It is based on a mythology that depression is simply a shortage of serotonin that can be fixed by increasing serotonin in the brain with a medication like Prozac. If that were the mechanism, why does it take two to four weeks for Prozac to work, since serotonin is increased after the first couple of doses? Neuroscientists and psychopharmacologists have understood for years that the serotonin replacement hypothesis does not explain the data. In fact, illustrations of medications working by boosting neurotransmitters have largely been relegated to advertisements for pharmaceuticals in magazines, and are no longer seriously considered by psychiatric and neuroscience researchers. Academic psychiatry, however, has largely stood by silent while the serotonin replacement model is promulgated by the pharmaceutical industry through its advertising endeavors. The serotonin replacement model is simple and easy to understand, and makes logical sense. It is easy to convey through colorful illustrations and one-line descriptions. The pharmaceutical companies traditionally have provided as much funding for research to academia as have government entities, so there was no incentive to set the record straight about how patients with depression respond to treatment. The serotonin replacement model also fit with the agenda of psychiatry, which has evolved into an industry of 15-minute visits that are reimbursable by insurance companies. It was easier in this short time period to present the disorder and its treatment in simple terms, and avoid complicated discussions of life circumstances and personal feelings that are difficult to conclude in a short period of time. Many clinicians also probably tell themselves that it is best not to open the can of worms and that patients are better off not delving into psychological areas for which there is not an easy resolution. In fact, this line of thinking is reasonable, since exploring the causes of mental illness that have to do with the individual often requires long term psychotherapy treatment for a proper resolution, and most people cannot afford this.

The neurobiological model of mental illness has other problems. Adherence to biological models like the serotonin replacement hypothesis, or other models that only consider neurobiology, leads to a situation where psychiatrists are forced into defending or proving a model that is essentially indefensible. This results in a straw man argument, where psychiatrists are set up as proponents of the biological model, and if the model fails this taken as proof that mental disorders are not valid. Antipsychiatrists and others hostile to the mental health field pour through the breach, resulting in a circling of the wagons, where any critical discussion within the field of psychiatry is discouraged, or even squelched. As an example of this, in 2012–2013 the committee charged by the American Psychiatric Association to come up with the next version of the *Diagnostic and Statistical Manual*, 5th ed. (*DSM-5*), held closed sessions and required committee members to sign non-disclosure agreements. External feedback was invited only after the committee had essentially come to final decisions. This led to both the heads of the *DSM-III* committee, Dr. Robert Spitzer, and the head of *DSM-IV,* Dr. Alan Francis, to write editorials and make public comments critical toward the process. Similar comments came from the American Psychological Association and the British Psychological Association. The criticism has also been raised that there may be no point in developing a revision of the prior version of the *DSM* when there is no new significant information upon which to based changes in the criteria for the psychiatric disorders.

The approach of the *DSM-5* committee is needless to say antithetical to academic tradition. This process is based on unbiased inquiry, rigorous scholarship, and the free exchange of ideas. To retain legitimacy, the scientific process requires careful scholarship, openness to new information, objective observation, lack of bias, a willingness to engage in vigorous debate, and above all transparency. The persistence of the *DSM-5* committee in the face of criticism, including from some of the leaders of academic psychiatry who chaired previous committees, showed an utter disregard for the scientific and academic process. The group's insistence on sticking to a rigid medical framework forced it to abandon the scientific process on which the framework was supposedly founded.

Another problem with the medical disease model is that it requires that psychiatric disorders be discreet from one another. If there is overlap, as naturally occurs for mental disorders, advocates of the biological disease model are forced to use terms like high comorbidity to account for the fact. The use of this term implies that these are discreet disorders, and the fact that they tend to occur together sometimes is treated as an anomaly. That would be like saying, "You sort of have a diabetes–hyperthyroidism condition." Not only is there high comorbidity between disorders, but also the actual symptoms also overlap.

The authors of the *DSM* partially sidestepped this issue but using different ways to describe the same phenomena. For instance, the symptom of feeling cut off from others in PTSD is analogous to the withdrawal or psychomotor retardation seen in depression. Many other symptoms, including sleep disturbance and irritability, are the same. Thus it can be seen that the trauma spectrum model more accurately described the nature of mental disorders as they exist in real clinical practice than the medical model of *DSM*. In fact, this is why many clinicians do not actually use *DSM* in their clinical practices, unless they need to use it for insurance billing or to justify the use of psychotropic medications.

The trauma-spectrum model obviates the problems of the medical model by accepting the fact that there is a spectrum of symptoms following psychological trauma. Patients with different disorders will have overlapping symptoms. This does not obviate the fact that there are also important differences between these disorders. An example of this related to neurobiological studies is reviewed in more detail below.

The medical model-based serotonin replacement hypothesis of depression fails in other respects. There is not room in the model to account for the complex array of factors that contribute to mental disorders. One important factor in the development of depression is the role of previous exposure to traumatic events, especially in childhood, which is often associated with the development of depression in adulthood (CDC, 2010; de Vries & Olff, 2009). Considering the interaction between traumatic experience and developmental stage of the individual at the time of the trauma is crucial to a proper understanding of the presentation of the patient. Developmental stage is important not only because the stage of development of the brain influences how the individual assimilates traumas and other experiences. The psychological profile of the individual, influenced by stage of psychological and social development at the time of the trauma, also plays a critical role.

Another disadvantage of a biological model like the serotonin deficiency hypothesis is that it leaves the individual in the recovery process. This is critical, because factors related to the individual, like motivation and self-growth, are amongst the most important variables in successful recovery from mental disorders. Medical models of mental illness tend to disempower the individual and remove the role of individual meaning and motivation in the process of recovery. The process of disease and recovery is relegated to a battle of chemicals, where the addition of new ones in the form of medications is expected to counteract problems with the ones in the brain. Not only is the individual removed from the process of recovery, it also trains people to be passive and fatalistic. Doing so takes away the possibility of enlisting the individual in recovery (other than asking them to remember to take their meds). Problems like PTSD and depression that are caused by traumatic events respond to processes like psychotherapy, journaling, and discussions with people in the support system who provide positive and empathic responses (although the opposite can have a negative effect). In addition, the biological model removes the process of individual meaning, effectively dehumanizing the individual in the process. This is in part why there has been a backlash against modern psychiatry in the form of the rise of the anti-psychiatry movement.

An example of this dehumanizing process is the medicalization of grief. Previous versions of the *DSM* listed bereavement as an exclusionary criterion for the diagnosis of major depression. The new version of *DSM-5,* however, has eliminated this exclusion, effectively forcing those who have had lost loved ones to either bypass the normal grieving process, or be labeled as someone with a mental illness. This carries with it the risk of being prescribed an antidepressant medication that the person may not need, and which may be associated with potentially dangerous side effects. The medicalization of the grieving process has put psychiatry into the odd role of blunting personal growth and development, when they are supposed to be stewards of mental health. That is because the normal grieving process has to take place for a person to grow through adverse life experiences and recover the capacity to form healthy future relationships. Those who are not allowed to grieve normally become limited in their ability to express a full range of emotions in the future. In fact, the process of responding to trauma can be conceptualized as an extended grieving period, in which the individual advances through individual stages of grief/recovery, and often circles around to begin the process from the beginning, strengthened by what one has learned in the earlier phases. Thus the creation of models like the serotonin replacement hypothesis represent a form of psychiatry declaring war against the processes that are needed for a full recovery from trauma.

The trauma-spectrum model is not presented as the only or best approach to psychiatric nosology, but rather as an example of an approach that can incorporate neurobiology without becoming a prisoner to it. Similarly, antidepressants are not considered to be the enemy, but it is considered essential to take an approach to medication that fits with the data, and to see psychopharmacology as one of many potential pieces of the recovery model, and not as a unique source of potential recovery.

For the trauma-spectrum model to be useful and relevant, it should be able to be used on multiple levels of interpretation. In other words, it should have relevance at the intrapsychic, psychological, clinical, interpersonal, social, philosophical, research, biological, and other levels. Its relevance on a psychological and intrapsychic level is illustrated by the fact that traumatic events, and the response to these events, are typically seen as major watersheds in people's lives. Traumatized people can learn, through reading, journaling, or participating in psychotherapy, that their thoughts, feelings, and behaviors may not be the result of being a bad person or having something wrong with them. Additionally, not viewing themselves as having only a medical disorder gives them more power and control, and brings them personally into the treatment picture. Similarly, on a clinical and research level, the trauma spectrum approach obviates the problems with high comorbidity and frees the clinician to focus on the client–patient as an individual rather than a collection of symptoms or diagnoses.

The trauma spectrum model also has relevance on a neurobiological level. The model predicts that brain circuits and systems involved in the stress response will be similarly affected in these disorders. Specifically, brain areas involved in fear and memory, like the amygdala, hippocampus and medial prefrontal cortex, and neurohormonal systems like cortisol and norepinephrine, should show similar alterations in these disorders that are not seen in anxiety disorders not related to trauma. In a series of studies we and others showed smaller hippocampal volume in patients with a history of childhood abuse and the diagnoses of PTSD (Bremner, Randall, Scott, et al., 1995) (see Figure 9.2), women with BPD and early life trauma (Driessen et al., 2000; Irle, Lange, & Sachsse, 2005; Schmahl, Vermetten, Elzinga, & Bremner, 2003), and women with abuse and DID (Vermetten, Schmahl, Lindner, Loewenstein, & Bremner, 2006). Women with abuse and BPD (Driessen et al., 2000; Schmahl, Vermetten, et al., 2003) and women with abuse and DID (Vermetten et al., 2006) also showed smaller amygdala volume, which is not seen in PTSD. Women with early childhood sexual abuse and depression had smaller hippocampal volume compared with women with depression without early abuse, and nonabused nondepressed women (Vythilingam et al., 2002). Patients with another anxiety disorder, panic disorder, did not show a reduction in hippocampal volume (Vythilingam et al., 2000), and other studies have not consistently shown smaller hippocampal volume in obsessive-compulsive disorder (OCD) or other anxiety disorders (Bremner, 2005a; Cannistraro & Rauch, 2003).

Patients with trauma spectrum disorders show other areas of overlap in terms of neurobiological profile. Both patients with PTSD or BPD related to childhood abuse show alterations in function of the hypothalamic-pituitary-adrenal (HPA) axis, and a functional dysregulation of the prefrontal-limbic axis (Donegan et al., 2003; Driessen et al., 2004; Juengling et al., 2003; Lange, Kracht, Herholz, Sachsse, & Irle, 2005; Schmahl & Bremner, 2006; Schmahl, Elzinga, et al., 2003; Schmahl, McGlashan, & Bremner, 2002; Schmahl, Vermetten, Elzinga, & Bremner, 2004a; Schmahl, Vermetten, Elzinga, & Bremner, 2004b). The trauma spectrum model, however, does not dictate that these disorders are synonymous, or that there should be no differences in neurobiological profile. Just as there are overlapping symptoms, with some symptoms being unique to a particular disorder, it is predicted that there will be areas of both overlap and difference in neurobiology. For instance, we found important differences in neurobiological profiles between women who, although they had similar childhood sexual abuse experiences, in adulthood developed different mental disorders, namely PTSD or BPD.

Our studies showed that BPD and PTSD patients have important differences in the types of stimuli that provoke physiological reactivity (Schmahl, McGlashan, et al., 2002). Women with a history of childhood sexual abuse, some of whom had PTSD and others BPD, were read scripts of both an abandonment experience (being left alone in a shopping mall) and of their specific traumatic childhood sexual abuse experience. Physiological responsiveness was measured with galvanic skin response and heart rate, measures of sympathetic nervous system function. Even though both groups had been exposed to similarly severe childhood sexual abuse, the BPD subjects responded to reminders (scripts) of abandonment but not trauma, and PTSD subjects had the opposite response (Schmahl, Elzinga, et al., 2004). Additionally, we found that abused women with PTSD presented with scripts of their childhood abuse experiences had decreased frontal lobe function (Bremner, Narayan, et al., 1999). Abused women with BPD, however, did not show this decrease with traumatic scripts (Schmahl, Elzinga, et al., 2003), although they did show decreased function in the frontal lobe when presented with scripts of an abandonment scenario (Schmahl, Elzinga, et al., 2003). These studies illustrate that neurobiological profiles highlight differences in the disorders that are clinically relevant.

These are just a few of the biological findings that are relevant to the concept of trauma spectrum disorders. The findings are consistent with a common neurobiology and neurocircuitry underlying the trauma-spectrum

disorders, including PTSD, DID, BPD, and depression related to early abuse. There are some commonalities in neural circuitry involving the prefrontal cortex and hippocampus, although there are important differences, such as differences in physiological reactivity to different types of traumatic or stressful reminders. This is consistent with the fact that there are both overlapping symptoms, as well as areas of symptomatic difference, in patients with these disorders. We discuss the neurobiology of stress in more detail later in the context of a multilevel analysis approach.

In recent years the term trauma-spectrum disorders has been used to include not only stress-related mental disorders but also mild traumatic brain injury (mTBI). This has mostly arisen as a result of the war in Iraq and Afghanistan with the large increase in returning soldiers affected by PTSD and/or mTBI. An increase in exposure of soldiers blast explosions from improved explosive devices (IED) is responsible for many of the cases identified as mTBI. This use of the term trauma spectrum disorders creates a convenient category of disorders that are of particular relevance to the Department of Defence (DOD) and the Veterans Administration (VA), PTSD and mTBI, since they are two of the most common disorders in soldiers returning from Iraq and Afghanistan, and are of major public health relevance and importance to the DOD and VA. PTSD and mTBI, however, overlap in terms of diagnosis, clinical presentation and treatment (Cifu, Cohen, Lew, Jaffee, & Sigford, 2010; Jaffee et al., 2009; Kennedy et al., 2007). MTBI is defined as a loss of consciousness following a blow to the head or sudden acceleration/deceleration, loss of memory for events before or after the event, a change in mental state (feeling dazed, disoriented or confused), or a focal neurological deficit that may or may not be transient (Mild Traumatic Brain Injury Committee of the Head Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine, 1993). Structural changes on brain imaging are not seen with mTBI. Cognitive symptoms often seen in PTSD patients, like headache or memory and concentration problems, are also seen in mTBI (Levin et al., 1987), which complicates diagnosis. Furthermore, rates of PTSD are increased following accidents with head injury (Walilko et al., 2009).

The use of the vague language categorizing mTBI as secondary to blast associated with any changes in mental state has thrown a broad net over soldiers returning from overseas. The most recent criteria do not require loss of consciousness, so virtually everyone who experiences a blast followed by the fog of war and later has problems with headaches or memory loss will meet criteria for mTBI. Many of these soldiers probably never had an actual brain injury, since exposure to blasts is less likely to injure the brain as a blow to the head or a car accident with rapid acceleration–deceleration that is more dangerous to the brain. Because of symptom overlap, symptoms of PTSD or mild stress reactions may be misattributed to mTBI, which complicates diagnosis and treatment.

Another dilemma in the field of PTSD and mTBI has been the question of the diagnosis of PTSD in cases of mTBI where there has been a loss of memory for the traumatic event. This is complicated by the fact that the requirements for intense fear, horror, or helplessness at the time of the event are technically not met (Bryant, 2001, 2008). Clinically, many patients develop PTSD after accidents for which they have no memory, possibly related to the formation of trace memories or memories not readily accessible to consciousness (Fani, Hampstead, & Bremner, 2006; McMillan, 1991). A consensus in the published literature, however, has arrived at the conclusion that PTSD can occur in the aftermath of brain injury events for which there is no conscious memory (Bryant, 2001; Harvey, Brewin, Jones, & Kopelman, 2003; Jones, Harvey, & Brewin, 2005; Mollica, Henderson, & Tor, 2002; Sumpter & McMillan, 2005).

The use of the term trauma-spectrum disorders as a description of both mental disorders related to psychological trauma and neurological brain disorders such as mTBI is problematic for a number of reasons. First, it is not possible to construct a valid rationale for the grouping of these disorders, other than as samples of convenience, or topics that should be given a high priority by governmental agencies. The construction of diagnostic criteria based on worthiness to receive government services or resources or for administrative convenience of course lacks scientific validity. One might speculate that this version of trauma-spectrum disorders was conceived as having a common neurological etiology, or an effort to bring trauma-related mental disorders into the spectrum of brain-based diseases. This approach, however, again runs into the problems that occur when emphasis is placed on a single factor in the development of a stress-related mental disorder.

Inclusion of mTBI in the group of trauma spectrum disorders has many of the same problems as the serotonin deficiency model. This revised trauma spectrum model emphasizes a common etiology of the disorders in neurology. The implication is that similar neurological pathways are involved in, say, PTSD and mTBI. However, the pathophysiology of PTSD involves fear circuits of the brain (amygdala, medial prefrontal cortex and hippocampus) and processes of learning, while mTBI

potentially involves shear injuries of neuronal processes that are most concentrated in the temporal lobe. Again, a singular focus on the neurological aspect of the disorders means that appropriate consideration is not given to other levels of analysis discussed above, such as the role of the personal experience and response in the aftermath of psychological trauma. This and the many other factors that were articulated above are critical to the understanding of the development of trauma-related mental disorders. Attempting to acquire acceptance for mental disorders by repackaging them as neurological disorders limits the ability to obtain a comprehensive assessment and therefore arrive at an appropriate treatment.

Trying to differentiate mTBI and PTSD may introduce an artificial dichotomy. Many soldiers exposed to blast also develop PTSD or other stress-related mental disorders. Since one of the factors contributing to PTSD is seen to be changes in neurobiological systems, there is no need to differentiate symptoms like memory loss in returning soldiers as related to a brain-based disorder (mTBI) versus a psychological disorder (PTSD). The multiple levels of analysis perspective, however, do not require such a distinction. Not focusing on make a dichotomous decision between two supposedly distinct disorders ultimately results in the best treatments for the patient. This was the consensus of a conference of PTSD and mTBI researchers and clinicians sponsored by the Department of Defense (DOD) in 2012. In other words, in the end it doesn't matter what causes the symptoms if the treatment is the same.

RELEVANCE OF THE MULTIPLE LEVELS OF ANALYSIS APPROACH TO DEVELOPMENTAL PSYCHOPATHOLOGY

An important part of the multilevel approach is an emphasis on the importance of development on the response to psychological trauma. As the individual moves from infancy through childhood and adolescence to adulthood changes take place on a psychological, social, behavioral, and neurological level (Feiring & Lewis, 1996). Different people may travel different developmental paths and end up at the same place (equifinality), or travel the same path with different ultimate outcomes (multipotentiality) (these concepts are discussed in greater detail below) (Cicchetti & Dawson, 2002; Cicchetti & Rogosch, 1996). An example of this is the fact that two people can be exposed to similar childhood traumas, but only one develops depression or PTSD in adulthood. The reason for these differences are not always clear, but factors such as individual resilience likely play a role (Vythilingam et al., 2009). Another example of this is the finding that some women arrive at the outcome of depression in adulthood following a history of childhood abuse, while other women develop depression without a history of abuse. An interesting clue related to this phenomenon is that women with a history of abuse and depression compared with both nonabused depressed women and nonabused, nondepressed women have smaller hippocampal volume on magnetic resonance imaging (MRI) (Vythilingam et al., 2002) and potentiated cortisol reactions to stress (Heim et al., 2000). This suggests a biological difference in the two groups of women, even though they have a similar nosology (i.e., symptoms of depression). Thus there may be an abuse-driven depression and a genetically driven type of depression. Therefore, one can arrive at the final depression end point by two different paths (e.g., early abuse or inherent disposition). Emerging evidence shows that these subtypes have different treatment responses (e.g., early abuse and depression responds more to therapy and less to medication). The use of the multi level assessment is therefore shown to have clinical relevance.

Richters and Cicchetti (also Richters and Hinshaw) have argued that diagnostic categories developed by psychiatry, as exemplified by the American Psychiatric Association's (APA) ever-evolving tome, *Diagnostic and Statistical Manual,* 4th ed., text revision (*DSM-IV-TR*; APA, 2000), represents a potentially false and forced application of the disease model to mental processes and dysfunctions (Richters & Cicchetti, 1993; Richters & Hinshaw, 1999). Following the one gene, one biological defect, one disorder model, psychiatric nosology, as discussed above, represents mental disorders as synonymous with medical disorders. According to this model, mental disorders represent harmful dysfunctions, that by implication are related to errors of evolution that lead to faulty genes manifesting in disorders (Wakefield, 1999).

The medicalization of mental disorders over the last few centuries can be interpreted as an extension of the cultural and societal response to the mentally ill. The etiology of mental disorders was once viewed as manifestations of evil spirits, infestation by the devil, or witchcraft. Although many cultures continue to harbor similar beliefs, for the most part in countries like the United States this is no longer the case. Patients with mental illness, however, continue to suffer from considerable stigmatization. The medical model was probably conceived by some good-intentioned clinicians as providing a framework whereby patients with mental disorders could avoid judgment as being inherently weak or morally defective

individuals. This is one advantage of the medical model, in that mental disorders can be presented to the patients as well as friends and family as brain-based diseases that are not their fault, just as someone should not be blamed for developing diabetes. The negativity and stigmatization associated with the personal blame approach can further hinder the recovery of patients from mental disorders, and offering this alternative way of looking at the disorder can be quite helpful in assisting patients in their recovery. The multilevel analysis approach takes advantage of the helpful approach of using neurobiology to further patient education and give traumatized patients a conceptual framework to understand their disorders in a way that reduces self-blame and fear. The fact that this framework is still imperfectly employed, however, is shown by the persistent stigma against people with mental disorders that continues to exist in our culture.

The medical model has seen limited application by clinicians who are actually at the front lines of providing treatment for patients with trauma-related mental disorders. Many clinicians complain that the application of psychiatric disorders based on strict criteria is not helpful in the clinical practice, where more nuanced assessments are required to deliver the maximum therapeutic benefit. Many clinicians continue to flock to the professional association meetings where they sit in rapt attention while their counterparts in the world of to them about the medical model of psychiatry. This psychotic split led to the situation where if asked directly clinicians would say something like, "I don't use the *DSM* in my practice, I just need to get a code (that corresponds to a specifically defined psychiatric disorder) to bill insurance with." Although clinicians are taught to diagnose a single condition and apply a single remedy, in the real world of clinical practice, faced with the inadequacy of this approach, they usually end up treating clusters of symptoms, or deal with patients on a one-to-one basis, as individuals.

The process of incorporating psychiatry and mental health treatment into the medical fold has never been completely achieved. This may be due to a number of factors, including persisting stigma, suspicions amongst the other medical professions that mental disorder weren't actually equivalent in nature to the medical disorders they were treating, or qualms about the reliability of the scientific foundation for the disorders. When a specific etiology of what was previously viewed as a mental disorder is identified, like a B12 deficiency for dementia, it tends to be transferred from psychiatry to other fields like neurology. For example, Parkinson's Disease originally was not recognized to be a disorder of dopamine deficiency related to degeneration of dopamine neurons in the striatum. Similarly, epilepsy was originally felt to be secondary to possession by evil spirits. It was only with the advance of medical science that the true etiology of epilepsy was discovered, namely that seizures were related to abnormal bursts of neuronal firing which caused damage in the hippocampus and other brain areas, increasing susceptibility to future seizures.

In the face of mounting challenges to the medical model of psychiatry, academic psychiatrists have responded by pulling the wagons into a circle and ratcheting up the defense of the model. They also attempt to deal with criticisms of the model by a continual tinkering with the diagnostic structure. Tomes like the *DSM* get progressively larger with successive editions as the number of diagnosable mental conditions expands exponentially. Indeed, the criticism has led to the conclusion that there is not time to wait for each successive version of the *DSM*. Rather, new versions of diagnostic criteria should be sent out into the field, like successive updates of software program, to find glitches in their actual use that will allow further tinkering back in the halls of academe. Never mind that no one would ever buy software made by a company with a business model of using its customers to test the software for bugs. The pharmaceutical industry, of course, have been ardent supporters of the medical model and associated institutions like the *DSM*. To not do so would probably be corporate malpractice, or a violation of their fiduciary duty to their shareholders, as there is so much potential for profit in a system that emphasizes one diagnosis with one treatment (i.e., an antidepressant), and that has a built in mechanism to continuously increase their market, as diagnostic shifts tend to include a greater percentage of the population in the category of disordered over time. The system also provides an excellent opportunity for companies to mount outreach and awareness campaigns (e.g., marketing shyness as social phobia), as well as provide education to clinicians, the outcome of all these efforts being an increase in their market share for antidepressant medications. As the number of psychiatric disorders multiply, the fact that the treatments remain limited in number is conveniently ignored. The fact that the treatments for different mental disorders is usually the same is also conveniently ignored. At one point Glaxo-SmithKline developed a handy card that it handed out to clinicians, which represented a decision tree to help them arrive at the diagnosis of the appropriate anxiety disorder based on the criteria of the *DSM*. The futility of the exercise, however, was highlighted by the fact that no matter the final outcome, the next step in the algorithm was always

to prescribe Paxil. The irony of such a useless exercise, which ultimately resulted in no effect on the treatment course dictated by the medical model, was apparently not appreciated by anyone involved.

Another argument against the medical or harmful dysfunction model of stress-related mental disorders is based on human evolution. The continued existence of depression and anxiety argues against them being specific diseases in the medical formulation. If they were such disorders, they should have been eliminated from the human species long ago as maladaptive phenomena through the natural selection process of evolution. If anxiety or depression only had the potential for harm that should have reduced the possibility that individuals with these tendencies would survive long enough to reproduce and pass their genes along to the next generation. Human evolution in the strict sense probably ended about 20,000 years ago, although the capacity of humans continued to evolve along with the evolution of culture (Richters & Hinshaw, 1999). The rapid acceleration of cultural evolution made biological evolution obsolete, as evidenced by the total domination of the planet and other animal species by humans, who now use other animals as pets or food, rather than as competitors in the game of natural selection.

Before the development of agriculture, humans were roving the Savannah in small bands of hunter-gatherers. Up until that point, the evolution of the human brain conveyed adaptive advantages, through the development of the capacity for abstract thought, language, and advanced social relationships. Even after the physical evolution of the brain reached its apex, however, the cultural and adaptive functions of the brain continued to evolve. Along with the development of these cognitive abilities came mental phenomena like anxiety and depression. These mental symptoms, however, are not necessarily affected by evolution. They could be accidental by-products of the development of the frontal cortex and other cortical brain areas that gave humans the potential to have such incredible adaptivity to changes in the environment and to continue with cultural evolution even after biological evolution came to a halt. Another possibility is that they are related to behaviors that had survival value, and therefore were selected in evolution. Whatever survival value they had for primitive hunter gatherers on the Savannah, however, is probably lost in the transition to modern culture, which brought with it living in buildings and days spent puzzling over financial accounts rather than chasing animals through the bush.

Symptoms of anxiety and depression may have served specific purposes that benefited humans, at least at one point in history. For instance, if there was a pack of lions in the area where a band of hunter-gatherers was camped, this could lead to an increase in fear and vigilance, which may have made the difference between life and death. These symptoms would persist for long periods of time, possibly after the threat had been removed. Children would sense the type of environment they were born into, and their developmental evolution would be adjusted accordingly. Children in a harsh, deprived, or nonsupportive environment would grow up being mistrustful and socially withdrawn. This might have survival value in protecting the child from potentially harmful persons in the absence of a functional parent to protect them.

Symptoms of depression also probably have had a behavioral function at some point in time. They are a by-product of the development of the capacity in humans to form close social attachments. When those attachments are broken, through death or separation, there is a natural process of grieving where individuals recover from the disruption of the social connection and form the capacity to form new connections. If they do not go through this process, they may not go on to reproduce with others in the future. In addition, depression causes a social withdrawal and decrease in activity. Death of a partner or parent may put the survivor at greater risk without the added protection, so withdrawal from potentially dangerous situations would also have survival value. Similar behavioral effects occur with illnesses such as infections, which probably have similar survival value in allowing the conservation of energy and resources.

Symptoms of anxiety and depression that were adaptive in the past do not necessarily serve an adaptive or helpful role in modern society. The fight or flight response that was critical to survival in the hunter-gather stage of the human species that had real and necessary survival value is no longer useful when we are rarely under actual physical threat. We nevertheless preserve the same stress response systems, but now rather than tiger attacks they are more likely to be triggered by getting caught in traffic or being passed over for a promotion. These stressors lead to the same outpouring of fight or flight neurohormones, even if they are useless for dealing with the present situation. Repeated activations of neurohormonal stress response systems serve no useful purpose in these situations and can only lead to a repetitive wear and tear on the body, or mental suffering in the individual. This perhaps explains the proliferation of books and classes about meditation, Buddhism, and the use of practices like mindfulness, which all boil down to an attempt to turn off the stress physiology system.

The medical model of *DSM* has latched onto the easy catch-all that a mental disorder exists when the requisite minimum of symptoms in different categories results in a significant impairment in work or social function. There are a number of problems with this definition, though. If there is a disruption in the marriage or relationship, how can you be sure it was related to the symptoms? Many people have trouble working or keeping relationships that do not have symptoms of mental disorders. Conversely, some spouses feel an important caretaker role in helping their mental disorder afflicted spouse, especially those with PTSD.

The environment has an important effect on whether or not symptoms of mental disorders reach the point of conditions associated with distress or impairment. The military is a good illustration of this. It isn't uncommon for soldiers to develop PTSD symptoms while in the military, but continue to be able to do their jobs and function normally. In combat arenas where there is a lot of heavy fighting, most of the soldiers will develop behaviors that could be classified as consistent with PTSD symptoms. Being jumpy or easily startled actually has survival value in a combat zone, especially when there is the continual threat of unexpected attack by insurgents. It is only when the soldier returns to the States and is unable to turn off the combat mind that he or she runs into trouble. Behaviors that were adaptive and complementary in one environment suddenly become not so in another environment. Overnight, because of modern jet travel, the person is transported from a combat zone in the Middle East to a leafy suburb in America. Many soldiers report this transition as a shock to the system. Although nothing about the person has changed, the change in venue has suddenly created a mental disorder. Sometimes a soldier returns to the States but remains an active duty soldier or officer. He or she may have symptoms of PTSD but be able to function because the military culture effectively supports the PTSD symptom burden, either because others have similar problems and are understanding, or there is a recognition that the symptoms and behaviors are related to military service overseas, something that is highly valued. In addition, the structure of the military is conducive to the maintenance of mental function. There is a set structure of what to do every day. Proper diet and exercise are regulated, and in fact required. The active duty military person, if they live on base, are surrounded by sympathetic persons, and may have little exposure to civilian life, with its stigma of mental illness. It is only after leaving the service, when the ex-soldier reverts to a poor diet and lack of exercise, there is increased access to alcohol and illegal drugs, and a lack of structure in the day, possibly even unemployment, that symptoms are associated with dysfunction. A similar phenomenon occurs in the civilian sector, where when people lose their job, they suddenly become dislodged and overwhelmed with traumatic memories or other symptoms. The preoccupation with work, and a pattern or working extended days that end in exhaustion and blissful sleep, may have served to keep at bay intrusive traumatic memories. When the busy job or career is removed, the individual is flooded with memories and becomes dysfunctional, or the dysfunction may be related that they seek drugs and alcohol to escape from the memories.

In addition to creating false models of disorders that have no utility in clinical practice, academic psychiatry and psychology have also become hostages of what has been termed the *abduction of disorder by psychiatry* (Richters & Hinshaw, 1999). As mentioned above, in academic psychiatry and the arena of psychiatric research, mental disorders are expected to conform to the medical model, which means that diagnoses should be pure and without comorbidity. When they fail to conform to model, rather than consider that there may be a problem with the model, the onus is put on the researcher to explain the discrepancy. Researchers then go off on a wild goose chase to go up with an explanation that doesn't have to mention the obvious. Namely that, in the trauma field at least, there is overlap of symptoms amongst different trauma-related disorders, consistent with the trauma spectrum model. This leads to some investigators, in the search for a pure disorder, to perform studies on patient groups that are so unusual that they have no applicability to the patients that actually present to clinical practice. For example, trauma patients with pure PTSD, who have no history of depression or other anxiety disorder, no past substance abuse, no medical problems, and preferably not treated with medications.

Studies of the neurobiology of trauma-related disorders, however, do no support the specificity of disorders. This is exemplified by brain imaging studies, but also in the field of genetics, where the data seem to show that genes can confer risk for a range of disorders previously not felt to be related, like attention disorders, psychotic disorders, etc. This is an illustration of the concept of multipotentiality (i.e., that a gene can lead to different disorders depending on the interaction with development and the environment).

The increased risk of physical disorders in patients with trauma-related mental disorders also requires a multilevel analysis. Both depression (Vaccarino et al., 2007) and PTSD (Vaccarino et al., 2013) have been shown to be independent risk factors for the development of heart disease. PTSD has also been associated with a range of other

medical disorders, including infectious diseases, diabetes, and asthma (Anda et al., 2008; Sareen et al., 2007; Zatzick et al., 2010). In addition, PTSD or childhood abuse is associated with increased obesity, which is a risk factor for diabetes, and increased rates of smoking, alcoholism, and drug abuse (Anda et al., 2006; Dube, Felitti, Dong, Giles, & Anda, 2003; Williamson, Thompson, Anda, Dietz, & Felitti, 2002). Therefore the most appropriate way to treat patients with PTSD and victims of childhood abuse is a multilevel approach that considers both mental disorders and physical disorders and does not make artificial distinctions between the two.

To have a proper perspective on the current gridlock our *DSM* era it helps to take a historical view of the mental health field. There is a long history of research in the field of traumatic stress. Popular culture has recognized traumatic stress for even longer. Below the subject of traumatic stress is examined in further detail, from the perspective of the individual, psychology, the context of the individual within society, as well as the effects on neurobiology, stress physiology, and physical health, risk factors and resiliency. This comprehensive approach characterizes the multiple levels of analysis viewpoint.

PSYCHOLOGICAL TRAUMA: THE LONG VIEW

There is a long history of scholarship in the area of traumatic stress. This predates the current era dominated by the *DSM* and its establishment of the posttraumatic stress disorder (PTSD) diagnosis in 1980. Trauma research dates back to 1830, or earlier. That was the time in England when a syndrome called railway spine or railway injuries was first described. Railway spine occurred after train accidents, and the symptoms looked very similar to what today we would call PTSD. It included problems with anxiety, memory loss, confusion, and amnesia. One of its symptoms, back pain, is common to many patients with PTSD, even though it is not part of the criteria for diagnosis (for most patients with back pain a physical etiology is never found; Bremner, 2009).

As described in a paper in the journal *The Lancet* in 1830, Railway spine was considered to be due to small contusions of the spinal cord that were below the limits of detection with the naked eye. This paper described for the first time a disorder caused by a psychological shock or trauma with no apparent physical blow or impact for its cause and no apparent physical injury. The syndrome was fully described in a book by Erichsen called *Railway and Other Injuries of the Spine*.

It was at about this time that psychiatrists in Germany first described what they called traumatic neurosis. The psychiatrist Oppenheim was the first to describe it. He wrote that a psychological stress or extreme shock could lead to long-term changes in physiology in the absence of physical injury. This was the first time that an environmental event was hypothesized to be solely responsible for changes in the brain. In other words, what you visually see, hear, and feel could cause a long-term disorder, a remarkably revolutionary concept at the time.

World War I (WWI) with its massive number of physical and psychological casualties saw the development of the concept of shell shock. This disorder, which affected soldiers in combat, was associated symptoms of becoming confused on the battlefield, and forgetting one's name or identity. The development of the concept of shell shock is similar to that of railroad spine, in that it originally was thought to be caused by the exploding of shells in proximity. However, it was observed some cases developed when the shells were far away (i.e., that a physical cause was not necessary for the development of the disorder). This led to the idea that the psychological trauma of combat could be the cause.

Freud was coming into prominence at this time and eventually his views would dominate current views on symptoms associated with trauma. Freud came up with the term combat neurosis to describe soldiers who developed mental symptoms in combat. In Freud's view it was caused by a suppressed urge to run from the battlefield. Combat neurosis was an extension of Freud's views that mental disorders were caused by unconscious conflicts that came to the surface in the form of symptoms. In the case of soldiers, the controlling ego battles to suppress primary instincts for self-preservation. This removed the possibility that the actual stress of war could be the cause. This fit with the agenda of governments at the time who were focused on keeping soldiers on the battlefield and were not interested in taking responsibility for the fact that they were creating tens of thousands of psychiatric casualties by exposing them to war. On the civilian front, Freud similarly applied his theories to explain the neurosis of his famous patient, Anna O., whom he first described as being the victim of sexual abuse by her father. In his reformulation there was no actual sexual activity, it represented repressed desires to have sex with her father and kill her mother, or the so-called Oedipal complex. The history of the next few decades of psychiatry, especially in the United States, was characterized by the total dominance of psychoanalysis. This left no room for the trauma of life in the development of mental disorders. There was little or no discussion of

the role of environmental events like psychological trauma on mental health.

The next chapter in the history of American academic psychiatry was the rise of biological psychiatry. Freud used the language of physics to describe the forces of the unconscious and the ego and superego in his model. However, by the 1970s psychoanalysis was viewed as being unscientific and not testable using the methods of science. In fact, psychoanalysis is more akin to a cultural entity than a hard science, which is why it has long been of interest to scholars in the arts and humanities. The supposed nonscientific, nonmedical nature of psychoanalysis was used by the biological psychiatrists who used it to take over leadership of the psychiatry departments in the universities and medical schools from the analysts.

To pull off this coup, however, the biological psychiatrists had to use their alliance with other disciplines in the medical sciences. They employed the common lingua of neuroscience and genetics, a language that all physicians and medically trained scientists understood and could communicate with. Another advantage of this approach was that the psychiatrists were able to exclude psychologists and others without formal medical training and thus consolidate their hold on power. Previously, in the world of psychoanalysis and psychotherapy, psychologists and social workers could compete equally, however now they suddenly lacked the training and expertise needed for this new role in this new age.

The arrival of the biological psychiatrists brought with it the expectation that a medical basis would soon be found for mental disorders. This was anticipated to parallel, for example, the discovery that a shortage of insulin was responsible for the puzzling symptoms of diabetes, which included excessive urination, feeling hungry, and thirst. The discovery of the cause would be followed by the invention of a cure. This was and continues to be paralleled in the media, which presents this view of psychiatry in the popular press. Although other medical specialties paid lip service to the new discipline of medical psychiatry or neuropsychiatry, they continued to harbor unexpressed misgivings that these disorders were equivalent to those in their own specialties.

The initial focus of the biological psychiatrists was on schizophrenia, which they viewed as a real disorder. The focus of the first editions of *DSM* was on schizophrenia and to a lesser extent major depression. The descriptive language of psychoanalysis for disorders related to anxiety, dissociation and somatic disorders, was not extensively modified, probably related to the unspoken belief that there was not a solid scientific basis for these disorders. For instance, there was long a resistance to the use of the diagnosis of PTSD, to the extent that 10 years after its introduction to the *DSM* in 1980, it was rarely used to apply to combat veterans with mental disorders (Bremner, Southwick, Darnell, & Charney, 1996). Dissociative disorder diagnoses continue to be met with skepticism by many clinicians. This was the basis for the fact that the initial editions of *DSM* continued to use the language of the neuroses.

The *DSM* was designed to have a collection of diagnoses that were not based on specific etiologies. This was an attempt to break psychiatry free from the grasp of psychoanalysis, which had a descriptive model that entailed all psychiatric disorders. This created, however, an inherent paradox, since the medical diagnosis is based on the etiology of the disorder. How could it be possible that major depression was a medical disorder, just like diabetes, when it wasn't known what caused it? One way to side step this problem was to assert that the etiology would soon be found, but in the meantime we needed specific criteria for diagnosis to further research on these disorders and standardize the field.

DSM-III, published in 1980, saw the final elimination of the language of psychoanalysis from psychiatric diagnosis. In its place came specific lists of mood and anxiety disorders described in neutral language. The development of *DSM-III* occurred at the time when soldiers were returning from Vietnam, and were clamoring for treatment and recognition of the mental symptoms they were suffering from in the aftermath of the war. This led to the description of a Vietnam War syndrome. The first edition of the *DSM* had gross stress reaction described as an acute reaction to the stress of combat, that were assumed to be transient in nature. If symptoms persisted this was considered to be secondary to a preexisting psychopathology or personality disorder. Based on this concept the military tried to screen recruits for personality problems to avoid stress reactions on the battlefield and enhance the fitness of their soldiers. Discussions about the etiology of the Vietnam War syndrome reintroduced the debate about whether psychological trauma in and of itself could cause lasting mental disorders.

Acknowledging that war caused mental illness would mean that the government was responsible for afflicted soldiers. This had political and societal implications. It was determined that objective research in the field of psychological trauma was needed to resolve this issue. Objective rating scales were developed to measure quantity of exposure to combat trauma and severity of mental symptoms. Studies did show that degree of combat exposure was

correlated with severity of PTSD symptoms (Keane, Caddell, & Taylor, 1988; Keane, Wolfe, & Taylor, 1987). Eventually the model that combat can cause mental disorders prevailed. This led to the inclusion in the *DSM-III* in 1980 of PTSD, emphasizing for the first time in the twentieth century the central role of trauma.

The struggle for recognition of the central role of trauma in the development of PTSD, however, was associated with its own problems. Proponents of the model became resistant to the idea that anything other than combat trauma was responsible for PTSD in veterans. Because of this there was resistance that other factors, such as a history of childhood abuse (Bremner, Southwick, Johnson, Yehuda, & Charney, 1993) or genetics (Goldberg, True, Eisen, & Henderson, 1990), could contribute to severity of PTSD. Accumulating research, however, demonstrated several factors that increase the risk for PTSD after trauma, including prior traumatization and mental disorders, social support, education, and age at the time of traumatization (Brewin, Andrews, & Valentine, 2000).

PTSD is the only disorder in the *DSM* that includes the presence of psychological trauma exposure in the criteria for the diagnosis. It is not the only disorder, however, that has an important link to trauma. As reviewed above, other disorders, including dissociative disorders, borderline personality disorder, and in cases of childhood abuse, depression, are also linked to trauma exposure (Battle et al., 2004; Bohus, Schmahl, & Lieb, 2004; Lieb, Zanarini, Schmahl, Linehan, & Bohus, 2004; Schmahl, McGlashan, et al., 2002; Zanarini, 1997; Zlotnick et al., 2003).

The requirement for trauma exposure was included in the "Criterion A in the criteria for PTSD, which first appeared in *DSM-III*. Defining psychological trauma, and stress in general, is not necessarily a simple exercise. Should it be based on an objective assessment of the impact of a trauma, or how it affects the individual? If it is objective, who will decide what constitutes a severe trauma? Psychiatrists? Does that paternalizing situation where the field of psychiatry determines who is and is not mentally ill and what shall be done about it? In the legal arena, the concept of vulnerability is described as the eggshell skull, i.e., someone may be more prone skull fracture than others. The first version of *DSM* that addressed the issue defined psychological trauma as an event beyond the range of normal human experience.

Subsequent research, however, showed that most people are exposed at some point to events like car accidents, robbery, assault, and abuse (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). The criterion was so all inclusive that it was essentially useless. In DSMIV the criterion was revised to include "exposure to a threat to life to self or significant other accompanied by intense fear, horror or helplessness" (pp. 1–17) (Saigh & Bremner, 1999). Using the new diagnosis of PTSD it was found that 8% of people in the United States suffered from PTSD as some point in their lives, with women affected twice as often as men (Kessler et al., 1995). In women PTSD is most commonly related to childhood sexual abuse, and physical assault in men (Kessler et al., 1995). Subsequent research showed that PTSD related to civilian traumas such as child abuse affected a far larger number people in the U.S. than combat veterans (MacMillan et al., 1997). The development of specific criteria, although not without its problems, allowed for an expansion of research in PTSD.

In conjunction with the development of the concept of Vietnam War syndrome, other trauma-related syndromes were being identified. For instance, clinicians described a rape syndrome in female rape survivors, and battered child syndrome in victims of childhood abuse. Also, different countries felt that their collection of symptoms related to their own particular wars or genocides were unique to their culture. Subsequent research, however, has shown that symptoms of PTSD are stable across cultures, with perhaps the main difference being how one interprets the meaning of the symptoms based on one's culture (Kirmayer, Lemelson, & Barad, 2007).

DSM-III PLUSES AND MINUSES

The advent of PTSD and psychological trauma in *DSM-III* had benefits in terms of ability to do research, however in some ways it was a Faustian bargain. As mentioned above, the *DSM* freed itself from psychoanalysis and in the process created a series of stand–alone mental disorders defined only by the face value of their presenting symptoms. What resulted was a series of disorders that in fact have many overlapping symptoms. Some symptoms are very similar, if not identical, between the disorders, although they may have received slightly modified descriptions. For instance, hyperarousal in PTSD could be seen as equivalent to psychomotor agitation in depression. Also, the flashbacks seen in combat veterans with PTSD were considered to be unique to the disorder, although in fact they are traumatic memories recalled in a dissociative state, similar to the dissociative disorders. The impetus behind promoting the diagnosis of PTSD in veterans as combat trauma related was associated with a resistance to association with other disorders that might not have the same prestige, or were considered marginal, like the

dissociative disorders. Also, clinicians and researchers focused on the different trauma-related disorders attended different meetings and belonged to different societies. This led to the development of different camps associated with the different disorders.

The trauma-spectrum model discussed above calls for a grouping of mental disorders linked to traumatic stress (Bremner, 1999, 2002a). The model explains the development of mental disorders based on a pathway where stress interacts with genetics, as well as personal, developmental, social, and other factors to produce stress-related psychiatric disorders. Bremner used the model to argue for inclusion of disorders related to trauma in a separate diagnostic category (Bremner, 1999, 2002a). The argument was made that the classification of PTSD as an anxiety disorder did not make sense from either a nosological, clinical, or biological level, as it shares little in common with the other anxiety disorders other than the symptom of anxiety.

In a series of studies, we and others showed that the trauma-spectrum disorders share important neurobiological fingerprints that differentiate them from the non-PTSD anxiety disorders. The neurobiology of obsessive-compulsive disorder, and to a lesser extent generalized anxiety disorder (GAD) and panic disorder (PD), are different from PTSD. For instance, brain imaging studies have implicated brain areas like the striatum in OCD, while the trauma disorders are more linked to the amygdala, hippocampus, and medial prefrontal cortex (Bremner, 2004, 2005a). Although some cases of depersonalization disorder have been reported where there is no obvious traumatic etiology (Simeon et al., 2000), essentially all patients with dissociative identity disorder (DID) have a history of severe childhood abuse (Vermetten et al., 2006).

TRAUMA AND THE SELF

One of the things that has been lost in the medical model of trauma and PTSD is the importance of the impact of the event on the individual. People develop a sense of personal meaning around their trauma experiences. Trauma may also make people come to believe that life has no meaning, however this is still a personal belief or value system. The medicalization of trauma does not encompass the effect of traumatic stress on the psyche, sense of self, character, and individual, considered both as him/herself and within society and culture they are a part of.

Trauma affects the way we view the world and ourselves. Traumatized people sometimes feel that they are somehow to blame for what happened to them, or that they are a bad person. Others may feel that their traumatic experiences are not necessarily negative. Or there may be a process where what was a negative experience is transformed through personal growth and becomes a source of strength and meaning. This has given rise to the concept of traumatic growth, or events that stimulate change and result in a person moving in a different path in life, sometimes with positive results. There are many artists and scientists who have taken their traumatic experience and used it as a source of inspiration and/or motivation. This response to trauma can often be healing.

One important aspect of psychological trauma is how it changes our perception of the world. Most of us go about our daily lives with the illusion that the world is a safe place. We may not even think about it, we just take it for granted. In fact, this is usually a good thing; otherwise, we would be paralyzed by anxiety and would not be successful in our endeavors. No one wants to be able to see into the future. If you knew in advance what was in store for you, it would make it difficult to live in the present. We therefore live in an illusion of safety that makes life easier. When this illusion is shattered by a traumatic event, it makes us realize how transitory life is and what an unsafe world we live in. A woman raped in an alleyway at night will probably never feel that an alleyway is a safe place in the future.

Countries also carry trauma histories with them. A country can respond to a traumatic event with avoidance and numbing and an attempt to forget. Look at Japan in the aftermath of World War II. However, if left alone, psychological trauma can be suppressed for only so long, and may come back later to haunt you (Bremner & Reed, 2014).

Trauma can take on political and societal dimensions. Terrorists use trauma as a political tool. It serves their purpose to violate the personal feelings of safety and security in others, because it challenges the controlling political or social institutions that they seek to overthrow. Targeting mass transit systems that everyone uses, like airplanes or trains, is a reminder that one is always in danger from another terrorist attack. The choices of targets are deliberate. Remember the anthrax scare? We all get letters in the mail.

RISK FACTORS FOR THE DEVELOPMENT OF TRAUMA-RELATED PSYCHOPATHOLOGY

One variable to consider in a multilevel analysis of psychological trauma is risk factors for the development of trauma-related mental disorders. About half of people or

more will be exposed to a psychological trauma at some point in their lives (Kessler et al., 1995). Only about a quarter or less of people develop PTSD following exposure to psychological trauma (de Vries & Olff, 2009; Reese et al., 2012). Twin studies proved that combat exposure is linked to PTSD, with the risk of developing PTSD increased by about ninefold in twins exposed to high combat compared with their noncombat-exposed twin brothers (Eisen, Neuman, Goldberg, Rice, & True, 1989; Goldberg, True, Eisen, Henderson, & Robinette, 1987; Goldberg et al., 1990; Henderson et al., 1990). Genetic factors account for 13–34% of the risk for the development of PTSD (Goldberg et al., 1990; True et al., 1993). Other studies demonstrated a genetic contribution to the risk of being exposed to traumatic stressors (Kendler, Thornton, & Gardner, 2000). One interpretation of this interesting finding is that certain inherited personality traits may determine who will walk point in a combat unit in Vietnam. Another view would be that certain families are walking disasters. For instance the family that due to alcoholism and family abuse and violence has a low socioeconomic status that causes them to live in a trailer in a rural area. That in turn exposes them to increased risks from natural disasters like hurricanes. The cycle of trauma keeps these family members trapped in a pattern of high risk. Overall, these studies demonstrated that a combination of genetic and environmental factors is responsible for the development of PTSD.

Other research looked at neurocognitive factors that could influence the risk for development of PTSD after exposure to psychological trauma. Some researchers have found pre-trauma exposure intelligence to increase the risk of PTSD (Macklin et al., 1998; McNally & Shin, 1995) while other studies found smaller hippocampal volume pretrauma predicted risk for PTSD (Gilbertson et al., 2002).

Genetic studies have examined the role of genes encoding various neuroreceptors in the risk of PTSD. Several studies have looked at the role of genes coding for the serotonin transporter, which controls reuptake of serotonin in the neuron, and is the target for the Selective Serotonin Reuptake Inhibitors (SSRIs). The genotype for the serotonin transporter (5HTTLPR) includes both S (short) and L (long) allele types. Genetic polymorphisms for the short form of the serotonin transporter were associated with increased risk for depression after stress exposure (Caspi et al., 2003). Studies in PTSD showed genes coding for the serotonin transporter and other serotonin receptors increased the risk (Kuzelova, Ptacek, & Macek, 2010; Pietrzak, Galea, Southwick, & Gelernter, 2012) including the short form of the serotonin transporter (Kenna et al., 2012; Koenen, Amstadter, & Nugent, 2009; Kuzelova et al., 2010; Lee et al., 2005; Wang et al., 2011). Other studies showed that that the serotonin transporter short form was associated with development of PTSD after natural disaster (Pietrzak et al., 2012) or exposure to childhood adversity (Xie et al., 2009). The L-S and G-A alleles of the serotonin transporter were examined, and the L (A) genotype was found to increase risk for PTSD (Grabe et al., 2009). The serotonin 5-HT_{2A} receptor is a postsynaptic receptor involves in regulation of behavior and other functions. The G allele was associated with an increased risk for PTSD in a sample of African-Americans (Mellman et al., 2009). Other studies showed positive response to selective serotonin reuptake inhibitor (SSRI) antidepressants with the LL allele of the serotonin transporter gene, and poor response in patients with the SS allele (Kenna et al., 2012; Mushtaq, Ali, Margoob, Murtaza, & Andrade, 2012), which was also associated with lack of response to cognitive-behavioral therapy (Bryant et al., 2010).

Studies have also looked at genes coding for the receptors and neurohormones in the HPA axis. A gene coding for the cortisol receptor, FKBB5, predicted the development of depression and response to treatment (Binder et al., 2005). Genes coding for corticotropin releasing factor (CRF) (Bradley et al., 2008) also predicted the development of depression.

In summary, these studies show that a combination of genetics, including patterns of physiological responses to stress, and the environment, via exposure to psychological trauma, play a role in the risk for PTSD following trauma (Kendler et al., 2000; Pitman, 2001).

Using the multilevel analysis approach we can combine all of these various factors to understand the effects of stress on the individual, including genetics, risk factors, neurobiology, personality, cultural, philosophical, and other factors.

THE INTERACTION OF DEVELOPMENTAL EPOCH AND THE BRAIN

One of the factors that need to be assessed in the multilayer assessment approach is the interaction between developmental epoch, brain development, and trauma. The age of the child and the level of brain development at the time of the trauma plays a critical role in determining long term outcomes. To understand this important variable we need to have an understanding of normal brain development, which we do here.

During the first 5 years of life there is an increase in both gray matter and white matter, which causes a general enlargement of the brain. Ongoing myelination results in an increase in white matter from age 5 to 18, while there is a decrease in gray matter secondary to neuronal pruning with no change in total brain size (Casey, Giedd, & Thomas, 2000; Durston et al., 2001; Giedd, Blumenthal, Jeffries, et al., 1999; Paus et al., 1999). The frontal and parietal cortex increase in volume during this time (Rapoport et al., 1999; Sowell et al., 1999) as do corpus callosum (Giedd, Blumenthal, & Jeffries, 1999; Thompson et al., 2000), hippocampus and amygdala (Giedd, Castellanos, Rajapakse, Vaituzis, & Rapoport, 1997; Giedd, Vaituzis, et al., 1996; Pfefferbaum et al., 1994) while there is a decrease in volume of the basal ganglia (Giedd, Blumenthal, & Jeffries, 1999; Thompson et al., 2000). In mid childhood lateral ventricular size increases in size for boys (but not girls), while caudate and putamen size decreases in boys, but not girls (Giedd, Snell, et al., 1996). After the age of about 18–21 there is little change in the brain until very late in life, in the absence of pathological conditions like arteriosclerosis or Alzheimer's disease.

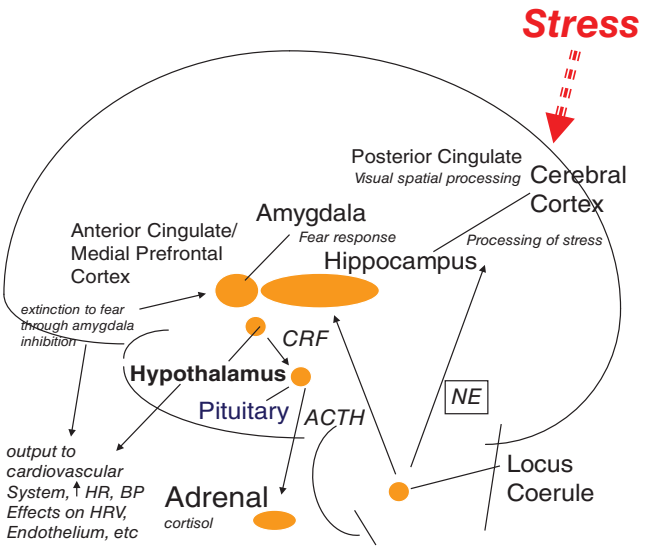

Figure 9.1 Model of how traumatic stress affects the brain. Stress is associated with acute increases in cortisol and norepinephrine. With chronic stress there is dysregulation of these systems with increased amygdala function and decreased hippocampal and medial prefrontal function. Outputs through the hypothalamus and medial prefrontal cortex increase peripheral sympathetic and cortisol function, increasing the risk of heart disease. See footnote 1.

BIOLOGICAL RESPONSES TO TRAUMA

Another variable in the multilevel assessment of trauma is the neurobiological response to trauma. Neuroscience has been touched on previously in this chapter but here we provide a more in depth view.

Trauma can have long-term effects on the body and physiological systems (Figure 9.1). Stress circuits like the cortisol and norepinephrine systems, and brain regions involved in memory, including the hippocampus, amygdala, and prefrontal cortex, are sensitive to stress (Bremner, 2002b; Bremner & Vermetten, 2001). These circuits and systems underlie symptoms of posttraumatic stress disorder (PTSD) and other stress-related mental disorders (Bremner, 2002a).

The hypothalamic-pituitary-adrenal (HPA) axis is activated by stress. Corticotropin-releasing factor (CRF) is released from the hypothalamus, with stimulation of adrenocorticotropin hormone (ACTH) release from the pituitary resulting in turn in cortisol release from the adrenal. CRF also acts centrally to create fear-related behaviors and triggers other neurochemical responses to stress, including the noradrenergic neurotransmitter system (Melia & Duman, 1991). Early life stress leads to long term sensitization of the HPA axis and CRF to further stressors (Coplan et al., 1996; Levine, Weiner, & Coe, 1993; Makino, Smith, & Gold, 1995; Plotsky & Meaney, 1993; Stanton, Gutierrez, & Levine, 1988). Stress also leads to over activation of the norepinephrine system, which plays a critical role in the fight-or-flight response (Bremner, Krystal, Southwick, & Charney, 1996a, 1996b).

A network of brain areas involved in memory and fear, including the hippocampus, medial prefrontal cortex, and amygdala, are involved in the brain's response to stress (Bremner, 2005b, 2011; Rauch, Shin, & Phelps, 2006). The hippocampus plays a critical role in memory and is also sensitive to stress. Studies in animals showed that stress resulted in damage to neurons in the CA3 region of the hippocampus (Gould, Tanapat, McEwen, Flugge, & Fuchs, 1998; Magarinos, McEwen, Flugge, & Fluchs, 1996; McEwen et al., 1992; Nibuya, Morinobu, & Duman, 1995; Sapolsky, 1996; Sapolsky, Uno, Rebert, & Finch, 1990). High levels of glucocorticoids seen with stress were also associated with deficits in new learning (Diamond, Fleshner, Ingersoll, & Rose, 1996; Luine, Villages, Martinex, & McEwen, 1994).

Brain-derived neurotrophic factor (BDNF) is a neuropeptide found in the hippocampus and other brain regions that has a trophic effect on neurons. Stress resulted in a reduction in brain-derived neurotrophic factor (BDNF) mRNA; CRF also had a direct effect

on the hippocampus in early development (Brunson, Eghbal-Ahmadi, Bender, Chen, & Baram, 2001). Antidepressant drugs, some anticonvulsants, and electroconvulsive therapy had the opposite effect on BDNF levels in the hippocampus (Malberg, Eisch, Nestler, & Duman, 2000; Nibuya et al., 1995; Watanabe, Gould, Cameron, Daniels, & McEwen, 1992).

Changes in the environment can also have an effect on the hippocampus, a finding that has implications for children growing up in abusive or neglectful families. Social enrichment increases hippocampal neurogenesis (Kempermann, Kuhn, & Gage, 1998). Maternal behavior influences glucocorticoid receptors in the hippocampus, an effect that can persist into adulthood (Liu, Diorio, Day, Francis, & Meaney, 2000; Meaney, Aitken, van Berkel, Bhatnager, & Sapolsky, 1988).

The medial prefrontal cortex also plays an important role in the stress response. This brain structure includes the anterior cingulate, orbitofrontal cortex, and adjacent areas. The mesofrontal dopamine system is involved in emotional responses and coping, and stress results in dopamine release in the medial prefrontal cortex (Arnsten, 2000; Deutch & Roth, 1990; Devinsky, Morrell, & Vogt, 1995; Pani, Porcella, & Gessa, 2000). The frontal cortex also inhibits function of the amygdala, a brain area involved in fear learning responses. This circuitry underlies extinction of fear responses (Milad & Quirk, 2002; Quirk, Garcia, & Gonzalez-Lima, 2006). Peripheral neurohormonal responses to stress are also regulated by the frontal cortex via relay stations in the spinal cord (Diorio, Viau, & Meaney, 1993; Feldman, Conforti, & Weidenfeld, 1995; Frysztak & Neafsey, 1994). This brain area is also sensitive to early stress, which leads to decreased branching of neurons (Radley et al., 2004).

Although understanding the interaction between childhood development, trauma, and physiology is critical, research in children is complicated by multiple factors. These include issues related to psychiatric diagnoses in children, reliability in assessment of trauma and symptoms, and informed consent (Cicchetti & Walker, 2001; Saigh, Yasik, Sack, & Koplewicz, 1990). Sexually abused girls were found to have normal baseline cortisol and blunted ACTH response to CRF (M.D. DeBellis, Chrousos, et al., 1994). Traumatized children with PTSD had increased levels of cortisol measured in 24-hour urines (DeBellis, Baum, et al., 1999). Emotionally neglected children from a Romanian orphanage had elevated cortisol levels over a diurnal period compared with controls (Gunnar, Morison, Chisolm, & Schuder, 2001). Elevated cortisol was also seen in children with clinical-level internalizing problems (Cicchetti & Rogosch, 2001). Depressed preschool children showed increased cortisol response to separation stress (Luby et al., 2003). Children with depression and abuse had an increased ACTH response to CRF challenge compared with children with depression without abuse (Kaufman et al., 1997).

The effects of early life trauma can result in neurobiological changes extending into adulthood (Cicchetti & Rogosch, 2001; Shea, Walsh, MacMillan, & Steiner, 2004). Women with childhood sexual abuse-related PTSD assessed with the Early Trauma Inventory (ETI), a reliable and valid measure of early abuse (Bremner, Bolus, & Mayer, 2007; J. D. Bremner, Vermetten, & Mazure, 2000) had decreased baseline cortisol based on 24-hour diurnal assessments of plasma with 10-minute sampling periods, a flattening of the normal diurnal cortisol curve, and increased pulsatility of cortisol reflecting dysregulation of CRF release, compared with women with abuse without PTSD, and women without abuse or PTSD (Bremner, Vermetten, & Kelley, 2007). Lower baseline cortisol was correlated with increased symptoms of PTSD in the PTSD group (Bremner et al., 2007). The normal cortisol rise after awakening has also has been shown to be blunted in PTSD patients (de Kloet, Vermetten, Heijnen, et al., 2007; Neylan et al., 2005; Wessa, Rohleder, Kirschbaum, & Flor, 2006), while pre-deployment cortisol response to awakening was not predictive of the development of PTSD (van Zuiden, Kavelaars, et al., 2011). Women with PTSD had increased cortisol responses in response to hearing personalized scripts of their childhood abuse (Elzinga, Schmahl, Vermetten, van Dyck, & Bremner, 2003). Childhood abuse-related PTSD was also associated with increased cortisol response to cognitive stressors (Bremner, Vythilingam, Vermetten, Adil, et al., 2003). Combat veterans with PTSD assessed with 24-hour sampling showed lower plasma cortisol levels and a flattening of the normal diurnal curve (Yehuda, Teicher, Levengood, Trestman, & Siever, 1994). Measurement of cortisol in 24-hour urine collections show either normal or low cortisol in PTSD (Yehuda et al., 1995; Yehuda, Teicher, Trestman, Levengood, & Siever, 1996) and increased suppression of cortisol to dexamethasone, reflecting increased sensitivity (Stein, Yehuda, Koverola, & Hanna, 1997; Yehuda, Halligan, Grossman, Golier, & Wong, 2002). Women with depression and a history of childhood abuse had increased cortisol response to a stressful cognitive challenge relative to controls (Heim et al., 2000) and a blunted ACTH response to CRF challenge (Heim, Newport, Bonsall, Miller, & Nemeroff, 2001).

Changes in glucocorticoid receptor (GR) function are seen in PTSD (Vermetten, 2008). Cortisol regulates glucocorticoid receptors in the pituitary and hypothalamus providing feedback to the HPA axis. A proxy of glucocorticoid function can be measured indirectly by assessing cortisol levels following administration of glucocorticoids (e.g., dexamethasone) or through measurement of receptors in lymphocytes. PTSD is associated with increased suppression of cortisol with low dose (0.5 mg) dexamethasone, suggesting increased sensitivity of glucocorticoid receptors (Goenjian et al., 1996; Stein, Yehuda, et al., 1997; Yehuda & Boisoneau, 1995; Yehuda et al., 1993), although one study found this effect in traumatized non-PTSD subjects as well (de Kloet, Vermetten, Heijnen, et al., 2007). Other studies in PTSD showed increased glucocorticoid receptors in peripheral lymphocytes (Yehuda, Lowry, Southwick, Mason, & Giller, 1991) and hypersensitivity of pituitary response to metyrapone (Yehuda, Levengood, et al., 1996) (although see (Kanter et al., 2001), consistent with increased feedback sensitivity in PTSD. Elevations of glucocorticoid receptors were shown to be predictive of the development of PTSD after combat deployment (van Zuiden, Geuze, et al., 2011). PTSD was associated with a blunted effect of glucocorticoids (dexamethasone) on declarative memory function, suggesting decreased sensitivity of glucocorticoid receptors in the hippocampus (J. D. Bremner, Vythilingam, Vermetten, Newcomer, & Charney, 2004). One study showed a decrease, however, in GR in leukocytes in both traumatized PTSD and non-PTSD subjects in comparison to healthy controls, and a blunted suppression response of T-cell proliferation in leukocytes to dexamethasone that was specific to PTSD (de Kloet, Vermetten, Bikker, et al., 2007).

PTSD is associated with increases in corticotropin releasing factor (CRF). Male patients with combat-related PTSD had increased concentrations of CRF in the cerebrospinal fluid (CSF; Baker et al., 2005, 1999; Bremner, Licinio, et al., 1997; Sautter et al., 2003) and plasma (de Kloet et al., 2008). A study of civilian PTSD with low levels of comorbid psychiatric diagnoses found no difference in CSF CRF from controls (Bonne et al., 2011). PTSD was associated with a blunted ACTH response to CRF challenge, suggesting decreased pituitary sensitivity to CRF (Smith et al., 1989). No difference between PTSD patients and controls was found in ACTH or cortisol after administration of dexamethasone followed by a CRF challenge (de Kloet et al., 2008).

Increased noradrenergic and peripheral sympathetic function is associated with PTSD (Bremner, Krystal, et al., 1996a, 1996b). Symptoms characteristic of increased noradrenergic function include irritability, increased startle, hyperarousal, and sleep disturbance (Bremner, Krystal, et al., 1996b). Increased baseline concentrations of norepinephrine and its metabolites were found in patients with PTSD (DeBellis, Baum, et al., 1999; DeBellis, Lefter, Trickett, & Putnam, 1994; Lemieux & Coe, 1995; Mason, Giller, & Kosten, 1988; Yehuda, Siever, & Teicher, 1998), although some studies showed no baseline differences (Blanchard, Kolb, Prins, Gates, & McCoy, 1991; McFall, Veith, & Murburg, 1992; Mellman, Kumar, Kulick-Bell, Kumar, & Nolan, 1995; R.K. Pitman & Orr, 1990; Southwick et al., 1993). Increased concentrations of baseline norepinephrine and its metabolites were also found in cerebrospinal fluid of PTSD patients (Geracioti et al., 2001). Reminders of the original trauma in the form of pictures and sounds or scripts resulted in increased noradrenergic reactivity, shown by an increase in heart rate, blood pressure, and skin conductance, all markers of sympathetic function (Blanchard, Kolb, Gerardi, Ryan, & Pallmeyer, 1986; Blanchard, Kolb, Pallmeyer, & Gerardi, 1982; Bremner, Krystal, et al., 1996b; Malloy, Fairbank, & Keane, 1983; McFall, Murburg, Ko, & Veith, 1990; Orr, Lasko, Shalev, & Pitman, 1995; Orr, Pitman, Lasko, & Herz, 1993; Orr & Roth, 2000; Orr et al., 1998), as well as increased norepinephrine and epinephrine in plasma (Blanchard et al., 1991; McFall et al., 1992). Increased baseline heart rate after trauma exposure predicted subsequent development of chronic PTSD (Shalev, Sahar, Freedman, & et al., 1998).

Other indications of altered noradrenergic function in PTSD include decreased binding to platelet alpha$_2$ receptors (Perry, Southwick, & Giller, 1991), decreased activity of the second messenger, cyclic adenosine monophosphate (cAMP; Lerer, Bennet, Ebstein, Balkin, 1990; Lerer, Ebstein, Shestatsky, Shemesh, & Greenberg, 1987), and decreased platelet monoamine oxidase activity (Davidson, Lipper, Kilts, Mahorney, & Hammett, 1985). These findings suggest chronic increases in norepinephrine leading to compensatory changes in receptors and messenger systems related to noradrenergic function. Administration of the alpha$_2$ adrenergic receptor, yohimbine, which increases firing of noradrenergic neurons in the locus coeruleus, increased PTSD symptoms and anxiety, as well plasma concentrations of the norepinephrine metabolite, 3-Methoxy-4-hydroxyphenylglycol (MHPG) (Southwick et al., 1993, 1997). PTSD patients had a decrease in brain function in the medial prefrontal cortex with yohimbine not seen in healthy controls (decreased frontal lobe function occurs with excessive release of norepinephrine in that

brain area; Bremner, Innis, et al., 1997). These findings all support increased noradrenergic function in PTSD.

Patients with PTSD have smaller volume of the hippocampus as measured with magnetic resonance imaging (MRI), and deficits in declarative memory function, consistent with animal studies (Bremner, 2005b). Studies in children with PTSD from a variety of traumas have shown deficits in verbal memory and verbal IQ (Moradi, Doost, Taghavi, Yule, & Dalgleish, 1999; Saigh, Yasik, Oberfield, Halamandaris, & Bremner, 2006; Saltzman, Weems, & Carrion, 2006). Bremner et al. (Bremner, Randall, Capelli, et al., 1995) found deficits in verbal declarative memory as measured by the Wechsler Memory Scale (WMS), the verbal Selective Reminding Test (vSRT), and other measures, in male and female adults with childhood physical or sexual abuse related PTSD compared controls. Deficits in verbal memory in the childhood abuse patients were significantly correlated with severity of childhood sexual abuse. One study in adult women with sexual abuse-related PTSD showed deficits in verbal declarative memory compared with both women with abuse without PTSD and nonabused non-PTSD women (Bremner, Vermetten, Nafzal, & Vythilingam, 2004). Another study in women with early childhood sexual abuse in which some, but not all, of the patients had PTSD, showed no difference between abused and nonabused women (Stein, Hanna, Vaerum, & Koverola, 1999). These studies suggest that early abuse with associated PTSD results in deficits in verbal declarative memory. Women with childhood abuse-related PTSD also show cognitive impairments as evidenced by an increase in false recall of critical lures on a memory test involving recall from a list of highly semantically related words (Bremner, Shobe, & Kihlstrom, 2000; Clancy, Schacter, McNally, & Pitman, 2000).

Studies have also consistently shown smaller hippocampal volume in both male and female adults with PTSD related to a range of traumas, including childhood abuse (Bremner, 2006; Karl et al., 2006; Kitayama, Vaccarino, Kutner, Weiss, & Bremner, 2005; Smith, 2005). A study of women with early sexual abuse, most of whom met criteria for PTSD, showed smaller hippocampal volume compared with nonabused women (Stein, Koverola, Hanna, Torchia, & McClarty, 1997). Women with early childhood sexual abuse and PTSD had smaller hippocampal volume compared with both abused women without PTSD, and nonabused non-PTSD women (Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Nazeer, et al., 2003). Another study showed smaller hippocampal volume in adult women with PTSD only in those who were abused at specific periods in early childhood (Andersen et al., 2008). Other studies in PTSD have found smaller hippocampal volume and/or reductions in NAA, a marker of neuronal integrity (Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Nazeer, et al., 2003; Emdad et al., 2006; Freeman, Cardwell, Karson, & Komoroski, 1998; Gilbertson et al., 2002; Hedges et al., 2003; Irle et al., 2005; Li et al., 2006; Lindauer, Olff, van Meijel, Carlier, & Gersons, 2006; Lindauer, Vlieger, et al., 2004; Lindauer et al., 2005;

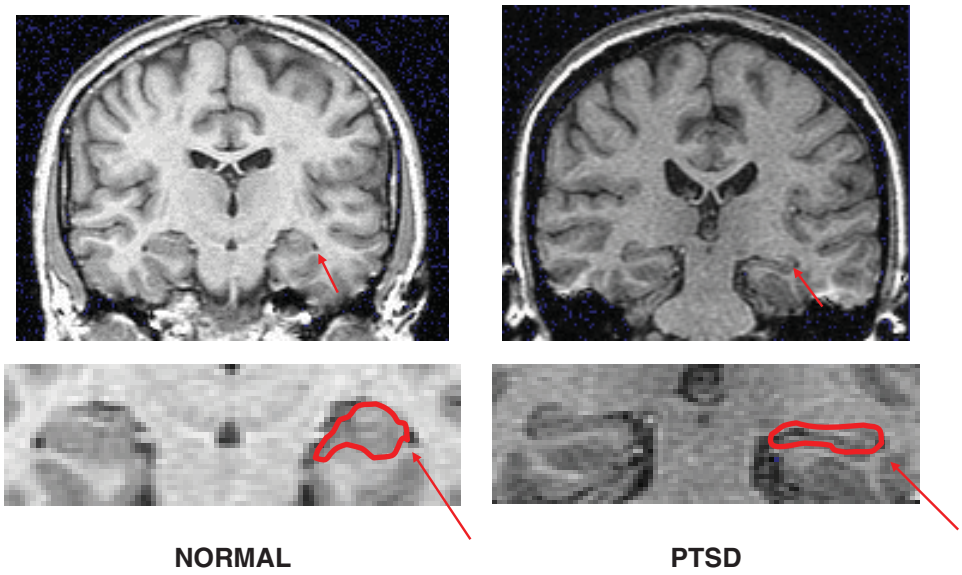

Figure 9.2 Hippocampal volume in PTSD on a coronal MRI. The hippocampus is visibly smaller in the PTSD patient compared with a normal control. See footnote 1.

Mahmutyazicioglu et al., 2005; Schuff et al., 2001; Shin, Shin, et al., 2004; Villarreal et al., 2002).

Studies of children with abuse-related PTSD have not shown smaller hippocampal volume (Carrion et al., 2001; DeBellis, Hall, Boring, Frustaci, & Moritz, 2001; DeBellis, Keshavan, et al., 1999), although one study showed a correlation between cortisol and reduction in hippocampal volume over time (Carrion, Weems, & Reiss, 2007). Meta-analyses show that smaller hippocampal volume is seen to an equal degree in both men and women with PTSD, related to both childhood abuse and adult traumas like combat, and in both left and right hippocampi (Kitayama et al., 2005; Smith, 2005). Findings of smaller hippocampal volume in adults with childhood abuse-related PTSD, but not in abused children, suggests a delayed effect of abuse on the brain, consistent with findings from animal studies (Brunson et al., 2005).

PTSD is also associated with deficits in hippocampal function. Women with childhood sexual abuse-related PTSD had deficits in hippocampal activation while performing a verbal declarative memory task as measured with brain imaging compared with non-PTSD women (Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Nazeer, et al., 2003). A reversal of hippocampal atrophy and hippocampal-based memory deficits was seen with treatment with the SSRI, paroxetine (Vermetten, Vythilingam, Southwick, Charney, & Bremner, 2003). Hippocampal dysfunction may memory dysregulation in PTSD, including increased fear learning, deficits in explicit memory deficits and fragmentation of memory in abuse survivors (Bremner, 2005b).

Alterations in the frontal cortex and other brain structures are associated with PTSD. Women with childhood abuse-related PTSD had smaller anterior cingulate volume as measured with MRI compared with controls (Kitayama et al., 2005), while other studies showed smaller anterior cingulate volumes in women with PTSD (Shin et al., 2009) as well as smaller frontal lobe volumes (Andersen et al., 2008). Reduced NAA (indicating loss of neuronal integrity) was found in medial prefrontal cortex in boys and girls with childhood PTSD (M.D. DeBellis, Keshavan, Spencer, & Hall, 2000). Other findings include smaller volume of the corpus callosum in women with childhood abuse-related PTSD (Andersen et al., 2008; Kitayama et al., 2007). In children with PTSD, boys showed greater reduction in corpus callosum and greater ventricular volumes than girls (DeBellis & Keshavan, 2003). In summary, these studies show structural alterations in the hippocampus and frontal cortex in PTSD (Bremner, 2011; Bremner & Vermetten, 2012).

THE NEURAL CIRCUITRY OF PTSD

A network of brain regions including the medial prefrontal cortex, amygdala, and hippocampus, are involved in mediating the symptoms of PTSD (Bremner, 2010). Girls with a history of poor emotional response to maltreatment had a relative decrease in left versus right frontal lobe activity as measured by electroencephalogram (EEG; Curtis & Cicchetti, 2007). Other studies showed alterations in EEG measures of brain activity in the frontal cortex and left hemisphere of traumatized children (Ito et al., 1993; Miskovic, Schmidt, Georgiades, Boyle, & MacMillan, 2010; Schiffer, Teicher, & Papanicolaou, 1995).

Brain imaging studies also show abnormalities in these areas in adults with PTSD (Bremner, 2011) (see Figure 9.3). Exposure to memories of childhood sexual abuse with personalized traumatic scripts in women with childhood sexual abuse-related PTSD resulted in decreased blood flow in the medial prefrontal cortex/anterior cingulate, including Brodmann's area 25, or subcallosal gyrus, and area 32, as well as decreased blood flow in parietal cortex and inferior frontal gyrus (Bremner, Narayan, et al., 1999; Shin et al., 1999) (see Figure 9.5), hippocampus and visual association cortex (Bremner, Narayan, et al., 1999). Retrieval of emotionally valenced words (Bremner et al., 2001; e.g., rape-mutilate) in women with PTSD from early abuse resulted in decreases in blood flow in the medial prefrontal cortex (Brodmann's areas 25, 32, 9), left hippocampus, and fusiform gyrus/inferior temporal gyrus, with increased activation in posterior cingulate, left inferior parietal cortex, left middle frontal gyrus, and visual association and motor cortex (Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Staib, et al., 2003). Decreased medial prefrontal cortical/anterior cingulate activation, and decreased visual association and parietal cortex function, was seen in women with abuse-related PTSD during performance of the emotional Stroop task (i.e., naming the color of a word such as rape; Bremner, Vermetten, Vythilingam, et al., 2004). A number of studies have replicated the finding of decreased medial prefrontal cortex function during exposure to traumatic reminders in the form of traumatic slides and/or sounds or traumatic scripts using PET, SPECT, or fMRI (Bremner, Narayan, et al., 1999; Bremner, Staib, et al., 1999; Britton, Phan, Taylor, Fig, & Liberzon, 2005; Lanius et al., 2001; Lanius et al., 2003; Liberzon et al., 1999; Lindauer, Booij, et al., 2004; Phan, Britton, Taylor, Fig, & Liberzon, 2006; Semple et al., 2000; Shin, Orr, et al., 2004; Shin et al., 1997, 1999, 2001, 2005; Yang, Wu, Hsu, & Ker, 2004).

Studies showed increased amygdala function in PTSD. Women with childhood sexual abuse-related PTSD had

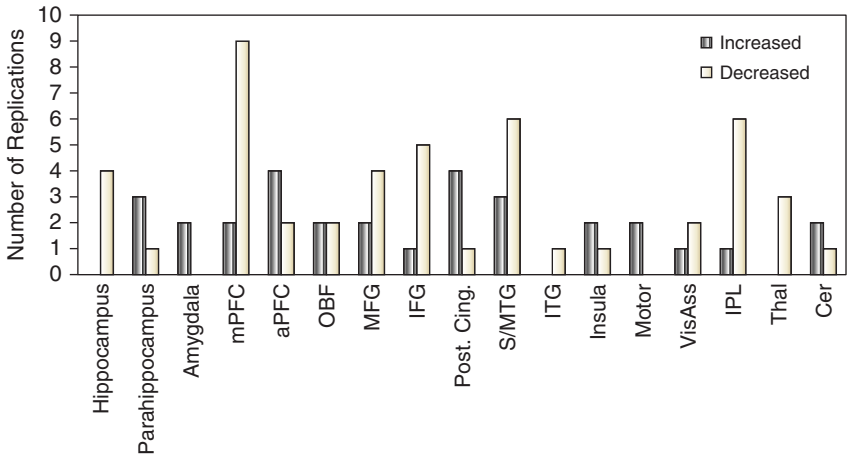

Figure 9.3 Replicated findings in PTSD. The most replicated findings related to symptom provocation are decreased medial prefrontal function. Other findings include decreased hippocampal and dorsolateral prefrontal function and increased amygdala function. See footnote 1.

increased amygdala activation with classical fear conditioning, and decreased medial prefrontal cortex function with extinction, compared with healthy nonabused women (Bremner et al., 2005; Figure 9.4). Increased amygdala function and decreased medial prefrontal function was seen with traumatic reminders (Shin, Orr, et al., 2004), indicating a failure of inhibition of the amygdala by the medial prefrontal cortex could account for increased PTSD symptoms with traumatic reminders. Other studies found increased amygdala and parahippocampal function and decreased medial prefrontal function during performance of an attention task (Semple et al., 2000), and increased amygdala function at rest (Chung et al., 2006), during a working memory task (Bryant et al., 2005), during recall of traumatic words (Protopopescu et al., 2005), with exposure to masked fearful faces (Armony, Corbo, Clement, & Brunet, 2005; Rauch et al., 2000), overt fearful faces (Shin et al., 2005), traumatic sounds (Liberzon et al., 1999; Pissiota et al., 2002), traumatic scripts (Rauch et al., 1996), or trauma-related smells (diesel in veterans; Vermetten, Schmahl, Southwick, & Bremner, 2007).

Other findings in studies of traumatic reminder exposure include decreased function with exposure to traumatic reminders in hippocampus (Bremner, Narayan, et al., 1999), thalamus (Lanius et al., 2001; Lanius et al., 2003), visual association cortex (Bremner, Narayan, et al., 1999; Lanius et al., 2003; Shin et al., 1997; Shin, Orr, et al., 2004), parietal cortex (Bremner, Narayan, et al., 1999; Rauch et al., 1996; Sakamoto et al., 2005; Shin et al., 1997; Shin et al., 1999), and inferior frontal gyrus (Bremner, Narayan, et al., 1999; Lanius et al., 2003; Rauch et al., 1996; Sakamoto et al., 2005; Shin et al., 1997; Shin et al., 1999; Shin et al., 2001), and increased function in posterior cingulate (Bremner, Narayan, et al., 1999; Bremner, Staib, et al., 1999; Lanius et al., 2001; Shin et al., 1997), insula (Vermetten et al., 2007), and parahippocampal gyrus (Bremner, Narayan, et al., 1999; Bremner, Staib, et al., 1999; Liberzon et al., 1999).

PET and SPECT studies of neuroreceptors in PTSD showed reduced binding of benzodiazepine receptors in the brain in combat veterans in the frontal cortex in some studies (Bremner, Innis, et al., 2000; Geuze et al., 2008) but not others (Fujita et al., 2004). One study found no changes in binding of the 5HT1A serotonin receptor in PTSD (Bonne et al., 2005). Other studies found a reduction in anterior cingulate opiate receptor binding (Liberzon et al., 2007) and an increase in hippocampal beta2 nicotinic acetylcholine receptor binding in PTSD (Czermak et al., 2008).

As mentioned already, the trauma-spectrum model of stress-related mental disorders (Bremner, 2002a) was tested by assessing similarities in neurobiology. We hypothesized that these disorders would have similar abnormalities in specific brain areas, including the amygdala, medial prefrontal cortex, and hippocampus. As mentioned above, these disorders include abuse-related PTSD, depression associated with early abuse, borderline personality disorder (BPD) associated with early abuse, and dissociative identity disorder (DID) with early abuse. Women with a history of childhood trauma with and without the diagnosis of BPD were exposed to the stress of a script outlining a personally upsetting abandonment scene in conjunction with PET imaging of the brain (Schmahl, Elzinga, et al., 2003). As predicted, women with BPD had

decreased function in the medial prefrontal cortex. They did not have similar responses to scripts of childhood abuse, unlike women with PTSD (Schmahl, Vermetten, et al., 2004a). Women with BPD and abuse had increased psychophysiological responses to abandonment scripts relative to trauma scripts, while women with PTSD and abuse had the opposite pattern (Schmahl, Elzinga, & Bremner, 2002). This showed differential responses in these two disorders in spite of the common exposure to early abuse. Studies of structural MRI showed smaller hippocampal volume across several trauma spectrum disorders, including abuse-related PTSD (Bremner, Randall, et al., 1997; Bremner, Vythilingam, Vermetten, Southwick, McGlashan, Nazeer, et al., 2003), DID with early abuse (Vermetten et al., 2006), BPD with early abuse (Driessen et al., 2000; Schmahl, Vermetten, et al., 2003), and depression with early abuse (Vythilingam et al., 2002). Patients with another anxiety disorder, panic disorder, did not show a reduction in hippocampal volume (Vythilingam et al., 2000).

Patients with trauma spectrum disorders exhibit other alterations in stress responsive neurohormonal systems. HPA axis dysfunction, and a functional dysregulation of the prefrontal-limbic axis, are seen in BPD that are similar to PTSD (Donegan et al., 2003; Driessen et al., 2004; Juengling et al., 2003; Lange et al., 2005; Schmahl & Bremner, 2006; Schmahl, Elzinga, et al., 2003; Schmahl, McGlashan, et al., 2002; Schmahl, Vermetten, et al., 2004a; Schmahl, Vermetten, et al., 2004b). There are also important differences in physiological reactivity between BPD and PTSD patients, even in groups where all subjects were exposed to childhood sexual abuse. BPD subjects respond to reminders (scripts) of abandonment but not traumatic memories, and PTSD subjects having the opposite response (Schmahl, Elzinga, et al., 2004). These findings are consistent with a common neurobiology and neurocircuitry underlying the trauma-spectrum disorders, including PTSD, DID, BPD, and depression related to early abuse, as well as some differences. The partial overlap of neurobiology then parallels the partial overlap in symptomatology in patients with trauma-related mental disorders.

EFFECTS OF TRAUMA ON THE BODY

The multiple levels of analysis approach include an examination of stress on physical health in addition to mental health. Traumatic stress has negative effects on several physical disorders especially when associated with diagnoses like PTSD and depression (Proctor, Harley, Wolfe, Heeren, & White, 2001; Proctor et al., 1998; Wagner, Wolfe, Rotnitsky, Proctor, & Erickson, 2000; Zatzick et al., 1997). PTSD is associated with an increased risk for heart disease, probably through multiple pathways including activation of neurohormonal or brain circuit pathways (Vaccarino & Bremner, 2011). Stress-induced activation of norepinephrine and cortisol or changes associated with chronic PTSD may lead to an increase in atherosclerosis or vulnerability to cardiac arrhythmias or other consequences that increase the risk for heart disease. Stress-induced mental disorders may lead to poor health outcomes directly, or through an increase in risk factors like smoking, lack of exercise, or obesity. For instance, childhood abuse is associated with an increase in smoking (Beckham, 1999; Butterfield, Forneris, Feldman, & Beckham, 2000; Dube et al., 2003), which leads to increased risk of cancer and heart disease. Childhood abuse is also associated with increased rates of substance abuse and obesity in adulthood (Dube et al., 2003; Williamson et al., 2002). Increased obesity leads to increased risk of both heart disease and diabetes, which is worsened by antipsychotic medications that are often used for the treatment of PTSD. A third possibility is that the same factors (e.g., genetic predisposition) that increase risk for physical disorders also increase risk for stress-induced mental disorders.

Heart disease is an important outcome from stress (Berkman, Vaccarino, & Seeman, 1993; Krumholz et al., 1998; Rozanski, Blumenthal, & Kaplan, 1999). Heart disease is increased in both depression (Carney & Freedland, 2003; Evans et al., 2005) and PTSD (Vaccarino et al., 2013). This is seen in depressed patients with (Barefoot, Helms, & Mark, 1996; Barth, Schumacher, & Herrmann-Lingen, 2004; Borowicz et al., 2002; Burg, Benedetto, Rosenberg, & Soufer, 2003; Carney, Rich, & Freedland, 1988; Carney et al., 2003; Connerney, Shapiro, McLaughlin, Bagiella, & Sloan, 2001; Frasure-Smith, Lesperance, Juneau, Talajic, & Bourassa, 1999; Frasure-Smith, Lesperance, & Talajic, 1993; Jenkins, Stanton, & Jono, 1994; Mallik et al., 2005; Mendes de Leon et al., 1998; Perski et al., 1998; Rutledge et al., 2006; van Melle et al., 2004) and without (Anda, Williamson, & Jones, 1993; Barefoot & Schroll, 1996; Carney & Freedland, 2003; de Jonge, van der Brink, Spijkerman, & Ormel, 2006; Ford et al., 1998; Fredman, Magaziner, Hebel, Hawkes, & Zimmerman, 1999; Hippisley-Cox, Fielding, & Pringle, 1998; Pratt et al., 1996) a prior history of heart disease (CHD).

Depression rates are higher in young women after myocardial infarction (MI, or heart attack) than other age and gender groups (Mallik et al., 2006), and depression

worsens outcomes in coronary artery disease (CAD) patients, whether symptoms are present at the time of the heart attack, or develop later (Parashar et al., 2006). Depression is also related to poor outcomes in congestive heart failure (CHF) patients (Vaccarino, Kasl, Abramson, & Krumholz, 2001).

Studies have shown that stress, which is linked to depression, can induce myocardial ischemia (decreased blood flow to the heart) in heart disease patients (Batten, Aslan, Maciejewski, & Mazure, 2004; Berkman et al., 1993; Boscarino, 1997; Brass & Page, 1996; Dong et al., 2004; Dube et al., 2003; Engel, Liu, McCarthy, Miller, & Ursano, 2000; Felitti et al., 1998; Joynt, Whellan, & O'Connor, 2003; Krumholz et al., 1998; Proctor et al., 2001; Proctor et al., 1998; Rosengren et al., 2004; Rozanski et al., 1999; Wagner et al., 2000; Williamson et al., 2002; Zatzick et al., 1997). Mental stressors can induce myocardial ischemia in certain vulnerable individuals on a daily basis (Arrighi et al., 2000; Arrighi, Burg, Cohen, & Soufer, 2003; Blumenthal et al., 1995; Burg, Jain, Soufer, Kerns, & Zaret, 1993; Soufer, 2004; Soufer et al., 1998; Stone et al., 1999) often occurring without pain in undiseased coronary arteries (possibly due to coronary vasospasm; Deanfield et al., 1984; Lacy et al., 1995), and often without the physical stress (e.g., exercise) that typically induces myocardial ischemia (Becker et al., 1996; Deanfield et al., 1984; Jain et al., 1998; Krantz et al., 1991; LaVeau et al., 1989; Ramachandruni et al., 2006; Rozanski et al., 1988; Schang & Pepine, 1977; Schiffer, Hartley, Schulman, & Abelmann, 1980). These studies showed that stress can induce painless myocardial ischemia that occurs with emotional activities and is not necessarily associated with emotion induced increased heart rate and blood pressure. Mental stress-induced ischemia, which can occur in normal vessels, is related to abnormal constriction of coronary arteries (Dakak, Quyyumi, Eisenhofer, Goldstein, & Cannon, 1995; Kop et al., 2001; Sherwood, Johnson, Blumenthal, & Hinderliter, 1999; Wittstein et al., 2005; Yeung et al., 1991) and may carry a greater risk than exertion related ischemia Mental stress-induced myocardial ischemia is associated with increased long-term risk for cardiac events that in many patients is more significant than exercise-induced myocardial ischemia (Goldberg et al., 1996; Jain, Burg, Soufer, & Zaret, 1995; Jiang et al., 1996; Krantz et al., 1999; Legault, Langer, & Armstong, 1995; Sheps et al., 2002). Psychological factors related to stress include the presence of strong emotions like anger (Boltwood, Taylor, Boutte Burke, Grogin, & Giacomini, 1993; M. M. Burg et al., 1993; Gabbay et al., 1996; Mittleman et al., 1995; Strike, Perkins-Porras, Whitehead, McEwan, & Steptoe, 2006; Strike & Steptoe, 2005). Anger and irritability, symptoms of PTSD, therefore contribute to increased risk of heart attacks.

Mental stress also causes a decrease in heart rate variability (the normal increase and decrease in heart rate that occurs with respiration (Lampert, Ickovics, Viscoli, Horwitz, & Lee, 1998) which increases the risk of sudden death from arrhythmia. Stress and emotion also have effects on myocardial electrical stability, increasing the risk for cardiac arrhythmias (Kop et al., 2004; Lampert et al., 2002; Lane et al., 2005).

Depression and PTSD, as noted above, could increase CHD risk through known associations with unhealthy behaviors, like lack of exercise, smoking, and poor diet, or through direct effects on the cardiovascular system (Hemingway & Marmot, 1999; Wulsin, Vaillant, & Wells, 1999). Stressful life events have been linked to the onset of episodes of major depression (Kendler et al., 2000) and stress could lead to both heart disease and depression and PTSD independently, it could mediate its effects through stress-related disorders, or vulnerability to both could be related to common factors. Stress is associated with increased cortisol and norepinephrine release, as well as increased heart rate and blood pressure (Bremner, Krystal, et al., 1996a, 1996b), which can impact negatively on cardiovascular function (Troxler, Sprague, Albanese, Fuchs, & Thompson, 1977). An excess in cortisol level may increase the risk for cardiovascular disease by injuring the intima (Kemper, Baggenstoss, & Slocumb, 1957; Nahas, Brunson, King, & Cavert, 1958) or by inducing inflammation in the artery wall (Gabay & Kushner, 1999; Musselman, Evans, & Nemeroff, 1998).

Both depression and PTSD are associated with elevations of sympathetic function, associated with increases in heart rate and blood pressure (Bremner, Krystal, et al., 1996a, 1996b; Delgado & Moreno, 2000). PTSD and depression related to childhood abuse, as discussed above, are also associated with increases in stress-induced cortisol release, especially related to specific traumatic reminders (Bremner, Vythilingam, Vermetten, Adil, et al., 2003; Elzinga et al., 2003; Heim et al., 2000). Stress-induced activation of norepinephrine may lead to damage to the endothelium, or inner lining of the coronary arteries, as well as accelerated atherosclerosis (Kaplan, Manuck, Adams, Weingand, & Clarkson, 1987; Kaplan, Manuck, Clarkson, Lusso, & Taub 1982; Troxler et al., 1977). An excess in cortisol levels with stress may also increase the risk for cardiovascular disease by injuring the endothelium (Kemper et al., 1957; Nahas et al., 1958).

Traumatic stress may also mediate its effects through brain areas sensitive to stress that are affected by PTSD and depression, including amygdala, medial prefrontal cortex, and hippocampus. These brain circuits have direct or indirect outputs through the hypothalamus and medial prefrontal cortex to neurohormonal systems (cortisol, norepinephrine) that influence heart function. The medial prefrontal cortex and anterior cingulate are unique in directly mediating cortisol and sympathetic responses to stress via the brainstem (Diorio et al., 1993). The hippocampus and medial prefrontal cortex have inhibitory pathways to the amygdala (Milad & Quirk, 2002; Morgan & LeDoux, 1995; Morgan, Romanski, & LeDoux, 1993; Phillips & LeDoux, 1992), which activates the stress response (Davis, 1992; Hitchcock & Davis, 1986; Hitchcock, Sananes, & Davis, 1989; LeDoux, 1993; Miserendino, Sananes, Melia, & Davis, 1990; Rosen & Davis, 1988), including activation of the peripheral stress response through pathways through the lateral hypothalamus which activate cortisol and sympathetic pathways in the periphery (Hitchcock & Davis, 1991).

Using the paradigm of inducing mental stress in the laboratory in conjunction with simultaneous heart and brain imaging, we have studied heart and brain correlates of stress in heart disease patients. These studies show that heart disease patients exposed to stress show involvement of the prefrontal cortex and other brain areas involved in the stress response (Soufer et al., 1998). In our studies we have patients undergo the stress of performing mental arithmetic or giving a stressful speech with negative feedback in conjunction with PET imaging of brain blood flow and injection of a radiopharmaceutical that takes a snapshot of heart blood flow. Subjects can then be moved to the SPECT camera for imaging of the heart. Using these techniques, we found that patients with a history of traumatic stress and depression had increased myocardial ischemia, typically experienced without chest pain, following stress as measured with cardiac SPECT (Bremner et al., 2009). Patients with depression and heart disease compared with heart disease patients without depression had decreased medial prefrontal responses during stress, with the greatest changes in those with stress-induced myocardial ischemia. Brain areas involved in stress and stress-related mental disorders were shown to be involved in the stress response in patients with stress-induced myocardial ischemia. Increased heart disease mortality in patients with PTSD or depression could be mediated through silent myocardial ischemia mediated by these brain pathways.

MULTIPLE LEVELS OF ANALYSIS

In this chapter we have reviewed the multilevel analysis approach as it applies to the study psychological trauma and its effects on the individual. We have advocated for the multilevel analysis approach as opposed to other approaches that look at the phenomenon from a unidimensional perspective, like the medical model of depression and PTSD. The multilevel analysis approach requires interdisciplinary team work, as it isn't possible for one person to have expertise in all of the areas involved, including psychology, psychiatry, psychotherapy, neurobiology, pharmacology, physical health, and general physiology, developmental psychology, sociology, and cultural aspects.

An example of the advantages of the multilevel analysis approach is in the field of heart disease. For years cardiologists focused on modifying the traditional risk factors

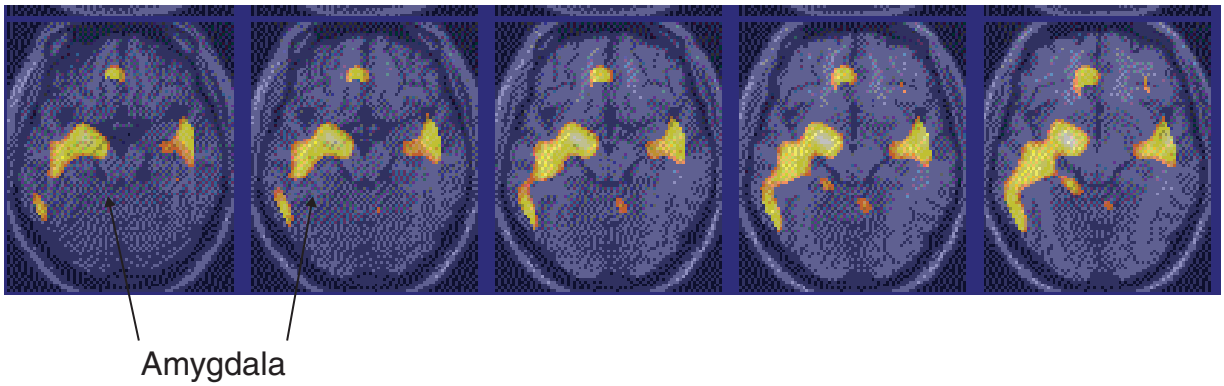

Figure 9.4 Amygdala function in PTSD. With classical fear conditioning (pairing of an unconditioned stimulus [shock] with conditioned stimulus [seeing a blue square on a screen] there was increased amygdala activation in PTSD relative to controls, suggesting increased sensitivity of the amygdala in the learning of fear. See footnote 1.

for heart disease, namely hypercholesterolemia, obesity, diabetes, and smoking. These factors, however, in total accounted for less than half of the risk for heart disease. The field was at an impasse until psychologists, psychiatrists, epidemiologists, and experts from other specialties got involved, and furthered research that demonstrated the important role of behavioral factors like stress and emotionally reactivity. Another problem with the pure medical model was that there was no recognition that early childhood abuse was independently associated with obesity and smoking. Therefore the relevant cause may be something different than it at first appears.

The single-level approach may limit the effectiveness of interventions. Rather than focus on smoking cessation programs, perhaps the individual needs psychotherapy or pharmacotherapy for PTSD. Once the PTSD symptoms are in control, it will not be as difficult to successfully stop smoking. This is just one example of how the multilevel analysis approach can improve treatment interventions and possibly outcomes.

Sometimes experts in different disciplines study the same things under different names. They may use a different language, or jargon, publishing in different journals, attending different meetings, and getting support from different sources. Cardiologists may be treating stress-related heart disease, while psychiatrists are dealing with PTSD patients suffering from chest pain or light-headedness. If these different disciplines can combine or join forces their collective effort will be superior to either acting alone. This was the impetus behind organizations like the National Institutes of Health or private foundations dedicated to supporting research and treatment for specific conditions to advocate for the breaking down of barriers or silos between different research groups and disciplines. It is also behind the new Veterans Administration practice of embedding psychiatrists in primary care clinics.

The multilevel analysis approach may be more complex or unfamiliar than the traditional single dimensional model. One cause, one treatment is simpler and easier to teach.

Research in the psychology field is typically based on self-report data. We rely on people to accurately and honestly report their symptoms. There is no objective or valid way of assessing mental disorders that does not involve the patient. People will arrive at similar points through different pathways; therefore, relying only on self-report data may not be useful or could even be misleading. The addition of other types of data, for instance, brain imaging results or genetic analyses, to the self-report data may provide a clearer picture of the disorder, which provides a

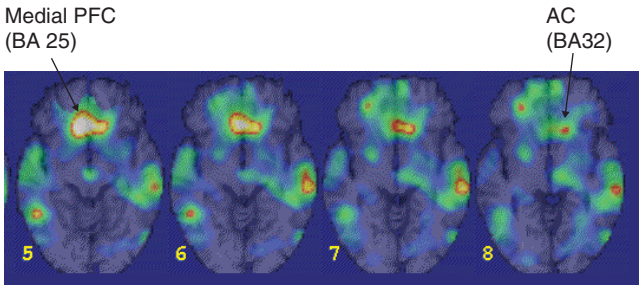

Figure 9.5 Effects of combat related slides and sounds on brain function. Outlined area shows decreased blood flow with combat slides in sounds in combat veterans with PTSD. This area normally inhibits the amygdala (involved in fear responses). See footnote 1.

view of the endophenotype (Kagan, Snidman, McManis, Woodward, & Hardway, 2002).

Neurobiology and psychology play off each other in important ways after a psychological trauma (Kopnisky, Cowan, & Hyman, 2002). Trauma can result in ruminative thinking that leads to a memory rehearsal effect. This may affect the formation of long-term traumatic memories that are indelible to intervention. Feelings of fear or upset with traumatic reminders results in enhanced cortisol and norepinephrine release, which in turn modulate memory storage (McGaugh, 2000). Brain areas involved in memory and the fear reaction including the hippocampus, amygdala, and prefrontal cortex further enforce the memory circuitry. Interventions like the teaching of mindfulness meditation may help patients break free from this cycle of ruminative memories and overconsolidation, with the long-term benefits for the patient (Bishop et al., 2004)

Biological research in the field of mental disorders also benefits from a multilevel analysis approach. For instance, there was originally the idea that a gene would be discovered for each of the psychiatric disorders, and that would correspond to an abnormality in a specific area of the brain as determined by brain imaging that would be different for each disorder. However, subsequent findings in genetics are more consistent with combinations of genes that may confer risk for multiple psychiatric disorders ranging from psychosis to attention deficit disorders. These disorders on the surface do not appear to be related. This is an illustration of multipotentiality. Alternatively, the equifinality model might state that bipolar disorder could be related to genetics in one individual, and childhood trauma in another. The two persons started out from different places but arrived at the same result. In a similar vein, as discussed already, brain imaging in the trauma spectrum disorders have discovered more similarities than differences, not consistent with the one disorder one brain lesion model. Researchers

are also forced to think in terms of functional circuits of brain regions that mediate symptoms of the disorder (Johnson, Halit, Grice, & Karmiloff-Smith, 2002).

Developmental psychopathology also benefits from the multilevel approach. Brain development interacts with environment and genetics in the formation and development of childhood mental disorders. Other factors are important, such as whether a child remains in an abusive home or ends up in foster care. Removal of the trauma will permit the process of healing to begin. Other children may grow out of their mental disorder. The effects of early trauma may not appear in the form of a mental disorder until later in life. This may be caused by a subsequent stressor that pushes the individual into a mental disorder, or the delayed effects of the primary trauma. Symptoms that appear one way at a specific developmental epoch may change in adulthood (Harrington, Rutter, & Fombonne, 1996). There may be the appearance of moving from one diagnosis to another as childhood transitions to adulthood (Harrington et al., 1996; Saigh et al., 2000).

Research on mediators and modulators that influence outcomes of the trauma response are also part of the framework of a multilevel analysis approach. Some individuals appear to be naturally resilient to the effects of psychological trauma (Bonanno, 2004). Social support (Keane et al., 1987), education level, older age (Brewin et al., 2000), and the absence of prior trauma (Bremner et al., 1993) positively affect long-term outcome. Prospective studies are needed to understand why some people develop chronic PTSD from psychological trauma and others don't. Applying the multilevel analysis approach to longitudinally collected data to assess responses at different stages of development and how they are influenced by individual, societal, cultural, economic, physical, and other factors will be useful.

TRANSLATIONAL IMPLICATIONS OF THE MULTILEVEL DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE

The multilevel developmental psychopathology approach has many implications for transfer of knowledge in multiple areas to practical applications that are beneficial to individuals exposed to childhood trauma. This approach allows for the drawing of knowledge from multiple areas and is based on the idea that no one single discipline or body of knowledge is sufficient for the optimal approach to the individual with a history of childhood trauma. By way of example, studies have shown that the combination of psychotherapy and antidepressant medication is superior to either one alone in patients with a history of childhood abuse and major depression (Nemeroff et al., 2003).

Incorporating developmental psychology into the approach to childhood trauma survivors has a number of advantages. Taking into account the developmental epoch (or epochs) at which the trauma occurred and the stage of development permits a more specific application of diagnosis and intervention. The multilevel developmental psychopathology approach will likely be of more service to individuals affected by psychological trauma.

FUTURE DIRECTIONS

The use of the multilevel analysis approach to the study of the effects of psychological trauma on the individual has been reviewed in this chapter. Multilevel analysis involves looking at phenomena on multiple levels, including psychological, biological, cultural, genetic, physical, social, and political. For complex questions such as the effects of trauma on the individual it is important to analyze multiple variables simultaneously. These elements often cannot be separated. For example a change in a sense of meaning which results from exposure to psychological trauma may be driven by changes in neurotransmitters and brain circuits associated with the development of PTSD. Alternatively, the symptoms of PTSD can change an individual's perception of the world. The process of recovery involves psychological, spiritual, biological, and cultural factors. Changes in brain areas involved in memory and the regulation of behavior, like the hippocampus and medial prefrontal cortex, may have implications for issues such as school performance and delinquency that have ramifications on societal, cultural, and judicial levels as well. The cycle of violence of childhood abuse that crosses generations can be understood on a psychological or metaphorical level as well as a social and judicial level.

Future research should incorporate the multilevel analysis approach in the area of psychological trauma. This involves the avoidance of false dichotomies between mind, brain, and body. Treatments can incorporate elements of behavior, emotion, spirituality, biology, and cognition. Research studies need to incorporate in their designs multiple outcomes, with measures of behavior, spirituality, biology, health, and cognition, and follow patients longitudinally whenever possible. Research that goes beyond limits of defined and restricted disciplines or areas of expertise will help us to discover more effective treatments and to more successfully facilitate recovery in our patients.

CONCLUSIONS

This chapter reviewed the limitations of the single disorder, single treatment approach. It presents an argument for going beyond the single etiology, single disease, single treatment model, which has not led to consistent improvements on patient responses. Biological therapies have a role in the treatment of the traumatized patient, but other aspects need to be addressed as well. Meditation can add a sense of control and facilitate the recovery process (Astin, 1997; Weissbecker et al., 2002), providing a way for trauma victims to gain control of their thoughts and memories and become less emotionally reactive. The distressing memory is passively observed without efforts to control it, interrupting the pattern of ruminative thinking (Teasdale, Segal, & Williams, 1995) which in turn blocks negative psychological states such as mental distress and depression (Teasdale et al., 2000). This process may modify the way traumatic memories are stored and transformed to an indelible state, possibly reducing the risk for chronic PTSD. Patients can achieve self-healing in this way.

The multilevel approach to treatment requires the inclusion of the patient in the recovery process. This involves addressing the meaning of the trauma and mental illness for the individual, as well as enrolling the patient in other aspects like medication compliance or changes in lifestyle. The disease model of PTSD carries the assumption that trauma is always bad; however, many individuals are resilient in the face of trauma, and others feel they are eventually able to grow through their experiences (Bonanno, 2004). Recovery models based on promoting the efficacy of the individual have potential promise (Bremner & Reed, 2014).

Research in the past few decades has amply demonstrated the potential negative impact of traumatic experiences, particularly when abuse and maltreatment occur in childhood. However, definitions of these terms—trauma, maltreatment, and abuse—remain unclear and are still subject to debate. Who decides whether an event is traumatic? At what point does an experience become traumatic? What makes a particular parenting practice harmful? Does it need to result in marks and bruises to count as maltreatment? Some children might experience spankings as a normal part of the disciplinary practices in their household while for other children, physical punishments can create overwhelming fear and may be experienced as traumatic.

According to the *Diagnostic and Statistical Manual of Mental Health,* 5th ed. (*DSM-5*; American Psychiatric Association, 2013), the diagnosis of Posttraumatic Stress Disorder (PTSD) requires exposure to a traumatic event, defined as "exposure to actual or threatened death, serious injury, or sexual violence" (p. 271). This definition precludes childhood neglect and emotional abuse, which have been shown to lead to similarly negative consequences as physical or sexual abuse as well as other traumatic experiences (for a review, see Chu & Lieberman, 2010). The Child Abuse Prevention and Treatment Act (CAPTA) includes neglect in its definition of child abuse; neglect and emotional abuse are also recognized by most states as part of childhood maltreatment in addition to physical abuse and sexual abuse (U.S. Department of Health and Human Services, 2012). Thus, whether trauma includes neglect and emotional abuse remains inconsistent.

Though we recognize the importance of preventing childhood neglect and understanding its impact, due to the inconsistency in the literature we focus in this chapter primarily on acts of commission with particular emphasis on childhood abuse and witnessing domestic violence. We review the prevalence of childhood abuse and witnessing domestic violence, manifestations of these types of traumatic stress in childhood, and treatment programs for addressing posttraumatic responses. To fully understand the impact of trauma, we also need to understand many of the contextual factors that surround the potentially traumatic experience such as risk and protective factors in the child, the family, and the community. Thus, we examine these broad topics in relation to the many correlates that influence the experience of and reactions to trauma, such as social/cultural factors, attachment and caregiving contexts, and gene by environment interactions. Many research studies include both abuse and neglect as inclusion criteria for childhood maltreatment in their samples and do not distinguish between the two types of experiences (e.g., Cicchetti & Rogosch, 2012; DeBellis, Hooper, Woolley, & Shenk, 2010; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008; Fang, Brown, Florence, & Mercy, 2012; Fisher, Ellis, & Chamberlain, 1999; Heim & Nemeroff, 2001). We employ the term *childhood maltreatment* when reporting

findings using samples that include both neglect and abuse. Neglect is discussed specifically where appropriate.

PREVALENCE: MEDIATORS AND MODERATORS

Childhood Abuse

In 2011, the national estimate of substantiated victims of childhood abuse and neglect reported to the state-level child protective service systems was 681,000 children, which translates to approximately 9.1 victims per 1,000 children aged birth to 18 in the population (U.S. Department of Health and Human Services, 2012). Though this number may appear to be relatively small in proportion to the total population, federal statistics are likely to include the more severe cases of childhood abuse and neglect. In 2011 the Center for Disease Control and Prevention (CDC) conducted a Youth Risk Behavior Survey and found that 11.8% of females and 4.5% of males reported forced sexual intercourse at least once in their lifetime (Eaton et al., 2012). The National Survey of Adolescents estimated that for youth between the ages of 12 to 17, 22% have experienced physical assault and 39% have witnessed domestic violence (Kilpatrick et al., 2003). Across numerous epidemiological and community-based studies, most estimates suggest that between 25 to 61% of children and youth have been exposed to at least one traumatic event (Copeland, Keeler, Angold, & Costello, 2007; Finkelhor, Turner, Ormrod, & Hamby, 2009). In these studies, traumatic events are widely defined and include (but are not limited to) child physical and sexual abuse, violence in families and communities, natural disasters and terrorism, accidental or violent death of a loved one, refugee and war experiences, impaired caregiving, and life-threatening injury and illness.

Age of Onset

Based on state-level child protective services data for the year 2011, children birth to 1 year of age had the highest rate of child maltreatment, with a rate of 21.2 per 1,000 children (U.S. Department of Health and Human Services; Administration for Children and Families, 2012). Of all child maltreatment victims, 27.1% were younger than 3 years of age while 20% were 3–5 years old. These rates of early childhood maltreatment seem to be on the increase. For example, 81.6% of all child fatalities in the year 2011 were younger than 4 years old, which was higher than the 75.7% of child fatalities younger than 4 years old in 2009 (U.S. Department of Health and Human Services; Administration for Children and Families, 2010). Consistent with these rates, infants are among the largest group of children to be placed in foster care. Infants also remain in foster care longer and experience more placements than children who are older (Wulczyn, Hislop, & Harden, 2002).

Some of the national population-based findings are in contrast to these official statistics which report that the rate of childhood abuse and neglect decreased with age (U.S. Department of Health and Human Services, 2012). Findings from one population-based sample of 4,549 children and youth aged 0–17 years recruited through random digit dialing for the National Survey of Children's Exposure to Violence suggest that physical abuse is relatively common across all age groups while sexual abuse and witnessing community assaults increase as age increases (Finkelhor, Ormrod, & Turner, 2009). Some researchers have suggested that the large population-based samples typically utilize retrospective parent reports versus substantiated cases of childhood maltreatment, which may introduce reporting bias into these prevalence rates.

Paying attention to childhood abuse rates as broken down by age group allows us to understand important trends beyond base prevalence rates. For example, in a three-wave longitudinal study with 1,467 children aged 2–17 recruited through random digit dialing to complete the Developmental Victimization Survey, findings suggest that polyvictimization (5+ types of victimizations) was most likely to occur within a 1-year period when children were 6 and 14 (Finkelhor, Ormrod, Turner, & Holt, 2009). These ages correspond roughly with school transitions (first grade and high school) when children are most likely to be distressed due to a new social and educational environment, thus more vulnerable to victimization.

Gender

Until the mid-1980s, few studies specifically examined male childhood sexual abuse. Since then, studies focusing on male sexual abuse have increased; however, research with sexually abused females continues to garner more attention than males. One contributing factor for this discrepancy may be that males are more reluctant than females to disclose abuse, due to struggles with the male ethics of self-reliance, stigma of homosexuality, and less likelihood to label certain childhood sexual activities with another individual as abusive (for review, see Romano & De Luca, 2001). Alternatively, females may be socialized to perceive (and report) violations in close relationships more so than males (DePrince & Freyd, 2002). In addition, mental health professionals continue to be biased against the existence of male sexual abuse; thus, professionals rarely ask adult males about childhood sexual abuse and

are reluctant to deal with child male victims (Romano & De Luca, 2001). Because systematic investigation of male childhood sexual abuse continues to be limited, comparisons between sexually abused males and females remain difficult to make.

Race/Ethnicity

Race and ethnicity disparities in the rates of childhood abuse persist. While some studies show a lack of group differences based on race or ethnicity (Elliott & Urquiza, 2006), child protective service records indicate consistent racial/ethnic differences in the referral rates for and number of substantiated cases of childhood abuse (U.S. Department of Health and Human Services; Administration for Children and Families, 2012). Researchers have pointed out that racial/ethnic group differences in prevalence rates may be influenced by a variety of factors, including acculturation levels, socioeconomic status, and neighborhood variables. One study showed that group differences between Black and White children in referral, substantiation, and entry to foster care rates were accounted for after adjusting for differences in socioeconomic and health factors (Putnam-Hornstein et al., 2013). Interestingly, Black children from low socioeconomic status families had a lower risk for referral, substantiation, and entry to foster care than their socioeconomically similar White peers. Similarly, among Latinos, children of U.S.-born mothers were significantly more likely than White children to come into contact with child protective services. However, once socioeconomic and health factors were included in the model, risk of referral, substantiation, and foster care entry was significantly lower for Latino children regardless of maternal nativity when compared with White peers.

Sexual Orientation

Another subgroup where prevalence estimates are hard to pinpoint is individuals who identify as gay, lesbian, or bisexual (GLB). Research findings have demonstrated that the prevalence rate of sexual victimization, and specifically childhood sexual abuse, are elevated in GLB individuals as compared with individuals who identify as heterosexuals (see Rothman, Exner, & Baughman, 2011). However, reported prevalence rates for GLB individuals range widely due to most studies utilizing convenience samples that are not generalizable. For example, a systematic review of studies with GLB individuals found the prevalence rate of childhood sexual abuse for males to range from 4.1% to 59.2% and for females to range from 14.9 to 76.0% (Rothman et al., 2011). The directionality between childhood abuse and sexual orientation also remains poorly understood despite the positive association found between childhood abuse and same-sex sexual orientation in adulthood due to the inability to create experimental designs to tease out causality.

Contextual Factors

Families living in poverty have more contact with system-based representatives and therefore may be more likely to have potentially abusive or neglectful behaviors reported to the authorities than wealthier families. In a healthy birth cohort of young children ages 1 to 3 years from an urban-suburban region, exposure to violence was particularly common among children living in poverty (Briggs-Gowan, Ford, Fraleigh, McCarthy, & Carter, 2010). The overall sample prevalence rate for violence exposure was 26.3% (14.5% noninterpersonal violence, 13.8% interpersonal violence) but when looking at the subsample of children living in poverty, the overall violence exposure rate increased to 49.0% (19.7% noninterpersonal violence, 33.7% interpersonal violence).

Many parental factors have been associated with increased likelihood of abuse such as young parental age, single parenthood, low education, low employment status, and psychopathology (see Oliver, Kuhns, & Pomeranz, 2006; Turner et al., 2012). Across these parenting factors that influence abuse risk, parental stress emerges as a common and potentially important variable (Chu et al., 2011).

Some additional common environment and social factors found to contribute to higher risk for childhood abuse include poverty-related factors (low income level, median residential housing/property value, unemployment, and low education), neighborhood structure (substandard or vacant housing, overcrowding, and residential instability; Coulton, Crampton, Irwin, Spilsbury, & Korbin, 2007). Neighborhood and environmental characteristics may influence social relationships within the community, which in turn may have an impact on childhood abuse risk. For example, residents in neighborhoods with greater social resources and community social network reported lower rates of childhood abuse (Coulton et al., 2007).

A substantial body of research continues to focus on identifying vulnerability and protective factors that moderate children's risk of abuse in the hopes of understanding the mechanisms underlying why and how childhood abuse occurs and how to prevent it from happening in the future (for a review, see Chu, Pineda, DePrince, & Freyd, 2011). However, as Stevens and Hassett (2007) point out, although we might understand the various factors that contribute to child abuse in identified patterns, abuse

often occurs in multiple contexts (families, neighborhoods, societies) which interact in complex and nonlinear ways that are not entirely predictable. Additionally, there are no identifiable factors that can absolutely protect a child from being abused.

Witnessing Domestic Violence

Estimates suggest that more than 3 million children witness some form of domestic violence (DV) each year (Straus, 1992). Reviews of the literature document a substantial co-occurrence of childhood abuse and witnessing DV, with 30–60% of families reporting both types of violence (Edleson, 1999; Margolin, 1998). Despite the large numbers of children exposed to DV, less than half of child welfare agencies indicate that they assess DV in reported childhood abuse cases (Hazen et al., 2007).

This lack of attention to DV exposure in the majority of child welfare protocols reflects a pervasive assumption that witnessing domestic violence does not constitute direct violence against the child. However, research evidence shows that exposure to DV negatively impacts children's development similar to abuse or neglect. For example, a recent review concluded that preschool children exposed to DV have difficulty expressing emotions, are more aggressive, and have less secure attachments than children without DV exposure (Howell, 2011).

Age of Onset

Pregnancy is a time of heightened risk for experiencing domestic violence for women. Pregnant women have approximately 35% higher risk of being a victim of domestic violence than nonpregnant women (Gelles, 1988). Domestic violence is also one of the most commonly reported trauma during pregnancy (Mendez-Figueroa, Dahlke, Vrees, & Rouse, 2013). Thus, if one considers the fact that DV also often occurs during pregnancy, the number of children impacted by DV is likely much greater than the prevalence rate currently suggests (Family Violence Prevention Fund, 2008). In turn, exposure to intimate partner violence during pregnancy is tied to negative medical conditions for both the mother and her infant, including later entry into prenatal care, low birth weight, premature labor, fetal trauma, and unhealthy maternal behaviors (for a review, see Jasinski, 2004).

Additionally, there may also be a delayed effect of DV exposure. In a sample of 3- to 5-year-old children who were part of the National Survey of Child and Adolescent Well-Being, those who had witnessed violence in the home during the ages of 3–5 (but not after age 5) showed no behavioral differences from those who had not witnessed DV during that same age period (Holmes, 2013). However, when followed prospectively, the group of children who were exposed to DV began showing increased aggression relative to the comparison group by the time they reached elementary school.

Gender and Sexual Orientation

Though research has established the pervasive impact of witnessing domestic violence, the majority of these studies have relied on samples of women from shelters for battered women (Edleson, 1999). While a large portion of DV victims are women, men can also be victims of DV (Strauss, 1992). Based on retroactive report, 50% of adults in a survey sample remembered their father hitting their mother during their teenage years while 19% recalled their mother hitting their father and 31% recalled both hitting the other. Additionally, the DV literature has been based on samples with heterosexual couples rather than same-sex couples. Therefore, we know little regarding the prevalence of or impact for children witnessing domestic violence where women are the perpetrators and men are the victims, or in families where the caregivers are in same-sex relationships.

Race/Ethnicity

National statistics suggest group differences based on race/ethnicity in experiencing domestic violence. For example, African American women appear to experience domestic violence at significantly higher rates when compared with Caucasian women, while Hispanic and Asian women report significantly lower raters of domestic violence as compared with Caucasian women (Rennison & Welchans, 2000). However, researchers and advocates have questioned whether the lower rates of DV in certain racial/ethnic groups are accurate estimates or perhaps the lower numbers might be due to under-reporting. Importantly, we also have little understanding regarding any differential impact of DV on children based on race/ethnicity variables.

Methodological Issues

Prevalence figures are often cited without great attention paid to the details in the operationalization of childhood abuse. Though researchers might uniformly agree that a 14-year-old child forced into sexual intercourse by an adult has been sexually abused, details within broad definitions are not always consistent. Some studies might include exposure, threats, and attempts while others may only focus

on more severe forms of abuse. As previously mentioned, samples with maltreated children have also often defined maltreatment history in a heterogeneous way, including neglect as well as emotional, physical, and/or sexual abuse. The age that separates childhood from adulthood abuse also differs widely across studies, with cutoffs ranging from 14 to 18 years (see Senn, Carey, & Vanable, 2008).

The majority of research to date dichotomizes the phenomenon of trauma, such that children are typically categorized into those who have or have not experienced childhood abuse. However, evidence is mounting to suggest that many children who are exposed to trauma actually experience multiple potentially traumatic events, including multiple types of abuse as well as other potentially traumatic events including (but not limited to) natural disasters, motor vehicle accidents, illnesses, war/terrorism, or death of a close other. A sample of urban children aged 3–6 admitted into community-based mental health or developmental services reported experiencing an average of 4.9 different *types* of potentially traumatic events (Crusto et al., 2010). Most operational definitions of trauma combine single versus multiple exposures, thus obscuring the true prevalence figures for single versus multiple exposures.

Studies that examine multiple victimizations utilize a broad define of victimization, including events such as child physical and sexual abuse, violence in families and communities, natural disasters and terrorism, accidental or violent death of a loved one, refugee and war experiences, impaired caregiving, and life-threatening injury and illness. While these methodological differences are to be expected, arriving at more convergence will serve to improve the rigor of our scientific pursuit.

SINGLE VERSUS CUMULATIVE TRAUMA

Multiple nationally representative samples reported similar rates of experiencing multiple types of victimizations. From the Developmental Victimization Survey, 7% reported seven or more types of victimizations by different perpetrators over the course of a single year, whereas 20% reported experiencing five or more types of victimizations (Finkelhor, Ormrod, & Turner, 2007). From the National Survey of Children's Exposure to Violence, 10.9% of children reported five or more direct exposures to violence in the past year (Finkelhor, Turner, Ormrod, & Hamby, 2009). A recent descriptive study on the core data collected by participating National Child Traumatic Stress Network (NCTSN) centers revealed a small but significant gender group difference in number of trauma types experienced, in that girls reported a higher mean number of trauma types as compared with boys (Briggs et al., 2013).

Epidemiological and clinical research has shown that the number of types of traumatic events exposed to in childhood is significantly correlated with the number and complexity of symptoms and diagnoses (see d'Andrea, Ford, Stolbach, Spinazzola, & van der Kolk, 2012). One of the seminal studies on cumulative risk comes from the study of Adverse Childhood Events (ACE's; Felitti et al., 1998). This prospective study showed that adults who at baseline reported four or more adverse childhood experiences were at greatly increased risk for negative physical and mental health outcomes over time. This pattern has been replicated numerous times, including a recent study where researchers found in an urban community clinic sample of 0–20-year-olds that increased number of ACEs was significantly correlated with increased risk of learning/behavior problems and obesity (Burke, Hellman, Scott, Weems, & Carrion, 2011). These findings are consistent with a growing body of literature indicating that developmental outcomes are best predicted by cumulative risk factors rather than by a single pathogenic condition (Rutter & Sroufe 2000).

In addition to cumulative risk factors, some researchers are also starting to examine the cumulative effect of trauma over time and across systems of functioning, otherwise known as the developmental cascades theory. The developmental cascades theory refers to the "cumulative consequences for development of the many interactions and transactions occurring in developing systems that result in spreading effects across levels, among domains at the same level, and across different systems or generations" (Masten & Cicchetti, 2010, p. 491). This approach suggests that antecedent conditions may yield varying probabilities for developing specific subsequent outcomes (Cox, Mills-Koonce, Propper, & Gariepy, 2010). The varying trajectories depend on the timing for development within and across various systems as well as the context within which the development is disrupted. In other words, functions at a basic level can impact functioning at higher levels through a spreading (or snowballing) effect or impact functioning over time on a domain that develops later in the developmental stage. The developmental cascade model proposes that developmental psychopathology results from the compounding of risk and protective factors. Earlier competencies or disruptions in functioning confer additional risk for the later development of adaptive or maladaptive behaviors.

MANIFESTATIONS AND CHILD OUTCOMES

Biological Manifestations

Brain Anatomy and Physiology

The two brain structures most often researched in children are the hippocampus and the amygdala (for a review, see Teicher et al., 2003). The hippocampus is implicated in the encoding and retrieval of information, most commonly studied in conjunction to learning and memory functioning. The amygdala is involved in evaluating potentially threatening information, fear conditioning, emotional processing, and memory for emotional events. The amygdala is also involved in the output of stress hormones which also impacts the hippocampus. Another brain region receiving increasing attention is the prefrontal cortex (PFC) for its role in many aspects of behavior, cognition, and emotion regulation.

Hippocampus. One meta-analysis indicated that hippocampus volumes were not significantly different when comparing maltreated children with PTSD to a control group of children without PTSD (Woon & Hedges, 2008). However, the same meta-analysis found that reduced bilateral hippocampus volume was found in adults with childhood maltreatment-related PTSD compared with healthy individuals. Interestingly, more recent longitudinal studies have found differences in the hippocampus of traumatized youths. Severity of PTSD and high cortisol levels predicted reductions in hippocampus volume over a 12- to 18-month interval (Carrion, Weems, & Reiss, 2007). Inconsistencies between the adult and child literature may be due to developmental processes or a latent effect where structural differences emerge over time during adolescence into adulthood. Supporting this idea, rat studies show that differences in hippocampus emerged only after young adulthood (Andersen & Teicher, 2004).

Amygdala. Neuroimaging studies also suggest that there are no amygdala volume differences between traumatized youth with PTSD and healthy controls (see Carrion & Kletter, 2012). One study found a 5.1% reduction in amygdala volume of maltreated youth compared with healthy controls, but when results were corrected for total brain gray matter, no significant differences remained (Carrion et al., 2001). Woon and Hedge's (2008) meta-analysis supports the general consensus that amygdala volumes are not significantly different when comparing maltreated children to healthy controls.

Prefrontal Cortex. Findings comparing the prefrontal cortex (PFC) volume of children with maltreatment and healthy controls are also mixed. One study reported no group difference (DeBellis et al., 1999), but another found smaller prefrontal volume and prefrontal white matter (DeBellis et al., 2002) in the maltreated group. Maltreated youth did not show the typical frontal lobe asymmetry (Carrion et al., 2009) due to the maltreated youth having larger left frontal lobe volume than healthy controls. Two other studies found larger gray matter volume of the middle-inferior and ventral regions of the PFC in children with PTSD (Richert et al., 2006; Carrion et al., 2009). One study examined the relationship between cortisol and the PFC in children exposed to interpersonal trauma versus children who were not exposed to interpersonal trauma (Carrion, Weems, Richert, Hoffman, & Reiss, 2010). Results showed that children exposed to interpersonal trauma and reporting PTSD symptoms had decreased ventral and left inferior prefrontal gray volumes. Furthermore, this decrease in PFC volume was associated with elevated bedtime cortisol levels.

In summary, knowledge is still in its early stages in this area. The brain continues to develop in the first 25 years of life; peak volumes of various brain structures occur in late childhood or early adolescence (see Giedd 2009). Consistent with the developmental cascade theory, concurrent psychopathology or adverse events during early childhood years can contribute to more heterogeneous physiological outcomes. Thus, the nature and timing of the adverse events during normal development can lead to different patterns of physiological response (Andersen et al., 2008).

Caregiving Context. The impact of the caregiving environment on brain structures remains an open question. There is almost no research available about the effects of witnessing domestic violence on brain development. There is also limited research on whether an enriched caregiving environment may play important roles in reversing the deleterious effect of trauma on brain structures. One longitudinal study showed that maternal support during a mildly stressful interactive task in early childhood (ages 3–5) predicted larger bilateral hippocampus volume at ages 7–13 (Luby et al., 2012). A randomized clinical trial with premature infants also demonstrated that early environmental enhancement in the neonatal intensive care unit was associated with positive changes in brain structure and functioning (Als et al., 2004).

Methodological Issues. Studies on children who experienced institutionalized care (e.g., Bucharest Early Intervention Project) provide a wealth of information on the impact of neglect and adversity on brain structures and functioning. However, we do not report on this

vast literature because the co-occurrence of childhood abuse with the neglect experienced during institutionalized care has not been clearly documented. This is a prime example regarding the lack of knowledge on the specific experiences of children in terms of the co-occurrence of neglect with instances of abuse that might be unreported or unidentified.

One additional complication in interpreting results on brain structures is that many studies conflate the experience of trauma with a diagnosis of PTSD. Many studies of adults and children have tended to recruit individuals with PTSD and compare to a group of participants without PTSD. This approach makes it difficult to tease apart effects unique to maltreatment experience (e.g., individuals with trauma histories but without PTSD) and current psychopathology.

Traditionally, the focus has been on how traumatic stress might impact cell development and brain structures, otherwise known as the neurotoxicity hypothesis. Specifically, the neurotoxicity hypothesis suggests that stress-induced prolonged exposure to glucocorticoids may lead to a reduction in cell complexity or cell death (Sapolsky, Uno, Rebert, & Finch, 1990). More recently, researchers are taking a further step to examine how structural differences might in turn present as a risk factor for persistent PTSD symptoms going into adulthood, otherwise also known as the vulnerability hypothesis (Teicher et al., 2003). In a twin study, Gilbertson et al. (2002) found that combat veterans with persistent PTSD symptoms had smaller hippocampus volumes than combat veterans without PTSD. However, the nontrauma exposed identical twins of the combat veterans with PTSD also had reduced hippocampus volumes, suggesting that the reduced hippocampus volumes may have preceded the development of PTSD symptoms. Additional twin studies and/or longitudinal designs are needed to further elucidate the directionality and time course of these processes.

The distinction between brain structural changes and functional anomalies also need to be better understood. DeBellis et al (2010) found in a sample of children aged 3–18 years that PTSD symptoms was significantly associated with poorer visual memory (typically associated with hippocampus functioning) although hippocampus volumes did not predict PTSD symptoms. Youth exposed to interpersonal trauma and reporting PTSD symptoms had increased amygdala activation in response to threatening facial expressions when compared with healthy controls (Garrett et al., 2012). Other recent fMRI studies demonstrated that children with experiences of maltreatment or family violence showed greater activation in the amygdala when viewing angry faces as compared with neutral faces (McCrory et al., 2011) or as compared with children without maltreatment histories (McCrory et al., 2013). These findings suggest that functional anomalies may occur prior to any evidence of structural differences.

HPA System/Cortisol

Most research studies on how violence and trauma can impact the human brain focus on stress responses in the HPA axis and the effects of cortisol, a potent stress hormone in the body (for a review, see Bevans et al., 2005). The catecholamine system/sympathetic nervous system (SNS) and the hypothalamic-pituitary-adrenal (HPA) axis are the body's major stress systems (see Bevans, Cerbone, & Overstreet, 2005; DeBellis et al., 1999; Schore, 2002). The catecholamine system is located in the brainstem and begins to develop very early in life. The release of corticotropin-releasing hormone (CRH) by the hypothalamus stimulates the catecholamine system. This in turn causes the locus coeruleus to release norepinephrine and the adrenal gland to release adrenaline and noradrenaline. These hormones affect the body's stress response by increasing blood pressure, heart rate, and perspiration. The HPA axis also works with the catecholamine system and mediates the fight–flight response. Like the catecholamine system, the stress response in the HPA axis begins when the hypothalamus produces and secretes CRH. CRH then stimulates the anterior pituitary gland to release adrenocorticotrophic hormone (ACTH) which in turn stimulates the production of glucocorticoids such as cortisol. In examining these systems, researchers typically examine the diurnal pattern of cortisol basal levels or cortisol reactivity to acute stressors.

In daily functioning, cortisol helps to maintain the timing of activities such as waking, sleeping, eating, and social interactions (Gunnar & Quevedo, 2007). The HPA axis follows a circadian rhythm; in typical development cortisol level is high in the early morning (with a peak within 30 minutes of waking up), sharply decreases by midmorning, and further declines throughout the day to the lowest level at bedtime. A circadian pattern of cortisol production typically emerges in the first few months of life. However, cortisol levels do not become stable or consistently predictable until children are about 4 years old (Bruce, Davis, & Gunnar, 2002; Gunnar & Quevedo, 2007; Watamura, Donzella, Alwin, & Gunnar, 2003). The pattern then maintains throughout the rest of the life span. As a result, we know little about the impact of trauma on cortisol levels in this developmental age range.

Another aspect of cortisol that is important to consider is the response after acute stress. An increase in cortisol in response to stress is adaptive and important for survival because it activates the fight or flight response. During a stress response, increases in cortisol levels produce additional energy and focus attention toward the stressor while postponing processes that are less important for immediate survival like immune response, growth, reproduction, digestion, and tissue repair (Johnson, Karmilaris, Chrousos, & Gold, 1992). From birth until about 4 months of age, infants reliably demonstrate a rise in cortisol in response to lab-based stressors, but by 6 months of age, similar stressors elicit increases in cortisol less reliably, and by 12 months, it is even more difficult to reliably elicit an increase in cortisol (for reviews, see Gunnar, Talge, & Hererra, 2009; Jansen, Beijers, Riksen-Walraven, & de Weerth, 2010).

Though a certain amount of activation in response to stress is adaptive, chronic exposure to stress can alter the overall development and functioning of the HPA system (Bremner & Vermetten, 2001; Gunnar & Vazquez, 2001). In turn, HPA system dysregulation is associated with significant health problems, cognitive functioning, and psychosocial disorders (DeBellis et al., 1999; Heim & Nemeroff, 2001). However, a review of cortisol data indicates that results across the age range are mixed on whether maltreatment leads to a hyperactivity in the HPA axis or hypoactivity (see McCrory, De Brito, & Viding, 2011). In recent years, researchers are beginning to suggest that a better representation of HPA axis functioning after experiencing trauma may be that both hyper- and hypoactivity are involved (McCrory et al., 2011). Studies are now turning to factors that might impact the dysregulation for both hyperfunctioning and hypofunctioning to understand why different response patterns emerge.

One study found that infants and toddlers less than 24 months of age in foster care (after having experienced abuse or neglect) showed higher baseline cortisol production compared with children not in foster care (Dozier, et al., 2008). However, in an older preschool aged sample, a small number of preschoolers had high levels of cortisol while most preschoolers in foster care exhibited lower levels of cortisol as compared with healthy children of the same age (Fisher et al., 2000). Researchers have suggested that the HPA axis may down-regulate in response to prolonged hyperactivation (e.g., Fries, Hesse, Hellhammer, & Hellhammer, 2005; Gunnar & Fisher, 2006). A meta-analysis with 107 studies of primarily adult samples indicated that chronic stress initially produced elevated cortisol, which rebounds to below normal levels as time passes after the stressor is removed (Miller, Chen, & Zhou, 2007). Though longitudinal studies have yet to be conducted to examine this hypothesis with children, adult findings suggest a change in HPA axis functioning based on the temporal timing of the stressor (i.e., time since onset or removal of stressor).

Researchers have also argued that early trauma experiences may lead to both hypo- and hyperreactivity in the HPA system because early chronic stressors may blunt overall basal HPA axis activity, but the system may be hyperreactive to acute stressors (e.g., DeBellis, 2001; Loman & Gunnar, 2010). For example, preschool children show an increase in cortisol reactivity across the first week of starting school, seen as a healthy adaptation to a naturally-occurring stressor (Graham et al., 2012). However, children in foster care show an even greater increase in cortisol reactivity in response to the start of preschool as compared with children not in foster care (Graham et al., 2012). The authors surmised that these findings suggest that dysregulation of the HPA axis for children with maltreatment histories might be characterized by an extended or a delayed cortisol response to stressors.

Additional work by Cicchetti and colleagues suggest that HPA axis dysregulation may depend on the presence of co-occurring internalizing or externalizing symptoms. In a sample of 553 children aged 7–13, those with early onset physical or sexual abuse and with high depressive or internalizing symptoms exhibited an attenuated diurnal decrease with lower morning basal level and higher afternoon basal level as compared with other children with later onset physical or sexual abuse or early occurring neglect or emotional abuse (Cicchetti et al., 2010). Due to the fact that most studies are cross sectional, the time sequence of comorbid conditions remains unknown. In other words, it is not clear whether psychopathology leads to HPA axis dysregulation, or if hyper/hypoactivity in the HPA axis leads to psychosocial difficulties. One longitudinal study that began to address this question examined social functioning and cortisol regulation in a sample of school-age maltreated and nonmaltreated children who attended a week-long summer camp for 2 consecutive years (Alink, Cicchetti, Kim, & Rogosch, 2012). Results indicated that lower levels of prosocial behavior and higher levels of disruptive/aggressive behavior were significantly associated with lower morning cortisol levels 1 year later. Withdrawn behavior was significantly related to higher afternoon cortisol levels 1 year later. Additional longitudinal studies are needed to determine if the altered HPA axis functioning may indeed lead to additional difficulties later in life.

Little is known about how additional characteristics of the traumatic event itself (such as recency of traumatic event or trauma type) or of the individual (e.g., gender) might impact the HPA response. Recency of the traumatic event may be one of the factors that impact HPA functioning. Pervanidou and colleagues (2007) found that after a motor vehicle accident, children (with PTSD) initially had elevated evening salivary cortisol, which then normalized in the 6 months after the trauma. In a sample of youth exposed to interpersonal violence, a higher level of salivary cortisol was also positively associated with PTSD among individuals with recent traumas in the previous year. However, for youth who reported distal traumas of more than a year prior to assessment, the more PTSD symptoms the lower the level of cortisol (Weems & Carrion, 2007). Another study showed down-regulation of cortisol production in girls with more pervasive maltreatment and girls who experienced maltreatment that was early onset and not recent (Doom, Cicchetti, Rogosch, & Dackis, 2013).

Cortisol patterns also may vary by trauma type, or the nature of the stressor. Physical and sexual abuse have been associated with high morning cortisol levels in children while those who have suffered multiple types of abuse are more likely to exhibit high morning and afternoon cortisol levels (Cicchetti & Rogosch, 2001). Miller and colleague's (2007) meta-analysis with adult samples suggested that stress that threaten physical integrity (e.g., combat) may impact the HPA system differently than threat to the social self (e.g., divorce). This hypothesis has not yet been tested in young children, but a parallel example might be threats to the caregiver.

Research is just beginning to examine gender differences in cortisol and HPA axis functioning. Elevated daily cortisol levels were reported for boys compared with girls in the group with more pervasive maltreatment. Boys with less pervasive maltreatment had lower DHEA and higher cortisol/DHEA ratio levels than girls with similar experiences, nonmaltreated boys, and boys with more pervasive maltreatment (Doom et al., 2013). Additional studies are sorely needed to better understand how additional contextual variables might impact the stress response of the HPA axis.

Caregiver Context. Not surprisingly, the caregiving environment plays an important role in the development of the HPA system and stress response for children. Recent advances in methodology has greatly contributed to our understanding of how maternal distress impacts the intergenerational transmission of traumatic stress via in vitro fetal exposure to increased cortisol (see Field, Diego, & Hernandez-Reif, 2006, for a review). When exposed to elevated maternal prenatal cortisol as a result of not only traumatic stress but also moderate levels of stress, the offspring experiences prenatal, perinatal, and postnatal complications including lower fetal weight delayed growth. In turn, these alterations can lead to a host of psychosocial difficulties and health conditions.

Furthermore, infants at 6 months of age whose mothers had a history of childhood abuse have been found to have significantly lower levels of baseline cortisol (Brand et al., 2010). In a sample of mother–infant dyads, maternal PTSD following the September 11 attacks was associated with significantly lower infant baseline cortisol levels at 9 months of age (Yehuda et al., 2005). Maternal depression has also been found to be significantly associated with increased levels of baseline cortisol levels in infants (Brennan et al., 2008). Morning salivary cortisol in adolescents who had been exposed to maternal postnatal depression was found to be elevated and more variable compared with nonexposed peers, a pattern associated with an increased risk of depression (Halligan, Herbert, Goodyer, & Murray, 2004).

Fisher and Stoolmiller (2008) also reported that one predictor of foster care preschool children's lower early morning cortisol levels was the stress level reported by foster caregiver. If a foster caregiver reported being highly stressed by the child's behavior on a given day, the child had lower cortisol levels the following morning relative to his/her levels on other days. Bernard, Butzin-Dozier, Rittenhouse, and Dozier (2010) compared cortisol production patterns in children remaining with birth parents to children placed in foster care following involvement of child protective services. Results showed lower waking cortisol levels and flatter diurnal slopes in both groups (compared with a control group of low risk children), with the flattest slopes in the group of children who continued to live in the high stress environments with their birth parents.

In terms of acute stress response, history of early maternal sexual and physical abuse and comorbid PTSD was associated with greater increases in infant cortisol levels in response to a laboratory stress task (Brand et al., 2010). Co-occurring maternal depression and anxiety was also significantly associated with increases in infant cortisol reactivity (Brennan et al., 2008). Disorganized infants showed cortisol increase in response to the Strange Situation tasks as compared with a play task (Bernard & Dozier, 2010). Organized infants did not show cortisol reactivity to either task.

Biological Context. Specific candidate genes that may play a role in explaining variability in cortisol reactivity have been identified. Infants with one or two T-alleles of the FKBP5 SNP and an insecure-resistant attachment showed a two-fold risk for heightened cortisol reactivity during the Strange Situation Procedure (Luijk et al., 2010). In a study with 6-month-old twins, when in the context of high family adversity cortisol levels was accounted for by genetic factors, and to a lesser extent by unique environmental factors. In low family adversity context, however, there was no genetic contribution and only environmental contributions to the cortisol levels (Ouellet-Morin et al., 2009). In a sample of maltreated and nonmaltreated children aged 6 to 12 years, those with two copies of the CRHR1 TAT haplotype showed an attenuated slope in cortisol across the day compared with maltreated children with zero or one copy of the TAT haplotype (Cicchetti et al., 2011). These same children with two copies of the CRHR1 TAT haplotype were also not different from nonmaltreated comparison children. The 5-HTTLPR gene did not impact cortisol dysregulation.

Genetics

Genetic polymorphism refers to the existence of more than one allele, or form of a portion of a gene. Polymorphisms in the dopaminergic, serotonergic, and oxytonergic systems have received increased attention in recent years. In the following sections, we review some of the more commonly studied gene by environment interactions in relation to childhood abuse.

Serotonin Transporter. The serotonin system is involved in affect and emotion regulation, with the serotonin transporter (5-HTT) gene facilitating the utilization of serotonin (5-HT). The polymorphism of this gene in the promoter region (5-HTTLPR) involves the short (s) or long (l) alleles in three possible configurations: s/s, l/l, and l/s. The short allele (s) has been linked to reduced 5-HTT transcription, lower 5-HTT protein levels, and diminished serotonin re-uptake compared with individuals with the long (l) allele. Thus, in response to stressful life events or trauma in childhood, the l/l genotype has been found to confer the highest level of resilience while the ss form has been found to be associated with the greatest vulnerability to depression and other psychiatric disorders (e.g., Caspi et al., 2003; Kaufman et al., 2006).

Dopamine Receptor. The dopaminergic system is involved in attention, motivation, and reward mechanisms (Robbins & Everitt, 1999). The dopamine receptor D4 is encoded by the DRD4 gene, which has a number of polymorphisms. One is a 48-base pair tandem repeat (48 bp VNTR in the coding region of the gene (exon 3). The 48 bp VNTR alleles range from 2 to 11 repeats. Receptor molecules coded by the 7-repeat allele have been shown to react less strongly to dopamine molecules as compare to the other frequent repeat alleles.

Studies have found an association between the 7-repeate allele and various outcomes in children including ADHD, aggressiveness, and temperament (e.g., Cicchetti, Rogosch, & Toth, 2011; LaHoste et al., 1996). Findings have also suggested an association between the 7-repeat allele and disorganized attachment behavior (e.g., Lakatos et al., 2000). In the longitudinal Budapest Infant-Parent Study, the 7-repeat variant of the 48 bp VNTR polymorphism was overrepresented in 1-year-old infants displaying disorganized attachment behavior with their mothers in the Strange Situation Procedure (Spangler, Johann, Ronai, & Zimmermann, 2009). The 7-repeat allele was found in 67% of infants with disorganized attachment versus 20% in infants with secure attachment and 50% in infants with avoidant and resistant attachments. The estimated risk among children carrying the 7-repeat allele for disorganized attachment was fourfold.

However, some questions regarding this association remain. A Dutch twin study failed to replicate this finding (Bakermans-Kranenburg & Van IJzendoorn, 2004). Some findings also suggest that this association is only when infants are reared by mothers who suffer from unresolved trauma and loss, in which case there is an almost 19-fold increased risk for disorganized attachment (Van IJzendoorn & Bakermans-Kranenburg, 2006). Additional data suggest that this association was significant only when the single nucleotide polymorphism (SNP) -521 C/T, another common polymorphism, was present in the promoter region of the DRD4 gene (Lakatos et al., 2002; Gervai et al., 2005).

Catecol-O-methyltransferase. Another common functional polymorphism is in the coding region of the catecol-O-methyltransferase (COMT) protein enzyme, which metabolizes catecholamines (e.g, dopamine, epinephrine, norepinephrine). This polymorphism involves a substitution of valine (Val) by methionine (Met) at codon 158 (Val-158-Met). The Met allele is associated with a fourfold reduction in enzyme activity compared with the Val allele (Scanlon, Raymond, & Weinshilboum, 1979). A protective effect has been reported for COMT heterozygotes (Val/Met) showing dopamine levels associated with optimal neurobehavioral outcomes, compared with both

homozygous groups (Wahlstrom, White, & Luciana, 2010). These differing levels of dopamine activity influences functions regulated by catecholamines, including reactivity in the HPA axis (Oswald, McCaul, Choi, Yang, & Wand, 2004). A study examining two large population samples found that disorganized attachment scores were higher in carriers of the Val/Met genotype as compared with the Val/Val and Met/Met carriers (combined effect of $d = 0.22$; Luijk et al., 2011).

Brain Derived Neurotropic Factor. The brain-derived neurotrophic factor (BDNF) factor supports the survival and growth of neurons in the central nervous system and the peripheral nervous system. In a sample of 8- to 13-year-old children who had lived in institutional care prior to being adopted by 6 years of age, the BDNF gene moderated attention problems and duration of institutional care (Gunnar et al., 2012). Results showed that ADHD scores were lower for children adopted within the first year of life and that ADHD scores increased as adoption age increased. Specifically, children with at least one Met allele of the Val66Met genotype had lower ADHD symptoms when adopted at a younger age and higher ADHD symptoms when adopted at an older age, resulting in a more marked association between age at adoption and ADHD symptoms. This finding suggests that children with at least one Met allele supports the development of attention regulatory competence at short durations of adversity but suppresses the development of attention regulatory competence at long durations of adversity.

Corticotropin Releasing Hormone Receptor. The corticotropin releasing hormone receptor 1 (CRHR1) gene is the key activator of the HPA axis. Polymorphisms of the CRHR1 are major determinants as to whether early-life trauma is associated with depression (Bradley et al., 2008). The impact of this gene also appears to occur in a sex specific manner. One study with a birth cohort from England showed that males with childhood trauma and a protective polymorphism had reduced cortisol response; however this buffer effect was not present in females (Heim et al., 2009).

Multiple Gene Interactions. Beyond the impact of single genes, some studies have also started looking at potential interactions of multiple candidate genes. In two large population samples (Generation R Study and the NICHD Study of Early Child Care and Youth Development), no consistent evidence emerged for additive effects of candidate genes involved in attachment security and disorganization (Luijk et al., 2011). However, other studies have found interaction effects of multiple genes for other types of outcomes.

Cicchetti and Rogosch (2012) examined in a sample of maltreated and nonmaltreated children aged 6 to 12 years from low income families four candidate genes: 5-HTT, DRD4–521 C/T SNP, OXTR, and CRHR1 (corticotropin releasing hormone receptor 1). Results indicated that genetic variation has a negligible effect for maltreated children in predicting resilient functioning. However, having specific genotypes (5-HTTLPR: s/s genotype variant, CRHR1: zero copies of the TAT haplotype for, DRD4–521 C/t SNP: TT genotype variant, and OXTR: AA or AG genotypes) contributed to higher resilient functioning in nonmaltreated children as compared with maltreated children with the same genotype. In this same sample, maltreated children who had two copies of the TAT haplotype of the CRHR1 and the l/l genotype of the 5-HTTLPR had higher levels of depression symptoms than nonmaltreated children with the same combination (Cicchetti, Rogosch, & Oshri, 2011). For children with two copies of the TAT haplotype of CRHR1 and the s/s or s/l genotype of the 5-HTTLPR or for children with zero or one copies of the TAT haplotype of CRHR1, maltreatment status was not associated with level of depression symptoms.

In a different sample, children with or without maltreatment history were examined for an interaction between the BDNF gene and the 5-HTT gene (Kaufman et al., 2006). Results indicated that genetic vulnerability associated with these two genetic variations was present only in maltreated children. Specifically, maltreated children with the Val66Met polymorphism of the BDNF gene and the *s*/*s* genotype of the 5HTTLPR had the highest depression scores as compared with maltreated children without this genotype or nonmaltreated children. The s/s 5HTTLPR genotype was associated with an increase in maltreated children's depression scores, which was greatest for the children without positive supports and the additional presence of the Val66Met allele of the BDNF polymorphism. A recent study also found a similar interaction between CRH-R1 and 5HTTLPR polymorphisms in moderating depression risk after childhood trauma (Ressler et al., 2010).

Gene by Environment Interactions. There has been a burgeoning of studies examining the interplay between trauma, genes, and the environment in terms of how early experiences might influence the expression of genetic coding. Caspi et al.'s (2002) landmark study on children with histories of childhood maltreatment and genotypes of the

enzyme monoamine oxidase A (MAOA) was one of the first to examine this gene by environment interaction. This study found that children with maltreatment histories who are carriers of the low activity MAOA allele were more likely to develop antisocial behavior as they grew older as compared with maltreated children who are carriers of the high activity MAOA allele. Subsequent research has provided additional support that there are no specific genes for inheriting disorders such as PTSD, depression, or antisocial behavior. Instead, genetic variants each add a small increment to the probability that someone may be vulnerable to or be protected from developing a psychiatric condition.

Several models have been proposed for gene–environment interactions. One of the more commonly described models is the diathesis–stress model, which proposes that genes that increase vulnerability (or resilience) are more likely to be expressed within adverse or stressful environments versus more favorable conditions. Recently, a differential susceptibility model has also gained traction (Belsky, 1997, 2005). The differential susceptibility model posits that children with certain biological or genetic predispositions are more susceptible to variations in the environment and respond more strongly than other children to both negative and positive environmental influences. Yet a third area focuses on how environmental influences can serve to regulate genetic expression by mediating both maladaptations as well as adaptations; otherwise known as epigenetics (Tsankova, Renthal, Kuman, & Nestler, 2007).

According to the diathesis stress model, children with a genetic vulnerability are disproportionately likely to be affected adversely by environmental stressors. In the absence of environmental adversity, the genetic vulnerability is not expressed, in which case these children are similar to those without the genetic risk. Extensive research supports this model.

The likelihood of having a disorganized attachment was significantly greater in infants who had the short allele polymorphism of the 5-HTT transporter gene and whose mothers exhibited low responsiveness (Spangler et al., 2009). In a study of more than 2,000 pairs of female twins, the presence of a traumatic stressor increased the probability of developing major depression in twins who were at low genetic risk for depression from 0.5 to 6.2% (Kendler et al., 1995). In twins who were at high genetic risk the likelihood of developing depression increased from 1.1 to 14.6%.

Though the diathesis-stress model focuses on the negative impact that adverse environments can have on genetic vulnerability, positive environments can also buffer genetic risk. Kaufman et al. (2006) demonstrated that children with environmental risk (maltreatment) and genetic vulnerability (the s/s genotype and BDNF met allele) for developing depression were buffered if they had social support. Another study examined infants with a short allele genotype (s/s or s/l), a genetic risk for insecure attachment, and their mothers during the Strange Situation Procedure at 15 months of age (Barry, Kochanska, & Philibert, 2008). Results showed that mothers who showed low responsiveness during the Strange Situation Procedure predicted particularly high risk for insecure attachment in the infants while mothers who showed high responsiveness offset the risk for insecure attachment. For infants with the l/l genotype variant, mother's level of responsiveness was not associated with infant attachment. Similarly, among children with the short allele genotype variant (s/s or s/l), those with insecure attachment developed poor regulatory capacities while those who with secure attachment developed as good regulatory capacities as children with the l/l genotype variant. This finding demonstrates that a secure attachment relationship can serve as a protective factor in the context of genetic vulnerability.

Unlike most gene by environment interactions that focus primarily on negative outcomes, the differential susceptibility model suggests that variations in experience may lead to worse or *better* outcomes based on genetic predispositions. In other words, children with high genetic risk in the context of negative environments show particularly negative outcomes while these same children in positive environments show better outcomes as compared with children without the genetic risk. This model has particular implications on treatment responsiveness, as discussed in a later section.

Epigenetic mechanisms refer to processes by which environmental influences, such as caregiving, can regulate gene activity (e.g., gene expression) without altering the DNA sequence. One often studied mechanism is DNA methylation, which alters the expression of genes in cells during cell division. DNA methylation occurs by either creating a barrier to transcription factor binding proteins or by recruiting proteins that generate a different shape for the methylated region of DNA. Whole-genome DNA methylation was studied in a sample of 7- to 10-year-old children, either raised in institutional care or with biological parents (Naumova et al., 2012). Results showed greater methylation in the institutionalized group relative to the biologically raised group. Methylation differences were found in genes involved in the control of immune response and cellular signaling systems, including neural

communication as well as brain development and functioning. One longitudinal study involved 15-year-old adolescents with parent reports of stress adversity during their child's infancy and preschool (Essex et al., 2013). Findings showed that greater levels of maternal stressors in infancy and paternal stressors in preschool years predicted higher levels of methylation at DNA methylation sites. This not only supports the occurrence of epigenetics but also suggests that epigenetic modifications have period-specific sensitivity sequentially dependent on maternal versus paternal stress. These data also support findings from a previous study where DNA methylation in 5-year-old children was also associated with maternal smoking during the intrauterine period (Breton et al., 2009).

Findings from these human studies also replicate results from animal research. A recent study employed a rodent model in which infant rats were exposed to caretakers under stress that showed abusive behaviors (Roth, Lubin, Funk, & Sweatt, 2009). Early maltreatment produced persisting changes in methylation of BDNF DNA which in turn altered BDNF gene expression in the PFC and hippocampus later on in adulthood. This finding is of particular interest as it documents the epigenetic effects of maltreatment in brain areas that are known to be both structurally and functionally altered in adults following maltreatment. Roth et al. (2009) also observed altered BDNF DNA methylation in the offspring of these females that had previously been exposed to maltreatment as pups. This suggests the possibility of a transgenerational transmission of epigenetic changes in gene expression even when the next generation had not been exposed to such environmental stressors.

Cellular Aging

Another area of biogenetic research that has received increasing attention in recent years as a potential mechanism between early life adversity and subsequent deleterious outcomes is cellular aging, or the changes in cells that occur over the life span. In particular, the length of telomeres, which are DNA repeats that cap the ends of chromosomes and promote stability, has become an important biomarker of cellular aging (Blackburn, 2001). As cells divide, telomeres get shorter, leaving the cell vulnerable to genomic instability, end-to-end chromosome fusion, and mitosis and cell replenishment dysfunction (Blackburn, 2001).

A burgeoning area of research has focused on risk factors for and correlates of shorter telomere length. For example, greater cortisol responses to an acute stressor and flatter day-time cortisol slopes were associated with shorter telomere lengths (Tomiyama et al., 2011). In turn, the shortening of the telomeres has been shown to be a risk factor for chronic age-related diseases and early mortality (Cawthon, Smith, O'Brien, Sivatchenko, & Kerber, 2003) as well as a host of psychiatric conditions (for review, see Price, Kao, Burgers, Carpenter, & Tyrka., 2013).

Importantly, a number of retrospective studies have shown that a history of childhood abuse and neglect is significantly associated with shorter telomeres. Tyrka and colleagues (2010) were the first to demonstrate this link in adults with or without a history of childhood maltreatment. Since that time, several other studies have replicated this finding (for a review, see Price et al., 2013). A recent longitudinal prospective study also demonstrated that children exposed to two or more traumatic stressors (such as domestic violence, bullying, abuse or neglect) at age 5 had significantly shorter telomeres at age 10 compared with same-aged peers exposed to less or no violent stressors after adjusting for sex, socioeconomic status, and body mass index (Shalev et al., 2013).

More recent research suggests that not only is there a link between shorter telomere length and childhood abuse and neglect but this association appears to be impacted by cumulative traumatic stress. In a sample of young to middle-aged adults, those with PTSD had shorter telomeres than same-aged peers without PTSD (O'Donovan et al., (2011). However, this association was driven by individuals with PTSD who had been exposed to multiple types of childhood trauma. In other words, individuals with PTSD who had none or one category of childhood trauma did not have significantly different telomere lengths than control participants without PTSD. Furthermore, greater number of categories of trauma exposure prior to age 14 was significantly related to shorter telomere lengths. Though telomere length is becoming an important biological marker of aging and the impact of traumatic stress, the ability to prevent or reverse telomere shortening remains an open question.

Psychosocial Manifestations

Attachment

Young children evolve their feelings of safety in the world around the physical and emotional availability of the attachment figure, monitoring the environment for signs of danger and seeking proximity and contact when faced with threat (Bowlby, 1969). In the moment of trauma, the child experiences overwhelming sensory stimulation in the form of pain and/or frightening visual, auditory, olfactory, and tactile sensations. An attachment figure who

is available to the child under conditions of risk and stress can buffer the child's response, whereas an unavailable or frightening attachment figure can exacerbate the child's fears. Several studies have shown that infants in secure attachment relationships are better able to modulate their physiological stress response as compared with infants in insecure attachment relationships, whereas infants with anxious or disorganized attachment are associated with greater dysregulation of physiological response (Gunnar & Cheatham 2003; Gunnar & Quevedo 2007). This pattern appears to extend into adulthood. A study with young adults showed that adult attachment in current close relationships mediated the relationship between childhood abuse and current symptoms (Muller, Thornback, & Bedi, 2012).

In addition to symptoms, attachment also appears to impact cognitive functioning. Busch and Lieberman (2010) found that a sample of preschool children who had witnessed DV displayed significantly stronger verbal abilities and perceptual-organizational skills when their mothers had a more secure (or coherent) attachment style. After controlling for maternal education level, maternal coherence of mind on the Adult Attachment Interview (AAI) explained 12% of variance on Performance IQ and 18% of variance on Verbal IQ. Children whose mothers were classified as secure scored 6 points higher on Performance IQ and 8 points higher on Verbal IQ than children of insecure mothers. An earlier meta-analysis based on primarily nonclinical, middle-class samples from 32 studies found a moderate association between infant attachment and children's language ability in the first 3 years of life ($r = .28$) and a smaller but significant association between infant attachment and intelligence ($r = .09$; IJzendoorn, Dijkstra, & Bus, 1995).

Contextual Factors. A recent review concluded that parental sensitivity only explains a small part of the total variation in infant attachment security (Bakermans-Kranenburg, Van IJzendoorn, & Juffer, 2003). Genetic variations may help explain some of the transmission gap in infant attachment security along with many other outcomes. Though we are beginning to understand the interaction between genetics and environment on the impact of attachment and other outcomes, we still have much to learn.

Internalizing and Externalizing Outcomes

A robust body of literature has demonstrated broad associations between childhood abuse and witnessing domestic violence to a range of difficulties in mental and physical health as well as problematic social interactions, additional peer victimization, academic difficulties, problem behaviors, and substance use (Chu and Lieberman, 2010). However, beyond understanding that exposure to traumatic events leads to negative outcomes, we need to understand the mediators and moderators for trajectories of outcomes.

Studies are beginning to examine the mechanisms that lead to the development and maintenance of trauma related symptoms after trauma exposure. For example, Stevens et al. (2013) found that difficulties with emotion regulation, lower social support, and greater exposure to adult interpersonal violence mediated the relationship between childhood abuse (before age 16) and adult PTSD symptoms. The model accounted for 63% of the variance in adult PTS symptoms.

Trauma symptoms are also increasingly seen as a potential mediator or moderator for a host of additional negative outcomes. Scheeringa and colleagues (2005) found that preschoolers with more severe trauma symptoms exhibited greater impairment in functioning in social activities and relationships 2 years later compared with children with less severe trauma symptoms. Trauma symptoms have also been found to mediate the relationship between maltreatment (including witnessing DV) and broadband internalizing and externalizing behaviors in preschoolers (e.g., Miller, Howell, & Graham-Bermann, 2012).

Traumatic expectations may generate hypervigilance and also constrict children's motivation to play, explore, and learn from the physical and interpersonal environment. In a sample of 1-year-old infants from abusive, neglecting, and nonmaltreating low-SES families, infants from abusive families demonstrated less independent and more imitative play than infants from neglecting and nonmaltreating families when observed during mother–child play (Valentino, Cicchetti, Toth, & Rogosch, 2006). At a 15-month follow-up when the children were about 2.5 years of age, these patterns held across groups (Valentino, Cicchetti, Toth, & Rogosch, 2011). Additionally, when examining the development of child play behaviors over time, higher levels of abuse at the initial assessment were associated with lower levels of child-initiated play at the 15-month follow-up.

Age of Onset. Careful specification of the age during which abuse occurs remains important as research is starting to suggest that distinct developmental periods may lead to divergent outcomes. In a sample of 553 children aged 7–13, those who experienced physical or sexual abuse prior to age 5 reported more internalizing symptoms

than children with abuse at later ages or children with no histories of abuse (Cicchetti, Rogosch, Gunnar, & Toth, 2010). Compared with abuse (sexual, physical, emotional) or physical neglect during infancy-toddlerhood (under 3 years of age) or middle childhood, abuse or physical neglect during the preschool years (3–6 years of age) was associated with the most severe externalizing symptoms (Manly, Kim, Rogosch, & Cicchetti, 2001).

Studies with adult samples replicate this pattern. Maercker and colleagues (2004) found in a large representative sample of almost 2,000 women aged 18–45 years that experiencing trauma (as defined by *DSM-IV* criterion A1) prior to age 13 predicted equal risk for depression and posttraumatic stress disorder (PTSD). However, if the trauma occurred after age 13, the risk for developing PTSD became much greater than the risk for depression. Another sample of adults whose age of onset of abuse or neglect was prior to 5 years of age reported higher levels of depressive and anxiety symptoms later in life as compared with individuals with a later age of onset who reported more behavioral problems (Kaplow & Widom, 2007).

These age distinctions also appear to impact development on a cellular level and on brain structures. A study with young adults between the ages of 24 to 32 years indicated that among individuals who had experienced physical abuse, those with onset between ages 3 and 5 years had heightened levels of Epstein-Barr Virus (EBV) antibodies compared with their peers whose onset of physical abuse was during adolescence (Slopen, McLaughlin, Dunn, & Koenen, 2013). EBV antibodies provide an indicator of cell-mediated immune function. Thus, higher levels of EBV antibodies signal the failure of cellular immune processes to impede reactivation of latent viruses. In another study with 26 young adult women aged 18–22 years, hippocampus volume was reduced in association with childhood sexual abuse experienced at ages 3–5 years and ages 11–13 years, and frontal cortex was attenuated in subjects with childhood sexual abuse at ages 14–16 years (Andersen et al., 2008). This is the first study to suggest a differential impact of age at onset of trauma on regional brain volumes. Similarly, Baker and colleagues (2013) found volumetric reductions in the anterior cingulate cortex and insula volumes only for individuals who experienced life stressors (including abuse, neglect, bullying, poverty, divorce, illness, and witnessing domestic violence) between ages 8 and 17 years, compared with individuals who experienced life stressors between ages 0 and 7 years or individuals without any experiences of trauma. These findings represent just the beginning of our understanding on how trauma might disrupt systems of development and bring about cascading effects when the trauma occurs at different time points along the developmental trajectory.

Race/Ethnicity. Any potential racial or other social group differences in the consequences of childhood abuse also remain poorly understood due to limited research on this topic. Lee and colleagues (2012) found that childhood maltreatment led to similar negative consequences for Black and White male youth in adolescence. However, in a sample of Latino women, risk of anxiety disorder was highest for women who had witnessed violence and reported the highest levels of family cultural conflict, providing limited evidence that acculturation moderates the influence of maltreatment on mental health outcomes (Warner, Alegría, & Canino, 2012).

Furthermore, racial discrepancies remain present in the criminal justice system for both juveniles and adults in addition to the child welfare system. For example, Black males are over-represented across all three systems (Fite, Wynn, & Pardini, 2009; Snyder & Sickmund, 2006). Early and severe childhood abuse has been found to be one of the most salient predictors of serious and violent criminal activity in adolescent and young adulthood (e.g., Asberg & Renk, 2013). Additionally, exposure to additional risk factors can further increase the likelihood of delinquent behavior. Some researchers have suggested a differential exposure (increased exposure due to environmental and societal inequalities) as the explanation for the racial disparity; others have put forth a differential sensitivity hypothesis due to exclusionary practices associated with institutionalized racism (see Fite et al., 2009). Overall, findings appear to provide mixed results in support of the differential sensitivity hypothesis. Instead, studies point to differential exposure to a range of risk factors, disparities in access to services, as well as racial biases among authority figures as explanations for the increased representation of non-White youth in the criminal justice system (see Langrehr, 2011). Thus, youth advocates are increasingly calling for competent and sensitive multicultural assessment and treatment in the child welfare and juvenile justice systems.

Sexual Orientation. Childhood emotional abuse showed a stronger association to PTSD and anxiety symptoms for African American individuals identifying as lesbian, gay, or bisexual (LGB) compared with White LGB individuals (Balsam, Lehavot, Beadnell, & Circo, 2010). Similarly, childhood physical abuse showed a stronger relationship with PTSD and anxiety symptoms for Latino LGB participants as compared with White LGB participants. While attention toward race and additional social identity groups is starting to increase across research areas, the impact

of intersecting identities remains an important topic area within the traumatic stress literature.

Caregiving Context. When the child grows up in the context of violence, traumatic expectations become the norm as the child learns to anticipate repeated and unrelieved pain and fear. When exposed to simulated adult conflict, infants under 1 year of age whose mothers reported experiencing domestic violence (DV) displayed more facial expressions of distress than infants whose mothers did not reported experiences of DV (DeJonghe, Bogat, Levendosky, von Eye, & Davidson, 2005). This finding suggests that infants exposed to DV may have a heightened sensitivity to adult verbal conflict.

The negative impact of exposure to parental conflict can manifest very early in life. In a sample of 6-month-old infants, higher levels of exposure to parental conflict was found to be associated with greater stress reactivity as measured by greater withdrawal of vagal tone during a laboratory stressor task (Moore, 2010). A functional magnetic resonance imaging study with a sample of healthy infants aged 6 to 12 months examined the association of parental conflict with neural responses to angry auditory input during natural sleep (Graham, Fisher, & Pfeifer, 2013). Results showed greater activation in brain regions associated with emotion and stress reactivity/regulation (e.g., rostral anterior cingulate cortex, caudate, thalamus, hypothalamus) for infants whose mothers reported higher levels of parental conflict.

Negative parenting practices can also significantly influence children's responses to traumatic events. For example, corporal punishment has been shown to be consistently linked with a range of negative child outcomes including aggression, lower levels of moral internalization, mental health, delinquent and antisocial behavior, and lower parent–child relationship quality (Gershoff, 2002). A longitudinal birth cohort of almost 2,000 children from 20 U.S. cities found that maternal spanking at age 5 predicted higher levels of child externalizing behavior at age 9, as compared with children who did not experience maternal spanking (MacKenzie, Nicklas, Waldfogel, & Brooks-Gunn, 2013). Paternal spanking at age 5 also predicted lower receptive vocabulary at age 9.

However, corporate punishment as a parenting practice remains a controversial practice with a sizeable portion of adults still in favor of this parenting practice (Bell & Romano, 2012). MackKenzie and colleagues found that 57% of mothers and 40% of fathers utilized spanking when the children were 3 years of age, while 52% of mothers and 33% of fathers spanked their children when the children were 5 years of age (MacKenzie et al., 2013). Some parenting advocates point out that corporal punishment may be a possible precursor to physical abuse given the unclear boundary between acceptable corporal punishment and physical abuse. Yet others suggest that the association between corporal punishment and negative outcomes may be due to third variables such as inconsistent parenting and parental stress; thus corporal punishment in of itself may not be a cause of negative outcomes (Gershoff, 2002).

Posttraumatic Stress Disorder

One of the most commonly examined outcomes of trauma exposure is posttraumatic stress disorder (PTSD). The recently released fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders,* (*DSM-5;* American Psychiatric Association, 2013) states that the essential feature of PTSD is the development of characteristics symptoms following exposure to an extreme traumatic stressor (criterion A1). Notably, the previous edition had included an A2 criterion of experiencing fear, helplessness, or horror as part of the traumatic event. The *DSM-5* no longer includes the A2 criterion because research suggested that this criterion did not improve diagnostic accuracy (Friedman, Resick, Bryant, & Brewin, 2011). The characteristic symptoms that were categorized into three clusters in the previous edition has been recategorized into four clusters: reexperiencing of the traumatic event (criterion B), avoidance of stimuli associated with the trauma and numbing of general responsiveness (criterion C), negative alterations in cognitions and mood (criterion D), and increased arousal (criterion E).Within each criterion, specific symptoms are described, and a logarithm is provided to determine whether the person meets the following criteria for diagnosis: at least one symptom from criterion B (reexperiencing), at least one symptom from criterion C (avoidance), at least two symptoms from criterion D (negative alterations in cognitions and mood), and at least two symptoms from criterion D (arousal). The full-symptom picture must be present for longer than 1 month (criterion F), the disturbance must cause clinically significant distress or impairment in important areas of functioning, such as work or social relations (criterion G), and the disturbance is not due to medication, substance use, or other illnesses.

There is wide recognition that the previous *DSM-IV* criteria for PTSD lacked developmentally informed considerations for infants, toddlers, and preschoolers. Scheeringa and colleagues (2003) compared 62 traumatized preschool children to 63 nontraumatized preschool children, all aged 20 months through 6 years. The children were recruited

from the community, including clinics, shelters, an intensive care inpatient unit of a level 1 trauma center, and a Head Start center. Parents reported on their children's symptoms. Findings showed that none of the traumatized children met the criteria for PTSD based on the *DSM-IV* (Scheeringa, Zeanah, Myers, & Putnam, 2003). However, when using an alternative criteria algorithm of one cluster B (reexperiencing) symptom, one cluster C (avoidance/numbing) symptom, two cluster D (arousal) symptoms, and four novel symptoms, they diagnosed PTSD at a rate of 26% in the same group of children. Using the revised algorithm, the group of children who were diagnosed with PTSD had significantly more comorbid symptoms (separation anxiety disorder; oppositional defiant disorder; major depressive disorder; attention-deficit/hyperactivity disorder; as well as general internalizing, externalizing, and total problems) when compared with children in the trauma/no-PTSD group or the no-trauma group.

Scheeringa and colleagues (2005) then reexamined these children's functioning one and two years following the initial time point and obtained information on community treatment. They found that those children initially diagnosed with PTSD at time 1 (from Scheeringa et al. 2003) showed significantly more PTSD symptoms and functional impairment in more domains over the course of 2 years than did children without PTSD. Children with PTSD symptoms did not show decreases in symptom levels over 2 years, even with community treatment. Specifically, avoidance/ numbing symptoms increased over time (particularly at 1-year follow-up), whereas reexperiencing symptoms decreased over time. Together, these findings argue for lowering the cluster C (avoidance/ numbing) symptom threshold criteria for younger children while keeping cluster B (reexperiencing) and D (arousal) symptom threshold criteria the same.

This alternative algorithm was further supported by a recent review which found that very few young children (0–5%) met the avoidance/numbing symptom cluster using the *DSM-IV* three-symptom threshold; however, when the threshold was reduced to one symptom, rates increased to 18–62% (De Young, Kenardy, & Cobham, 2011). Notably, reexperiencing was the most commonly endorsed symptom cluster in young children, with rates ranging from 35 to 80% followed by hyperarousal (32–45%). In fact, prevalence rates of PTSD in young children varied from 6.5% to 60% when using the alternative PTSD algorithm, depending on the type of trauma, time of assessment posttrauma, and type of sample. De Young and colleagues noted that if the *DSM-IV* criteria had been used for the PTSD diagnosis, prevalence rates would have been substantially lower.

Thus, to meet the specific needs of children aged birth to five, *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood* (*DC:0–3* and *DC:0–3R*) was created by Zero to Three: National Center for Infants, Toddlers and Families (Zero to Three, 1994, 2005). The diagnostic criteria for PTSD in the *DC:0–3R* manual specifically reflect the developmental manifestations of traumatic stress in the first 5 years of life. The criteria are written to conform to the algorithm initially proposed by Scheeringa and colleagues: at least one reexperiencing symptom (posttraumatic play, recurrent and intrusive recollections of the traumatic event outside play, repeated nightmares, physiological distress, and episodes of flashbacks or dissociation), at least two hyperarousal symptoms (sleep problems, concentration problems, hypervigilance, exaggerated startle response, irritability/anger), and at least one numbing of responsiveness or interference with developmental progress symptom (increased social withdrawal, restricted range of affect, markedly diminished interest or participation in significant activities, and efforts to avoid trauma reminders). The diagnostic criteria also include associated symptoms (regression of developmental skills, new aggression, new fears, and inappropriate sexual behaviors). This pattern of symptoms should last for at least 1 month.

Prior to the release of *DSM-5*, Scheeringa and colleagues (2012) assessed for diagnosis of PTSD using four diagnostic criteria sets in a sample of 284 3- to 6-year-old trauma-exposed children: *DSM-IV*, PTSD-alternative algorithm, *DSM-5* proposed criteria, and *DSM-5* criteria with 2 additional symptoms. The *DSM-IV* criteria resulted in the lowest rate (13%) of diagnosis out of the four. The PTSD-Alternative Algorithm yielded 45% of PTSD diagnoses while the *DSM-5* proposed set resulted in 44%. Using the *DSM-5* criteria with 2 additional symptoms, the rate of PTSD was at 49%. The three alternative criteria sets to *DSM-IV* showed high agreement on the presence of diagnoses (100%) but low agreement on the absence of diagnoses (58–64%). The authors suggested that these findings lend support to a developmental subtype for PTSD.

Consistent with research in the last two decades with young children, the *DSM-5* now includes a preschool subtype for PTSD in children who are 6 years or younger (American Psychiatric Association, 2013). The criteria for the preschool subtype are more behaviorally anchored and developmentally sensitive to detect PTSD in young children. The reexperiencing and arousal symptom clusters remain largely similar to the set of PTSD criteria in adults. The major changes are in the avoidance and

negative cognition/mood symptom clusters where symptom descriptions were modified to enhance face validity and the symptom threshold is now one symptom in either the avoidance cluster or the negative cognition/mood cluster (which is a decrease from the previous threshold of three symptoms in the avoidance cluster).

Caregiving Context. Several models have been proposed to explicate the intergenerational transmission of psychopathology from parent to child. Scheeringa & Zeanah (2001) propose a relational PTSD model where caregiver's responses to the traumatic stressor can have several types of effect on the young child. The moderating effect suggests that the degree to which the caregiver can accurately read the child's cues and respond effectively to the child's needs may intensify or reduce the adverse effect of the trauma event on the child's symptoms. The vicarious traumatization effect suggests that if a caregiver's responsiveness to the child is affected by a traumatic event that the child did not experience directly, the impact of the trauma on the caregiver–child relationship accounts for the effect of the trauma on the child's symptoms. The compound effect suggests that when both caregiver and child are exposed to trauma, the posttraumatic symptomatology in one partner exacerbates the symptoms of the other.

Lyons-Ruth and colleagues (1999) proposed a relationship diathesis model where vulnerability to stress-related dysfunction is determined by at least three factors: the characteristics of the stressor, the individual's genetic vulnerability to stress, and the capacity of the attachment system to modulate the high levels of arousal that accompany stress. In this model, children respond with emotional and behavioral symptoms either when the stressor is too overwhelming or when the attachment relationship is unable to modulate the child's intensely negative affective response.

Extensive empirical evidence supports these theoretical pathways linking the child's traumatic stress responses with parental stress, particularly with parental depression, PTSD, separation, and insecure attachment. A sample of preschool children exposed to the September 11th attacks and their mothers were recruited to examine children's behavioral problems as measured by mother and preschool teacher report (Chemtob et al., 2010). Children of mothers with both depression and PTSD had the highest rate of clinically significant behavior problems compared with children of mothers with only depression or mothers with neither disorder, as rated by both mothers and preschool teachers. Children of mothers with depression and PTSD also exhibited a larger number of behavior problem clusters. Crusto and colleagues (2010) also found that parenting stress partially mediated the relationship between family violence and trauma exposure and posttraumtic stress symptoms. Additional negative outcomes for young children with depressed mothers include increased parent–child conflict, behavioral problems, and peer relationship difficulties (for a review, see Markese, 2011).

While the majority of research focuses on the impact of negative or adverse caregiving environments, there is minimal research on whether the impact of early trauma can be reversed with a nurturing caregiving environment. One of the exceptions is a recent study found that 34 5–12-year-old children placed into the child welfare system due to abuse or neglect and reactive attachment disorder who were adopted into well-functioning families exhibited typical profiles of cortisol secretion (Kocovska et al., 2013).

Methodological Issues

To date, most studies on the impact of childhood trauma tend to examine either broadband maltreatment (i.e., collapsing all types of abuse and neglect together) or to compare the absence versus presence of a specific type of traumatic event. For example, a longitudinal study following a large cohort of approximately 2,700 sexually abused children over 43 years using a public psychiatric database found that childhood sexual abuse is a substantial risk factor for developing a range of mental disorders (Cutajar et al., 2010). However, this study did not examine children with other types of abuse as a comparison group or as a comorbid condition.

More recent studies are beginning to suggest that outcome patterns may vary by abuse type and we should begin examining profiles of abuse and neglect. Pears and colleagues (2008) examined profiles of abuse and neglect in 117 preschool-age foster children. In terms of outcome, the profile with sexual abuse had higher cognitive functioning as compared with other profiles (supervisory neglect; physical abuse; or sexual and physical abuse). However, this profile also had the highest level of externalizing problems. Internalizing problems was associated with three profiles: physical abuse; sexual abuse; or both sexual and physical abuse (Pears, Kim, & Fisher, 2008). Another study with a community sample of 2–3-year-old children exposed to different types of violence found that interpersonal violence exposure was associated with symptoms of depression, anxiety, posttraumatic stress disorder, and disruptive behavior while potentially traumatic exposure that were noninterpersonal in nature was primarily associated with phobic anxiety (Briggs-Gowan et al., 2010).

Another often-cited criticism of trauma research is the lack of experimental designs, where randomization cannot be done due to ethical reasons. Therefore, causality is often approximated from limited longitudinal designs. One methodology to better assess causality without utilizing a true experimental design involves propensity score matching (Rosenbaum & Rubin, 1983). The propensity score is the conditional probability of assignment to a treatment condition based on a range of covariates. Individuals are matched based on similar propensities and compared based on the treatment condition of interest. Causal inferences can be made using this methodology because propensity score matching balances all observed covariates prior to estimating treatment effects, thereby controlling for pretreatment selection bias.

Utilizing this methodology, a recent study examined the causal impact of childhood-limited maltreatment and adolescent maltreatment on early adult adjustment (Thornberry, Henry, Ireland, & Smith, 2010). The findings demonstrated that childhood-limited maltreatment was significantly related to drug use, depressive symptoms, and suicidal thoughts, which the authors characterized as internalizing problems. Adolescent maltreatment was significantly related to a broader range of outcomes including criminal activities, alcohol and drug use, risky sexual behaviors, and suicidal thoughts. Because of the propensity score matching, the authors were able to conclude that maltreatment was not merely a risk factor for these later outcomes but that it acted as a causal agent. As the field moves toward more complex approaches, researchers are able to start answering the questions of why, how, and under what conditions does trauma exposure lead to maladaptive outcomes.

ENVIRONMENTAL INTERVENTIONS

Prevention

In an earlier section we reviewed various risk factors for exposure to child abuse at different ecological levels (e.g., individual, family, societal). Identifying risk factors is important and valuable for prevention; to date, most prevention programs target the risk factor of parenting practices. A meta-analysis of 40 different early prevention programs for families with young children (0 to 3 years old) at risk for physical child abuse and neglect showed a treatment effect size of 0.29 (Geeraert et al., 2004). The programs, mostly with nonrandomized designs, showed significant decreases in abusive and neglectful parenting and increases in child functioning, parent–child interaction, parent functioning, and family functioning. Another review of 15 studies on 14 different prevention programs for children ages birth to 5 years indicated an effect size of 2.9% reduction post program participation, which equals a 31% reduction in actual maltreatment rates (Reynolds, Mathieson, & Topitzes, 2009). The authors noted that common elements of the programs showing effectiveness included implementation of curriculum by professional staff, high dosage and intensity of sessions, and comprehensiveness on scope of program content.

Other than parenting practices, we still know little about ways to prevent childhood abuse. In general, finding methods to study protective factors that keep children safe from abuse remains a challenge. The cross sectional nature of this research means that we know little about how risk or protective factors change over time. This is particularly important considering the tremendous cognitive, emotional, and social development that occurs across the first 18 years of life. Also, protective factors are often simply the flip side of identified vulnerability factors; for example, if female gender is a risk factor, then male gender is protective. We therefore still know little about protective factors independent of risk for experiencing childhood abuse. Further, most programs currently involve treatments to ameliorate the effects of trauma on childhood development and functioning versus prevention of childhood maltreatment.

Resilience

Resilience is typically thought of as the ability to function adaptively after experiencing an adverse or traumatic event. Though specific operationalization differs across studies, three main types of psychosocial protective factors for promoting resilience in children have emerged, similar to the risk factors reviewed above. Findings show that individual characteristics (e.g., intellectual functioning, self-regulation skills, temperament, personality), nurturing family environment (e.g., positive connections with adults, maternal warmth), and broader contextual variables (e.g., positive social support) all help facilitate positive adaptation in the face of adversity or trauma (see Masten, 2001).

Cicchetti and colleagues have noted that the majority of research on resilience to date has primarily focused on single-level analyses of psychosocial processes (Cicchetti, 2013; Curtis & Cicchetti, 2003). Studies with multilevel analyses focusing on the interaction of biological, genetic, and psychological systems are just beginning to add to our knowledge base regarding resilience. For example, Curtis and Cicchetti (2007) found that there was greater

electroencephalogram (EEG) activity in the left hemisphere of children who showed more resilience. Lower morning cortisol was found to be related to higher resiliency in nonmaltreated children while higher morning cortisol was related to higher resiliency in physically abused children (Cicchetti & Rogosch, 2007). Additionally, maltreated children with high resiliency exhibited an atypical rise in dehydroepiandrosterone (DHEA) levels from morning to afternoon.

Sapienza and Masten (2011) similarly described four waves of research regarding resilience. The first wave focused on descriptive data to figure out what makes a difference in increasing resilience. The second wave shifted to the process of how resilience functions. The third wave promoted resilience through interventions. Currently, in the fourth wave, researchers are adapting the developmental cascades model to examine the processes of interaction across system levels that influence individual development within the larger context. The fourth wave has been informed by multiple areas of research, such as the gene x environment interaction, epigenetic processes, and differential susceptibility (e.g., Cicchetti & Rogosch, 2012). As these studies continue to advance our understanding of resilience, it remains important to translate that knowledge into targeted and timely efficacious preventions and interventions.

Treatment

The Agency for Healthcare Research and Quality initiated the Effective Health Care Program in 2005 to provide reviews on the comparative effectiveness of different medical interventions to help consumers and providers to make informed choices among different treatment options. Two reports were completed recently to review clinical interventions for children exposed to traumatic experiences. The first review included 24 clinical trials and one cohort study testing interventions for children ages birth to 14 years who have specifically experienced abuse or neglect (Goldman Fraser et al., 2013). The report concluded that although there were a number of promising intervention programs addressing child outcomes after exposure to maltreatment, there was generally insufficient or low strength of evidence to draw firm conclusions regarding efficacy or effectiveness due to small sample sizes or only one or two trials for each intervention. No studies on pharmacotherapy met eligibility criteria to be included in the review. The report also noted various gaps in the literature. There were no studies that compared the efficacy or effectiveness of interventions with different characteristics (e.g., setting, service delivery format, theoretical orientation). The authors were unable to identify any studies that addressed race or ethnicity variables. Intervention studies also did not examine dosage effects—in other words, how many sessions of an intervention is needed to produce change—or impact of maltreatment characteristics (e.g., severity, chronicity, timing) on treatment outcome.

The second report reviewed interventions for children ages birth to 17 years who were exposed to traumatic events other than child maltreatment or family violence (Forman-Hoffman et al., 2013). The report included 21 clinical trials and one observational study that evaluated 19 different interventions. The authors found that some psychotherapy treatments were promising, particularly programs with elements of cognitive behavioral therapy which showed good effect sizes. However, there was again generally low strength of evidence to draw firm conclusions due to small sample sizes or only one or two trials for each intervention. Importantly, no studies attempted to replicate findings of effective interventions. Also, no pharmacotherapy intervention showed effectiveness in outcomes. Although both comparative effectiveness reviews pointed out gaps in the literature and noted that the field is still in its infancy, a number of interventions do show benefits for children exposed to abuse. We highlight some of those interventions below.

Infant–Parent Psychotherapy. Cicchetti, Rogosch, and Toth (2006) also compared a similar relationship-based therapy with infants, infant–parent psychotherapy (IPP), with a psychoeducational parenting intervention (PPI) and community standard (CS) controls who received usual standard of care under Department of Human Services management, all administered to maltreated children. These groups were compared with a normative comparison group with nonmaltreating families. At baseline, mothers in the maltreatment groups reported having experienced more abuse and neglect in their own childhoods, more negative representations of their childhood, and more negative relationships with their own mothers currently as compared with the mothers in the nonmaltreatment group. They also reported less availability of social support from family members, higher current parenting stress, less parenting competence, more social isolation, more health concerns, and less understanding of appropriate parenting attitudes and practices. During mother–child observations, the mothers from the maltreatment groups also demonstrated lower sensitivity in interactions with their infants. Infants in maltreating families exhibited significantly higher rates of insecure attachment with their

mothers, and only one infant (<1%) was classified as securely attached. In contrast, the rate of secure attachment for infants in nonmaltreating families was 32.7%. At postintervention, the rate of secure attachment increased significantly in the two intervention groups (IPP and PPI) to 60.7% and 54.5%, respectively. In comparison, the rate of secure attachment in the CS group remained low (1.9%). Furthermore, the rate of secure attachment in the normative comparison group remained at 38.6%, which was also significantly higher than the CS group.

Child–Parent Psychotherapy. Child–parent psychotherapy (CPP) is a relationship-based intervention grounded in psychoanalytic, attachment, and trauma theory that also includes social learning and cognitive behavioral intervention strategies as vehicles for change (Lieberman & Van Horn 2005, 2008). Because young children organize their responses to stress and danger around their caregiving relationships, CPP is organized around the premises that young children turn preferentially to their parents or primary caregivers for protection and safety and that trauma shatters the child's perception of the parent as a competent and reliable protector. Using the format of joint child–parent sessions, CPP therapists help to translate the emotional meaning of behaviors between the parent and the child, enabling them to co-construct a trauma narrative that holds developmentally appropriate meaning for both partners.

In a number of studies, CPP as an attachment theory informed intervention has shown efficacy in improving secure attachment and reducing rates of disorganized attachment (e.g., Cicchetti et al., 2006; Lieberman, Weston, & Pawl, 1991; Lieberman, Van Horn, & Ippen, 2005; Lieberman, Ippen, & Van Horn, 2006; Stronach, Toth, Rogosch, & Cicchetti, 2013). For example, in a randomized controlled trial comparing CPP to case management plus community intervention as usual, CPP was significantly more effective than the control group treatment in reducing (1) children's behavior problems and PTSD symptoms and (2) mothers' symptoms of avoidance (Lieberman et al., 2005).

When examining treatment effectiveness for children's level of trauma exposure, results indicated that children at high risk exposure as well as low risk exposure demonstrated improvements in symptoms (Ippen, Harris, Van Horn, & Lieberman, 2011). Specifically, children who reported four or more adverse childhood events who participated in CPP reported greater reductions in PTSD and depression symptoms as compared with children in a control condition. Children who reported four or less adverse childhood events who participated in CPP reported greater reductions in PTSD symptoms as compared with children in a control condition.

The impact of CPP on secure attachment and child behaviors appear to maintain over time. In one 6-month follow-up study, changes in child behavior problems were sustained posttreatment (Lieberman, Ippen, & Van Horn, 2006). PTSD symptoms were not measured at the 6-month follow-up for either mother or child, but general functioning continued to improve in mothers who received CPP whereas functioning of the mothers in the comparison group did not. In another 1-year follow-up study, toddlers in the CPP group had higher rates of secure attachment and lower rates of disorganized attachment as compared with children in a comparison parenting intervention or community standard intervention group (Pickreign Stronach et al., 2013). Thus, early intervention appears to be effective in promoting and sustaining secure attachment over time.

Attachment and Biobehavioral Catch-up. Attachment and Biobehavioral Catch-up (ABC) is a 10-session manualized intervention that targets three core issues for young foster children (Dozier, Higley, Albus, & Nutter, 2002). First, children in foster care often regulate physiology and behavior differently than do other children (Dozier et al., 2006). Young children in foster care often behave in ways that push new caregivers away. Third, foster parents' own issues sometimes create difficulties in providing nurturance. Whereas birth children can often cope effectively with nonnurturing care, children in foster care often develop disorganized attachments to nonnurturing caregivers, which in turn puts them at risk for a number of problematic outcomes. ABC helps foster parents create an environment that enhances regulatory capabilities. Various components of the intervention help caregivers to (*a*) follow the child's lead, (*b*) appreciate the value of physical contact with their child, (*c*) create conditions that allow their child to express, recognize, and understand emotions, and (*d*) provide nurturing care. Sessions include psychoeducation, discussions, and interactions between the foster parent and child.

Dozier and colleagues (2006) examined preliminary data from the first 60 children who were randomly assigned to receive the ABC treatment or an educational comparison intervention (Developmental Education for Families, which targets cognitive development) and an additional 104 children in a nonfoster care control group. At 1-month posttreatment, children whose foster caregiver received the ABC intervention showed a.m. and p.m. cortisol levels

comparable to the nonfoster care group. Children whose foster caregiver received the control intervention displayed higher-than-typical levels of cortisol across the day. For children in the ABC intervention group, older children (18–36 months) had lower problem behaviors based on parent report as compared with younger children (0–17 months). Children in the intervention group also showed stronger cognitive flexibility and theory of mind skills than children who received the control intervention; the intervention group was similar to comparison group of children who were never in foster care (Lewis-Morrarty, Dozier, Bernard, Terracciano, & Moore, 2012).

Multidimensional Treatment Foster Care Program. The Multidimensional Treatment Foster Care Program (MTFC) is a multicomponent program where foster parents complete intensive training prior to placement. In the preschool version, the Multidimensional Treatment Foster Care Program for Preschoolers (MTFC-P; Fisher, Ellis, & Chamberlain, 1999), foster parents first complete an intensive 12-hour training. After child placement, they receive daily telephone calls with a consultant who provides support and supervision, weekly support groups, and 24-hour on-call access. Children receive services from a behavior specialist and attend weekly therapeutic play-group sessions. If possible, a family therapist works with birth parents or additional adult caregivers to familiarize them with parenting skills. These services last for 6 to 12 months, including any transition periods to a permanent placement.

Fisher and Kim (2007) examined results in a randomized trial of the MTFC-P over a 12-month period after a new foster care placement. Fifty-seven children who participated in the intervention showed significant increases in secure behavior and decreases in avoidant behavior as compared with 60 children in the control condition who received foster care services as usual (Fisher & Kim, 2007). Both groups showed significant decreases in resistant behavior over 12 months. For participants in MTFC-P, children who entered foster care at older ages experienced greater increases in secure behavior over time compared with children in the control condition, who showed the opposite pattern. Preschool children who received the intervention also exhibited cortisol activity that became comparable over time to a comparison nonmaltreated community sample from low-income families (Fisher, Stoolmiller, Gunnar, & Burraston, 2007). Children in foster care who did not receive the intervention exhibited increasingly flattened morning-to-evening cortisol activity over time. Fisher and Stoolmiller (2008) found that foster parents who received the intervention reported a significant decrease in parenting stress related to child problem behavior compared with an increase in caregiver stress in foster parents who were in the control condition. Intervention also decreased the permanent placement failure rate and mitigated the effects of multiple foster placement on risk for permanent placement failure (Fisher, Burraston, & Pears, 2005).

The Multidimensional Treatment Foster Care for Adolescents (MTFC-A; Chamberlain, 2003) version has also shown positive outcomes for adolescents in foster care. In MTFC-A, foster care parents are also intensively trained, supervised, and supported similar to the preschool version on ways to provide positive adult support and mentoring, close supervision, and consistent limit setting. Youth placed in the specialized foster family also receive in-home services and peer as well as educational support. Results from multiple trials show effectiveness in reducing arrest rates and deviant peer affiliations, placement disruption, pregnancy rates, and externalizing as well as internalizing behaviors (for a review, see Leve et al., 2012).

Multisystemic Therapy for Child Abuse and Neglect (MST-CAN; Swenson, Penman, Henggeler, & Rowland, 2010) was adapted from the standard Multisystemic Therapy (MST; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 2009). MST-CAN utilizes a recursive process to identify, develop, and prioritize interventions based on the needs of each family. The first phase is focused on assessing the goals, strengths, and needs of each family across each ecological level (e.g., individual, peers, family, school). Then target behaviors are identified across these systems and interventions designed using empirically supported treatment methods to improve the target behaviors. If target behaviors do not improve, the assessment is conducted again in an iterative process until the desired outcomes are achieved. Given the outcome based approach, treatment length varies by each family's needs. As part of MST-CAN, the treatment team works closely with child protective services (CPS) to foster interactions between the family and the CPS system as well as to ensure CPS decision making based on clinical needs or progress. Parents also received treatment for their own trauma-related symptoms if appropriate.

MST has been utilized widely in many communities, primarily for substance use and antisocial behaviors, and has shown efficacious and effective outcomes (Henggeler et al., 2009). A randomized effectiveness trial on MST-CAN with children who have experienced physical abuse also demonstrated that MST-CAN was significantly more effective than outpatient treatment in reducing mental

health symptoms, parent psychiatric distress, maladaptive parenting behaviors, and youth placements (Swenson, Schaeffer, Henggeler, Faldowski, & Mayhew, 2010).

Trauma-Focused Cognitive Behavioral Therapy. Cohen & Mannarino (2008) described an evidence-based treatment, trauma-focused cognitive behavioral therapy (TF-CBT), for parents and traumatized children. This particular intervention provides children and parents with stress management skills prior to the processing of children's traumatic experiences together. A particular strength of this study was the documented feasibility of treatment in terms of the frequency by which children understood concepts given the young age of the children and concerns of their level of understanding. However, a limitation of the study was the high attrition rate. Although additional outcome studies are needed to further establish effectiveness of this treatment, it has been designated the treatment with the best established efficacy (e.g., Chadwick Center for Children and Families & Child and Adolescent Services Research Center, 2009) and has been disseminated on a large scale.

Resilient Peer Treatment. Fantuzzo and colleagues (2005) tested the effectiveness of Resilient Peer Treatment, a peer-mediated classroom-based intervention for socially withdrawn preschool children with a history of maltreatment. Resilient Peer Treatment involved 15 play sessions (three per week) over a 2-month period. The target child was paired up with a play buddy in the same classroom who was coached by a play supporter in positive play interactions with the target child. Eighty-two socially withdrawn children, with and without histories of maltreatment, were randomly assigned to resilient peer treatment or attention-control interventions. Teacher report and observational coding indicated that treatment led to higher levels of collaborative peer play interactions as compared with the control intervention. This treatment effect was present for both maltreated and nonmaltreated children.

Intervention Impact on Neurobiology

In addition to psychosocial outcomes, recently published studies with children exposed to traumatic stress show that intervention programs also have a positive impact on biological functioning. Specifically, HPA functioning has shown improvement after short-term interventions, particularly with regard to the diurnal rhythm in cortisol production (Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008; Fisher, Stoolmiller, Gunnar, & Burraston, 2007). Cicchetti and colleagues found in a sample of 1-year-old infants that morning cortisol levels for maltreated infants receiving child–parent psychotherapy or psychoeducational parenting intervention became indistinguishable from nonmaltreated infants while a control group of maltreated infants receiving standard community services showed progressively lower levels of morning cortisol (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011). This group difference first appeared at mid-intervention and was maintained at 1-year postintervention when the infants were approximately 3 years of age.

Importantly, research is beginning to show evidence that there are genetic and biologically based sensitivities to intervention. Infants who scored relatively high on irritability as newborns showed more benefits from a security-promoting intervention compared with infants who scored low on irritability (Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011). An intervention for children with disruptive behavior disorder was effective only for those displaying high cortisol reactivity (Van De Wiel, Van Goozen, Matthys, Snoek, & Van Engeland, 2004).

A randomized control trial found that an attachment-based parenting intervention (Video-Feedback Intervention to Promote Positive Parenting and Sensitive Discipline) with 1- to 3-year-old toddlers is most effective at reducing externalizing behaviors and daily cortisol production for children with the DRD4 7-repeat polymorphism (Bakermans-Kranenburg, Van IJzendoorn, Pijlman, Mesman & Juffer, 2008; Bakermans-Kranenburg, Van IJzendoorn, Mesman, Alink, & Juffer, 2008). Other studies have shown similar treatment responsiveness in children with the DRD4 7-repeate allele (e.g., Beach, Brody, Lei, & Philibert, 2010; Kegel, Bus, & Van IJzendoorn, 2011).

Van den Hoofdakker and colleagues (2012) found that a behavioral parenting training intervention produced greater treatment effects on ADHD behaviors in children (aged 4–12) with zero or one copies of the DAT1 dopamine transporter gene 10-repeat allele as compared with a control condition. However, the same intervention did not produce any significant treatment effects in children with two copies of the DAT1 10-repeat alleles.

These findings all point to a differential susceptibility model where children with certain genetic predispositions show particular benefit from positive contexts. However, the mechanisms underlying these associations and the differential susceptibility model remain unclear. One line of research is beginning to explore potential explanations for the link between genetic predispositions and differential susceptibility to interventions. Hayden and colleagues (2008) compared nondepressed and depressed 7-year-old children's reactions to sad movies or a sad

imaginary scenario. Children with the ss allele genotype of the 5-HTT gene had more negative self-referential responses to the tasks. Since depression is associated with negative information processing as well as increased activity in the amygdala, the authors surmised that the genetic predisposition for heightened activity in the amygdala may be responsible for the negative cognitive distortions so common in depression (Beck, 2008). In support of this hypothesis, Eley and colleagues (2012) also documented intervention benefits restricted to short allele carriers of the 5-HTT gene.

CONCLUSION

Policy

Estimates show that more than 90% of public sector service systems for children and families do not deliver evidence-based practices (Garland, Landsverk, Hough, & Ellis-Macleod, 1996; Landsverk, Garland, & Leslie, 2002). A National Child Traumatic Stress Network (NCTSN) descriptive study indicated that children who experienced at least one type of traumatic event were involved with many different kinds of systems that provide services for children, including social services, school-based services, juvenile justice, health, and mental health (Briggs et al., 2013). The authors noted that the pervasiveness of trauma exposure across various child service systems point to the need for all child service systems to become more trauma informed, to conduct comprehensive screenings for trauma histories, and for cross-system coordination. Thus, further training and dissemination of evidenced-based practices is warranted.

Future Directions

Recently, the Agency for healthcare Research and Quality commissioned a set of systematic reviews to provide comprehensive information on the effectiveness and safety of clinical interventions. Two separate reports on interventions that address trauma-related symptoms in children and adolescents concluded that there was preliminary support for a number of interventions which were beneficial relative to no treatment. However, most of the studies showed low strength of evidence due to small samples and methodological limitations; far more research is also needed to demonstrate comparative effectiveness of interventions (Goldman et al., 2013; Forman-Hoffman et al., 2013).

The studies reviewed here point to several important policy issues related to child welfare practices. For example, continued training is needed for professionals who interact with children and families across a range of settings, such as in the medical system, to recognize and assess maltreatment based on cutting edge research on vulnerability and protective factors. Researchers such as Hibbard and Desch (2007) have noted that many health workers do not receive sufficient training on the identification of certain risk factors, such as disabilities, for child abuse and neglect.

Because the literature on vulnerability and protective factors has been anything but static, trainings must be updated as the research literature advances. As new research emerges, we continue to identify additional vulnerability and protective factors as well as complex interactions among those factors. Training professionals to identify children who are at risk for abuse or who have been abused must, therefore, capture the complex relationship between risk factors. For example, it would be an unwelcome outcome if data on ethnicity and abuse led to focused attention on certain subgroups without considering the interaction between ethnic identity and other vulnerability/protective factors to understand the risk across and within various groups.

With up-to-date training, health care providers and other professionals will be in a unique position to use their knowledge to identify maltreated children as well as educate parents and families on ways to protect their children. To the latter point, we urgently need to learn to better use this body of research for risk assessment to prevent maltreatment from occurring, which will have to involve both policy and research agendas. For example, we need rigorous research methods to examine whether the vulnerability and protective factors identified in samples that rely on documented abuse reflect actually underlying differences (e.g., between groups) versus biases in the system.

Additionally, prevention of maltreatment requires programs to systematically and comprehensively address multiple risk and protective factors, including the family and surrounding community (Herrenkohl et al., 2008). While we have recommended that future research target multiple levels of influence on maltreatment, so too should policy-makers address the implications of multiple system interactions. For example, mothers who are victimized by their partners may not be able to fully protect their children because leaving the abusive partner may also result in loss of their economic means of support or increased safety risks to mothers and children. While insuring the safety

of children is paramount, policies can help to strengthen communities to support families and to reduce prevalence of child maltreatment (Coulton et al., 2007). Community social support appears to be an especially important protective factor that warrants further research to identify specific policies that can build this capacity to decrease child abuse risk.

Furthermore, a more collaborative team-approach response will help future data collection and provide more comprehensive responses to children who have experienced maltreatment. For example, because there is no federal mandate that information be collected on families involved in multiple systems (e.g., a family with identified child abuse that is also engaged in mandated substance treatment), the information available on how risk and protective factors interact are largely estimates based on an interpolation of research studies. Future studies should establish accurate estimates of families who access multiple systems to more fully assess the need for services, and in turn develop appropriate service capacity to respond to that need. In particular, states and communities need to fully understand the size, scope, and extent of the issue of families who are involved in systems in their jurisdictions as these factors may also vary depending on geographic locations and neighborhood characteristics. In sum, researchers and policy makers must work together to provide comprehensive and collaborative services in both the prevention and treatment of child maltreatment.

CHAPTER 11

Child Maltreatment and Developmental Psychopathology: A Multilevel Perspective

DANTE CICCHETTI and SHEREE L. TOTH

INTRODUCTION 457
DEFINITIONAL CONSIDERATIONS 458
ETIOLOGICAL MODELS OF CHILD MALTREATMENT 460
SEQUELAE OF CHILD MALTREATMENT 462
THE ORGANIZATIONAL PERSPECTIVE ON DEVELOPMENT 463
AFFECT DIFFERENTIATION AND EMOTION REGULATION 464
EMOTION RECOGNITION 466
FORMATION OF ATTACHMENT RELATIONSHIPS 468
DEVELOPMENT OF AN AUTONOMOUS SELF 469
PEER RELATIONSHIPS 471
ADAPTATION TO SCHOOL 472
EFFECTS OF MALTREATMENT ON MEMORY 473
PERSONALITY ORGANIZATION AND PSYCHOPATHOLOGY 474
GENE–ENVIRONMENT INTERACTION 476
MALTREATMENT AND ALLOSTATIC LOAD 480
NEUROENDOCRINE REGULATION AND REACTIVITY 481
ADVERSE PHYSICAL HEALTH OUTCOMES 482
MALTREATMENT EXPERIENCES AND NEUROBIOLOGICAL DEVELOPMENT 483
NEUROIMAGING AND CHILD MALTREATMENT 484
CHILD MALTREATMENT AND RESILIENCE 486
RACE AND ETHNICITY 490
METHODOLOGICAL ISSUES IN MALTREATMENT RESEARCH 491
Definitional Considerations 491
Multiple Subtypes 491
Comorbidity 491
Economic Adversity 491
Prevention and Intervention 492

THE NEXT GENERATION: NEW FRONTIERS IN CHILD MALTREATMENT RESEARCH 498
REFERENCES 501

INTRODUCTION

In this chapter, we infuse a *developmental psychopathology* perspective into our understanding of the sequelae of maltreatment. Specifically, we highlight the importance of employing a *multilevel perspective* when examining aspects of socio-emotional, cognitive, psychophysiological, neurobiological, and genetic functioning. Utilizing a developmental lens we discuss: affect differentiation and emotion regulation, emotion recognition, attachment, the development of an autonomous self, peer relationships, adaptation to school, memory, and personality organization and psychopathology. We also present findings on gene–environment interaction (GxE) and epigenetics, neuroendocrine functioning, physical health outcomes, and neurobiological development. Studies elucidating resilience despite caregiving adversity also are presented. We then address methodological issues in maltreatment research and the translation of research into *prevention*, *intervention*, and *social policy* arenas. We conclude by directing our attention to necessary next steps to foster work in this area. We highlight advances in research that are likely to increase our understanding of the effects of *child maltreatment* across the life course. We also recommend strategies for fostering advances and addressing challenges that have and will continue to accompany investigations into this all too pervasive societal problem.

Portions of this chapter were previously published in other works by these authors.

Acknowledgments: Our work on this chapter was supported by grants from the National Institute of Drug Abuse (DA17741, DA12903), the National Institute of Mental Health (MH083979, MH091070), and the Spunk Fund, Inc.

Child maltreatment represents a pathogenic relational environment that confers significant risk for maladaptation across both psychological and biological domains of development. Importantly, the deleterious sequelae accompanying child maltreatment not only result in adverse consequences during childhood, but also often initiate a negative developmental cascade that continues throughout the life course (Cicchetti & Tucker, 1994; Font & Berger, 2015; Masten & Cicchetti, 2010). The proximal environment involving the nuclear family, as well as more distal factors associated with the community and culture more broadly, transact to undermine normal biological and psychological developmental processes in children who have experienced maltreatment (Cicchetti & Toth, 2006). Childhood maltreatment has been associated with increased internalizing and externalizing problems, suggesting that etiological pathways exist between these symptoms and a number of psychiatric disorders (Keyes et al., 2012). In a recent meta-analytic examination of 16 epidemiological studies with over 23,000 participants, childhood maltreatment was associated with an elevated risk of experiencing recurrent and persistent depressive episodes (Nanni, Uher, & Danese, 2012). A further meta-analysis of 10 clinical trials with over 3,000 participants found that childhood maltreatment was also related to lack of response to treatment or lack of remission of depression during treatment (Nanni et al., 2012).

The public health implications of the adverse effects accompanying child maltreatment are enormous. According to the Center for Disease Control (Fang et al., 2012), one year of confirmed cases of child maltreatment (including cases of physical, sexual, and verbal *abuse and neglect*) costs $124 billion over the lifetime of the abused children. Information garnered from the Adverse Childhood Experiences Survey (ACES; Anda, 2006), one of the largest and arguably most important public health studies in the United States, indicates that childhood trauma, including maltreatment, is associated with an extraordinary number of adult health risk behaviors, including psychosocial and substance abuse problems. Importantly, individuals with elevated ACES are also at increased risk for diseases, including diabetes, immunological and cardiovascular problems, and early morbidity. Perhaps most strikingly, the ACES findings demonstrate that childhood trauma in not a rare occurrence, with over 2/3 of the adults surveyed in this middle-income population having experienced one or more types of adverse childhood experiences and with 87% having experienced two or more types of trauma. Thus, the magnitude of the effects of childhood maltreatment and the toll it exerts on society cannot be underestimated.

Currie and Widom (2010) conducted a long-term follow-up of the effects of child abuse and neglect on economic outcomes in adulthood. They discovered that adults with documented histories of childhood abuse and/or neglect had lower levels of education, employment, earnings, and fewer assets as adults, compared with matched nonmaltreated comparisons. Currie and Widom (2010) found that there was a 14% gap between individuals with histories of abuse/neglect and nonmaltreated comparisons in the probability of employment in middle age, controlling for background demographic characteristics. Thus, abused and neglected individuals experience large and enduring economic consequences.

The sophistication of research conducted on child maltreatment has increased substantially in more recent years. Although early studies were fraught with methodological limitations, current approaches are empirically rigorous and both intervention and social policy initiatives are increasingly informed by the results of empirical studies (Toth & Cicchetti, 2006). We begin our discussion of the consequences of child maltreatment by addressing aspects related to the definition of child abuse and neglect, a fundamental issue that must be addressed if this area of research and practice is to continue to move forward.

DEFINITIONAL CONSIDERATIONS

Perhaps one of the most important advances in understanding child maltreatment was related to refining the approach to defining child maltreatment. To be able to compare findings across laboratories and effectively communicate research results more broadly to both clinicians and policymakers, systematized definitions of maltreatment are essential. Historically, consensus on an operational definition of maltreatment was lacking. Issues that contributed to difficulties in defining maltreatment included: divergence regarding what constitutes acceptable versus inappropriate parenting, uncertainty about whether to define maltreatment based on caregiver actions, child outcome, or a combination of the two, controversy over whether criteria of harm or endangerment should be utilized, and disagreements about whether similar definitions were applicable for scientific, legal, and clinical purposes.

One of the most comprehensive and sustained efforts to understand the magnitude of the problem of child abuse and neglect in the United States emanated from the National Incidence Study (NIS), a congressionally mandated effort initiated in 1974 in response to the requirements of the Child Abuse Prevention and Treatment Act.

Initially, data were collected beginning in 1979. The NIS includes not only children reported to Child Protective Services (CPS), but also those who were screened out by CPS without an investigation. Thus, NIS estimates are based on a nationally representative sample that includes both maltreated children designated as such by CPS and those identified by the community who were not officially designated as maltreated.

NIS-4, the most recent survey, was conducted in 2005 and 2006 (Sedlak et al., 2010). According to NIS classifications, maltreatment includes both abuse (physical, sexual, and emotional) and neglect (physical, emotional, educational). Standardized NIS definitions describe both acts of commission and omission for each subtype. In addition, a number of additional features such as the child's relationship to the perpetrator, the severity of the harm, and the amount of evidence existing about the perpetrator are recorded. NIS definitional standards include the Harm Standard, which is the more stringent definition requiring demonstrable harm to the child, and the Endangerment Standard, which includes children who are endangered but not yet harmed. NIS-4 reports an overall decrease in the incidence of maltreatment since NIS-3, with a 19% decrease according to the Harm Standard. When accounting for the growth in the child population during this time period, this equated to a 26% decline in maltreatment. Statistically reliable changes were not apparent in the incidence of children who experienced maltreatment according to the Endangerment Standard. Importantly, NIS-4 documents that maltreatment is also associated with a number of co-occurring risk factors, including parental unemployment, low socioeconomic status, and race. With respect to race, a higher incidence of maltreatment was observed for Black children. Because socioeconomic status and race are often highly correlated, it is difficult to disentangle the relative contributions that each of these factors may make to the increased rate of maltreatment. NIS-4 was the first U.S. survey to detect racial differences in rates of maltreatment (we will discuss this later in the chapter).

It is important to note that maltreatment is a global problem. In 2000, the National Society for the Prevention of Cruelty to Children (NSPCC) published groundbreaking information on the prevalence and impact of child maltreatment in the United Kingdom. A more recent report by NSPCC that included a random probability sample of parents, children, and young adults found similar rates of neglect but found that rates of severe child maltreatment were lower in 2009 than in 1998, suggesting a similar decline in the prevalence of maltreatment as was found in the United States (Radford, Corral, Fisher, Bassett, Howat, & Collishaw, 2011). Despite this decline, a substantial number of children continued to experience severe maltreatment, with 5.9% of children under 11 years and 18.6% of those aged 11–17 years experiencing severe maltreatment. All forms of abuse during childhood were associated with worse mental health outcomes and elevated delinquent behavior. According to NSPCC, maltreatment is defined as "all forms of physical and/or emotional ill-treatment, sexual abuse, neglect or negligent treatment or commercial or other exploitation, resulting in actual or potential harm to the child's health, survival, development or dignity in the context of a relationship of responsibility, trust or power" (Butchart, Putney, Furniss, & Kahane, 2006, p. 9). Determination of the incidence of maltreatment is intertwined with reporting procedures and definitions utilized and, thus, the extent of documented maltreatment varies considerably across Europe and is also related to societal norms and values (Daro, 2006). Compared with incidence rates reported in the NSPCC survey, a World Health Organization prevalence study of maltreatment in Romanian families found that 24% of adolescents aged 13–14 years had experienced physical abuse, 9% had experienced sexual abuse, and 46% had experienced physical neglect (Browne, 2002). In general, between 7% and 36% of women and 3% and 29% of men internationally have experienced sexual abuse, with rates remaining constant for almost 2 decades (Finkelhor, 1994; Pereda, Guilera, Forns, & Gomez-Benito, 2009).

Despite increased agreement regarding the classification of maltreatment subtypes (Manly, 2005), some divergence remains in the field regarding how best to ascertain the presence of maltreatment. Although some advocate for reliance on information obtained from officially documented reports of maltreatment (Manly, 2005), other investigators maintain that caregiver and child reports are preferable because inclusion only of officially documented cases may result in only the most severe forms of maltreatment being captured. Moreover, more recently child protective systems have begun utilizing less adversarial approaches to families who have engaged in less severe forms of maltreatment. Therefore, cases that may have been indicated as veridical maltreatment a decade ago no longer appear as such on official roles. Ideally, a multipronged approach to defining maltreatment is preferable, including systematic coding of documented reports, access to information obtained in medical records, and interview information from caregivers and children. One system for coding official records examined in the aforementioned study, the MCS (Barnett et al., 1993) captures not only

subtype of maltreatment but also dimensions such as severity, frequency/chronicity, perpetrators, and developmental periods during which maltreatment occurred. The MCS has been used in more than 50 research laboratories in both the United States and Europe and has demonstrated excellent reliability and validity. To obtain supplementary information, the Maternal Maltreatment Classification Interview (MMCI; Cicchetti, Toth, & Manly, 2003) also can be administered to caregivers. Other widely utilized measures for assessing childhood maltreatment include the Childhood Experience of Care & Abuse instrument (Bifulco, Brown, & Harris, 1994) and the Childhood Trauma Questionnaire (Bernstein & Fink, 1998).

Despite advances related to improved definitions of child maltreatment, far too many investigations fail to utilize validated classification systems or to provide comprehensive information on the maltreatment experience. Issues related to the perpetrator of maltreatment, chronicity and severity of maltreatment, and when in the developmental period maltreatment occurred frequently are not considered. Attainment of a comprehensive portrayal of maltreatment becomes even more difficult in retrospective investigations that rely on the recall of maltreated individuals. Moreover, societal mores and attitudes toward corporal punishment vary considerably across cultures and further complicate estimates on the incidence and prevalence of child maltreatment. Issues such as these continue to contribute to discrepant conclusions across investigations and warrant increased attention in future studies (Baker, 2009; Barnett et al., 1993).

In addition to arriving at a consensus on how child maltreatment is defined, considerations regarding conceptualization of the etiology of child maltreatment are of paramount importance in investigations of maltreatment.

ETIOLOGICAL MODELS OF CHILD MALTREATMENT

In discussing the etiology of child maltreatment, it is important to recognize that most forms of maltreatment are part of a pattern of maladaptive behavior that emerges over time. Early views on the development of maltreatment emerged from a main effects perspective, in which it was thought that single risk factors such as parental psychopathology, poverty, or a parental history of maltreatment could provide an etiological account of the occurrence of child maltreatment (Cicchetti & Rizley, 1981). These unidimensional views on the etiology of child maltreatment soon gave way to more complex causal models, as it became clear that no single risk factor or set of risk factors would explain the development of maltreatment (Belsky, 1980; Cicchetti & Rizley, 1981).

Applying Bronfenbrenner's (1979) theory of human development, the etiological model proposed by Belsky (1980) initiated dramatic changes in the conceptualization of child maltreatment, as it necessitated the consideration of the broader environment in which maltreatment occurs. According to Belsky, child maltreatment is a social-psychological phenomenon that cannot be understood in isolation from the community and the culture within which the family and the individual are embedded. As such, his model contains four levels of analysis: the *macrosystem*, including the cultural beliefs and values that contribute to and influence child maltreatment; the *exosystem*, including aspects of the community that contribute to the incidence of maltreatment; the *microsystem*, including factors within the family that contribute to the occurrence of maltreatment; and *ontogenetic* development, including factors within the individual that are associated with being a perpetrator of maltreatment. Given that proximity to the individual increases with each subsequent level of the ecology (from the macrosystem to the ontogenetic context), Belsky further highlighted that risk factors at ecological levels that are closer to the individual exert a more direct influence on an individual's development. Moreover, interactions exist between and among all levels of the ecology, contributing to and influencing the occurrence of child maltreatment.

Cicchetti and Rizley (1981), drawing on the work of Sameroff and Chandler (1975), introduced additional elements to the etiological model of maltreatment by proposing a transactional model. This model focused on the reciprocal interactions of the environment, the caregiver, and the child, which together contribute to the outcomes of child development. An important distinction was made between two classes of risk factors: those that are potentiating, thereby increasing the risk for maltreatment, and those that are compensatory, which decrease the risk for maltreatment. Additionally, a temporal dimension was added to distinguish between risk factors that are transient versus those that are enduring. By combining these categorical and temporal dimensions of risk factors, Cicchetti and Rizley (1981) proposed four classes of determinants for the occurrence of child maltreatment:

1. *Enduring vulnerability factors* include all relatively long-lasting factors, conditions, or attributes that serve to potentiate maltreatment. These may involve parental, child, or environmental characteristics. Vulnerability

factors may be biological in nature, historical (e.g., a parent with a history of being maltreated), psychological, and sociological.

2. *Transient challengers* include short-term conditions and stresses such as loss (of status, a job, or a loved one), physical injury or illness, legal difficulties, marital or family problems, discipline problems with children, and the emergence of a child into a new and more difficult developmental period.
3. *Enduring protective factors* include relatively permanent conditions that decrease the risk of maltreatment. Examples of likely protective factors include a parent's history of good parenting and a secure quality of intimate relationship between the parent figures.
4. *Transient buffers* include factors that may protect a family from stress, such as sudden improvement in financial conditions, periods of martial harmony, and a child's transition out of a difficult developmental period.

It is the transactions among ecological levels that result in potentiating and compensatory factors and in mechanisms for the precursors and sequelae of child maltreatment. The Cicchetti and Rizley (1981) model conceptualized the risk for child maltreatment as probabilistic, proposing that the likelihood of maltreatment occurring is determined by the balance among risk and protective factors and processes. Overall, the balance of potentiating and compensatory factors that are present in the various ecological levels is thought to determine in a probabilistic fashion the absence or presence of child maltreatment.

Integrating the etiological models of Belsky (1980) and of Cicchetti and Rizley (1981), Cicchetti and Lynch (1993) proposed the ecological-transactional model of child maltreatment. By incorporating the ideas of the average expectable environment (Cicchetti & Lynch, 1995) and probabilistic epigenesis (Gottlieb, 1992) into a broad integrative framework, this model explains how processes at each level of the ecology exert reciprocal influences on each other and shape the course of child development (Cicchetti & Lynch, 1993). As such, potentiating and compensatory risk factors associated with maltreatment are present at each level of the ecology and can influence processes in the surrounding environmental levels. These dynamic transactions, which operate both horizontally and vertically throughout the levels of ecology, determine the amount of risk for maltreatment that an individual faces at any given time. The levels of ecology most proximal to the child have the most direct impact on child development relative to the more distally located macrosystem (Cecil, Viding, Barker, Guiney, & McCrory, 2014; Lynch & Cicchetti, 1998a; Maughn & Cicchetti, 2002). Although characterized by an overall pattern in which risk factors outweigh protective factors, there are infinite permutations of these risk variables across and within each level of the ecology, providing multiple pathways (known as equifinality) to the occurrence of maltreatment.

It is important to consider that factors that increase or decrease the likelihood of risk during one period of children's development may not do so during other developmental periods. Moreover, the temporal dimension of potentiating and compensatory risk factors is not static. Risk factors that are enduring can become transient and vice versa. For example, potentiators that originally are associated with relatively transient factors, such as initial unemployment, can become enduring when they persist over time, as in the case of chronic unemployment. Risk factors that had acted as potentiators can also be associated later on with compensatory risk factors. Perhaps the successful handling of a challenge can result in the development of new compensatory factors. For example, children who are able to survive the direct and indirect challenges presented by such potentiating factors as child maltreatment, poverty, and community violence develop inner characteristics that later are able to function as compensatory factors. The reverse is also possible. A compensatory risk factor could become a potentiating risk factor for maladaptation. Behaviors that are positive at one developmental period, such as a young child's dependence on a caregiver for support, might become counterproductive if continued into late adolescence, when more autonomy is expected.

Ultimately, it is the child's own ontogenetic processes, as manifested by the particular developmental pathway that individuals engage that culminate in eventual adaptation or maladaptation. The challenges or supports presented to children by the family, community, and society contribute to these ontogenetic processes; however, children also play an active role in their organismic development as they respond to these influences and engage in the resolution of stage-salient developmental issues. In the case of child maltreatment, one could imagine how the increased presence of enduring vulnerability factors and transient challenges associated with maltreatment at each level of ecology contributes to unsuccessful resolution of stage-salient developmental issues, setting the child on a pathway to maladaptive developmental outcomes and psychopathology (Cicchetti & Toth, 2006). The ecological-transactional model of Cicchetti and Lynch (1993) may also aid in providing an account for resilient outcomes. The presence of enduring protective factors may approximate features

of the average expectable environment, thus allowing some children to display successful adaptation in the face of maltreatment (Cicchetti, 2013).

We next turn our attention toward the effects of child maltreatment, with a particular focus on the developmental processes involved.

SEQUELAE OF CHILD MALTREATMENT

Empirical research on the developmental sequelae of child maltreatment has been conducted for the past half century. Studies of the consequences of maltreatment are very important for enhancing the quality of clinical, legal, and policy-making decisions for maltreated children. Decisions concerning such issues as whether to report a child as maltreated, whether to remove a child from the home, how to develop interventions to meet the specific psychological needs of maltreated children, and how to evaluate the efficacy and the effectiveness of these interventions all necessitate a solid and sophisticated data base on the developmental sequelae of child maltreatment. As Aber and Cicchetti (1984) cautioned, "Without rigor in design and method . . . myth will be put forward in place of knowledge as a guide to social action" (pp. 196–197).

Child abuse and neglect represent a severe dysfunction in parenting, as well as a substantial disturbance in parent–child relationships that may result in serious child maladaptation and aberrant development across the life span (Belsky & Jaffee, 2006). In fact, child maltreatment may constitute the greatest failure of the caregiving environment to provide opportunities for normal development (Cicchetti & Lynch, 1995). Moreover, maltreatment experiences may provide serious challenges to the species-typical organism-environment coactions that play important roles in the emergence and timing of normal developmental change.

The most important early study of the developmental consequences of child abuse and neglect is also the most controversial. Previously, none of the studies investigating the effects of child abuse and neglect had employed a matched comparison group; however, Elizabeth Elmer (1977) studied abused children matched on age, race, gender, and socioeconomic status (SES) to a group of children who had experienced accidents but were not abused. The abused children and the accident children initially were studied when they were approximately 12 months of age. These children were followed up again eight years later. Additionally, Elmer added a nontrauma comparison group of children at the follow-up assessment.

The major findings of the study were the absence of group differences in health history, intellectual status in school, language development, and self-concept. Despite the maltreatment classification, measurement, conceptual, and sampling flaws in the study (see Aber & Cicchetti, 1984), Elmer concluded that membership in the low-SES may have as profound an impact as abuse on child development. Elmer's conclusion placed the issue of what constitutes developmental risk in a stark sociopolitical light. It was essential that future investigations transcend the scientific flaws of Elmer's study (see Aber & Cicchetti, 1984).

Developmental scientists took up the challenge during the 1980s and began conducting investigations of the sequelae of child maltreatment (see, e.g., Cicchetti & Carlson, 1989; Egeland & Sroufe, 1981; Lamb, Gaensbauer, Malkin, & Schultz, 1985). Consistent with the tenets of the field of developmental psychopathology, these investigators believed that it was possible to learn more about an individual's normal functioning by studying its pathology and, likewise, more about its pathology by studying its normal conditions (Cicchetti, 1984; Cicchetti & Toth, 2009; Sroufe & Rutter, 1984). It was thought that theorizing about development without considering deviations that might be expected from the prominent and wide-ranging intra- and extraorganismic disturbances, as well as the transactions that occur among them, would eventuate in incomplete and ambiguous accounts of developmental processes. Methodologically rigorous examinations of the consequences of child maltreatment, in comparison to comparable groups of nonmaltreated children drawn from low-SES environments and informed by developmental theory and research, provided researchers with an excellent opportunity to test the veridicality of Elmer's (1977) conclusions and to uncover potential developmental deviations, as well as the ecological disturbances associated with them. These initial developmentally informed and well-designed investigations, as well as decades of subsequent sound research, unquestionably demonstrate that the deleterious effects of child maltreatment transcend those of poverty (Cicchetti & Toth, 2005).

The study of maltreated children can make numerous contributions to the processes underlying normal development—primarily through contributing precision to developmental theory, affirming it, challenging it, and impelling theoreticians and researchers to examine extant developmental theories more critically in relation to knowledge about maladaptation, psychopathology, and resilience. Conversely, before one is capable of grasping deviances that exist in a developing system, one must

also possess an accurate description of the system itself. To comprehend how abnormalities are transmitted from one developmental level to another, we must know how the normal transitions from one level of functioning to another are accomplished. Only when we understand the total ongoing development of normal systems can we comprehend developmental deviations as adaptational irregularities of those systems (Cicchetti, 1984, 1993; Sameroff, 1983; von Bertalanffy, 1968).

Through investigations of the effects of severe environmental disturbances such as child abuse and neglect, researchers may be able to gain insight into processes that normally are so subtle and gradual that they are not observed. For example, by examining the development of children who have not experienced a benign rearing environment, such as is the case with children who have been maltreated, researchers may be able to elucidate the impact that the quality of caregiving can exert on neurobiological structure and function (Belsky & deHaan, 2011; Cicchetti, 2002a, 2002b).

Research on child maltreatment also informs, and can be informed by, the significant functions of normal parenting (Belsky & Vondra, 1989; Rogosch, Cicchetti, Shields, & Toth, 1995). The specific acts of omission and commission that define child maltreatment are salient features of maltreated children's microsystems. It is in this immediate context of deviant parenting that maltreated children's atypical development takes shape. Close analysis of the maltreating caregiving environment and its links with poor developmental outcomes can shed light on the protective processes associated with appropriate parenting.

Investigations of the determinants of resilient functioning in maltreated children also can provide information about the multiple possible pathways of development. Despite having different specific experiences, many maltreated children exhibit similar failures in the stage-salient tasks of development (i.e., equifinality). On the other hand, not all maltreated children are equally affected by their experiences (i.e., multifinality) with some achieving resilient outcomes and the rest exhibiting maladaptive development (Cicchetti, 2013). Research investigations of maltreated children's development and struggles with adaptation can teach us about the range and variability of individual response to challenge and adversity. Instances of maltreated children succeeding at particular developmental tasks or who otherwise achieve resilient adaptation can teach us about the self-righting properties inherent to development despite poor quality care (Sameroff & Chandler, 1975; Waddington, 1957). On the other hand, findings that reveal the relative rarity with which maltreated children display resilient outcomes highlight some of the real constraints on children's self-righting abilities.

Although a comprehensive review of the sequelae of child maltreatment is not addressed in the present chapter, we cover developmental issues that forebode later maladaptation in the absence of efficacious evidence-based intervention. Moreover, although some investigations reveal negative sequelae associated with specific subtypes of maltreatment, it is extremely difficult to disentangle specific effects of maltreatment by subtype given their frequent overlapping occurrence. As investigations continue to refine definitions of dimensions of maltreatment, it will be increasingly possible to ascertain if there are any sequelae that are more likely to be associated with a specific subtype of maltreatment.

THE ORGANIZATIONAL PERSPECTIVE ON DEVELOPMENT

Much research conducted on the effects of child abuse and neglect is guided by the ecological-transactional model and an organizational perspective on development, a powerful theoretical framework for conceptualizing the intricacies of a life span approach to risk and resilience, as well as to normal development (Cicchetti, 1989; Cicchetti & Toth, 1995, 1998; Sroufe, 1997; Sroufe & Rutter, 1984). The organizational perspective focuses on the quality of integration both within and between the biological and psychological systems of the individual. Moreover, the organizational perspective addresses how development occurs, specifically identifying a progression of qualitative reorganizations within and among the biological and psychological systems that proceed through differentiation and subsequent hierarchical integration (Werner & Kaplan, 1963). In accord with the organizational perspective, development is not viewed as consisting of a series of tasks that need to be accomplished and that subsequently decrease in importance. Rather, development is conceived as comprising a number of age- and stage-relevant tasks. Although the salience of these tasks may wane in relation to newly emerging issues, the tasks remain important to adaptation over time (Cicchetti, 1993). A hierarchical picture of adaptation emerges in which the successful resolution of an early stage-salient issue increases the probability of subsequent successful adjustment (Sroufe & Rutter, 1984). As each new stage-salient issue comes to the fore, opportunities for growth and consolidation, as well as challenges associated with new vulnerabilities, arise. These tasks include the development of emotion regulation, the

formation of attachment relationships, the development of an autonomous self, the formation of effective peer relationships, and successful adaptation to school. To our knowledge, little research has been conducted on the stage-salient issues of adolescence and emerging adulthood in child maltreatment, such as psychological autonomy, forming close relationships within and across gender, and deriving a cohesive sense of self-identity (Cicchetti & Rogosch, 2002; Masten & Coatsworth, 1998). These issues deserve future research attention.

Despite the fact that more distal historical factors and current influences are important to the process of development, individual choice and self-organization have increasingly been viewed as exerting critical influences on development (Cicchetti & Rogosch, 1997; Cicchetti & Tucker, 1994). Across the developmental course, the evolving capacities of individuals and their active choices allow for new aspects of experience, both internal (e.g., genetic/biological) and external, to be coordinated in increasingly complex ways. Moreover, not only because biological factors can influence psychological processes, but also because social and psychological experiences exert actions on the brain by feeding back on it to modify gene expression and brain structure, function, and organization (Cicchetti & Tucker, 1994; Eisenberg, 1995; E. R. Kandel, 1998; Szyf & Bick, 2013), developmental plasticity can be brought about by both biological and psychological self-organization (Cicchetti, 2002a; Cicchetti & Tucker, 1994). Thus, for example, the fact that most maltreated children evidence at least some self-righting tendencies in the face of extreme adversity attests to the strong biological and psychological strivings toward resilience that virtually all humans and living organisms possess (Cicchetti & Curtis, 2006; Cicchetti & Rogosch, 1997; Waddington, 1957). In contrast, the absence of such resilient self-strivings in some maltreated children attests to the deleterious and pernicious impact that traumatic experiences can exert on core biological and psychological developmental processes. We next address the effects of maltreatment on stage-salient issues.

AFFECT DIFFERENTIATION AND EMOTION REGULATION

An early stage-salient issue in infancy involves the ability to differentiate and regulate emotions. Conceptualized as the monitoring, evaluating, and modifying of emotional reactions for the purpose of achieving individual goals, emotion regulation optimizes one's adaptive engagement with the environment (Thompson, Lewis, & Calkins, 2008). Cicchetti, Ackerman, and Izard (1995) argued that emotion regulation is critical both in initiating, motivating, and organizing adaptive behavior, and in preventing stressful levels of negative emotions and maladaptive behavior.

Emotion regulation is a developmentally acquired process that emerges from increasing differentiation and hierarchical integration of biological and psychological systems. Emotion regulation evolves as a function of both intrinsic features and extrinsic socio-emotional experiences within the context of early parent–child interactions (Cicchetti, Ganiban, & Barnett, 1991). At the biological level, important intra-organismic factors for the development of emotion regulation include individual differences in genotypic variation, organizational changes in central nervous system structure and function, cerebral hemispheric lateralization, and the development of neurotransmitter systems. Extra-organismically, children's emotional experiences, expressiveness, and arousal are influenced by caregivers' response to and tolerance of affect (Sroufe, 1996). Parents' socialization of affect displays during early interpersonal exchanges serves as the model through which aspects of emotional regulation may be learned (Hesse & Cicchetti, 1982; Thompson et al., 2008).

Child maltreatment represents a significant threat to the optimal development of affective processing abilities. Given the severe disturbances in the average expectable environment provided by maltreating families, considerable evidence has mounted to demonstrate the detrimental effects of aspects of maltreatment on children's emotional development and regulation. Specifically, maltreated children have shown deviations in emotion expression, recognition, communications, and understanding (Cicchetti & Ng, 2014). Moreover, in accord with the organizational perspective, adequate emotion regulation serves as a foundation for the development of secure attachment relationships, an autonomous and coherent self-system, and effective relationships with peers, whereas early affect-regulatory failures increase the probability that a child will develop future insecure disorganized attachment relationships, self-system impairments, and peer difficulties (Cicchetti & Valentino, 2006).

Divergence in maltreated children's emotional expression has been noted as early as 3 months of age, where severely physically abused infants have evinced increased rates of fearfulness, anger, and sadness during mother-infant interactions (Gaensbauer, Mrazek, & Harmon, 1981). The expression of fear and anger among physically abused infants at 3 months of age is a

particularly salient finding considering that the normative ontogenetic development of these affects does not typically occur until approximately 7 to 9 months of age (Sroufe, 1996). In contrast, neglected infants have been shown to display an attenuated range of emotional expression and an increased duration of negative affect as compared with nonmaltreated infants (Gaensbauer et al., 1981). Thus, excessive amounts of negative affect or blunted patterns of affect have been observed in maltreated infants long before they occur in normal development.

It is likely that early malevolent care accelerates the development of negative affect circuitry in the brains of maltreated infants. This may be accomplished by excessive synaptic pruning of the positive affect neurobiological circuits as a result of inadequate or insufficient early positive experiences by abused babies. The accelerated development of negative affect circuitry may lay the groundwork for the negativity bias (Ayoub et al., 2006) manifested by abused children in behavioral and psychophysiological studies of attention to facial expressions and in studies of social information processing (Pollak, 2005; Teisl & Cicchetti, 2008). Thus, maltreated children may already be at risk for developing differential emotion regulation developmental pathways by 3 months of life.

The early maladaptive processing of stimuli that contributes to affective regulatory problems may lay the foundation for future difficulties in modulating affect. Corroboration for the prediction, emanating from the organizational perspective, that maltreated children are at increased risk for evidencing a developmental progression from affect-regulatory problems to behavioral dysregulation, has been obtained in a number of cross sectional investigations. Maltreated toddlers have been shown to react to peer distress with poorly regulated and situationally inappropriate affect and behavior, including anger, fear, and aggression, as opposed to the more normatively expected response of empathy and concern (Main & George, 1985). Likewise, maltreated preschool and school-age children have been found to exhibit a range of dysregulated behaviors that are frequently characterized by disruptive and aggressive situations. In addition, physically abused preschool boys who witnessed an angry simulated interaction directed at their mothers evinced greater aggressiveness and more coping directed toward the alleviation of maternal distress than did nonabused boys (Cummings, Hennessy, Rabideau, & Cicchetti, 1994).

Shields, Cicchetti, and Ryan (1994) have shown in an observational study that maltreated children are deficient in affective and behavioral regulation, and that this attenuated self-regulation mediates the negative effects of maltreatment on children's social competence with peers. In accord with an organizational perspective, although affective and behavioral self-regulatory processes were interrelated, each appeared to represent a distinct developmental system that differentially and individually affects children's competence. Finally, in an investigation of 4- to 6-year-old children, approximately 80% of maltreated preschoolers exhibited patterns of emotion dysregulation (i.e., undercontrolled/ambivalent and overcontrolled/unresponsive types) in response to witnessing inter-adult anger, compared with only 37% of the nonmaltreated comparison children. Undercontrolled/ambivalent emotion regulation patterns were associated with maternal reports of child behavior problems and were found to mediate the link between maltreatment and children's symptoms of anxiety or depression (Maughan & Cicchetti, 2002). Findings such as these support a sensitization model whereby repeated exposure to anger and familial violence results in greater emotional reactivity.

During the school-age years, children continue to develop emotion regulation skills as they encounter increasing socialization demands from peers as well as from family. In an investigation conducted in the context of a research summer day camp, Shields and Cicchetti (1998) examined the interplay among emotion, attention, and aggression in a sample of school-age maltreated and nonmaltreated children. A central focus of this investigation was to examine mechanisms underlying maltreatment's deleterious effects on behavioral and emotional dysregulation.

Shields and Cicchetti (1998) found that maltreated children were more verbally and physically assaultive than were the nonmaltreated comparison children, with physical abuse placing children at heightened risk for aggression. Maltreated children also were more likely than comparison children to exhibit the distractibility, overactivity, and poor concentration characteristic of children who experience deficits in attention modulation. Physically and sexually abused children also displayed attention disturbances suggestive of subclinical or nonpathological dissociation, including daydreaming, blank stares, and confusion. Deficits in emotion regulation also were evident, in that maltreated children were less likely than comparison children to show adaptive regulation and more likely to display emotional lability/negativity and contextually inappropriate emotion expressions. Such pervasive deficits in maltreated children's regulatory capacities are cause for special concern, as the ability to modulate behavior, attention, and emotion underlie children's adaptive functioning in a number of key domains, including self-development,

academic achievement, and interpersonal relationships (Cicchetti, 1989, 1991; Shonk & Cicchetti, 2001).

Shields and Cicchetti (1998) also demonstrated that impaired capacities for attention modulation contribute to emotion dysregulation in maltreated children. Specifically, attention deficits mediated maltreatment's effects on emotional lability/negativity, inappropriate affect, and attenuated emotion regulation. Attention processes that suggest subclinical or nonpathological dissociation also contributed to maltreated children's deficits in emotion regulation. Thus, abuse seems to potentiate disruptions in attention that result in both a relative detachment from and unawareness of one's surroundings, as well as in hyperattunement and hyperreactivity to the social surround (Pollak & Tolley-Schell, 2003; Rieder & Cicchetti, 1989). Together, these deficits appear to compromise maltreated children's ability to regulate behavior and affect in social settings.

In another investigation, Shields and Cicchetti (2001) examined children who were maltreated by their caregivers to ascertain whether these children would be more likely to bully others and to be at increased risk for victimization by peers than would nonmaltreated comparison children. An additional focus was to investigate emotion's role in bullying and victimization among maltreated children. Maltreated children were found to be more likely than nonmaltreated children to bully other children. Bullying was especially prevalent among abused children who experienced maltreating acts of commission (physical or sexual abuse). Maltreatment also placed children at risk for victimization by peers. As expected, both bullies and victims evidenced problems with emotion regulation. Furthermore, logistic regression analyses suggested that emotion dysregulation made a unique contribution to differentiating bullies and victims from children who did not evince bully or victim problems. Additionally, maltreatment's effects on children's risks for bullying and victimization were mediated by emotion dysregulation.

In a short-term longitudinal study, Kim and Cicchetti (2010) found that children who are more adept at regulating negative emotions show higher social competence in peer interactions and higher peer competence, resulting in lower levels of internalizing symptomatology. In contrast, poor emotion regulation is a significant predictor of both maladaptive social functioning, such as peer rejection and internalizing symptomatology. Furthermore, Kim-Spoon, Cicchetti, and Rogosch (2013) investigated the longitudinal contributions of emotion regulation and emotion lability-negativity to internalizing symptomatology. A sample of over three hundred maltreated ($N = 171$) and nonmaltreated ($N = 151$) children were followed from age 7 to 10 years. For both maltreated and nonmaltreated children, emotion regulation was a mediator between emotion lability-negativity and internalizing symptomatology, whereas emotion lability-negativity did not mediate the relation between emotion regulation and externalizing symptomatology. Early maltreatment was associated with high emotional lability-negativity (age 7) that contributed to poor emotion regulation (age 8), which in turn was predictive of increases in internalizing symptomatology (from age 8 to 9).

These findings suggest that emotion regulation and emotion lability-negativity may be important factors in identifying distinct pathways to child psychopathology. Specifically, low emotion lability-negativity and adaptive emotion regulation appear to play protective roles in the development of internalizing symptomatology. The findings also suggest that emotion regulation is an important mediational process between emotion lability-negativity and internalizing symptomatology. Therefore, to alter emotional processes that are related to the subsequent development of internalizing symptomatology, a focus on improving emotion regulation skills in children is likely to be an effective strategy that can impede the progression of internalizing problems. The results also imply that emotion regulation can be targeted to reduce the deleterious effects of emotion lability-negativity heightened by early maltreatment experiences, thus preventing internalizing symptomatology.

In a particularly important mega-analytic study designed to examine the effects of family violence on children's behavioral problems, Sternberg and colleagues found that children who experienced multiple forms of family violence were at heightened risk for behavior problems compared with those who experienced only a single type of violence (Sternberg, Baradaran, Abbott, Lamb, & Guterman, 2006). Regardless of type of abuse, age, or gender, more children had behavior problems in the nonclinical than in the clinical range. This was the case even for children who were abused and also witnessed family violence, where only 28–50% of the children in any group had clinically significant behavior problems. These results highlight the remarkable resilience that can be present, even in the context of extreme family adversity.

EMOTION RECOGNITION

To examine the affective input that maltreated children receive, Camras and colleagues (1988, 1990) conducted a series of investigations of maternal facial expressions. When asked to deliberately produce facial expressions, maltreating mothers' demonstrations of emotion faces were

less easily identified by observers than were the expression of nonmaltreating mothers (Camras et al., 1988). During mother-child interactions, maltreating mothers differed from nonmaltreating mothers with regard to the expression of sadness (Camras et al., 1990). Taken together, the emotion displays of abused and neglected infants highlights the centrality of interactions with caregivers in shaping the development of affect expression or differentiation. Moreover, maternal emotional expression ability contributes to their children's ability to recognize facial emotions (Camras et al., 1988).

Difficulties in mentally representing and processing social information have also been noted in children with histories of maltreatment. Children who have been neglected have difficulty discriminating emotional expressions, whereas physically abused children demonstrate a response bias to angry emotional expressions (Pollak, Cicchetti, Horning, & Reed, 2000). Pollak et al. (2000) hypothesized that physically abused preschool children would demonstrate an increased sensitivity to anger-related cues, perhaps also resulting in decreased attention to other emotional cues. The results of their study revealed that, when physically abused children were exposed to a perceptual scaling task, they perceived angry faces as highly salient and more distinctive than other emotion categories (Pollak et al., 2000). Additionally, when asked to match facial expressions to an emotional situation, physically abused children showed a response bias for anger such that, when they were uncertain which facial expression to choose, they showed a lower threshold for selecting anger. Pollak and Sinha (2002) further demonstrated that physically abused children required less sensory input than did comparison children to accurately identify facial displays of anger. Pollak and Sinha utilized a gradual evolution of images depicting facial expressions of various emotions. Physically abused children detected angry emotions at lower steps of the sequence but did not exhibit increased sensitivity for the other facial displays. The authors concluded that physically abused children have facilitated access to representations of anger. Similarly, in a task in which pairs of photographs of emotional expressions were morphed into each other (Pollak & Kistler 2002), physically abused children detected anger with lower signal strength than did controls. In combination, these studies suggest that physically abused children can detect facial expressions of anger more accurately and at lower levels of perceptual intensity than other emotions.

In an investigation of the attentional mechanism underlying the finding that physically abused children overattend to angry experiences, Pollak and Tolley-Schell (2003) found that children who had experienced physical abuse demonstrated delayed disengagement when angry faces served as invalid cues and exhibited increased attention to valid angry trials. These results suggest that early adverse experiences influence maltreated children's selective attention to threat-related signals.

In addition, Pollak, Vardi, Bechner, and Curtin (2005) examined the effects of early child physical abuse on 4-year-old children's regulation of attention in the presence of interpersonal hostility. Pollak et al. (2005) measured abused children's reactions to the unfolding of a realistic interpersonal emotional situation through multiple methods, including autonomic nervous system changes (i.e., heart rate; skin conductance level) and overt behavioral performance on an attention task. Although the physically abused and nonabused comparison children did not differ in terms of their baseline levels of arousal, marked differences emerged in physically abused children's regulatory responses to background anger. The findings suggest that children with physical abuse histories exhibit anticipatory monitoring of the environment in response to the emergence of anger. Relatedly, Pollak, Messner, Kistler, and Cohn (2009) presented abused children with arrays of stimuli that depicted the unfolding of facial expressions, from neutrality to peak emotions. These investigators found that abused children were able to recognize anger early in the formation of the facial expression, when few physiological cues were available. The speed of children's recognition was associated with the degree of self-reported anger/hostility by the child's parent. Thus, these findings highlight the ways in which perceptual learning can shape the timing of emotion perception.

Perlman, Kalish, and Pollak (2008) conducted an investigation of emotion understanding in maltreated and nonmaltreated children. To assess how well children understood the antecedents of emotional reactions in others, children were presented with a variety of emotional situations that varied in outcome and equivocality. Children were told the emotional outcomes and asked to rate whether a situation was a likely cause of such an outcome. The investigators tested the effects of maltreatment experience on children's ability to map emotion to their eliciting events and their understanding of emotion-situation pairings. Nonmaltreated children were able to distinguish between common elicitors of positive and negative events, whereas children who developed within maltreating contexts interpreted positive, negative, and equivocal events as being equally plausible causes of sadness and anger.

Maltreated children are exposed to an atypical emotional environment, characterized by less positive emotion (Bugental, Blue, & Lewis, 1990) and more negative emotion (Herrenkohl, Herrenkohl, Egolf, & Wu, 1991) in

comparison to that expressed in nonmaltreating homes. Among maltreating families, physically abusive parents are more negative than neglecting parents and engage in higher rates of aggression directed toward their children. Neglected children experience an impoverished emotional environment, marked by infrequent affective exchanges with their caregivers (Crittenden, 1981). Ultimately, it is believed that these aberrant emotional experiences eventuate in neuropathological connections that undermine effective emotion-regulation capabilities.

Shackman et al. (2010) evaluated the quality of facial and vocal emotional expressions in abusive and nonabusive mothers and assessed whether mothers' emotional expression quality was related to their children's cognitive processing of emotion and behavioral problems. Relative to nonabusive mothers, abusive mothers produced less prototypical angry facial expressions, and less prototypical angry, happy, and sad vocal expressions. In addition, children's cognitive processing of their mothers' angry faces was related to the quality of mothers' facial expressions. The finding that abusive mothers' expressions of anger were characterized by less intensity and arousal may lead to their children interpreting these expressions of anger as hard to predict and more difficult to interpret (Shackman et al., 2010). Accordingly, abused children's exposure to poorer quality emotional signals may deprive them of an important source of information about the meaning of emotional expressions.

Psychophysiological studies also provide evidence that maltreated children allocate more attentional resources to the detection of anger (Pollak, Klorman, Thatcher, & Cicchetti, 2001). In particular, measurement of cognitive event-related brain potentials (ERP) indicates that school-age maltreated children display larger P3b amplitude when their attention is directed toward angry, as opposed to happy, targets (Pollak et al., 2001; Pollak & Tolley-Schell, 2003; Shackman, Shackman, & Pollak, 2007). Moreover, this pattern of response appears to be specific to anger, rather than to negative emotions in general (Pollak et al., 2001). Similar findings indicate that maltreated infants exhibit brain-based abnormalities in the processing of facial affect as early as 15 months of age (Curtis & Cicchetti, 2013). Together, these results suggest more efficient cognitive organization and processing of anger among abused children.

Behavioral and psychophysiological evidence of maltreated children's differential processing of affective information suggests that early experience influences subsequent emotional development and shapes implicated brain circuitry (Cicchetti, 2002a). The effects observed among maltreated children may reflect experience-dependent processes that involve the fine-tuning of attention, learning, perceptual, and memory systems that facilitate the rapid identification of anger (Pollak, 2009).

For the physically abused child, displays of anger may be the strongest predictor of threat; however, increased sensitivity to anger could result in decreased attention to other emotional cues. Conversely, the neglected child may suffer from an extremely limited emotional learning environment. A solution to the problem created for maltreated children by aberrant emotional signals from parents may be general constraints imposed on children in the form of immature or limited resources, which require young children to filter or select some environmental cues over others (Bjorklund, 1997). This developmentally normal aspect of selective attention suggests that, irrespective of the initial state of the organism, emotional development is contingent on the nature of the input or experiences made available to the child.

In a recent meta-analysis examining emotion recognition and understanding in children with histories of maltreatment (including abuse and/or neglect), maltreated children evidenced poorer performance on a range of indicators (Luke & Banerjee, 2013). Moderator analyses revealed more pronounced deficits in emotion understanding than in emotion recognition. Developmental effects were also found, with poorer performance emerging in early and middle childhood, but not in adolescents and adults. Taken in conjunction with the extant body of research, this meta-analysis confirms that maltreated children evidence deficits in a wide range of skills associated with social understanding. The meta-analysis also highlights the importance of future investigations utilizing a developmental framework and striving to disentangle the effects of specific dimensions of maltreatment on functioning.

FORMATION OF ATTACHMENT RELATIONSHIPS

The establishment of a secure attachment relationship between an infant and his or her caregiver represents a primary task during the first year of life. As development proceeds, attachment theorists have posited that a secure attachment relationship provides a base from which to explore and, ultimately, contribute to the integration of cognitive, affective, and behavioral capacities that influence ongoing and future relationships, as well as the understanding of the self (Bowlby, 1969; Sroufe, 1990). Children construct internal working models of

their attachment figures out of their interactions with their caregivers, their own actions, and the feedback they receive from these interactions. Once organized, these internal working models tend to operate outside of conscious awareness and are thought to be relatively resistant to change. Children formulate their conceptions of how acceptable or unacceptable they are in the eyes of their attachment figures (i.e., their self-image) based on their interactional history with their primary caregivers. Maltreated children experience distortions of the caregiving environment in which internal working models develop. Exposed to insensitive and pathological care, maltreated children develop negative expectations regarding the availability and trustworthiness of others, as well as mental representations of the self as incompetent and unworthy.

There are differences in the expression of internal working models between maltreated and nonmaltreated children (Pickreign Stronach et al., 2011; Toth, Cicchetti, Macfie, Maughan, & Vanmeenen, 2000). For example, Toth, Cicchetti, Macfie, and Emde (1997) found that maltreated children had significantly more negative maternal and self-representations. Furthermore, physically abused children had a greater number of negative representations than children who had experienced other subtypes of maltreatment.

Maltreated children are especially at risk for developing insecure disorganized attachments (see Cyr, Euser, Bakermans-Kranenburg, & van IJzendoorn, 2010 for a meta-analysis). Estimates of the manifestation of disorganized attachment among maltreated children range from 80% to over 90% (Cyr et al., 2010). In the Strange Situation paradigm, Type D infants demonstrate inconsistent and disorganized strategies for coping with separations from and reunions with their caregivers (Hesse & Main, 2006). In addition, these infants display bizarre behaviors such as freezing, stilling, and stereotypies, as well as contradictory behavior directed toward their attachment figures (e.g., approaching their parent with heads averted; Hesse & Main, 2006).

A number of explanations have been proffered to account for the preponderance of disorganized attachment relationships between maltreated children and their primary caregivers. Because inconsistent care is a hallmark of maltreating families (Rogosch et al., 1995), some have hypothesized that the combination of insensitive overstimulation and insensitive understimulation may lead to the contradictory behaviors observed among maltreated infants classified as type D. According to Hesse and Main (2006), attachment disorganization is caused by frightened and frightening (FR) parental behavior, which is believed to have its origins in unresolved parental trauma. Maltreating behaviors are arguably among the most frightening parenting behaviors, placing children in an irresolvable paradox in which their attachment figures are simultaneously their source of safety and their source of fear (Hesse & Main, 2006).

Genetic variation also has been explored as a contributor to the development of disorganized attachment; however, little consistent evidence has emerged for a candidate gene main effect on attachment disorganization (see Luijk et al., 2011). Among maltreated children, Cicchetti, Rogosch, and Toth (2011) found that neither the serotonin transporter gene (5-HTT) nor the dopamine receptor D4 gene (DRD4) were associated with disorganized attachment. They concluded that the anomalous aspects of maltreating parenting may be so robust that they overpower the potential effect of genetic variation in the etiological pathway to attachment disorganization (Cicchetti et al., 2011).

Although attachment is conceptualized as an important stage-salient developmental task during the first year of life, attachment security continues to exert its influence on development across the life span. First, substantial stability in insecure and disorganized patterns of attachment have been observed among maltreated children (Barnett, et al., 1999). Second, disorganized attachment initiates a maladaptive trajectory that heightens the risk for future relational dysfunction, as well as various forms of psychopathology (Hesse & Main, 2006). In a recent 22-year longitudinal investigation of the influence of early infant attachment to mother on emotion regulation in adulthood, attachment status at 18 months predicted neural responding during the regulation of positive affect 20 years later (Moutsiana et al., 2014). These findings demonstrate the powerful influence that early disturbances in attachment can exert across the life span.

DEVELOPMENT OF AN AUTONOMOUS SELF

The development of an integrated sense of self typically occurs in the toddler and preschool years, arising from the successful resolution of previous stage-salient tasks, such as the formation of a secure attachment relationship. Early caregiving experiences serve as the basis for the development of representational models of the attachment figure, as well as corresponding and coherent representational models of the self and of the self in relation to others (Sroufe & Fleeson, 1986). As discussed already, many maltreated infants fail to develop an organized pattern

of attachment, increasing the probability of subsequent perturbations in representational development. Indeed, maltreated children show disruptions in many aspects of the self system.

Aberrations in self-development have been observed as early as 18 months of age, as demonstrated by investigations of visual self-recognition. On the mirror-rouge paradigm, an assessment of the presence of a cognitive self, maltreated and nonmaltreated children are comparable in their capacity to recognize themselves; however, differences emerge with respect to their affective responses (Schneider-Rosen & Cicchetti, 1991). Specifically, maltreated toddlers are more likely than nonmaltreated comparison children to display neutral or negative emotions upon seeing their images in a mirror, which may be interpreted as reflecting negative feelings about the self.

In a longitudinal study of mother–child play and emerging social behavior among infants from maltreating and nonmaltreating families, no group differences were found in infants' play maturity at 13 or 28 months. However, infants from abusing families demonstrated more imitative play than infants from nonmaltreating families, and engaged in less independent play than infants from neglecting and nonmaltreating families, suggesting a delay in emerging social behaviors. At 28 months, once again there were no differences among the groups of children from abusing, neglecting, or nonmaltreating families in child play maturity. However, children from abusing families again engaged in less child-initiated play than the children from neglecting or nonmaltreating families. Evidence that toddlers from abusing families continued to demonstrate less autonomous and self-initiated behaviors suggests that it would be important for early intervention efforts to concentrate on supporting child autonomy and facilitating maternal autonomy support among abusing families (Valentino, Cicchetti, Rogosch, & Toth, 2011).

At 30 months of age, maltreated children demonstrate disruptions in their development of an internal-state lexicon. Even after controlling for receptive vocabulary, maltreated toddlers produce proportionately fewer internal state words, show less differentiation in their attributional focus, and are more context-bound in their use of internal-state language than nonmaltreated comparisons (Beeghly & Cicchetti, 1994). In particular, maltreated children appear to be most reluctant to talk about their negative internal states (Beeghly & Cicchetti, 1994). This result is corroborated by findings that maltreated children may actually inhibit negative affect, especially in the context of their relationships with their caregivers (Lynch & Cicchetti, 1991). Maltreated children may adopt a strategy designed to suppress the expression of their own negative feelings to avoid eliciting adverse responses from their caregivers. Although this approach may be adaptive in the context of a maltreating relationship, it can become maladaptive and lead to social incompetence in other interpersonal contexts. Additionally, the inability of maltreated children to identify and discuss their own distress may play a major role in these children's difficulties in displaying empathy toward their peers.

Negative self-system processes continue to be evident in the preschool period. Maltreated children's narrative representations of parents and of self are more negative than those of nonmaltreated children (Toth, Cicchetti, Macfie, Maughan, & Vanmeenen, 2000). With respect to maltreatment subtype, neglected children have been found to tell narratives containing more negative self-representations than nonmaltreated children, whereas physically abused children possess more grandiose self-representations. These variations by subtype may reflect differences in maltreating experiences. For example, grandiose self-representations may reflect a coping process to maintain personal control in an adverse and threatening home environment, while negative self representations may develop from the chronic absence of attention and validation in a neglecting home (Toth et al., 2000). In a recent investigation of the mediating role of self-system processes in physically abused 4–7-year-old children, subgroups of abused children that differed in their internal working models of relationships were identified (Hawkins & Haskett, 2014). Moreover, these differences were related to child adjustment, with children who had more positive and fewer negative representations evidencing fewer internalizing or externalizing behavior problems.

Maltreated children also show delays in the development of false belief understanding, an important aspect of theory of mind (ToM; Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003). The onset of maltreatment during the toddler period and physical abuse were the features of maltreatment associated with delay in the development of false belief understanding. The centrality of the relation between maltreatment during the toddler period and ToM deficits flows from the importance of self-development for false belief understanding. Internal state language, increased individuation and self-other differentiation, advances in language, conceptual development, and symbolic maturity, and the development of self-conscious emotions all occur during early childhood. Maltreated youngsters manifest difficulties in these aspects of self-development, each of which is a precursor of ToM development. Thus, harsh caregiving, especially early in a child's life, impairs the development of ToM abilities.

Research among school-age maltreated children provides further evidence of self-system deviation. Relative to teacher ratings, younger maltreated children overestimate their own sense of social competence and peer acceptance (Vondra, Barnett, & Cicchetti, 1989). These children may be engaging in defensive processing to increase their sense of competence. In fact, research indicates that the development of a grandiose self, as reflected by inflated social self-efficacy, may serve as a protective factor in the link between maltreatment and internalizing symptomatology (Kim & Cicchetti, 2003). However, as maltreated children mature, they tend to underestimate their competence and are rated by teachers as having lower self-esteem (Vondra et al., 1989).

In another examination of self-system processes in maltreated children, Bennett, Sullivan, and Lewis (2010) studied shame proneness in child neglect. Shame is a highly negative and psychically painful state in which the individual perceives the entire self as defective.

Bennett et al (2010) found that neglected children reported more shame proneness and more depressive symptomatology than nonmaltreated comparison children. Prior investigations of heterogeneous groups of physically abused, sexually abused, and neglected children found elevated levels of shame. Thus, the finding of Bennett et al (2010) extended work on shame to a group of neglected children and are consistent with the results of these earlier studies.

Finally, maltreated children are at risk for developing dissociative features and disorders, perhaps the most severe deficit in the integration of the self (Macfie, Cicchetti, & Toth, 2001a, 2001b; Toth, Pickreign Stronach, Rogosch, Caplan, & Cicchetti, 2011; Valentino, Cicchetti, Rogosch, & Toth, 2008). The link between maltreatment and dissociation has been observed across a wide age range, from preschoolers to adults. Among preschoolers, physical and sexual abuse appear to be most robustly related to dissociative features, with physical abuse emerging as particularly salient for the development of dissociation at clinical levels. Furthermore, longitudinal research indicates that fragmentations in self-organization have been found in sexually abused adolescent girls, who demonstrated deviant splitting between both positive and negative self-references (Calverley, Fischer, & Ayoub, 1994).

PEER RELATIONSHIPS

Consistent with an organizational perspective on development, it has been theorized that the negative relational patterns acquired in a maltreating environment become incorporated into the structures that are pertinent for successful peer relations. Within the context of their early caregiving experiences, maltreated children may develop negative expectations regarding the self and others, as well as a concept of relationships as involving victimization and coercion. These internalizations lead to the selection and structuring of later social interactions, such that familiar relationship patterns are recreated and validated (Sroufe & Fleeson, 1986). Research supports this conceptualization of continuity in relational functioning, as maltreated children have been shown to exhibit a broad range of difficulties in the peer domain.

With regard to peer relations, maltreated children appear to traverse one of two general developmental pathways: (1) withdrawal from peer interactions; or (2) heightened aggression toward peers. In addition to these two generally diverging pathways, a subgroup of maltreated and nonmaltreated children has been identified who demonstrate both aggressive and withdrawn behaviors (Rogosch & Cicchetti, 1994). Among maltreated children, those who evidence high aggression and high withdrawal demonstrate lower social effectiveness than is the case for nonmaltreated youngsters. This unusual pattern of interaction with peers is consistent with the attachment history of maltreated children, which may be related to disorganized representational models and may result in disturbances in social encounters. By revealing indications of a response predisposition to both fight and flight, maltreated children's interactions with peers lends support to the notion that these children have internalized both sides of their relationships with their caregivers (Troy & Sroufe, 1987). Thus, maltreated children's representational models may have elements of both the victim and the victimizer, and these models may be enacted in their peer relationships. The link between maltreatment and aggressive behavior is particularly robust (e.g., Cullerton-Sen et al., 2008; Shields & Cicchetti, 2001). Moreover, aggression appears to largely account for the association between maltreatment and peer rejection (Bolger & Patterson, 2001).

Maltreatment also places children at risk for being victimized by their peers. Schwartz and colleagues (1997) demonstrated that abusive family treatment predicted boys' status as aggressive victims. In an investigation of bullying and peer victimization that included both boys and girls, Shields and Cicchetti (2001) found that maltreated children were more likely than nonmaltreated children to bully other children and more likely to be victimized by their peers. Gender did not act as a moderator, suggesting that maltreated boys and girls are at comparable risk for bullying and victimization (Shields & Cicchetti, 2001).

The effects of maltreatment on disrupted peer group functioning may be explained by perturbations in cognitive

and emotional processes. With regard to social information processing, physically abused children make errors in encoding social cues, exhibit biases toward attributing hostile intent, generate more aggressive responses, and positively evaluate aggression as an appropriate response (Teisl & Cicchetti, 2008). These deficits, in turn, mediate the association between physical abuse and aggression in the peer context. Whereas maladaptive social cognition emerges as a salient explanatory factor for physically abused children, emotion dysregulation appears to play an integral role in the link between maltreatment and aggression for all maltreated groups. Poor emotion regulation also mediates the association between maltreatment and victimization by peers (Shields & Cicchetti, 2001; Teisl & Cicchetti, 2008).

In addition to their difficulties in the larger peer group, maltreated children demonstrate weaknesses in developing and maintaining friendships (Parker & Herrera, 1996). Maltreated children report less caring and validation and more conflict and betrayal in their friendships than nonmaltreated children. In an observational setting, Parker and Herrera (1996) found that friendship dyads containing a physically abused adolescent displayed more conflict and less intimacy than dyads without an abused adolescent. Alternatively, having friends may serve as an important buffer for maltreated children against feelings of loneliness, low self-esteem, and victimization by the larger peer group.

ADAPTATION TO SCHOOL

Adaptation to school represents the major extra-familial environment in which children are exposed to a novel group of unfamiliar peers and adults. As such, it presents both a challenge to functioning and an opportunity to break free of patterns that have been established within a maltreating home. However, because an organizational perspective suggests that children's experiences in the home provide a foundation on which future transitions are built, probabilistically children who have been maltreated are at risk for failure in the school environment.

Abused and neglected children are at considerable risk for academic failure (Eckenrode, Laird, & Doris, 1993). Maltreated children perform worse on standardized tests, achieve lower grades, and are more likely to repeat a grade. Furthermore, they score lower on tests that assess cognitive maturity. Several studies have found that maltreated children have an increased risk of attaining lower levels of educational achievement and intellectual performance, as well as higher rates of truancy, school expulsion, and grade retention (Lansford, Dodge, et al., 2002; Perez & Widom, 1994). However, it is unclear whether these difficulties can be attributed to cognitive or motivational issues. With regard to motivation, Aber and Allen (1987) proposed that effectance motivation, which is the intrinsic desire to deal competently with one's environment, and successful relations with novel adults are important factors related to children's ability to adapt to their first major out-of-home environment. As such, they defined the concept of secure readiness to learn, as characterized by high effectance motivation and low dependency, as a representation for the ability to establish secure relationships with adults while feeling free to explore and engage in the environment in ways that promote cognitive development. Maltreated children score lower on secure readiness to learn than do nonmaltreated children, which is consistent with what one might expect given the insecurity or atypicality that pervades maltreated children's attachment histories. In efforts to identify those factors that might further mitigate against the impact of abuse on school performance, Trickett, McBride-Chang, and Putnam (1994) conducted an investigation with adolescent girls who had been sexually abused. Previous abuse was found to predict poorer social competence, impaired competence in learning, and lower overall academic performance. Higher levels of anxious depression, bizarre destructiveness, and dissociation were also present in victims of sexual abuse. Importantly, cognitive ability and perceived competence emerged as mediators of overall academic performance and achievement, whereas dissociative and destructive behaviors exacerbated the children's level of school success. Okun, Parker, and Levendosky (1994) also sought to examine the independent and interactive effects of physical abuse, recent exposure to additional life events such as death or illness, and social disadvantage on children's social, cognitive, and affective adjustment during middle childhood. Abused children were found to evidence difficulties in three areas: peer adjustment, self-perception, and depression. Further analyses identified unique effects of negative events and socioeconomic disadvantage on children's adjustment. Additive contributions of abuse status and socioeconomic disadvantage also predicted behavior problems at school and in the home.

In yet another investigation of links between relationship patterns and school adaptation, Toth and Cicchetti (1996) found that the security that a child experienced in relation to his or her mother, in interaction with maltreatment status, significantly affected school functioning. Nonmaltreated children who reported secure patterns of relatedness to their mothers exhibited less externalizing

behavior problems, more ego resilience, and fewer school risk factors (e.g., poor attendance, poor achievement test performance, suspensions, failure in 50% of courses, and grade retention) than did maltreated children who reported insecure patterns of relatedness. Moreover, nonmaltreated children with secure patterns of relatedness to their mothers exhibited more positive school adaptation than did nonmaltreated children who reported insecure patterns of relatedness.

In an investigation of more than 200 low-income children, impairments in academic engagement, social skills, and ego resiliency were found to be present in children with histories of maltreatment (Shonk & Cicchetti, 2001). Maltreated children manifested multiple forms of academic risk and exhibited more externalizing and internalizing behavior problems. The effects of maltreatment on academic adjustment were partially mediated by academic engagement, while maltreatment's effects on behavior problems were fully mediated by social competencies and ego resiliency.

Lansford et al. (2002) conducted a 12-year prospective study of the long-term consequences of early childhood physical maltreatment on academic, behavioral, and psychological problems in adolescence. These investigators found that adolescents who were maltreated early in life were absent from school more often and were less likely to anticipate attending college compared with nonmaltreated adolescents. Maltreated adolescents also exhibited higher levels of aggression, anxiety/depression, social withdrawal, dissociation, PTSD symptoms, and thought problems than those evidenced by nonmaltreated adolescents. The participants in the Lansford et al. (2002) study were recruited from a randomly selected sample of children from the community. The results of the Lansford et al. (2002) investigation demonstrate that undetected maltreatment in adolescents who are not receiving protective services warrants identification and intervention.

Finally, Manly, Oshri, Lynch, Herzog, and Wortel (2013) examined the impact of child neglect during the first 4 years of life on adaptation to school during kindergarten and first grade in the context of neighborhood poverty (NP). Processes related to the development of school competencies were examined, including the mediational role of cognitive functioning and ego-resiliency (ER) in shaping children's school outcomes. A total of 170 low-income urban children were followed prospectively for 2 years (ages 4–6). Results indicated that neglected children had significantly lower scores on kindergarten classroom behavior and first-grade academic performance than nonneglected children. Children's cognitive performance at age 4, controlling for maternal intelligence quotient, mediated the relation between severity of neglect and children's behavior in kindergarten as well as their academic performance in first grade. Moreover, severity of neglect was related to children's ER at age 4. However, additional ecological adversity in the form of NP moderated the link between ER and classroom behavior, such that at lower levels of poverty, ER mediated the relation between severity of neglect and school adaptation. Conversely, when NP was extreme, the effects of ER were attenuated and ER ceased to predict behavioral performance in kindergarten. Preventive interventions should focus on reducing the occurrence of child neglect as well as assisting families with promoting cognitive and coping skills when children have experienced neglect. Ameliorating negative environments for children in extreme poverty also is critical to reduce risks of school failure.

Now that we have addressed stage-salient aspects of the sequelae of maltreatment, we next direct our attention toward memory, personality organization, and molecular genetic and neurobiological domains.

EFFECTS OF MALTREATMENT ON MEMORY

There are a number of reasons why maltreatment might be expected to alter basic memory processes (Howe, Cicchetti, & Toth, 2006). For example, the experience of stress associated with living in a maltreating home may potentiate neurological changes in the structures implicated in encoding and storing information. Observed delays in intellectual functioning, executive functioning, and language may also play roles in potential memory deficits. Furthermore, maltreated children are at risk for the development of posttraumatic stress disorder (PTSD) and dissociation, both of which have been linked to memory distortion among adults.

For the most part, hypothesized adverse effects of maltreatment on memory have not been empirically supported. Although the field is still in its infancy, many studies show no differences between maltreated and nonmaltreated children in terms of basic memory processes. Maltreated children are comparable to their nonmaltreated peers with respect to basic recall and recognition, as well as in their degree of suggestibility to misinformation (Eisen, Goodman, Qin, Davis, & Crayton, 2007; Howe, Cicchetti, Toth, & Cerrito, 2004; Porter, Lawson, & Bigler, 2005). Moreover, Beers and DeBellis (2002) did not find any differences in basic memory processes between maltreated children with PTSD and normative comparison youth.

Similarity in memory functioning is evident in studies involving both neutral and emotionally laden stimuli (Howe et al., 2004; Howe, Toth, & Cicchetti, 2011). In addition, differences in memory processes fail to emerge with respect to ecologically valid and stressful information (Eisen et al., 2007). For example, Eisen and colleagues (2007) tested memory for an ano-genital exam that occurred in the context of an inpatient abuse assessment. Memory accuracy and suggestibility did not vary by abuse status.

Although no between-group differences have been discovered, within-group investigations suggest variation in basic memory processes as a function of maltreatment subtype (Toth & Cicchetti, 1998). For example, in a depth-of-processing incidental recall task of self-referent information, neglected children demonstrated a greater proportion of negative false recall and less positive false recall than did the abused children, suggesting greater memory inaccuracy among neglected children (Valentino, Cicchetti, Rogosch, & Toth, 2008). In another study by Valentino, Cicchetti, Rogosch, and Toth (2008), subtype differences emerged for memory of maternal-referent information, such that abused children exhibited lower recall compared with neglected children. These findings are suggestive of defensive processing of information that activates the attachment system as a protective mechanism among abused children. Relatedly, Lynch and Cicchetti (1998b) examined the links among trauma, representational models of caregivers, and children's memory for mother-referent information. Results were consistent with the hypothesis that experiences of trauma and representational models of caregivers are associated with differences in the way children process and retrieve information about positive and negative mother-attribute words. Specifically, victimized children with insecure representational models of their caregivers recalled the highest proportion of negative mother stimuli. Finally, Cicchetti, Rogosch, Howe, and Toth (2010) showed that children with a history of neglect and/or emotional maltreatment and low cortisol evinced increased levels of memory inaccuracy.

In addition to subtype differences in basic memory processes, Valentino et al. (2009) revealed subtype-specific variation in autobiographical memory for nontraumatic events. Abused children's memories were more overgeneral than the memories of neglected and nonmaltreated children. Retrieving memory in generic form may reflect a strategy for avoiding negative affect associated with painful memories. Consistent with a dynamic skills framework, defensive, traumatogenic responses become more habitual and generalized over time, resulting in less integration of memories.

PERSONALITY ORGANIZATION AND PSYCHOPATHOLOGY

Child maltreatment ushers in motion a probabilistic path of epigenesis for abused and neglected children that often results in a profile of relatively enduring vulnerability factors that increase the probability of the emergence of maladaptation and psychopathology. Indeed, consistent with the concept of multifinality, maltreated children develop a broad range of psychopathological outcomes.

In general, the literature indicates that exposure to child maltreatment increases the risk for greater lifetime prevalence of high levels of many psychopathological symptoms and disorders (Scott, Smith, & Ellis, 2010). These include, but are not restricted to, mood and anxiety disorders (Kim & Cicchetti, 2006; Widom, DuMont, & Czaja, 2007), dissociation and suicidal behavior (Yates, Carlson, & Egeland, 2008), substance use disorders (Rogosch, Oshri, & Cicchetti, 2010; Widom, Marmorstein, & White, 2006), disruptive and antisocial behaviors (Egeland, Yates, Appleyard, & van Dulmen, 2002; Widom & Maxfield, 2001) and psychosis (Arseneault et al., 2011; Toth, Pickreign Stronach, Rogosch, Caplan, & Cicchetti, 2011).

Toth, et al. (2011) conducted the first prospective investigation that demonstrates the deleterious consequences of maltreatment on children's ability to think coherently. Maltreated and nonmaltreated school-age children individually participated in a story game designed to elicit speech samples. Children were instructed to listen to two recorded stories and prompted to retell the stories. Children were then asked to create their own story from possible topics. Maltreated children exhibited more illogical thinking than nonmaltreated children, and the level of illogical thinking in maltreated children was in the clinically pathological range. The occurrence of multiple subtypes of maltreatment and the chronicity of the maltreatment also were associated with illogical thinking. Although interventions provided to maltreated children typically address behavior problems and maladaptive cognitive processing, less attention is directed toward ascertaining whether the thinking of these children reflects actual thought distortions. Efforts to assess illogical thinking and to intervene to modify these patterns before they become more consolidated might ultimately help to decrease the risk for future serious psychopathology, including bipolar disorder and schizophrenia.

Longitudinal research by Kaplow and Widom (2007) suggests that the age of onset of maltreatment may be an important factor in differentiating the effects of maltreatment on later mental health outcomes. In particular, individuals who were maltreated earlier in life (i.e., before the age of 6 and/or during the infancy or preschool years) evinced higher levels of internalizing problems as adults, whereas those who were older at the time of maltreatment went on to develop more externalizing outcomes in adulthood. The preschool years emerged as a potential sensitive period during which maltreatment may have an especially robust effect, potentiating the development of both internalizing and externalizing disorders (i.e., anxiety, depression, antisocial personality disorder).

Rogosch, Oshri, and Cicchetti (2010) tested a longitudinal developmental cascade model of associations among child maltreatment, internalizing and externalizing psychopathology, social competence, and cannabis abuse and dependence (CAD) symptoms. Children were assessed at four developmental periods: age 7 to 9, 10 to 12, 13 to 15, and 15 to 18. Results indicated significant paths from child maltreatment to early externalizing and internalizing problems and social competence, as well as to CAD symptoms in adolescence. Youth CAD symptoms were primarily related directly to child maltreatment and externalizing problems. Childhood internalizing symptoms contributed to later childhood decreases in social competence, which predicted increases in later externalizing problems.

In a longitudinal investigation, Oshri, Rogosch, and Cicchetti (2013) found that a personality typology derived from the California Q-set Items representative of ego resiliency and ego control (Block & Block, 1969, Block & Block, 1980) was associated with child maltreatment and predicted adolescent psychopathology. Maltreated children were significantly more likely than nonmaltreated children to be classified in the overcontrolled and undercontrolled profiles compared with the resilient profile. The undercontrolled profile reported higher cannabis symptoms and externalizing problems in adolescence than the other two profiles. The overcontrolled group showed the highest levels of internalizing and lowest levels of alcohol problems compared with the other profiles. Person-centered mediation analyses showed that the overcontrolled and the undercontrolled profiles significantly and differentially mediated the link between number of child maltreatment subtypes and the development of adolescent psychopathology.

Manly, Kim, Rogosch, and Cicchetti (2001) found that the severity of emotional maltreatment in the infancy and toddlerhood period and physical abuse during the preschool period predicted externalizing behavior and aggression. Severity of physical neglect, particularly when it occurred during the preschool period, was associated with internalizing symptomatology and withdrawn behavior. Additionally, maltreatment during the school-age period contributed significant variance after earlier maltreatment was controlled. Chronic maltreatment, especially with onset during infancy and toddlerhood or preschool periods, was linked with more maladaptive outcomes (Manly et al., 2001). The significance of chronic maltreatment attests to one of the tenets of the organizational perspective on development, in terms of links between adversity across multiple developmental periods and detrimental impact on later functioning. An examination of the interplay among developmental timing, severity, and subtype in relating to adaptation of maltreated children in the Manly et al. (2001) study provided a more clearly delineated picture of multifinality of outcomes within the phenomenon of maltreatment than a global categorization could provide.

Keiley, Howe, Dodge, Bates, and Pettit (2001) conducted a longitudinal study from kindergarten (roughly, ages 4 to 5) through eighth grade (age 12). Growth modeling was used to determine the developmental trajectories of mother-reported and teacher-reported internalizing and externalizing behaviors for two groups of physically abused children—early-harmed (pre-age 5), later-harmed (after age 5) and a group of nonharmed children. Children who experienced early physical harm from significant adults in their lives were more likely to experience adjustment problems in early adolescence. Over multiple domains, early physical maltreatment was related to more negative sequelae than the same type of maltreatment occurring at later periods. In addition, the fitted growth models revealed that the early-harmed group exhibited somewhat higher initial levels of teacher-reported externalizing problems in kindergarten and significantly different rates of change in these problem behaviors than other children, as reported by mothers over the 9 years of this study. The early-harmed children also were seen by their kindergarten teachers as exhibiting higher levels of internalizing behavior. The later-harmed children were seen by their teachers as increasing their externalizing problem behaviors more rapidly over the 9 years than did the early- or nonharmed children. Like those of Manly et al. (2001), these findings indicate that the timing of maltreatment is a salient factor in examining the developmental effects of physical harm.

Maltreatment has also been implicated in the etiology of personality disorders. Given that personality disorders do not emerge spontaneously at the age of 18, the age

cutoff established in the psychiatric nomenclature, some researchers have adopted a developmental psychopathology approach by seeking to identify early precursors and processes that confer vulnerability to later personality pathology (Cicchetti & Crick, 2009). Consistent with this approach, Rogosch and Cicchetti (2005) found that maltreated children exhibit higher mean levels of potential precursors to borderline personality disorder (e.g., emotional lability, conflictual relationships with adults and peers, relational aggression, self-harm) than do nonmaltreated comparisons. Bemporad, Smith, Hanson, and Cicchetti (1982); Hecht, Cicchetti, Rogosch, and Crick (2014); Widom, Czaja, and Paris (2009); and Zanarini (2000), among others, have found that maltreatment is associated with higher levels of borderline personality symptoms. An examination of early risk factors for paranoid personality identified a history of child maltreatment as a predictor, alongside significant behavioral disturbances and negative peer relationships (Natsuaki, Cicchetti, & Rogosch, 2009). In a prospective investigation of personality organization, Rogosch and Cicchetti (2004) found that 6-year-old maltreated children exhibited lower agreeableness, conscientiousness, and openness to experience, as well as higher neuroticism than did nonmaltreated children. Analysis of personality clusters revealed that the majority of nonmaltreated children were represented in the adaptive Gregarious and Reserved personality clusters, whereas maltreated children largely accounted for the makeup of less adaptive personality profiles (i.e., undercontroller, overcontroller, and dysphoric). Furthermore, longitudinal stabilities were observed across ages 7, 8, and 9, suggesting continuity in maltreated children's personality liabilities.

GENE–ENVIRONMENT INTERACTION

Research in molecular genetics suggests that maltreated children's risk for psychopathology is not inevitable. GxE occurs when the effect of exposure to an environmental factor on a behavioral, health, or biological phenotype is conditional upon a person's genotype or, conversely, when the genotype's effect is moderated by the environment (Moffitt, Caspi, & Rutter, 2005). In the past decade, our understanding of the role of the environment and its interaction with genes has been further clarified, with reciprocal coactions between the environment and the individual resulting in differential expression of genetic material. Environmental conditions may interact with an individual's genetic makeup to alter processes such as the timing of the initiation of transcription and translation for a specific gene, the direction for which it does so, or whether the gene will ultimately be expressed.

In a landmark epidemiological study, Caspi and colleagues (2002) followed a large sample of male children from birth to adulthood to ascertain why some maltreated children grow up to develop antisocial personality disorder, whereas others do not. Results revealed that a functional polymorphism in the promoter of the monoamine oxidase A (MAOA) gene moderated the effect of child maltreatment. The MAOA gene is located on the X chromosome and encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, rendering them inactive. Maltreated children with the genotype conferring high MAOA activity were significantly less likely to develop antisocial behavior problems than maltreated children with the low MAOA-activity genotype. In addition, maltreatment and nonmaltreatment groups did not differ on MAOA activity, suggesting a lack of an evocative gene-environment correlation as an explanation for the GxE findings. Many, but not all, subsequent studies have been successful in replicating Caspi et al.'s original findings and in extending them downward to samples of children and adolescents (Kim-Cohen et al., 2006).

Byrd and Manuch (2014) conducted a meta-analysis of studies testing the interaction of MAOA genotype and childhood genotype on antisocial outcomes in predominantly nonclinical samples. Consistent with the findings of Caspi et al. (2002), for males early maltreatment predicted antisocial outcomes more strongly for low-activity, relative to high-activity, MAOA genotype. In contrast, for females MAOA did not interact with early life adversities, whereas maltreatment alone predicted antisocial behaviors in females who had the high-activity MAOA genotype.

In another seminal study, Caspi et al. (2003) examined the prospective link between maltreatment and depression. Caspi et al. (2003) found that genetic variation in a functional polymorphism (5-HTTLPR) in the promoter region of the serotonin transporter gene (5-HTT) plays a moderating role. The particular serotonin gene variants (s/s, s/l, and l/l) affect the amount of serotonin transporter protein that is produced. The serotonin transporter is a protein that is critical to the regulation of serotonin function in the brain, through terminating the action of serotonin in the synapse via reuptake. The serotonin transporter gene plays a pivotal role in brain development and in individual differences in mood and behavioral regulation. Thus, 5-HTTLP was an excellent candidate gene for Caspi et al.'s (2003) research. Adults carrying the *s* allele (s/s or s/l) were

found to exhibit more depressive symptoms, diagnosable depression, and suicidality in response to stressful life events than individuals homozygous for the l (l/l) allele. In addition, an examination of early life stress showed that a history of child maltreatment predicted depression in adulthood, but only among *s* carriers.

Whereas work in behavior genetic and in molecular genetic research using genome-wide association studies did not examine GxE, the Caspi et al. (2002, 2003) investigations generated much excitement because they suggested that the combination of molecular genetic elements and well-measured environments and phenotypes could not only increase our understanding of the development of psychopathology, but also uncover additional genes that play roles in the etiology of psychopathology that would not have been discovered in main effects molecular genetic studies. GxE research, however, has not been without critics (Duncan & Keller, 2011; Duncan, Pollastri, & Smoller, 2014; Hewitt, 2012; Keller, 2014). Some of the most notable emanated from the findings of the meta-analysis conducted by Risch et al. (2009) in which they concluded that 5-HTTLPR does not moderate the relation between stress and depression in contrast to the findings of Caspi et al. (2003).

In response, Caspi et al. (2010) evaluated multiple lines of evidence for the 5-HTT stress-sensitivity hypothesis. The evidence was drawn from experimental neuroscience, nonhuman primate research, and studies of genetically engineered 5-HTT mutations in rodents and dispels some misconceptions about GxE research. Relatedly, Karg, Burmeister, Shedden, and Sen (2011) critically reviewed two meta-analyses that examined the interaction between 5-HTTLPR and stress in the development of depression (Munafo, Durrant, Lewis, & Flint, 2009; Risch et al., 2009). Contrary to Risch's meta-analysis, Karg and colleagues (2011) found strong evidence in support of the hypothesis that 5-HTTLPR moderates the relationship between stress and depression.

We next selectively review GxE research on maltreated children, adolescents, and adults who report having experienced maltreatment in their childhoods. We focus on studies that examined the most commonly studied candidate genes in GxE research on child maltreatment, namely 5-HTTLPR, corticotropin releasing hormone receptor gene (CRHR1), and MAOA.

Kaufman et al. (2004) found that maltreated children with the s/s genotype of 5-HTTLPR evinced depression scores that were almost twice as high as the depression scores of maltreated children with the s/l and l/l genotypes. Kaufman et al. (2006) replicated these findings in a subsequent study, the results of which revealed a significant three-way interaction between brain derived neurotrophic factor (BDNF) genotype, 5-HTTLPR, and maltreatment in predicting heightened levels of depression. (see also Grabe et al., 2012, for similar results). In another instance of gene–gene–environment interaction (GxGxE), Cicchetti, Rogosch, and Sturge-Apple (2007) found that adolescents with a history of sexual abuse who carried both the s/s genotype and the low MAOA-activity genotype evinced higher levels of depression symptomatology than sexually abused adolescents with alternative combinations of the variants of the 5-HTT and MAOA genes.

Cicchetti and Rogosch (2014) examined genetic moderation of the effects of child maltreatment on depression and internalizing symptoms in a large sample of 7- to 12-year-old (mean age—10) low-income maltreated and nonmaltreated African American children (N = 1,096). Lifetime child maltreatment experiences were independently coded from Child Protective Services records and maternal report. Child depression and internalizing problems were assessed in the context of a summer research camp by self-report on the Children's Depression Inventory and adult counselor report on the Teacher Report Form. DNA was obtained from buccal cell or saliva samples and genotyped for polymorphisms of the following genes: serotonin transporter linked polymorphic region (5-HTTLPR), brain-derived neurotrophic factor (BDNF), norepinephrine transporter, and corticotropin releasing hormone receptor 1. Analyses of covariance with age and gender as covariates were conducted with maltreatment status and respective polymorphism as main effects and their GxE interactions. Maltreatment consistently was associated with higher Children's Depression Inventory and Teacher Report Form symptoms. The results for child self-report symptoms indicated a GxE interaction for BDNF and maltreatment (cf. Kaufman et. al., 2006). In addition, BDNF and triallelic 5-HTTLPR interacted with child maltreatment in a GxGxE interaction. Analyses for counselor report of child anxiety/depression symptoms on the Teacher Report Form indicated moderation of child maltreatment effects by triallelic 5-HTTLPR. These effects were elaborated based on variation in developmental timing of maltreatment experiences. Norepinephrine transporter was found to further moderate the GxE interaction of 5-HTTLPR and maltreatment status, revealing a GxGxE interaction. This GxGxE was extended by consideration of variation in maltreatment subtype experiences. Finally, GxGxE effects were observed for the co-action of BNDF and the corticotropin releasing hormone receptor 1 haplotype. The findings illustrate the variable influence

of specific genotypes in GxE interactions based on variation in maltreatment experiences and the importance of a multigenic approach for understanding influences on depression and internalizing symptoms among African American children.

Differential pathways may suggest implications for preventing depression in African American children and for intervening with individuals where depression has occurred. Depression among African Americans children and adolescents is an important public health concern (Byck, Bolland, Dick, Asbeck, & Mustanski, 2013). In addition, distressed African American youth are less likely to receive treatment (Carson, Cook, & Alegria, 2010; Kodjo & Audinger, 2004). Moreover, racial discrimination contributes to the development of depressive symptoms (English, Lambert, & Ialingo, 2014). Thus cultural considerations will be important in any intervention initiatives. The design and implementation of effective intervention approaches will be advanced by attention to the diversity of multilevel processes involved in differential pathways to depressive outcomes among African American children and adolescents.

Banny, Cicchetti, Rogosch, Oshri, and Crick (2013) examined child maltreatment, peer victimization, and 5-HTTLPR as predictors of depressive symptomatology. Path analyses revealed that both relational and overt victimization mediated the association between child maltreatment and depressive symptoms. Bootstrapping procedures used to test moderated-mediation demonstrated that genotype moderated the indirect effects of relational and physical victimization on child depressive symptoms, such that victimized children with the l/l genotypic variant of 5-HTTLPR were at increased risk for depressive symptoms compared with victimized children carrying a short allele.

A number of investigations have demonstrated that individuals who had been maltreated possessed a significantly greater risk of experiencing suicidal behaviors (i.e., suicidal ideation; suicide attempts; completed suicide) than comparable samples of nonmaltreated persons from the same socioeconomic status. These studies have demonstrated that the experience of sexual and physical abuse are significant risk factors for suicidal behaviors in adolescents and adults (Brodsky & Stanley, 2008). Cicchetti, Rogosch, Sturge-Apple, and Toth (2010) investigated whether genotypic variation of 5-HTTLPR moderated the effect of maltreatment on suicidal ideation in a sample of low-income maltreated and nonmaltreated school-age children. Higher suicidal ideation was found among maltreated than nonmaltreated children. Children with one to two maltreatment subtypes and s/s or s/l genotypes had higher suicidal ideation than those with the l/l genotype; suicidal ideation did not differ in nonmaltreated children or in children with three to four maltreatment subtypes based on 5-HTTLPR variation. Results were applicable to emotionally maltreated/neglected and to physically abused/sexually abused children. Interestingly, for the more extensively maltreated (i.e., those with three to four subtypes), children expressed higher levels of suicidal ideation, irrespective of genetic variation. Thus, the pathogenic relational environment of children who experienced extensive maltreatment appears to have predominated over genotypic variation in the risk for, or protection against, suicidal ideation.

In a final illustration of 5-HTTLPR as a moderator of depression in maltreated children, Uher et al. (2011) conducted a prospective longitudinal examination of G×E interaction in two large samples, one in New Zealand, and one in England. The former sample was followed until age 32, the latter until age 40. The prospective nature of this analysis is unique in that most studies of 5-HTTLPR × maltreatment on depression have been cross sectional. Uher and colleagues (2011) found that, in both longitudinal cohorts, statistical analyses of GxE interactions revealed positive results for depression that runs a persistent course in adulthood, but not for single-episode depression. Individuals with two short 5-HTTLPR alleles and child maltreatment had elevated risk of persistent but not single-episode depression. Thus, research that does not distinguish persistent course and single-episode depression may underestimate GxE effects and could explain some of the nonreplications found in GxE research (Duncan & Keller, 2011).

CRHR1 is another gene that has been shown to be a viable candidate gene that influences vulnerability to depression. Corticotropin-releasing hormone is the key activator of the hypothalamic-pituitary-adrenal (HPA) axis, binding to receptors that initiate the stress response, culminating with release of cortisol from the adrenal cortex. Overactivity of the HPA-axis has been shown to be partially caused by hyperactivity of CRH neurons. Additionally, CRH activity at the CRH type 1 receptor (CRHR1) in extra-hypothalamic regions also are thought to bring about internalizing disorders, such as depression and anxiety (Bradley et al., 2008). Published investigations to date suggest that hyperactivity of the HPA axis may be a function of early life stress (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Heim et al., 2008).

Bradley and colleagues (2008) conducted a study to test the hypothesis that genetic polymorphisms that alter

the functionality of CRHR1 may moderate the effects of child maltreatment on adult depression. These investigators found that a G×E interaction was important for the expression of depressive symptoms, or lack thereof, in adults who possess CRHR1 risk or protective alleles in conjunction with a history of child maltreatment. In keeping with Moffitt et al. (2005), the findings of Bradley et al. (2008) underscore the importance of taking the environment into account in genetic association and linkage studies that otherwise might miss many important genetic variants that are involved in the etiology of complex diseases. An extension and partial replication of the Bradley et al. (2008) study was conducted by Polanczyk et al. (2009). As in the investigation of Bradley et al. (2008), a CRHR1 haplotype was shown to exert a protective effect against depression in adults who were maltreated in their childhood; however, the replication only occurred when a retrospective, but not a prospective, measure of child maltreatment was used. The authors speculated that the protective effect of the CRHR1 haplotype was likely related to its function in consolidating memories of emotionally arousing experiences.

DeYoung, Cicchetti, and Rogosch (2011) examined the influence of CRHR1 variation on neuroticism, in interaction with child maltreatment, in a large sample of maltreated children and a well-matched nonmaltreated comparison group. Neuroticism, one of the Big Five personality characteristics, is a risk factor for mood and anxiety disorders. The biological systems involved in neuroticism are thus of great import in the etiology of internalizing disorders. Genes that are involved in the systems that are stress responsive, such as CRHR1, are thus important candidates for studies of the genetic moderation of the effects of major stressors like maltreatment.

DeYoung et al. found that the CRHR1 TAT haplotype significantly moderated the association of child maltreatment with neuroticism. Having two copies of the TAT haplotype of CRHR1 was associated with higher levels of neuroticism among maltreated children relative to nonmaltreated children, with the exception of sexually abused children and children who had experienced 3 or 4 types of maltreatment. The findings of this study are also important because they contribute to a growing body of evidence that variation in the CRHR1 gene moderates the effects of child maltreatment.

Research reviewed shows that GxE interactions mediating depressive symptomatology have been identified in both the stress-sensitive serotonergic (5-HTTLPR) and corticotropin-releasing hormone (CRHR1) systems. In an innovative investigation of African Americans of low-SES, Ressler et al. (2010) sought to determine whether the effects of child maltreatment are moderated by GxGxE interactions between CRHR1 and 5-HTTLPR polymorphisms. Ressler and colleagues first replicated the interaction of child maltreatment and 5-HTTLPR on lifetime major depressive disorder. They next replicated earlier work in their laboratory by Bradley et al. (2008), once again finding that an interaction between a CRHR1 haplotype and child maltreatment predicted current depressive symptoms. Furthermore, Ressler et al. (2010) discovered that a G (5-HTTLPR s allele) x G (CRHR1 haplotype) interaction with child maltreatment predicted current depressive symptoms.

MAOA is a mitochondrial enzyme that is expressed predominantly in catecholaminergic neurons and is responsible for the degradation of a variety of biogenic amines (Caspi et al., 2002). A well-characterized *u*-VNTR polymorphism exists in the promoter region of the MAOA gene that is known to affect gene expression. The number of tandem repeats of this polymorphism (i.e., 2, 3, 5 vs. 3, 5, 4) determines the efficiency (i.e., high activity, low activity) with which MAOA is transcribed and ultimately produced within individuals (Caspi et al., 2002).

Weder et al. (2009) examined a GxE interaction of MAOA genotype and maltreated children. The maltreated children represented the extreme on a continuum of adversity. They were assessed at a highly stressful time—shortly after they had been removed from their parents' care because they had been physically abused. A total trauma index score was derived based on inclusion of physical abuse, sexual abuse, domestic violence exposure, multiple out-of-home placements, and community violence exposure. Scores were rated from mild to moderate to extreme. Weder et al. (2008) detected a significant interaction between exposure to moderate levels of trauma and the low activity MAOA genotype in conferring increased risk for aggression. Children who were exposed to extreme levels of trauma had high aggression scores regardless of MAOA genotype. Extreme levels of trauma appear to overshadow the effects of MAOA genotype, especially during a period when traumatized children are experiencing acute stress. The findings of Weder and colleagues are consistent with those of Caspi et al. (2002).

To provide a final example, as in Caspi et al.'s (2002) original study, Cicchetti, Rogosch, and Thibodeau (2012) conducted an investigation to examine a G×E interaction of MAOA genotype and child maltreatment on early signs of antisocial behavior in school-age children. Because the MAOA gene is sex-linked and located on the X chromosome, males have one allele on the X chromosome.

In contrast, females have an MAOA allele on each X chromosome; however, only one of the alleles is active. Consequently, ambiguity results in determining which allele is active among females who are heterozygous for MAOA activity level alleles (i.e., high-low or low-high activity). Thus, analyses involving MAOA were conducted only among boys.

For lifetime antisocial behaviors, Cicchetti et al. (2012) did not find MAOA to contribute to models of antisocial behavior as reported by peers or adults beyond the influence of maltreatment effects. The GxE interaction effect was significant. Among nonmaltreated children, those with low activity MAOA genotypes had significantly higher observer-reported symptoms of antisocial behavior than those with high-activity MAOA genotypes. Moreover, maltreated children in the low-activity MAOA group had higher self-reported antisocial behavior than nonmaltreated children. A similar pattern of findings was observed for child self-report of antisocial behavior in the past 6 months, as the GxE interaction was significant. Specifically, maltreated children with low MAOA-activity genotypes had higher recent antisocial behavior than those with high activity genotypes. No significant differences were found among nonmaltreated children based on the MAOA genotype group. Furthermore, maltreated children with low MAOA activity genotypes had higher-level self-reported antisocial symptoms than nonmaltreated children. The risk for antisocial behavior associated with child maltreatment was reduced among children with high MAOA-activity genotypes. The findings of Cicchetti et al. (2012) are consistent with those reported by Caspi et al. (2002) and Weder et al. (2008) (for a meta-analysis, see Kim-Cohen et al., 2006).

Cicchetti, Rogosch, Hecht, Crick, and Hetzel (2014) conducted an investigation in which gene-environment-gender effects in predicting child borderline personality disorder among maltreated and nonmaltreated low-income children (N = 1,051) were examined. Adult-, peer-, and self-report assessments of borderline precursor indictors were obtained, as well as child self-report on the Borderline Personality Features Scale for Children. Genetic variants of the oxytocin receptor genotype and the FK506 binding protein 5 gene CATT haplotype were investigated. Children who self-reported high levels of borderline personality symptomology were differentiated by adults, peers, and additional self-report on indicators of emotional instability, conflictual relationships with peers and adults, preoccupied attachment, and indicators of self-harm and suicidal ideation. Maltreated children also were more likely to evince many of these difficulties relative to nonmaltreated children. A series of analyses of covariance, controlling for age and ancestrally informative markers, indicated significant maltreatment–gene–gender (MxGxG) three-way interactions. Consideration of the maltreatment parameters of subtype, onset, and recency expanded understanding of variation among maltreated children. The three-way interaction effects demonstrated differential patterns among girls and boys. Among girls, the gene-environment interaction was more consistent with a diathesis-stress model (Gottesman & Shields, 1972), whereas among boys a differential-sensitivity (Belsky et al., 2007; Ellis et al., 2011) interaction effect was indicated. Moreover, the genetic variants associated with greater risk for higher borderline symptomatology, dependent on maltreatment experiences, were opposite in girls compared with boys. The findings have important implications for understanding variability in early predictors of borderline personality.

MALTREATMENT AND ALLOSTATIC LOAD

In addition to GxE effects, child abuse and neglect are also implicated in the disruption of biological systems, including neuroendocrine functioning, immunological functioning, health outcomes, and neurobiology. The concepts of allostasis and allostatic load (AL) provide an integrative framework for understanding how exposure to chronic stress, such as child maltreatment, potentiates long-term liabilities for physical and mental health (Danese & McEwen, 2012). Allostasis is a process that involves the activation of multiple interactive physiological systems (e.g., HPA, sympathetic-adrenal-medullary axes, cardiovascular, immune, and metabolic systems). In the short term, mobilization of these systems exerts a protective effect on the body and promotes an adaptive response to stress; however, with chronic activation, physiological reactions to stress become less efficient in protecting the individual. Ensuing damage to the body results in allostatic overload, which, in turn, contributes to changes in brain structure and function and the development of various disease states.

Shonkoff, Boyce, and McEwen (2009) differentiated among three types of stress that children may experience. Normative and routine life challenges that are embedded within a context of protective factors, such as positive, supportive relationships, are considered tolerable stress. Alternatively, toxic stress involved conditions in which the child is exposed to chronic, severe, and prolonged stress, often occurring in the absence of protective

factors. Abuse and neglect constitute an example of toxic stressors.

Allostatic load theory suggests that an accumulation of stress-comprised regulatory processes across multiple systems provides a better global index of the degree of allostatic overload that is operating than any one system measured in isolation.

NEUROENDOCRINE REGULATION AND REACTIVITY

Cicchetti and Rogosch (2001a) examined the extent to which maltreated children vary with respect to cortisol regulation, a biomarker of AL. Although no differences in cortisol regulation were found between the maltreated and nonmaltreated groups, findings revealed significant within-group variation as a function of maltreatment subtype. In particular, children who had experienced both physical and sexual abuse, in combination with neglect and/or emotional maltreatment, exhibited substantial elevations in morning cortisol levels (i.e., hypercortisolism). In addition, a subgroup of physically abused children showed a trend toward lower morning cortisol relative to nonmaltreated children (i.e., hypocortisolism). Furthermore, the neglected and emotionally maltreated groups did not differ from nonmaltreated children in terms of cortisol regulation.

Longitudinal analysis of the developmental course of cortisol dysregulation accommodates findings of both hyper- and hypocortisolism among maltreated children. Trickett, Noll, Susman, Shenk, and Putnam (2010) measured cortisol activity at six time points spanning childhood, adolescence, and young adulthood to determine the effects of maltreatment on cortisol regulation. Although the cortisol levels of sexually abused females were initially higher compared with nonabused females, their levels were lower by early adulthood. Results support an attenuation hypothesis, whereby the HPA axis adapts to hypersecretion by down-regulating its response to stress, eventually resulting in hyposecretion.

In another longitudinal investigation, Alink, Cicchetti, Kim, and Rogosch (2012) aimed to elucidate the effect of maltreatment on social functioning and cortisol regulation over time. Results of this study suggest that maltreated children are more likely to experience difficulties in social functioning which, in turn, are related to cortisol regulation one year later.

Research investigations also have examined whether cortisol differentially relates to social and psychological functioning based on maltreatment status (see Tarullo & Gunnar, 2006, for a review). This hypothesis was supported by the findings of Cicchetti and Rogosch (2001b), which indicated that depressed maltreated children exhibited a pattern of cortisol dysregulation that was not evident among depressed nonmaltreated children. Similarly, in a later study by Cicchetti et al. (2010), children who had experienced early sexual and/or physical abuse (i.e., in the first 5 years of life) and who also had high internalizing symptoms uniquely exhibited an attenuated diurnal decrease in cortisol, whereas nonmaltreated children with high internalizing symptomatology did not evince neuroendocrine dysregulation. The findings were specific to early sexual and physical abuse rather than later onset physical and or sexual abuse or early occurring neglect or emotional maltreatment.

Trickett, Gordis, Peckins, and Susman (2014) examined the association of recent maltreatment experiences with cortisol reactivity in a large group of maltreated ($N = 303$) and nonmaltreated ($N = 151$) adolescents. Cortisol reactivity was assessed by a laboratory stressor, a modified version of the Trier Social Stress Test. Results indicated that the maltreated adolescents showed a blunted or attenuated response to the stressor as compared with those in the comparison group.

Quellet-Morin et al. (2011) found that maltreated/bullied children had lower cortisol responses than comparison children who exhibited a significant increase. Lower cortisol responses were, in turn, associated with more social and behavioral problems among maltreated/bullied children.

Tyrka et al. (2009) conducted a study to determine whether CRHR1 polymorphisms interact with child maltreatment to predict HPA-axis reactivity, which has been linked both to early life stress and to depression. Several single nucleotide polymorphisms (SNPs) of CRHR1 showed a significant interaction with maltreatment in the prediction of cortisol response to the dexamethasone (DEX) suppression test. For the adults who experienced maltreatment in their childhood, the GG genotype of each of the CRHR1 SNPs was associated with elevated cortisol responses to DEX. Tyrka et al. (2009) conjectured that excessive HPA axis activation could represent a mechanism of interaction of risk genes with stress in the development of mood disorders.

Relatedly, Cicchetti, Rogosch, and Oshri (2011), within an allostatic load framework, investigated the effect of GxE interactions on diurnal cortisol regulation and internalizing symptomatology. Variation in the CRHR1 TAT haplotype and 5-HTTLPR was identified in a sample of

maltreated and nonmaltreated children. GxE effects for CRHR1 and maltreatment and early abuse (before age 5) on diurnal cortisol regulation were observed; CRHR1 variation was related to cortisol dysregulation only among maltreated children. Early abuse and high internalizing symptoms also interacted to predict atypical diurnal cortisol regulation. The interaction of CRHR1, 5-HTTLPR, and child maltreatment (GxGxE) identified a subgroup of maltreated children with high internalizing symptoms who shared the same combination of the two genes. The findings provide support for an allostatic load perspective on the effects of the toxic stress associated with child maltreatment on cortisol regulation and internalizing symptomatology as moderated by genetic variation.

There are different models of how the effects of excesses, deficits, and dysregulation in the primary mediators of AL, particularly cortisol, may affect brain structure and function. Further, developmental considerations are important. In this regard, the timing of periods of severe stress may be critical. For example, variation in the age of maturation of brain structures, notably the hippocampus, prefrontal cortex, and the amygdala, may result in differential effects on functioning and health (Lupien, McEwen, Gunnar, & Heim, 2009; Shonkoff et al., 2009). Sensitive periods in the development of these brain structures may generate heightened vulnerability to the neurotoxic effects of excess glucocorticoids, thereby creating a long-term liability as development proceeds. Alternatively, the cumulative exposure to stressful experiences and concomitant dysregulation of the HPA axis may contribute to ongoing wear and tear on these brain structures. These effects of chronic stress are heightened, given that these areas of the brain have dense concentrations of glucocorticoid receptors, thereby promulgating progressive inefficiency in brain structure and function. For children in low-income environments and those subjected to abuse and neglect, the consequences may be particularly salient for health outcomes across the life span.

ADVERSE PHYSICAL HEALTH OUTCOMES

In addition to cortisol dysregulation, maltreatment appears to be associated with other adverse health outcomes that may be implicated in the development of allostatic overload. For example, maltreatment predicts increased risk for hospital-based treatment of asthma, cardio-respiratory, and infectious disease in childhood (Lanier, Jonson-Reid, Stahlschmidt, Drake, & Constantino, 2010). Early child abuse has been linked to more health-related symptoms (e.g., sleep, eating, general health status), higher body mass index (BMI), lower high density lipoprotein, leptin deficiency, obesity, chronic fatigue syndrome, fibromyalgia, and compromised immune system functioning in childhood and adolescence (Danese et al., 2014; Danese et al., 2011; Danese & Tan, 2014; Heim et al., 2006; Lee, 2010; Miller, Chen, & Parker, 2011; Shirtcliff, Coe, & Pollak, 2009). Furthermore, health liabilities extend into adulthood, as child maltreatment has been found to predict adult cardiovascular disease, elevated inflammation levels, type II diabetes, HIV-risk, self-reported physical symptoms across a range of organ systems, and decreased longevity (Danese et al., 2007; Felitti et al., 1998; Wilson & Widom, 2011). Moreover, child maltreatment has been linked to shortened leucocyte telomere length and it is thought that maltreatment may influence cellular aging (Tyrka et al., 2010).

Miller, Chen, and Parker (2011) proposed a conceptual model to explain why those who experience child maltreatment have an enhanced proinflammatory phenotype. Miller and colleagues (2011) state that stress that occurs during a sensitive developmental period, i.e., when immune function is highly malleable/plastic, becomes embedded in the functioning of the cells that regulate inflammation. Coelho, Viola, Valss-Bass, Brietzke, and Grassi-Oliveria (2014) reviewed 20 studies that examined the association between adults' recollections of child maltreatment and inflammatory markers. Coelho and colleagues (2014) concluded that a history of maltreatment was associated with increased levels of C-reactive protein (CRP), an inflammatory biomarker that is indicative of systemic inflammation. Reichlin (1993) proposed that the neuroendocrine and immune systems interact. Immune responses are thought to alter neural and endocrine function. In turn, neural and endocrine activity are seen as modifying the function of the immune system. The dysregulation of the HPA axis in maltreated persons, who manifest pituitary hyporesponsiveness to corticotropic releasing hormone (CRH) or increased glucocorticoid sensitivity to cortisol, has the potential to bring about a systemic proinflammatory state.

As discussed earlier, a valuable series of studies have examined diverse, long-term health outcomes in an extensive sample of HMO members who were exposed to varying adverse childhood experiences (ACE; Felitti et al., 1998). The ACE factors that were examined included exposure to childhood emotional, physical, and sexual abuse, substance abuse in the family, parental mental illness, domestic violence, and adult criminal behavior. The accumulation of adverse experiences across these risk domains was determined and linked to a range of adult health outcomes. For example, a gradient of exposure to

increasing numbers of ACE factors was associated with a cumulative index of health risk behaviors linked with adult disease and mortality, (i.e., smoking, alcoholism, drug abuse, suicide attempts, high number of sex partners, sexually transmitted diseases, inactivity, obesity). Moreover, a dose–response relationship between ACE exposures and leading causes of death, including heart disease, cancer, chronic bronchitis or emphysema, hepatitis, skeletal fractures, and poor self-rated health, was also observed. Furthermore, ACE factors have been associated with hospitalization for diagnosed autoimmune diseases decades into adulthood and graded relationships between ACE factors and prescription rates for psychotropic medications have been found. This latter finding further illustrates the high rate of serious adult psychiatric morbidity that ensues among children exposed to high levels of adversity.

Cicchetti, Handley, and Rogosch (2015) conducted a study examining child maltreatment, inflammation, and internalizing symptoms. In this multilevel investigation, Cicchetti and colleagues (2015) explored the roles of C-reactive protein, gene variation, and neuroendocrine regulation. The goal of the study was threefold: (1) Determine whether the effect of the timing of child maltreatment on C-reactive protein (CRP), an inflammatory marker, varies by CRP gene variation; (2) explore whether links between salivary CRP and childhood internalizing symptoms depend on the presence and timing of maltreatment experiences; and (3) investigate the role of CRP in the relations between child neuroendocrine regulation and internalizing symptoms and examine whether these associations are moderated by the presence and timing of child maltreatment.

Results indicated that among children with recent onset maltreatment, those with at least one A allele from CRP SNP rs1417938 evidenced significantly higher CRP levels compared with recently maltreated children carrying the TT genotype. Moreover, higher levels of CRP were associated with higher levels of internalizing symptoms only for recently maltreated children. Finally, Cicchetti et al. (2015) did not find support for salivary CRP as a mechanism in the relation between neuroendocrine regulation and childhood internalizing symptoms. These findings highlight the importance of the timing of child maltreatment and have important implications for characterizing variability in inflammation and internalizing symptoms among youth.

Consistent with the concept of AL, Rogosch, Dackis, and Cicchetti (2011) conducted a multidomain assessment of stress-sensitive systems among low-income maltreated and nonmaltreated comparison children. An AL composite was created from measurements of salivary cortisol and dehydroepiandrosterone (DHEA), BMI, waist-hip ratio, and blood pressure. Results indicated that maltreatment and AL independently predicted psychopathology and health difficulties (i.e., parent report of child's physical health status and utilization of health care system). As AL increased, the level of child health and psychological problems increased for all low-income children. Child maltreatment had an additive effect, contributing to the degree of physical and mental health problems beyond that accounted for by the AL composite. Therefore, children with both high AL and a history of maltreatment had the most health problems.

The findings of this investigation have important implications for programs designed to promote physical and mental health in the lives of low-income and maltreated children. Heckman (2006) emphasized the economic and humanitarian value to society of reducing the impact of adverse early family environments on developing children to ameliorate the diminished cognitive capacities ensuring from deprivation and high stress. AL is likely a major influence on these unrealized potentials, through the negative sequelae of stress occurring in early sensitive periods of brain development and progressive accumulation of liabilities that extend to other stress-sensitive systems. Although broad-based efforts to reduce the impact of poverty are crucial, targeted interventions to advance cognitive functioning and self-regulatory capacities (Blair & Diamond, 2008) are vital for enhancing self-righting processes and promoting resilience. For the most vulnerable children in low-SES environments, concerted efforts to prevent the occurrence of child abuse and neglect are of fundamental importance. Early intensive interventions in child maltreatment to establish more sensitive and nurturant parenting, secure attachment, and neurobiological reorganization in maltreated youngsters (Cicchetti, Rogosch, & Toth, 2006; Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011) hold great promise for instilling adaptive developmental trajectories. Consolidated, multisystemic approaches beginning early in development are necessary to reduce environmental stress exposure, child maltreatment, and allostatic overload to improve physical and mental health across the life span.

MALTREATMENT EXPERIENCES AND NEUROBIOLOGICAL DEVELOPMENT

Abnormal brain development is a dynamic, self-organizing process. The perturbations that occur during abnormal brain development can potentiate a cascade of maturational and structural changes that eventuate in the

neural system proceeding along a trajectory that deviates from that generally taken in normal neurobiological development (Cicchetti, 2002b; Cicchetti & Tucker, 1994; Courchesne, Chisum, & Townsend, 1994). For example, early maltreatment, either physical or emotional, may condition young neural networks to produce cascading effects through later development, possibly constraining the child's flexibility to adapt to new challenging situations with new strategies rather than with old conceptual and behavioral prototypes. Thus, early psychological trauma may eventuate not only in emotional sensitization, but also in pathological sensitization of neurophysiological reactivity.

Children who are endowed with normal brains may encounter a number of experiences (e.g., poverty, community violence, child maltreatment) that exert a negative impact on developing brain structure, function, and organization and contribute to distorting these children's experiences of the world (Hackman, Farah, & Meaney, 2010). This provides a unique opportunity for comprehending how environmental factors can bring about individual differences in neurobiological development.

Children may be especially vulnerable to the effects of pathological experiences during periods of rapid creation or modification of neuronal connections. Pathological experience may become part of a vicious cycle, as the pathology induced in brain structure may distort the child's experience, with subsequent alterations in cognition or social interactions, thereby causing additional pathological experience and added brain pathology (Cicchetti & Tucker, 1994). Because experience-expectant and experience-dependent processes may continue to operate during psychopathological states, children who incorporate pathological experience may add neuropathological connections into their developing brains instead of functional neuronal connections (Black, Jones, Nelson, & Greenough, 1998).

As has been stated, child maltreatment affects both neurobiological and psychological processes. Physiological and behavioral responses to maltreatment are interrelated and contribute to children's making choices and responding to experiences in ways that typically produce pathological development. Because maltreated children experience the extremes of caretaking casualty (Sameroff & Chandler, 1975), they provide one of the clearest opportunities for scientists to discover the multiple ways in which social and psychological stressors can affect biological systems. Numerous interconnected neurobiological systems are affected by the various stressors associated with child abuse and neglect (DeBellis, 2001, 2005). Moreover, each of these neurobiological systems influences and is influenced by multiple domains of biological and psychological development. Furthermore, in keeping with the principle of multifinality, the neurobiological development of maltreated children is not affected in the same way in all individuals. Of note, not all maltreated children exhibit anomalies in their brain structure or functioning and identifying protective mechanisms in these children emerges as an important area of future research.

NEUROIMAGING AND CHILD MALTREATMENT

There has been a burgeoning of interest in comprehending how early adverse experiences, such as child maltreatment, exert their effects on the developing brain (Lupien, McEwen, Gunnar, & Heim, 2009). Multiple brain regions and neural circuits are disrupted by the experience of child abuse and neglect. The aberrant neuronal circuitry most likely contributes to the multifinal phenotype observed in maltreated individuals. Magnetic resonance imaging (MRI) technology provides a noninvasive and safe methodology for examining brain morphology, physiology, and function in individuals who have been maltreated. Over the past several decades, neuroimaging investigations increasingly have been conducted with maltreated children and adolescents. Herein, we provide a selective review of these studies.

DeBellis, Keshavan, and colleagues (1999) reported the results of an in-depth whole-brain volumetric analysis of a group of hospitalized maltreated children and adolescents with PTSD and a group of medically and psychiatrically well nonmaltreated comparison subjects. In contrast to findings reported in studies of adults who retrospectively reported their histories of child maltreatment, DeBellis et al. (1999) did not find a reduction in hippocampal volume in the group of maltreated children and adolescents with maltreatment and PTSD. The discrepant findings between the child and adult studies on the effects that maltreatment exerts on hippocampal volume may be a function of the increase in volume that normatively occurs in neurobiological development during adolescence (Spear, 2000). During adolescence, subcortical gray matter structures that include the hippocampus continue to develop, and these normative processes of adolescent brain development may mask any effects that maltreatment and PTSD may exert on the developing limbic system. Alternatively, because the maltreated children with PTSD who comprised the DeBellis et al. (2001) sample were involved in ongoing individual or group treatment, these

psychotherapeutic interventions may have contributed to an increase in hippocampal neurogenesis, thereby eliminating any actual difference between hippocampal volume in maltreated and nonmaltreated individuals.

After controlling for intracranial volume and SES, DeBellis and colleagues (DeBellis, Keshavan, et al., 1999) discovered a number of additional MRI-based brain structural anomalies in their sample of maltreated children and adolescents with PTSD. These included smaller intracranial volumes, cerebral volumes, and midsagittal corpus callosum areas and larger lateral ventricles than in the group of nonmaltreated comparison children and adolescents. DeBellis, Keshavan, et al. also found a positive correlation between intracranial volumes and age of onset of PTSD trauma as well as a negative correlation with the duration of maltreatment that led to a PTSD diagnosis, suggesting that there may be sensitive periods and dose effects for stress-related alterations in brain development. Furthermore, according to DeBellis, Keshavan, et al. their finding that enlarged lateral ventricles in maltreated children and adolescents were correlated positively with the duration of the maltreatment experienced suggested that there may have been neuronal loss associated with severe stress.

In another investigation, DeBellis, Keshavan, Spencer, and Hall (2000) used magnetic resonance spectroscopy (MRS), a safe and novel neuroimaging methodology, to investigate the in-vivo neurochemistry of neurobiological alterations in children's brains. DeBellis and colleagues measured the relative concentration of N-acetyl aspartate (NAA) and creatine in the anterior cingulate cortex of a small group (n = 11) of maltreated children and adolescents who also had PTSD and a healthy nonmaltreated comparison group (n = 11) matched on SES. NAA is considered to be a marker of neural integrity; moreover, decreased concentrations of NAA are associated with increased metabolism and loss of neurons. DeBellis et al. found that maltreated children and adolescents with PTSD had lower NAA-to-creatine ratios, which are suggestive of neuronal loss in the anterior cingulate region of the medial prefrontal cortex, than did the nonmaltreated, SES-matched comparisons. The reduction in the ratio of NAA to creatine buttresses the hypothesis that maltreatment in childhood may alter the development of cortical neurons.

Approximately a dozen studies have replicated the results of DeBellis et al. (1999) that maltreated children and adolescents with PTSD do not have lower hippocampal volume than nonmaltreated comparisons (McCrory, DeBrito, & Viding, 2010). Thus, it appears that the hippocampal reduction effect may be specific to adults with a history of maltreatment (Teicher, Anderson, & Polcari, 2012). Perhaps the stress-induced prolonged exposure to glucocorticoids had a neurotoxic effect and contributed to a reduction in the complexity of hippocampal cells and even to cell death (Lupien et al., 2009). Preclinical research suggests that repeated exposure to stress hormones during development negatively affects neuronal migration, myelination, and neurogenesis, resulting in reduced dendritic spines, gray matter, and white matter connectivity in affected brain regions (Dackis, Rogosch, Oshri, & Cicchetti, 2012; Dannlowski et al., 2012). Therefore, child maltreatment may lead to neurotoxic effects within limbic regions during sensitive periods of development.

Teicher and colleagues (2004) investigated the corpus callosum in children who had been abused or neglected to ascertain whether there were structural abnormalities in its regional anatomy. The corpus callosum connects the left and right hemispheres and is the major myelinated tract in the brain. Regional corpus callosum area was measured by MRI in three groups of children: abused and neglected children, children admitted for psychiatric evaluation, and healthy comparisons. Teicher et al. found that the total area of the corpus callosum of the children who had experienced abuse and neglect was smaller than that of the children evaluated for psychiatric problems and the healthy comparisons. The latter two groups of children did not differ from each other. Child neglect was associated with a 15% to 18% reduction in corpus callosum regions; in contrast, reduced corpus callosum size in girls was most strongly associated with sexual abuse. These findings are congruent with the earlier assertion that negative early experiences can adversely affect neurobiological development.

With respect to corpus callosum and cerebellar volume, there is sound evidence for reduced volume in individuals who have experienced adversity (McCrory et al., 2010). On the other hand, structural MRI results are less consistent for the prefrontal cortex (PFC). It is unclear why there are inconsistent results for volumetric studies of the PFC. Among the possibilities are age differences across studies, variation in maltreatment subtype experienced (e.g., sexual abuse vs. witnessing domestic violence), and methodological differences in scoring MRI scans (e.g., manual tracing, which characterized early studies, vs. automated techniques such as voxel-based morphometry).

Structural neuroimaging studies also provide evidence for deficits in brain volume and in gray and white matter in several regions of the brain. The most prominently affected

appear to be the anterior cingulate cortex, the dorsolateral, orbitofrontal, and ventromedial prefrontal cortex and the hippocampus, amygdala, and corpus callosum (Hart & Rubia, 2012). Diffusion tensor imaging (DTI) studies have revealed deficits in structural connectivity between these areas, thereby suggesting abnormalities in neural networks.

In comparison to the number of studies that have examined structural neurobiological differences in maltreated children, adolescents, and adults, fewer studies have investigated brain functional differences between maltreated and nonmaltreated individuals. Moreover, a very small percentage of these functional studies have been conducted with children. In terms of functional MRI (fMRI), investigations suggest that maltreatment experiences are associated with hypoactivity in the PFC of the dorsofrontal and ventromedial prefrontal cortex. The atypical activation in these brain regions occurs during response inhibition, working memory, and emotion processing tasks (Hart & Rubia, 2012). Relatedly, a neurocognitive study of 3–9-year-old maltreated and nonmaltreated children revealed that the experience of maltreatment during infancy and a chronic history of maltreatment were associated with poorer working memory and inhibitory control performance than children without a history of maltreatment (Cowell, Cicchetti, Rogosch, & Toth, 2015).

Most fMRI studies of maltreated individuals have been conducted during emotion processing tasks (see, e.g., Dannlowski et al., 2013; Grant, Cannistraci, Hollon, Gore, & Shelton, 2011; van Harmelen, et al., 2012; McCrory et al., 2013). The most prominent functional deficits associated with early child maltreatment are in the fronto-limbic brain areas and neural networks that mediate behavioral and affect control (Hart & Rubia, 2012). These investigations have predominately examined amygdala reactivity to various emotion stimuli in maltreated and nonmaltreated adolescents and adults. Herringa, et al. (2013) examined the association of maltreatment experiences during childhood, resting state functional brain connectivity of the amygdala and the hippocampus, and internalizing symptoms. Thus, maltreatment in adolescence may alter the regulating capacity of the fear circuit of the brain leading to increased internalizing symptoms.

Although our discussion of the sequelae of child maltreatment elucidates numerous negative outcomes, it is important to recognize that not all maltreated children are affected similarly and not all succumb to the adverse outcomes accompanying maltreatment. Within developmental psychopathology, the identification of resilience in the context of extreme adversity also has received considerable attention.

CHILD MALTREATMENT AND RESILIENCE

Deviations from the average expectable environment potentiate some individuals toward the development of maladaptive functioning, whereas others demonstrate positive adaptation in the face of the same challenges (Cicchetti, 2010; Masten, 2001). Resilience is conceived as a dynamic developmental process encompassing the attainment of positive adaptation despite exposure to significant threat, severe adversity, or trauma that typically constitute major assaults on the processes underlying biological and psychological development (Cicchetti, 2010; Luthar, Cicchetti, & Becker, 2000). Resilience is not a magical phenomenon (Masten, 2001). The same developmental cascades which can amplify maladaptive outcomes over time can perpetuate or amplify positive outcomes when the individual benefits from some combination of experiences and/or biological propensities that tip the initial balance towards adaptive outcomes (Cicchetti, 2013).

The occurrence of resilient outcomes in approximately 10%–25% of maltreated children point out that self-righting tendencies in human development may be strong, even in the face of deviance and failure in the environment (Cicchetti, 2013; Sameroff, 1983). At one level, different parts of the brain may attempt to compensate, and at another, maltreated individuals may seek out new experiences in areas where they possess strengths. Because plasticity is a central feature of the mammalian brain, early neurobiological anomalies or aberrant experience should not be considered as determining the ultimate fate of the maltreated child (Cicchetti & Curtis, 2006). Discovering how maltreated children develop and function resiliently despite their multitude of adverse experiences offers promise for informing the design, implementation, and multilevel evaluation of prevention and intervention programs (Luthar & Cicchetti, 2000).

Research on the correlates, pathways, and developmental course of resilient functioning in maltreated children has predominantly been gleaned from investigations that have focused on psychosocial variables (see Cicchetti, 2013 for a review). For example, in a 3-year longitudinal study conducted in a summer camp context, Cicchetti and Rogosch (1997) found that ego-resiliency and moderate ego-control, as well as self-system variables, predicted resilient functioning in maltreated children; in contrast, ego-resiliency, perceived emotional availability of the

mother, and relationship quality with camp counselors were significantly more likely to be predictive of resilient functioning in nonmaltreated children from comparable low-SES backgrounds. Relationships were more critical to developing resilient outcomes in nonmaltreated children, whereas self-system processes and personality characteristics were more central to resilient outcomes in maltreated children. Thus, self-reliance, personal conviction, and self-confidence, in concert with interpersonal reserve, may bode well for the development of resilient adaptation in maltreated children.

In 2003, Curtis and Cicchetti urged researchers to incorporate neurobiological and molecular genetic assessments into their measurement batteries aimed at discovering pathways to resilient functioning. Technological advances in neuroscience and molecular genetics have helped to pave the way for an unprecedented opportunity to examine resilience from a multiple levels of analysis perspective. To date, few multilevel studies of resilient functioning in maltreated children have been completed. As investigations of biological contributions to resilience only have been conducted recently, each of these studies has been cross sectional in nature.

Curtis and Cicchetti (2007) sought to discover whether the positive emotionality and increased emotion regulatory ability associated with resilient functioning would be related to greater left frontal EEG activity. A large body of literature concerning the meaning and correlates of hemispheric asymmetries in EEG activity has suggested that this ubiquitous phenomenon indexes a neural system that has emotion-specific influences whereby the two hemispheres of the cerebral cortex have been found to be differentially involved in emotion (Davidson, 2000). Specifically, the left hemisphere is associated with positive emotions/approach behavior and the right hemisphere is linked with negative emotions/withdrawal behavior. Emotions, and in particular, positive emotion and good emotion regulatory abilities, have consistently been associated with resilient adaptation. For example, Bonanno et al. (2007) coded genuine (Duchenne) smiling and laugher and non-Duchenne smiling from videotapes of older adolescent and young adult females. Approximately half of the women had experienced sexual abuse during their childhoods. Bonanno and colleagues found that women who displayed genuine positive affect were significantly more likely to have better social adjustment two years later. In contrast, sexually abused women who expressed positive emotion in the context of describing a prior childhood sexual abuse experience had poorer long-term social adjustment, whereas those who exhibited positive affect when describing nonabuse experience had improved social adjustment. Thus, the potential connection of hemispheric EEG asymmetry with resilience lies in their common linkages with emotion and emotion regulation.

EEG asymmetry across central cortical regions distinguished between children with high and low resilient functioning such that left hemisphere activity characterized those maltreated children, who were adapting resiliently based on a competence composite index (e.g., good peer relations, adapting successfully to school, low levels of depressive symptomatology, low externalizing and internalizing psychopathology). Moreover, a behavioral measure of emotion regulation based on 35 hours of observation of the children, also independently contributed to the prediction of resilience in maltreated and nonmaltreated children.

The investigation of a neural-level phenomenon such as hemispheric EEG asymmetry, in the context of resilient adaptation underscores that there is certainly no one single characteristic that will be ascendant in the process of resilience over the course of development. Resilience is a dynamic, interactive, and bidirectional process between multiple levels across time, none of which holds primary importance at any given moment. However, the relative importance of various biological and psychological processes, although inevitably interrelated, may also vary across development.

In another multilevel investigation, resilient functioning in maltreated and nonmaltreated low-income children in relation to the regulation of two stress-responsive adrenal steroid hormones, cortisol, and dehydroepiandrosterone (DHEA), as well as the personality constructs of ego resiliency and ego control, was examined. The steroid hormones chosen as potential predictors of resilience were the two primary adrenocortical products of secretory activity of the hypothalamic-pituitary-adrenal (HPA) axis. The capacity of individuals to elevate cortisol levels in response to exposure to acute trauma is important for survival. DHEA exerts an impact upon a diverse array of biological actions, including effects on the immune, cardiovascular, endocrine, metabolic, and central nervous systems.

A composite measure of resilience was utilized that included multimethod, multi-informant assessments of competent peer relations, school success, and low levels of internalizing and externalizing symptomatology. Cicchetti and Rogosch (2007) found that personality characteristics, ego resiliency and moderate ego overcontrol and the adrenal steroid hormones associated with stress (i.e., cortisol and DHEA) made independent and noninteractive contributions to resilience. Although operating at different

levels of analysis, behavioral/psychological and biological factors each made unique contributions to resilience.

Cicchetti and Rogosch (2007) found that higher morning levels of cortisol were related to lower levels of resilient functioning for the nonmaltreated children. High basal cortisol may indicate that nonmaltreated children are experiencing greater stress exposure and, consequently, are constrained in their ability to adapt competently. Within the group of maltreated children, differences in cortisol regulation were found as a function of the subtypes of maltreatment experienced. Physically abused children with high morning cortisol had significantly higher resilient functioning than physically abused children with lower levels of morning cortisol. The positive role of increased cortisol for physically abused children is divergent from the more general pattern of higher cortisol being related to lower resilient functioning that was discovered in the nonmaltreated and sexually abused children in this study.

Prior research on neuroendocrine regulation has indicated that physically abused children generally exhibit lower levels of morning cortisol secretion (Cicchetti & Rogosch, 2001b), especially children who experienced physical abuse early in life (Cicchetti et al., 2010; Cicchetti et al., 2011). It may be that the subgroup of physically abused children who were able to elevate cortisol to cope with stressful vicissitudes in their lives were demonstrating a greater striving for resilient adaptation. In contrast, the larger subgroup of physically abused children with lower levels of morning cortisol may have developed hypocortisolism over time in response to chronic stress exposure. As a result, for these children there may be a diminished capacity to mobilize the HPA axis to promote positive adaptation under conditions of ongoing stress. In addition, Cicchetti and Rogosch (2007) found that the very low level of resilience among sexually abused children with high basal cortisol may be a product of their different traumatic experiences and consequences of chronic excessive vigilance and preoccupation, with commensurate HPA axis hyperarousal.

Finally, maltreated children with high resilient functioning exhibited a unique atypical pattern of a relative DHEA diurnal increase. Maltreated children who have the capacity to elevate DHEA over the course of the day may be better equipped to cope with the demands of high chronic exposure to stress and to adapt competently. In contrast, the nonmaltreated children who functioned resiliently did not exhibit the pattern of diurnal DHEA increase; instead they displayed the lowest levels of DHEA across the day. DHEA has been shown to generate effects that are associated with resilience. For example, DHEA counteracts the harmful effects of hypercortisolism, thereby potentially conferring neuro-protection on the brain (Charney, 2004).

The GxE studies on psychopathology reviewed earlier in this chapter are instructive and relevant for research on resilient functioning because they provide an illustration of how genetic variation may confer protection against mental disorder on individuals who have experienced child maltreatment. However, in our view, the absence of mental disorder is conceptually distinct from resilience, a dynamic multidimensional developmental process indicated by positive adjustment across domains of competent functioning despite the experience of significant adversity. Moreover, the presence of mental disorder does not preclude the achievement of resilient functioning. Many persons with mental disorder not only experience periods of remission, but also an appreciable number manage to function in an adaptive fashion for prolonged periods of their lives (Hinshaw & Cicchetti, 2000).

To our knowledge, there has been only one molecular genetic investigation that has specifically set out to test the hypothesis that particular genetic variants might be related to resilient functioning in the presence of child maltreatment. To examine the processes underlying the development of resilience at the molecular genetic level of analysis, Cicchetti and Rogosch (2012) embarked on research aimed at discovering whether there were genetic elements, in interaction with the experience of child maltreatment, that were associated with higher levels of resilient functioning in maltreated and nonmaltreated school-aged children. A multicomponent index of resilient functioning was identified. Four theoretically and empirically informed genes that have been found to be related to behaviors known to be associated with resilient functioning, 5-HTTLPR, CRHR1, DRD4—521C/T, and OXTR, were chosen and genetic variants in each of these genes were investigated.

Maltreatment consistently exerted a strong, adverse main effect on resilient functioning; however, none of the gene variants of the four respective genes were shown to have a main effect on resilience. In contrast, GxE effects were obtained and a similar pattern emerged for all four genes—a particular genotype was found to differentiate between the level of resilient functioning in maltreated and nonmaltreated children more strongly. Contrary to the typical GxE studies on psychopathology, the results of the Cicchetti and Rogosch (2012) investigation revealed that genetic variation had a negligible effect for the maltreated group in predicting resilient functioning. In contrast, genotype was shown to contribute to higher resilient functioning in nonmaltreated children when they possessed

a particular genotype, at least relative to the maltreated children with the same genotype.

In the case of 5-HTTLPR, nonmaltreated children with the SS genotypic variant were significantly more likely to have higher resilient functioning, whereas maltreated children who possessed the same genetic variant had significantly lower resilient functioning. These findings are consistent with a differential susceptibility to environmental influences interpretation (Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011). According to this perspective, the characteristics individuals possess that render them disproportionately vulnerable to adverse experiences also make these same individuals disproportionately likely to profit from supportive contexts. For children who possess the same s/s genotypic variant of 5-HTTLPR, nonmaltreated children, in the context of a more normal childrearing environment, achieved higher resilient functioning, whereas maltreated children, in the context of an adverse childrearing environment, demonstrated lower resilient functioning (cf. van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012).

For CRHR1, nonmaltreated children with zero copies of the TAT haplotype had significantly higher levels of resilient functioning relative to maltreated children with the same number of copies of the TAT haplotype. Once again, these findings are consistent with a differential susceptibility to the environment perspective (Belsky & Pluess, 2009; Ellis et al., 2011). Maltreated and nonmaltreated children had the same genetic variant (i.e., zero copies of the TAT haplotype); however, the nonmaltreated children showed higher levels of resilient functioning, whereas the maltreated children (living in a more stressful context) evinced lower levels of resilient functioning.

Analyses of the DRD4 (dopamine receptor) -521C/T single nucleotide polymorphism (SNP), revealed that nonmaltreated children and, in particular, those with the TT genotype, were more likely to exhibit significantly higher resilient functioning scores than were maltreated children with this same genotype. The maltreated children manifested significantly lower levels of resilient functioning. As with the previous results for 5-HTTLPR and CRHR1, findings with DRD4 -521C/T provide support for the differential susceptibility to environmental influences perspective.

In further analyses, Cicchetti and Rogosch (2012) examined the relation between number of maltreatment subtypes and DRD4 -521C/T genotype to resilient strivings. Maltreated children who had experienced three or four subtypes fared dramatically worse with the TT genotype, whereas nonmaltreated children with this genotype fared the best. Maltreated children with 3–4 subtypes of maltreatment with the CC or CT genotypes were indistinguishable in level of resilient functioning from nonmaltreated children with these genotypes. Despite the very large detrimental effect that extensive maltreatment exerts on resilient functioning independent of genotype, these results exemplify how the three to four maltreatment subtype groups exhibit the same level of resilient functioning as do nonmaltreated comparisons with the same CC or CT genotypes.

Finally, with OXTR (oxytocin receptor), not being maltreated was related to significantly higher resilient functioning scores; in contrast, maltreatment was strongly related to lower levels of resilient functioning. In particular, nonmaltreated children who had either the AA or AG genotypes of OXTR displayed greater levels of resilient functioning than maltreated children with these same genotypes. Consistent with the findings obtained with the three previous candidate genes, the results provide strong support for the differential susceptibility to environmental influences framework.

It is noteworthy that Cicchetti and Rogosch (2012) identified different gene variants as differentially important through contrasting maltreated and nonmaltreated children and their level of resilient functioning (i.e., low, medium, high). The variation among the genotypes and their relation to functioning differences would not be apparent without the consideration of experience. The genes did not have a singular role, outside of experiential context. The contrast between groups of maltreated and nonmaltreated children was therefore important for understanding development in normal and atypical rearing environments.

Cicchetti and Rogosch's (2012) findings suggest that the genes included in this investigation appear to be minimally related to resilient functioning in maltreated children. Maltreatment consistently had a statistically significant main effect on resilient functioning for each of the genes examined. Genetic variation had more of an impact on resilient functioning among the nonmaltreated children who also resided in stressful poverty-laden environments. Accordingly, it appears that the powerful maltreatment main effects may have overshadowed any potential contribution of genetics to resilient functioning in abused and neglected children. Despite the multidomain assessment of adaptive functioning and the large well-defined sample of maltreated and nonmaltreated children, a limitation of the study is its cross sectional nature. Because resilience is a dynamic developmental construct that is not immutable, future investigations of gene-environment

interaction and resilient functioning should be prospective and longitudinal.

Although many investigations of child maltreatment include racially and ethnically diverse populations, possible differences associated with these demographic characteristics are not consistently discussed. Thus, we next turn our attention to this important demographic variable.

RACE AND ETHNICITY

In part as a function of concerns about the overrepresentation of children of color in the child welfare system and heightened awareness about disparities in access to quality health and mental health services for ethnic minorities, examinations of child maltreatment have increasingly sought to incorporate an understanding of issues related to race and ethnicity. The importance of this movement is underscored by findings from the most recent National Incidence Study. As stated earlier, NIS-4, the first NIS to detect racial and ethnic differences in rates of child maltreatment in the United States (Sedlak et al., 2010), found that Black children experience maltreatment at higher rates than do White children in several subtypes of maltreatment, including higher rates of physical abuse, overall abuse and overall maltreatment according to both the Harm and the Endangerment Standard. Under the Endangerment Standard, Black children also had higher rates of emotional neglect and overall neglect. The authors of the report qualified these findings by noting that NIS-4 estimates were more precise than those contained in prior NIS reports. Importantly, they also highlighted the role of socioeconomic status in these findings, noting widening income gaps between Black and White families, with children in Black families being more likely to reside in low-income families.

A growing body of literature has examined factors such as ethnic differences in the disclosure of abuse (Meston, Heiman, Trapnell, & Carlin, 1999), utilization of varied definitions of abuse (Collier, McClure, Collier, Otto, & Polloi, 1999), and differences between what constitutes culturally sanctioned parenting and abusive parenting (Miller & Cross, 2006). However, despite recognition of the importance of better understanding maltreatment in the context of racial and cultural milieus, research in child maltreatment to date has done little to clarify these issues (Elliott & Urquiza, 2006). Unfortunately, progress on research in this area has been hindered by confounds between race and ethnicity, considerations related to low socioeconomic status among minorities, reliance on retrospective reports of maltreatment, and the utilization of small and geographically diverse samples. Thus, with the exception of robust differences in parenting styles identified among diverse ethnic and racial groups, research on race, ethnicity, and child maltreatment has yielded conflicting results (Elliott & Urquiza, 2006; Sedlak et al., 2010).

Much less of the extant child maltreatment literature has examined differential effects of maltreatment as a function of racial and ethnic backgrounds. Current theoretical perspectives differ with respect to predictions about the consequences of maltreatment for children of different races and ethnicties. The racial invariance hypothesis maintains that the effect of social influences on outcomes should be similar, regardless of race or ethnicity, if there is equal exposure to the environmental event (Sampson & Bean, 2006). In accord with this perspective, the sequelae of child maltreatment should not be expected to differ as a consequence of race/ethnicity. Conversely, another perspective maintains that effects of maltreatment may be magnified for children from minority groups due to their exposure to racism and other forms of violence (Wyatt, 1990). Finally, it is possible that the effects of maltreatment may be less severe for members of racial/ethnic minorities because children from these backgrounds may have developed resilience as a function of coping with higher levels of stress. Although an appealing perspective, the low rates of resilience typically found in maltreated children argue against this possibility.

While some studies have identified racial differences in individuals with histories of maltreatment with respect to increased arrests for violent crimes (Maxfield & Widom, 1996), posttraumatic stress symptoms (Canez 2000; Roberts, Gilman, Breslau, & Koenen, 2011), and alcohol problems in adulthood (Caetano, Field, & Scott, 2003), others have failed to identify differences (Hatcher, Maschi, Morgen, & Toldson, 2009; Lau, Litrownik, Newton, Black, & Everson, 2006). In efforts to shed further light on this issue, multiple domains of functioning were examined in adults with documented histories of neglect during childhood (Widom, Czaja, Wilson, Allwood, & Chauhan, 2013). The findings of this investigation yielded support for each of the theoretical perspectives previously described. Thus, rather than providing clarification on the relation between maltreatment and outcomes, these findings highlight the complexity of this area of investigation as numerous other factors such as racism and differences in acceptance of mental health services may have contributed to the findings on outcomes in adulthood.

Although inconsistency exists with respect to racial/ethnic differences in child maltreatment, clear differences

emerge with respect to case status in the child welfare system (Hill, 2007). Black and Latino children are more likely to be removed from their homes, to remain in foster care longer, to have more placement changes once removed from their homes, and to be less likely to be reunified with their parents once removed (Hill, 2007). Thus, the criticality of continuing to understand the role of ethnic and racial factors in relation to child maltreatment and the importance of incorporating these variables into future research cannot be minimized. Similarly, considerations associated with gender also warrant attention.

Now that we have concluded our discussion of the consequences of child maltreatment, it is important to consider methodological issues that may affect the strength of conclusions to be drawn from this body of work.

METHODOLOGICAL ISSUES IN MALTREATMENT RESEARCH

Despite advances that have occurred with respect to the sophistication of empirical research in the area of child maltreatment, a number of difficult methodological issues require further attention. As evident from our discussion of the sequelae of child maltreatment, research in maltreatment is complex for a number of reasons, which we elaborate below.

Definitional Considerations

As discussed earlier it is critical that agreement on definitions of child maltreatment occurs. Despite the fact that progress has been made in terms of increased rigor in definitions of child maltreatment, investigators continue to vary in their approaches to definition. Results across studies are likely to diverge considerably if single subtypes of maltreatment are examined rather than addressing the high prevalence of multiply occurring subtypes. Issues related to perpetrator, severity, chronicity, and developmental period during which maltreatment occurs also should be considered. However, limitations related to sample size, difficulty accessing comprehensive information due to legal restrictions on access to maltreatment registries, and report biases in parents and children often impede such efforts. Although the conduct of statistical analyses for all such variables may not be possible, ideally investigators should present descriptive information on these issues. In addition, clear information needs to be provided on how the maltreatment experience, including decisions on the assignment of subtype, was determined. Moreover, sequelae associated with particular subtypes that may not be immediately apparent but that may emerge over time highlight the importance of conducting longitudinal investigations.

Multiple Subtypes

It is clear that it is rare that a child who has been maltreated experiences a single subtype of maltreatment. When multiple subtypes occur, it is challenging to determine how best to categorize the maltreatment experience. One strategy that has been used involves basing the main subtype designation for analytic purposes on the most societally egregious form of maltreatment, with categorization of sexual abuse, physical abuse, neglect, and emotional maltreatment ranging from most to least severe. In this methodological approach, if a child had been both physically abused and neglected, then they would be categorized as physically abused. Another approach suggests that assignment of the main subtype of maltreatment be based on the most severe form of maltreatment experienced. Thus, if a low level of physical abuse occurred, but a very severe neglect experience were present then the child would be classified as neglected. Regardless of the method adopted, it is critical that investigators clearly describe how the assignment to maltreatment group was made.

Comorbidity

Although concerns around the presence of comorbid disorders are a challenge for psychopathology research in general, this is a particularly problematic issue when investigating the sequelae of child maltreatment. Research consistently demonstrates that maltreatment is highly associated with other negative outcomes, including depression, PTSD, antisocial behavior, and substance use/abuse. When present, therefore, it becomes difficult to ascertain if a given negative outcome is directly attributable to maltreatment or to the co-occurring psychopathology. This is particularly challenging because it is usually impossible to ascertain which condition preceded the other. Again, although it may not be possible to categorize and analyze participants by the presence or absence of co-occurring psychopathology, when possible descriptive information on the presence of psychopathology should be provided.

Economic Adversity

Much of the extant research on child maltreatment has been conducted with economically disadvantaged samples.

Although maltreatment is not limited to the low-income sector, children who come to the attention of authorities are much more likely to reside in families from the lower socioeconomic strata. Because a myriad of risks accompany residing in poverty, including exposure to community and/or domestic violence, stressors associated with difficulty meeting basic needs, and being a member of a racial or ethnic minority group, it can be particularly challenging to recruit and to retain participants. In fact, no-show rates with this population, even when home visits are schedule, frequently average 50% of scheduled appointments. Moreover, research staff are routinely faced with very difficult situations when they enter high crime communities. Thus, safety concerns need to be addressed. In addition to challenges accessing and retaining research samples, it is difficult to disentangle the effects of maltreatment from the co-occurring risk factors that are present. In efforts to minimize these issues, increased research needs to be conducted with maltreated children from a range of socioeconomic backgrounds.

Prevention and Intervention

Methodological challenges also accompany the conduct of research on prevention and intervention outcome studies. As discussed earlier, recruitment and retention, even for basic research studies, is quite difficult. This becomes even more complex when enrolling maltreating families in intervention trials. Maltreating families are often not seeking treatment and typically may not even acknowledge that there is a problem and that they or their children require assistance. We know that retention in randomized control trials (RCTs) is problematic even in treatment-seeking populations, so it is not surprising that it emerges as a significant issue with nontreatment seeking maltreating families. Once enrolled, further complications arise. When ongoing maltreatment is detected, a report must be filed with Child Protective Services, often resulting in a family becoming angry and withdrawing from treatment. Attrition is further exacerbated if a child is placed in foster care or, when studying children already in foster care, if placement changes occur. Issues related to high housing mobility and too often disconnected or changing cell phone numbers also make the consistent tracking of families difficult. Given the high co-occurrence of domestic violence and child maltreatment, the offending partner may be threatened by the involvement of the child or partner in services and interfere with their participation. All of these variables coalesce to make the attainment of large samples in maltreatment intervention studies particularly challenging. Unfortunately, smaller sample size results in reduced statistical power to detect treatment effects. As the conduct of multilevel investigations of treatment outcome becomes increasingly important, the incorporation of psychophysiological and genetic assessments into research batteries will require even larger samples. Although investigators have developed creative methods of facilitating recruitment and retention of participants, attaining large samples remains difficult. One possible solution is to utilize multiple sites for enrollment. However, the feasibility of this is hampered by the high costs of RCTs in combination with federal funding caps.

In summary, although much progress has occurred since child maltreatment was first identified as a factor that contributes to atypical developmental processes, significant challenges remain that need to be addressed if this area of research is to continue to advance. Moreover, the importance of ensuring the translation of this body of knowledge into clinical and social policy domains has been increasingly recognized.

TRANSLATIONAL RESEARCH

Translational research refers to the examination of how basic behavioral and biological processes can inform the diagnosis, prevention, treatment, and delivery of services for individuals at risk for, or who have developed, a mental illness (National Advisory Mental Health Council on Behavioral Science Workshop, 2000). Consistent with a developmental psychopathology perspective (Cicchetti & Toth, 2006, 2009; Rutter & Sroufe, 2000), translational research can best be viewed as reciprocal in nature, with both basic researchers and individuals involved in the provision of clinical care benefitting from input derived from the other domain. The impetus to conduct translational research in the behavioral sciences emanated largely from the National Institute of Mental Health (Insel, 2005; Insel & Scolnick, 2006) and was spurred by the recognition of the tremendous individual, social, and economic burden associated with mental illness (National Advisory Mental Health Council on Behavioral Sciences, 2000). As discussed earlier, a considerable body of research has examined the effect of child maltreatment on psychological and, increasingly, biological functioning (Cicchetti & Valentino, 2006; McCrory et al., 2010) and this scientific knowledge lends itself to the development, evaluation, and exportation of models of intervention designed to disrupt the cascade of negative developmental processes (Masten & Cicchetti, 2010).

Because the formation of a secure attachment relationship with the primary caregiver is one of the most important and universal tasks during the first year of life, and because child maltreatment has been shown to disrupt the development of secure attachments, the provision of interventions to promote attachment security in maltreated children has emerged as an important area of translational research.

Dozier and colleagues (2008), working with a maltreated foster care population, developed Attachment and Biobehavioral Catch-up (ABC) as an intervention for foster parents. The three main components of this brief attachment theory informed intervention are to 1) provide an environment in which the foster child can feel nurtured and loved even when the parent feels pushed away by the child; 2) help the caregiver work through personal issues that may be interfering with their caregiving abilities; and 3) offer a highly controllable interpersonal environment to allow children to better regulate at the bio-behavioral level (Dozier, 2003; Dozier et al., 2008). The ABC intervention is delivered in 10 joint parent–child sessions, and research supports its efficacy at promoting adaptive child attachment behaviors and regulating cortisol. Children from dyads participating in the ABC intervention displayed fewer avoidant behaviors in attachment system eliciting situations compared with children from dyads who received an educational intervention (Dozier et al., 2009). Additionally, cortisol production in foster infants and toddlers who received the ABC intervention resembled patterns similar to those found in children who had never been in foster care and was different from patterns found in foster infants and toddlers whose caregivers participated in an educational intervention (Dozier et al., 2008).

Moss and colleagues recently demonstrated the efficacy of a very brief (eight, 90-minute sessions) parent–child intervention compared with a control condition to reorganize attachment for maltreated children ages 1 to 5 (Moss et al., 2011). Intervener structured parent–child play sessions were videotaped and then watched immediately with the parent during the session to discuss parental observations and reinforce sensitive parental behavior (Moss et al., 2011). Children in the intervention condition were more likely to change from insecure or disorganized attachments to secure attachments after the 8-week intervention than the children in the control condition.

A widely utilized and evaluated intervention for young children with histories of maltreatment, Child Parent Psychotherapy (CPP; Lieberman & Van Horn, 2005), has its origins in attachment theory, developmental psychopathology, and stress and trauma work, while also being informed by cognitive-behavioral and social learning theories (Lieberman & Van Horn, 2009). In recent years, CPP has gained increased attention as an evidence-based, culturally sensitive treatment for maltreated children and their caregivers.

Rather than focus individually on the child or parent, the therapist's client in CPP is the relationship between the caregiver and child. Through dyadic sessions, the therapist utilizes the child's spontaneous play and naturally occurring interactions between the parent and child as a vehicle for understanding maladaptive relational patterns and as an entryway for therapeutic change. The therapist encourages mutually enjoyable interactions between the parent and child, provides a voice for the child to interpret needs that the parent may be struggling to understand, and encourages developmentally appropriate parental expectations.

An additional focus of CPP involves helping the parent develop insight into how the ghosts from maladaptive relationships in his or her past can be influencing the present day interactions with the child in an effort to break the intergenerational transmission of maladaptive relational representations from parent to child (Fraiberg, Adelson & Shapiro, 1975). The CPP model also recognizes the influence of broader contextual factors on the occurrence of child maltreatment and on the developing relationship between the parent and the child.

CPP has been found to be efficacious in a number of RCTs. Cicchetti and colleagues conducted an RCT of CPP compared with a psychoeducationally based parenting intervention (PPI) for maltreated infants and their primary caregivers (Cicchetti, Rogosch, & Toth, 2006). Preintervention, 87.5% of infants in the CPP condition and 83.3% in the PPI intervention evidenced disorganized attachments. Postintervention, these rates had decreased to 32% and 45% respectively for CPP and PPI, with the majority of toddlers in each intervention developing secure attachments by the end of the intervention. The two intervention groups had higher rates of securely attached children postintervention than the community standard group, although they did not differ from each other. Results provide strong support for the efficacy of CPP in promoting secure attachments in infants from maltreating families.

Another randomized clinical trial, conducted by Toth and colleagues, sought to explore the impact of CPP on preschool children's representations of self and mother (Toth et al., 2002). Children and their caregivers were randomly assigned to CPP, PPI, or community standard, and representational models were assessed with the MacArthur Story-Stem Battery (Bretherton et al., 1990).

Children in the attachment-based intervention, CPP, experienced significant declines in negative self-representations and maladaptive maternal representations and significant increases in positive self-representations and mother-child relationship expectations from pre-to postintervention. While changes in representations were also found in the PPI condition, negative self-representations decreased significantly more in CPP than with PPI, and positive self-representations and mother–child relationship expectations improved nonsignificantly in the CPP relative to the PPI condition. These findings highlight the efficacy of CPP for reworking representations of self and other in maltreated children.

In addition to promoting attachment security in maltreated infants and improving representations of the self in maltreated preschoolers, CPP also promotes positive child adaptation in other domains. CPP was more effective than community-standard-plus –case-management at decreasing child behavioral problems and trauma symptoms for children aged 3 to 5 years who had been exposed to marital violence (Lieberman, Van Horn & Ghosh Ippen, 2005). A 6-month follow-up study of CPP found that reductions in child behavior problems were maintained, suggesting the durability of CPP for treating child symptoms (Lieberman, Ghosh Ippen & Van Horn, 2006). More recently, the sustained efficacy of CPP in promoting secure attachment 1-year posttreatment has been demonstrated (Pickreign Stronach, Toth, Rogosch, & Cicchetti, 2013). Not only did children receiving CPP have higher rates of security than children in the psycho-educational parenting model, but rates of disorganized attachment did not differ between children who received CPP and the nonmaltreated comparison children. Thus, although CPP and a psychoeducational parenting intervention both facilitated the completion of treatment, only CPP resulted in sustained security of attachment, suggesting that, while parenting interventions alone may be effective in the short term, they may not result in sustained attachment security over time.

The previous findings support the efficacy of CPP in controlled research trials; however, it is critical that preventive interventions be exported to the clinical world more broadly once efficacy has been established. CPP was recently examined in a community setting emphasizing wraparound care for diverse youth in foster care (Weiner, Schneider & Lyons, 2009). Child traumatic stress symptoms and behavioral and emotional needs decreased significantly for African American, biracial, and Hispanic children receiving the CPP intervention, but not for White children (Weiner et al., 2009). Additionally, risk behaviors decreased and strengths increased for African American and biracial children participating in this study (Weiner et al., 2009).

The feasibility and effectiveness of CPP was also examined in a community setting with families in which the parents had maltreated their children and were court-ordered to participate or were identified as at high risk for abuse or neglect (Osofsky et al., 2007). Attrition was high, with more than 50% of families dropping out before engagement or during treatment; however, increased behavioral and emotional responsiveness and positive discipline were observed in the caregivers who completed treatment, as was decreased intrusiveness. Additionally, development improved in at least one domain (communication, gross motor, fine motor, problem solving, or personal–social) for 50% of the children receiving CPP who had previously been screened as at risk for developmental delay. Importantly, during the first three years of the pilot study, there were no new reports of child abuse or neglect involving children completing CPP. These studies provide preliminary evidence for the feasibility of utilizing CPP with families willing to engage in a community setting, and results suggest that child symptom reduction and improved parenting are attainable when CPP is exported from the laboratory into the nonacademic clinical arena.

More recently, research has coalesced to suggest that early preventive interventions with maltreated children are capable of promoting normative neurobiological development (Cicchetti et al., 2011; Fisher, Stoolmiller, Gunnar & Burraston, 2007), highlighting the continued importance of studying change processes in the lab while applying efficacious interventions in the community.

A relatively new frontier with respect to evaluating and translating knowledge on efficacious interventions emanates from genetics research. As knowledge on the interplay of genes and the environment has increased, the benefits for prevention efforts have been suggested by both animal and human research. Importantly, as knowledge of genetic moderation with respect to prevention and treatment outcome increases, ethical questions also arise. Some may suggest that more cost-effective and efficient interventions could be delivered if youth with particular genetic constellations that place them at risk for maladaptive outcomes are screened and that only those most likely to benefit from a given intervention subsequently receive it. However, a number of considerations argue against this approach (Howe et al., 2010). First, single genes or single GxE combinations fail to account for sufficient variance in outcomes to support screening for intervention provision. Most likely, multiple developmental pathways will eventuate in positive outcomes, a concept consistent with

multifinality. It is more likely that genes will constrain or enhance various pathways than that whey will deterministically contribute to outcomes, in part because the same genetic pattern may constrain a pathway in one context and enhance the same pathway in another context (Howe et al., 2010). The multiply influenced course of development cautions that genetic screening for selective intervention is unlikely to provide significant benefits in advancing intervention efforts, particularly given the current nascent state of research on GxE and intervention outcomes.

Although basic research is increasingly being translated to the prevention and treatment of child maltreatment, the growth of basic research knowledge has generally surpassed its application to mental disorders more generally. The prevention of and treatment for the sequelae of child maltreatment is not an exception to this unfortunate reality. Perhaps even more disconcerting is the fact that the majority of maltreated children do not present at mental health clinics but rather are in contact with systems such as child welfare, law enforcement, and criminal justice where their trauma histories are typically not identified (Harris, Lieberman, & Marans, 2007). As a result, even when evidence-based treatments are available, maltreated children typically fail to receive them.

To bridge the gap between basic and applied research and its application to problems of clinical importance associated with child maltreatment, investigators and clinicians must stretch beyond traditional boundaries. Collaborations across disciplines are necessary if areas as diverse as neuroscience, genetics, emotion, cognition, social cognition, and interpersonal processes are to be incorporated into addressing the needs of children in maltreating families (Toth, Manly, & Nilsen, 2008). The needed areas of expertise also will necessarily differ depending on the ultimate goals but could include individuals with expertise on various cultural contexts and knowledge of various systems that would be needed to support the translational efforts and community acceptance. As efforts have expanded to incorporate basic research knowledge into clinical arenas, it has become increasingly clear that this is a gradual process. To begin, it is critical that those conducting basic research are committed to conceiving their questions with the goal of having findings ultimately inform applications of the knowledge gained (Cicchetti & Toth, 2006). Clearly, before theoretically informed models of prevention or intervention can be developed, applied to maltreating populations, and evaluated, there must be an understanding of the mechanisms and processes that contribute to a maladaptive course of development. As an exemplar of this process, the extensive basic research conducted on attachment theory and the consequences associated with children developing insecure or disorganized attachments to their primary caregivers contributed to the development of CPP. This theoretically derived intervention was then rigorously tested in multiple efficacy trials to determine its utility for maltreating families and for families with domestic violence in highly controlled research settings. Now that efficacy has been established, effectiveness studies have been and are currently being undertaken to determine the feasibility of exporting this empirically based treatment into the broader clinical arena. As a last step in this process, it is important for the scientific community to be open to feedback from those implementing interventions in the field and to use this information when revising interventions and seeking mediators and moderators of treatment efficacy. As will be discussed below, it also is critical that evidence-based models of intervention continue to be evaluated once exported to new community settings. Such initiatives will increase the probability that research will ultimately result in informing social policy for maltreated children.

An example of the exportation of evidence-based models into community settings with continued evaluation is currently being conducted in Rochester, New York. In 2007 the Monroe County Department of Human Services and the United Way of Greater Rochester funded an initiative to aid the community in making progress towards translating efficacy findings and increasing the availability of prevention services for child maltreatment. Building Healthy Children (BHC) targets young mothers who have had a child before the age of 21 and are living in poverty. Mother–child dyads are referred through Pediatrics Departments at local hospitals. There are numerous risk factors within this population, including: domestic violence, maternal depression, criminal activity, indicated CPS reports as children, and sexual abuse histories.

BHC provides a tiered service pyramid that offers evidence-based interventions according to each family's level of need (Paradis, Sandler, Manly, & Valentine, 2013). Families enrolled in the program begin with a home visit by a pediatric social worker and a paraprofessional outreach worker, during which time the needs of mother and child are assessed and community service referrals are made. Families who do not exhibit symptoms of maternal depression or poor parent–child attachment are assigned to a Parents as Teachers educator (Pfannenstiel & Seltzer, 1989). PAT is a didactic intervention that provides caregivers with parenting support, teaching principles of child development, and addressing psychosocial issues. It is delivered through weekly visitations to the family's home

and continues until the child turns 3 or the intervention goals are fully met. For families with a higher level of need, CPP is provided. Finally, mothers with depressive symptoms may also receive Interpersonal Psychotherapy (IPT; Weissman, Markowitz, & Klerman, 2000).

Preliminary results from BHC have shown that mothers who completed the program exhibited decreased levels of depression, parental rigidity, child abuse potential, difficulty in social relationships, and perceived loneliness. In addition, families in BHC evidenced increased rates of infant immunizations and well-baby visits, and more perceived social support from family members. The willingness of the funders of this program to recognize the importance of continued program evaluation and to commit financial resources to this initiative for almost a decade is particularly noteworthy.

SOCIAL POLICY PERSPECTIVES

The value of translational research leads directly into considerations related to the social policy arena. The personal and economic burden of child maltreatment highlights the importance of utilizing information derived from research to inform policy initiatives. However, despite what should be an almost seamless integration of research, practice, and social policy, reciprocally beneficial interactions among these arenas have been difficult to achieve (Toth & Cicchetti, 2006). In reflecting upon impediments to this integration, Shonkoff (2000) suggested that, whereas scientists are trained to raise questions and to be guided by facts, policymakers are more prone to be governed by political and economic forces. Similarly, service providers are more like policymakers because they are often faced with situations that require immediate action before empirical data are available to inform specific intervention strategies. In reflecting on this tension, Shonkoff (2000) stated, "Science is focused on *what we do not know*. Social policy and the delivery of health and human services are focused on *what we should do*" (p. 182, italics in original). Even when data are available to inform intervention strategies, the realities of heavy clinical caseloads and lack of access to easily assimilable empirical information by clinicians and policy advocates may limit the likelihood of clinicians and policy advocates adopting evidence-based interventions. Unfortunately, over a decade since these observations were made, individuals committed to addressing the problem of child maltreatment continue to struggle to achieve an integration of research, practice, and social policy.

Recently, increased calls have been made for the utilization of science to guide policymaking and funding decisions (Baron & Haskins, 2011; Haskins & Baron, 2011). In fact, the Obama Administration has done much to advance the incorporation of scientific data into policymaking decisions. During his initial inaugural address, Obama stated that an important goal of his Presidency would be to expand social programs that work and to eliminate those that are ineffective (Haskins & Baron, 2011). Early in his Administration, six initiatives to expand evidence-based social programs were launched, including the utilization of home visitation to improve maternal and child health, early childhood development, and family functioning and programs to prevent teen pregnancy (http://www.whitehouse.gov/omb/blog/09/06/08/BuildingRigorousEvidencetoDrivePolicy). Unfortunately, even when evidence exists that a program is ineffective, political forces may make it difficult to eliminate funding for these programs and redirect the funding toward those that are evidence based (Baron & Sawhill, 2010).

In a compelling essay, Haskins and Baron (2011) argued that better population-level outcomes in education, crime reduction, and child well-being would occur if policy and funding decisions were made based on evidence of what works. The call for the utilization of evidence-based approaches, referred to as technocracy, is the norm in physical health care (Dodge & Mandel, 2012). However, in addressing the contrast between health care and issues affecting children, Baron (2007) stated:

> In medicine . . . rigorous evaluations are common, and often drive policy and practice. By contrast, in education and most other areas of social policy, such studies are relatively rare. In these areas, policy and practice tend to be driven more by advocacy studies and anecdote than by rigorous evidence, costing billions of dollars yet often failing to produce meaningful improvements . . . (p. 32).

In view of the magnitude of the adverse consequences of child maltreatment on both psychological and physical health outcomes, it is imperative that policy makers address and remedy difficulties in accessing high quality trauma-informed services. Because evidence-based services for children who have been maltreated are increasingly available (Toth, Gravener, Guild, & Cicchetti, 2013), the failure to ensure their widespread availability is particularly egregious. To reduce impediments to access, partnerships among professionals working with children, elected officials, and public interest advocates are critical (Harris, Lieberman, & Marans, 2007; Toth & Cicchetti, 2006).

It is unlikely that anyone invested in promoting the welfare of children would disagree with the importance of attaining the above stated objectives. Why then has the reduction of the divide among research, practice, and social policy been so difficult to realize? A number of issues

need to be considered, including points of entry to care, allocation of resources, and community-wide uptake.

Entry to Care

Chu and Lieberman (2010) discuss entry points to care for young children exposed to trauma. Although pediatric care providers are the professionals most likely to come in contact with young traumatized children, their effectiveness in identifying possible trauma may be hindered by a number of issues, including the brief visit duration, lack of training in recognizing trauma flags, and minimal knowledge regarding referral sources if trauma is revealed. Mental health providers may similarly lack knowledge regarding the identification of trauma in young children and when trauma is identified they may not have adequate training on the provision of evidence-based models of intervention. Childcare providers also are unlikely to have adequate training on the identification of trauma. Despite the high co-occurrence of domestic violence and child maltreatment, domestic violence shelter staff most typically focus on the needs of adult victims and fail to assess or address the presence of child trauma. Although the court system can mandate treatment for victims of child abuse, court personnel are also unlikely to be adequately versed in understanding the effects of trauma and the need for treatment. Unfortunately, the child welfare system also often focuses on addressing parenting and may fail to consider the needs of maltreated children. When the need for treatment is recognized, far too few professionals are available to provide evidence-based trauma-informed treatments. Fortunately, systemic barriers to access to care can be minimized through large-scale educationally based initiatives that encourage collaborations among professionals from diverse disciplines. One such national initiative, the National Child Traumatic Stress Network (http://www.nctsn.org), has been very successful in increasing the availability of evidence-based services for traumatized children and improving the quality of care for children and families throughout the United States.

Allocation of Resources

Although there has been increased recognition of the importance of supporting evidence-based social programs, political forces that operate do not always act in accord with this goal. The decisions of policymakers are governed by myriad issues, including program cost, input from constituents, the position of party leaders, public opinion, pressure from lobbyists, and their own political philosophies. Far too often, politically favored programs are held intact or allocated increased resources. At times, even scientific evidence that identifies iatrogenic effects of programs is ignored (Barlow, 2010). As we accrue more and more evidence regarding effective prevention and treatment programs for children who have been maltreated, it will be increasingly important that we strive to ensure that research findings are disseminated to and incorporated into the funding decision process. However, that is not to say that funding should be eliminated to support efforts to develop new innovative programs. Unfortunately, it is all too clear that even programs with strong scientific support are not equally effective for all individuals. Moreover, despite decades of research dedicated to evaluating programs designed to foster positive outcomes for children faced with economic and familial disadvantage, many with favorable outcomes, the overall effect sizes for these programs remain within the small to moderate range (Shonkoff & Fisher, 2013). Moreover, some evidence-based models, although shown to be effective for a designated population, address only a small percentage of individuals in need. For example, although the outcomes for the Nurse-Family Partnership home visitation program have been shown to be effective in a number of important arenas, such as improving parental caregiving and child health and preventing child abuse and neglect (Kitzman et al., 1997; Olds, Henderson, & Kitzman, 1994), it limits enrollment to first-time mothers who are identified during their first trimester of pregnancy. Because many young mothers living in poverty do not seek prenatal care, these inclusion criteria result in the ineligibility of significant numbers of very high-risk mothers. Therefore, although we applaud efforts to increase the availability of evidence-based programs, it would be premature to conclude that resources should be directed only toward those programs that have been supported by rigorous evaluation. Rather, funding should be eliminated for programs that have been shown to be ineffective and *resources should be* channeled toward a combination of evidence-based models and innovative approaches designed to address unmet needs or to improve the magnitude of positive outcomes for vulnerable children and families.

Community-Wide Uptake

Most typically, the evidence base for programs is derived from university-based randomized control trials (RCTs). Although these approaches reflect the gold standard in the field, they are not without challenges with respect to dissemination into community settings (Sternberg, 2006; Toth & Manly, 2011). RCTs are conducted under very controlled and often ideal settings, including utilization of strict inclusion and exclusion criteria for participants that make them unrepresentative of those seeking mental

health care in community settings. Unfortunately, and not surprisingly, when such social programs are disseminated into community settings, they yield not only low rates of utilization with respect to individuals eligible for such services, but also tend to be less effective due to issues such as lower credentialed and less experienced providers, lack of supervision, and failure to ensure fidelity of implementation (Dodge & Mandel, 2012). This has been referred to as the scale-up penalty and estimated at 50% (Welsh, Sullivan, & Olds, 2010). Moreover, some changes during dissemination are planned and do not always lead to the intended positive outcome, resulting in considerable variation in the effectiveness of programs provided as part of RCTs and those exported to community settings (Weisz & Jensen, 1999). The way in which an intervention is conceptualized is also very likely to contribute to whether a community is invested in providing it and adhering to its fidelity (Dodge, 2008). Therefore, to promote community uptake, it is critical to consider the ultimate goal of exportation from the initial conceptualization of an RCT. Loosening parameters around the inclusion/exclusion of participants, for example, ultimately might result in the likelihood that the intervention can be disseminated more effectively (Toth, Pianta, & Erickson, 2010). Regardless, despite best efforts to ensure effective implementation of an evidence-based model in community settings, it is critical that evidence on fidelity of implementation and outcomes within a given community be assessed. For this reason, some advocate that legislation should provide a mandate for ongoing evaluation of federally funded programs once evidence-based models have been disseminated to communities and provide the funding to make such evaluation possible (Haskins & Baron, 2011).

Now that we have concluded our discussion of definitional considerations and etiological models of child maltreatment and addressed the psychological and biological sequelae accompanying maltreatment, as well as implications for intervention, translational research, and social policy, we turn our attention toward exciting future opportunities for those committed to continuing the journey to prevent child maltreatment and its deleterious consequences.

THE NEXT GENERATION: NEW FRONTIERS IN CHILD MALTREATMENT RESEARCH

There is now no doubt that the experience of child abuse and neglect, and the accompanying poor quality care, exert a harmful impact on the development and functioning of multiple biological and psychological systems across the life course. However, despite considerable progress in understanding the consequences of maltreatment, important frontiers remain to be discovered.

It is of paramount importance that rigorous and precise definitions of the maltreatment experience be incorporated into all investigations of child maltreatment. Unless this very basic goal is routinely achieved, it will be impossible to move forward in increasing convergent findings related to the sequelae associated with various subtypes and dimensions of maltreatment. Such coherence is particularly important when seeking to translate research from basic investigations into the design and evaluation of prevention and intervention trials.

Studies of psychopathology and mental health have largely neglected the period between adolescence and adulthood (Schulenberg, Sameroff, & Cicchetti 2004). This unfortunate omission is no less true in research that has been conducted on child maltreatment. Although early experience is critical, its influence on subsequent psychopathology and mental health is highly likely to be moderated by later experience (Cicchetti & Tucker, 1994; Sroufe, 1997). The failure to adequately account for the effect that experiences during this critical transitional period may exert on future functioning becomes particularly problematic when the retrospective recall of adults is relied upon to gauge the effects of early maltreatment. The conduct of investigations on the transition to adulthood in individuals with histories of child maltreatment emerges as a largely untapped arena. In this regard, the examination of relevant stage salient mechanisms that may be operative during this period is particularly important. Longitudinal research will be needed to provide vital information about how maltreated adolescents and adults resolve later stage-salient developmental issues such as identity formation, autonomy, the development of personal relationships, intimacy, and work.

Most investigations of the consequences of child maltreatment have examined neurobiological and psychological systems separately. The time has come to emphasize the conduct of longitudinal research that examines biological and psychological systems concurrently over developmental time. In addition to multilevel investigations in basic maltreatment research, the incorporation of multilevel measurement strategies into RCTs of interventions for individuals with histories of maltreatment will be particularly important (Cicchetti & Gunnar, 2008). Such strategies may highlight very divergent mediators and moderators of treatment outcome in individuals with the same disorder who have or who have not experienced

maltreatment. Moreover, determining the multiple levels at which change is engendered through RCTs that incorporate biological and psychological assessments of intervention efficacy will provide more insights into the mechanisms of change and the extent to which neural plasticity may be promoted.

It is important to conduct longitudinal neuroimaging studies of maltreated children and adolescents. Moreover, there is a paucity of neuroimaging investigations that focus on brain function (i.e., fMRI and magnetoencephalography [MEG]) in maltreated individuals. Likewise, it is essential that neuroimaging research includes community samples of maltreated persons. Most of these studies have been conducted on maltreated individuals residing in psychiatric hospitals. These samples present many challenges to disentangling the effects of maltreatment on brain structure and function from other competing conditions (e.g., comorbid psychopathology; substance abuse; medication; psychotherapy).

Although groups of abused and neglected children have been found to differ from groups of nonmaltreated children from similar social class backgrounds on the vast majority of the biological and psychological systems investigated to date, not all maltreated children are affected by their experiences in the same fashion. Despite experiencing significant adversity, there are maltreated children who develop in a psychologically resilient fashion.

Furthermore, the neurobiology of some maltreated children does not appear to be structurally or functionally aberrant and may be reflective of an enhanced neural plasticity in resilient individuals (Cicchetti & Curtis, 2006). It remains to be discovered whether the neurobiological structural and/or functional difficulties displayed by abused and neglected children are irreversible, or, if reversible, whether there are sensitive periods when it is more likely that neural plasticity can occur. In addition, investigations must be conducted that examine whether some neural systems may be more plastic than other neural systems or whether particular neural systems may be more refractory to change, or have a more time-limited window when neural plasticity can occur. Because the brain is a dynamic, self-organizing system that is mutable, future neuroimaging research should strive to ascertain whether the brain structure and functioning of resilient maltreated children differ from those of resilient nonmaltreated children.

Relatedly, because resilience is a dynamic developmental process, it is critical that short- and long-term longitudinal studies on the determinants of resilient functioning are conducted in the future. Resilient functioning is not irreversible. Transitional "turning points" (Rutter, 2012) provide opportunities and challenges for individuals either to remain on a positive trajectory despite ongoing adversity, to "bounce back" from a decline in functioning, to persist on a maladaptive trajectory, or to exhibit a decline in functioning from positive functioning (Cicchetti & Rogosch, 1997). In these longitudinal investigations, resilience should be conceptualized as a multidomain, multidimensional construct. Changes in one domain of competent functioning can cascade to affect other developmental domains over time (Cicchetti & Tucker, 1994; Masten & Cicchetti, 2010). Hence, a longitudinal multiple levels of analysis approach to investigating resilient functioning in maltreated children will help to ensure that resilience processes are examined in a thorough and developmentally appropriate fashion.

Findings from examinations of resilience in maltreated children hold great potential for informing preventions and intervention initiatives (Cicchetti, 2013). When indicators of resilience are identified, they can be incorporated into the development of RCTs. The conduct of longitudinal investigations of resilience will be particularly important in contributing to ensuring that interventions are timed, guided, and implemented as closely as possible to the identification of deviations from adaptive functioning (Luthar & Cicchetti, 2000; Toth & Cicchetti, 1999).

Although we have increased the number of evidence-based interventions that are available to treat children and adults with histories of maltreatment, the dissemination and wide availability of evidence-based models must be expedited. Toward this end, exportation to community settings and the subsequent conduct of effectiveness trials must be a priority for individuals involved with the development and conduct of RCTs demonstrating efficacy. Unless a commitment to dissemination is made upon the completion of successful efficacy trials, valuable treatments may languish in academic settings. In addition, far more evidence-based models are available for treating the aftermath of maltreatment than for preventing its occurrence. Therefore, more attention needs to be directed toward the development of interventions directed toward the prevention of maltreatment. The field also would benefit greatly from research targeted toward identifying factors related to stopping the transmission of maltreatment across generations so that protective factors could be built into interventions for families that are at risk for multigenerational maltreatment.

Future investigations of molecular genetic contributions to resilience also should pay more attention to the process of development (D). For example, GxExD studies

could provide valuable information about how a particular genotypic variant may operate differently depending on the developmental period or environmental context.

We possess virtually no information about the effects of child maltreatment in middle- or upper-socioeconomic environments. Maltreatment clearly transcends social class. Consequently, research on the developmental consequences of child maltreatment and on pathways to resilient adaptation in children raised in nonlow-SES environments is important to conduct to discover similarities and differences in the development of resilient functioning across various social class strata. It would be interesting to ascertain whether family and community protective factors are more likely in middle-SES maltreating families than in maltreating families from the low-SES. Would any of the resources that are more common in nonlow-SES maltreating families result in different pathways to maladaptive or resilient functioning, or to a significantly higher percentage of resilient children? Nonmaltreated children in affluent backgrounds are not immune to developing substance abuse or psychopathology (e.g., depression). Indeed, youth from affluent families can even exhibit more problematic functioning than youth from the low-SES (Luthar & Barkin, 2012). Thus, comparison of maltreated children from different SES backgrounds may shed light on differential pathways to resilient functioning.

In view of the paucity of cohesive findings on race and ethnicity, it will be increasingly important for investigators to conduct research with diverse samples. Moreover, rather than simply utilizing demographics on race and ethnicity in a descriptive manner, examining possible differences among individuals with diverse backgrounds will be particularly important. In this regard, it is equally important to conduct multilevel research on the pathways to resilient adaptation in maltreated children from different cultures.

Maltreatment experiences can exert enduring effects on brain and behavioral development. Epigenetics, the study of heritable changes in gene function that do not alter the DNA sequence, but instead provide an extra layer of transcriptional control that regulates gene activity and plays an important role in the acute regulation of genes in response to environmental changes, is a promising avenue for both basic and intervention research on child maltreatment. Epigenetic mechanisms may explain the stable and dynamic developmental sequelae of maltreatment experiences. Epigenetic research has the potential to serve as a mechanism to explain how maltreatment experiences confer risk for physical and mental health problems.

DNA methylation has been the most studied epigenetic mechanism in research on child abuse and neglect. Alterations in methylation, which manifest as changes in CpG (a site at which cytosine [C] resides next to guanine [G] in the DNA sequence) motifs, may persist in a stable form over a long time. Alterations in the structure of chromatin influence gene expression. Specifically, genes are switched off when chromatin is silent, and they are switched on (i.e., expressed) when chromatin is active. These dynamic states of chromatin are controlled by a number of processes, including epigenetic patterns of DNA methylation. Individual differences in DNA methylation thus are a potential biomarker of the contributions that environmental factors make to the divergence in phenotypes of maltreated individuals who possess similar genetic endowments.

Several investigations have used a candidate gene approach to examine the effects of child abuse and neglect on methylation. Epigenetic regulation is a viable candidate mechanism through which caregiving behaviors, including child maltreatment, may exert long-term effects on HPA activity and neuronal function (Szyf & Bick, 2013). Candidate genes utilized in this regard to date include the serotonin transporter gene, the glucocorticoid receptor gene, and FKBP5 (the binding protein 5 gene; see, e.g., Beach et al., 2009; Tyrka, Price, Marsit, Walters, & Carpenter, 2012). These studies have found that child abuse was associated with increased methylation in both the serotonin transporter and the glucocorticoid receptor genes (see Yang et al., 2013, for a review). Moreover, Klengel et al. (2013) found that FKBP5, an important functional regulator of the stress hormone system, increased the risk of developing stress-related psychiatric disorders in adulthood through allele-specific (i.e., a particular functional polymorphism), childhood trauma-dependent DNA demethylation in functional glucocorticoid response elements of FKBP5.

Most investigations with humans have employed a candidate gene approach to identify specific sites of DNA methylation changes (e.g., see Romens, McDonald, Svarent, & Pollak, 2014). Investigations that have utilized a genome-wide approach have found that these methylation changes occur at many gene loci (see e.g., Labonte et al., 2013; Metha et al., 2013; Suderman et al., 2014). Research with animals who experience abuse demonstrates that experience-induced changes in DNA methylation occur in brain circuits that have functional relevance to trajectories of normal and abnormal behavior. Accordingly, experience-driven DNA-methylation changes in maltreated individuals also have implications for disruptions in neural circuitry and behavior (see Szyf & Bick, 2013; Weder et al., 2014). Likewise, using salivary DNA specimens,

whole-genome methylation differences have been found between maltreated and nonmaltreated children at 2,868 CpG sites. A substantial number of genes implicated in prostate, colorectal, breast, colon, and ovarian cancer were contained in the set of genes that showed differential methylation between maltreated and nonmaltreated children (Yang et al., 2013). These studies each focused on a site-specific gene and collected DNA from lymphoblasts (Beach et al., 2011) or from whole postmortem brain tissue in maltreated adults who committed suicide (McGowan et al., 2009). The results of these investigations suggest that epigenetic mechanisms also may be associated with risk for developing major health problems in later life (Yang et al., 2013).

There is nothing that can be done to prevent the DNA sequence variations that eventuate in the emergence of risky phenotypes. On the other hand, DNA methylation changes in response to experiences such as child abuse and neglect could help to bring about the design, implementation, and multilevel prevention and intervention strategies that change the expression of risky genes through reversal or demethylation and thereby promote healthy physical and mental health development. Szyf and Bick (2013) concluded that DNA methylation adaptations early in life are system-wide and that they involve multiple gene circuits. Thus, because responses to social adversity such as child maltreatment are not limited to the brain and also likely affect peripheral tissues, it is also possible to assess the efficacy of an intervention in peripheral cells.

Prevention and intervention strive to alter the environment to bring about positive outcomes. Research on epigenetics suggests that prevention and intervention also may change the epigenome and that this also could result in improved outcomes. If we are to understand the mechanisms through which early adverse experiences such as child maltreatment impart maladaptation, psychopathology, or resilience, then it is critical that we examine genetic variation (functional polymorphisms) and epigenetic modifications (cf. Klengel et al., 2013).

The knowledge base on the effects of child abuse and neglect has increased exponentially since the early stages of this research were initiated approximately 50 years ago. More recent technological advances open up more avenues for elucidating the mechanisms and processes that contribute to the deleterious consequences associated with maltreatment, and to the development of resilient functioning in the face of adversity, as well as for shedding light on the development and implementation of exciting and effective prevention and intervention strategies.

Although our knowledge on the deleterious effects of child maltreatment on biological and psychological development has burgeoned in recent decades, far too many children continue to be victimized by this pernicious societal problem. Moreover, despite the increased availability of efficacious models of prevention and intervention, the dissemination of these models to communities most in need continues to lag significantly behind the knowledge base. Dissemination of empirically generated results to policy arenas must be expedited if the lifelong scars accompanying child maltreatment are to be addressed adequately.

REFERENCES 546

INTRODUCTION

Foster care—the practice of temporarily placing children with nonbiological parents as a way to promote their safety and well-being—is a custom that is likely as old as humanity itself. Allusions to children being cared for by foster caregivers can be found as far back as biblical times in the Talmud and the Old Testament. However, the formal public foster care and child welfare systems in the United States that have been created by regulatory statutes and are administered by federal, state, and county governments are a relatively modern invention, originating in the early twentieth century. How it is that current policies and practices designed to protect vulnerable children and families evolved during the centuries following European colonization of the New World is a matter of some historical interest. Tracing this history is a useful exercise, not only for those who wish to know the origins of family-based care in the United States (as an alternative to institutional care or no care at all), but also for students of typical and atypical child development. An analysis of the historical record reveals many approaches for addressing the problem of parentless children that were identified by observers at the time as clearly not facilitative of positive adjustment. From the emergence of beliefs that children are more than property, to the growth of understanding that childhood is a distinct period of development during which a nurturing environment facilitates well-being across the life span, to commentaries about the high mortality rates in orphanages and recognition of the fundamental needs and rights of children to be reared in families, the evolution of our current foster care system parallels the emergence of the science of psychology.

In this chapter we consider the study of foster care and foster children from a developmental psychopathology perspective. As described by Cicchetti and Toth (2009), this perspective emphasizes a number of key focal points for scientific investigation. In particular, developmental psychopathology seeks to highlight the recursive relationship between research on typical development and atypical development. It uses multiple levels of analysis, from molecular genetics to neurobiology to the individual, family, and society, to examine relevant phenomena. It views prevention and intervention research not only as a way to improve outcomes, but also as a way to understand developmental processes and their underlying neural mechanisms—and as such, as a means for grounding theoretical models of human development. It incorporates conceptualizations of diversity in both process and outcome. Finally, it emphasizes equally the negative outcomes that occur from adverse experiences and the ability of individuals to exhibit significant resilience in the face of adversity.

Our discussion begins with an examination of the roots of the modern foster care system and the origins of research on foster care. We then provide a summary of the extant scientific knowledge base. The chapter concludes with a discussion of future directions for the field.

A HISTORY OF FOSTER CARE AND FOSTER CARE RESEARCH

In North America, from the early European settlements in the 1600s through colonial times, there were no systematic efforts for providing for the needs of dependent children. Rather, as McGowan (1983) noted in her history of foster care in the United States, many citizens were primarily concerned with sustaining the resources needed for survival and considered children as property; in contrast, the concepts of childhood and children's rights that we may take for granted today were unknown, and the children of paupers and orphans fell under the auspices of the English Poor Laws. This led to a number of possible outcomes for dependent children: being housed in almshouses, becoming indentured servants, being *farmed out* (i.e., auctioned off to citizens who were paid to house them), or staying with their families, who were given minute amounts of subsistence aid. Most commonly, dependent infants and young children were cared for in almshouses until they were old enough to be indentured.

The growth of slavery in colonial America reduced the need for indentured servitude. Moreover, the rise of the abolitionist movement in the early nineteenth century further led to opposition to indentured servitude because it amounted to treating white children in ways that many had come to believe were morally wrong for black children and adults. As such, by the 1830s, institutional care in almshouses became the predominant form of care for children of all ages.

The economic expansion that came after the end of the Civil War was followed by mass industrialization, urbanization, and immigration. These changes and the strongly held religious values in many communities made

it a priority and a possibility to devote resources to caring for the poorest and most needy children and families in America's cities. Newly established private Christian and Jewish philanthropies and public welfare organizations took up the cause of providing support for these individuals. However, care for the needy was still largely provided in orphanages and other institutional settings.

In 1854 Charles Loring Brace, founder of the New York Children's Aid Society, was among a group of social reformers who first identified the propensity for poor outcomes among children in institutional care. Of particular concern to Brace and others was the practice of housing children together with adults, which led to many abuses. Brace and his colleagues promoted an alternative strategy that involved the practice of *placing out* poor and parentless children from eastern cities. These children were put aboard trains and sent to live with families in rural areas in the upper Midwest and upstate New York. The practice proliferated quickly: By one estimate, 40,000 children had been placed out by 1879 (Bremner, 1970–1974).

In addition to the practice of placing out children, the late nineteenth and early twentieth centuries saw the rise of the Children's Home Society movement in the United States. These statewide agencies provided free-of-charge foster placements; like the practice of placing out children, the growth of this movement was rapid. By 1916, there were Children's Home Societies in 36 states. As might be expected, the so-called *orphan trains* and Children's Home Society family placements produced a wide range of outcomes; these practices led to much better lives for some children, while others experienced ongoing neglect and maltreatment (O'Connor, 2004).

The orphan trains and the Children's Home Society movement marked the beginning of a societal shift toward family-based care as an alternative to institutional rearing in the United States (Herman, 2008). Throughout the twentieth century in the United States, opposition to institutional care grew steadily, at least among professionals. For example, the renowned pediatrician Henry Dwight Chapin (1926) noted that mortality rates for children younger than age 2 years in orphanages was exponentially higher than in the general population:

> In 1914 the then American Association for Study and Prevention of Infant Mortality attempted a study of this question. In their review the New York State Department of Charities is quoted as presenting the statistics from 1909 to 1913 of eleven institutions in the State in which the death rate for babies under two years, during this period, based on the total number of children cared for, varied in the different institutions from 183 to 576 per 1,000, with an average mortality rate for the eleven of 422.5 per 1,000. During these same years the death rate for children under two years, based on the estimated population for the state at that age, was 87.4 per 1,000 or about one-fifth of that in institutions. (P. 486)

By the mid-twentieth century, professionals working with the large number of children orphaned and displaced by World War II had repeatedly documented the numerous negative effects of institutional care on children's healthy development (Freud & Burlingam, 1974). During this era, Renee Spitz (1945) coined the term *hospitalism* to refer to children whose growth and functioning had been impaired by long periods of time spent in institutional settings. Psychodynamically oriented research on human attachment by John Bowlby (1953) and animal research examining the effects of maternal separation on rhesus monkeys by Harry Harlow (Harlow & Harlow, 1962) provided further evidence of the importance of a strong bond with a primary caregiver to a child's development and well-being.

Although professionals in the fields of social work, psychology, and pediatric medicine were already strong advocates for foster family care by the mid-twentieth century, institutions remained a very common form of care during this time. Barr (1992) estimated that, in 1910 in the United States, there were more than 100,000 children in institutions and more than 50,000 children in foster care. It was not until 1950 that the number of foster children exceeded the number of institutionalized children.

Although the original foster care programs in the United States were run by charitable and religious organizations, efforts to organize a governmental foster care system did enter the social policy landscape early on. Programs at the federal level can be traced to the first White House Conference on Children in 1909, followed by the establishment of the Children's Bureau in 1912. The Children's Bureau was charged with protecting the welfare of all children in the United States. The New Deal era brought with it numerous federal and state government programs designed to provide a social safety net for the needy, including Social Security. By the 1960s, the growth of these government social welfare programs had led to a formal foster care system funded at the federal level but administered at the state level through a network of county child welfare offices. During the 1960s, the size of the foster care population in the United States began to grow rapidly, a trend that continued through the end of the twentieth century. Indeed, between 1983 and 2000, the foster care population more than doubled in size, from approximately 250,000 children to estimates of close to 600,000 children (U.S. Department of Health and Human Services, 2000).

This trend was attributed to a number of factors: changes in regulations and laws regarding child abuse and neglect reporting, including the passage of the Child Abuse Prevention and Treatment Act (PL93–247) in 1974; more children entering than exiting care; and the combination of increases in poverty, urban and rural substance abuse, and other mental health and social problems in the face of decreasing budgets for social services (Barbell, 1997).

In the years since 2000, the size of the foster care population in the United States has stabilized and no longer appears to be increasing. However, there is increased concern regarding the large proportion of very young foster children, who many consider to be most vulnerable. For a period of time in the 1990s, the number of young foster children was growing at twice the rate of other foster children (U.S. General Accounting Office, 1994), and children younger than 6 years came to represent one-third of the children in care (U.S. Department of Health and Human Services, 1999). While mining several large foster care databases to document these trends, Wulczyn, Ernst, and Fisher (2011) noted that foster children ages 2 years and younger tended to spend more time in care than did their older peers and showed particularly high vulnerability for delayed development.

Notably, in countries outside the United States and especially in developing countries that have historically relied upon institutional care for children in need of out-of-home placements, there has also been some growth in the use of foster care. As we discuss elsewhere in this chapter, this development may be in part a response to widespread documentation—much of it from the scientific literature—that the absence of a primary caregiver that occurs in the case of institutionalized rearing produces the worst outcomes possible. As such, the use of foster care as an alternative to institutional care must be viewed as a positive development.

Foster Care Research

For almost as long as foster care has been an organized system of care in the United States, it has been the subject of systematic research. The first known empirical study of foster care outcomes (van Senden Theis, 1924) examined outcomes from close to 1,000 children placed in care by the New York State Charities Aid Association during the previous 2.5 decades. The study found what numerous subsequent investigations have continued to replicate (e.g., Clausen, Landsverk, Ganger, Chadwick, & Litrownik, 1998; Glisson, 1994, 1996; Halfon, Mendonca, & Berkowitz, 1995; Pilowsky, 1995; Trupin, Tarico, Benson, Jemelka, & McClellan, 1993; Urquiza, Wirtz, Peterson, & Singer, 1994): Foster children fare far better than children who remain in maltreating families but manifest poorer adjustment and increased problem behavior compared with nonmaltreated children.

Despite remarkably consistent evidence that foster children lag behind their peers on most measures of development and well-being, the policies and programs designed to address the needs of foster children have been almost continuously in flux. McGowan (1983) observed that child welfare policies have been akin to a pendulum swinging back and forth along a number of key dimensions. They include the rights of parents to maintain their family with integrity versus the vulnerability of children and their need for protection; the need to provide families with support versus the need to keep children safe; federal responsibility versus state, local, or individual family responsibility for the care of the child; public versus charitable and philanthropic funding for services; services to support children's development versus services to prevent harm; family preservation versus child-centered services; maintaining clearly defined boundaries among services designed to meet the needs of families (e.g., child welfare, family service, juvenile justice, other services) versus integrating services within systems of care; patient- or client-centered approaches to intervention tailored to the specific needs of the individual versus uniform standards of treatment; and specialized professional services versus paraprofessional, community-based supports. One explanation for the fluctuations in policies has been the lack of penetration of scientific knowledge about child development, and the needs of foster children in particular, into legislative settings. This has begun to change as researchers have endeavored to engage in translational communications designed to be useful in programmatic decision making and resource allocation, and policy makers have embraced evidence-based practice as a standard of care. Whatever the explanation for the historical instability of policies, however, although we tend to think of the latest trends in foster care services as novel and innovative, and although vast resources are regularly put into reengineering public child welfare systems, few trends have not been the focus of prior reform efforts, and no approach or combination of approaches has substantially reduced the disparities found among foster children.

Over and above documenting the trends in foster care and the ongoing needs of the children and families involved, and germane to the subject of this chapter, research on foster care provides a window into how extreme variations in typical early rearing experiences

affect development. Although animal models involving rodents and primates have provided extensive information in this area, only a few other contexts in research on human development (e.g., adoption) allow such questions to be investigated empirically. Similar to research on the broader topic of child maltreatment, research on foster care can delineate how variations in specific dimensions of adversity affect the trajectories of children's lives; in addition, this work can uniquely inform us about how the alterations in the caregiving environment that occur with placement in care and subsequent caregiver transitions, including reunification with birth parents and subsequent foster placements, mitigate or compound the effects of adversity. As such, this work informs our understanding of which behavioral, cognitive, and biological systems are most pliable (and, thus, affected positively or negatively) at specific times during the course of development. In addition, prevention and intervention research in this area is helping to inform our understanding of the best strategies to use to maximize opportunities for recovery from early adversity. Finally, and perhaps most remarkably, research on foster care informs our understanding of typical development under the most adverse conditions and which intrinsic and environmental factors buffer individuals from experiences that would ordinarily disrupt health and well-being.

The remainder of this chapter focuses on a developmental psychopathology perspective (Cicchetti & Toth, 2009) on how research on foster care can increase our understanding of typical and atypical development. A great deal of literature pertains to this topic—for example, searching *foster care* on the PsycNET scientific database results in more than 5,000 empirical publications between 1950 and the present. As such, it can be challenging to synopsize the scientific knowledge base in this area, and we strongly emphasize that this chapter is not intended to be an exhaustive review of the field of foster care research. We acknowledge that the organizational scheme we have used is somewhat arbitrary and some readers will undoubtedly fail to incorporate *all* important domains. Moreover, with respect to much of the research in this area, it is often not possible to disentangle the effects of maltreatment and other forms of adversity from the effects of placement in foster care, which itself may conflate factors such as separation or loss with the effects of care by nonbiologically related adults. In short, there are clear limitations to the amount of scientific control that can be applied to investigations in this area. Consequently, we fully expect this summarization of a developmental psychopathology perspective on foster care research will be updated, extended, and broadened in future discussions. With these qualifications in mind, we assert that foster care research provides evidence that:

- Early adversity increases the likelihood of atypical emotional, psychological, and cognitive development.
- Early adversity has the potential to alter biological development and to increase risk for disease.
- The timing and duration of adversity is associated with differential outcomes, with a general trend of longer lasting adversity producing the most profound effects.
- Neglect is a particular cause for concern because of its pervasiveness and its propensity to disrupt healthy development and exert a lasting impact on health and well-being.
- Transitions among primary caregivers are a specific class of adverse experience worthy of attention because they appear to negatively affect the development of key cognitive and behavioral skills needed for social and academic success.
- The combined effects of prenatal stress, especially prenatal substance exposure, and early adversity on neurobehavioral development are additive and produce worse outcomes than do prenatal stress or early adversity alone.
- Resilience (i.e., typical development in the face of adversity) is evident in all samples of foster children, although what contributes to it is not well understood.
- Family-based care, including foster care, is as a general rule better than institutional care.
- Systematic, well-timed, family-based interventions have the potential to mitigate the effects of early adversity on healthy development.

The next section elaborates upon each of these topics. A unifying discussion follows that includes future directions and implications for research in the emerging field of translational neuroscience.

EARLY ADVERSITY INCREASES THE LIKELIHOOD OF ATYPICAL EMOTIONAL, PSYCHOLOGICAL, AND COGNITIVE DEVELOPMENT

Perhaps the strongest conclusion that can be drawn from foster care research with respect to development is that it provides convergent evidence, along with evidence from many other areas of research, that early adversity alters typical life-course trajectories in a negative manner. This is consistent with a large body of animal research on the effects of adverse rearing conditions (Levine, 2005)

and research on child maltreatment (Cicchetti, 1996; Toth & Cicchetti, 2013). It is also consistent with research on other forms of human adversity, such as poverty (Duncan, Magnuson, Kalil, & Ziol-Guest, 2012; Duncan, Ziol-Guest, & Kalil, 2010). Put simply, foster children as a group consistently lag behind their peers on measures of development and show poorer psychological adjustment (Pears & Fisher, 2005a, 2005b). In this section, we summarize the research on psychological, developmental, and cognitive problems that have been observed among foster children.

Mental Health Outcomes

One of the best-investigated domains in this area is foster children's mental health. The National Survey of Child and Adolescent Well-Being (NSCAW) is a landmark study that provides some of the most compelling evidence of the disparities of foster children in the United States in this area. The NSCAW is a nationally representative sample of more than 6,000 children and families who have been investigated by public child protective services programs in the United States between 1997 and 2014. This study was funded by the U.S. Administration of Children and Families and has produced a multitude of technical reports and peer-reviewed publications to date. Two cohorts of children were recruited into the NSCAW study, and information was gathered from the children, their parents, other caregivers, caseworkers, teachers, and administrative records.

Analyses of the NSCAW dataset have revealed that emotional and behavioral problems are present in more than 50% of the children in the sample (Burns et al., 2004). Numerous other publications using the NSCAW data set have documented the prevalence of specific mental health problems in this population (e.g., Casanueva, Cross, Ringeisen, & Christ, 2011; Orton, Riggs, & Libby, 2009; Southerland, Casanueva, & Ringeisen, 2009)

High rates of mental health problems in foster children are not specific to the United States. Rates in Norway have been shown to be similar to those observed in the NSCAW study; for example, one in two children out of a sample of 279 foster children have been shown to exhibit some form of mental health disorder (Lehmann, Havik, Havik, & Heiervang, 2013). Similarly, English foster children have been shown to exhibit close to four times higher rates of mental health disorders than children living in economically disadvantaged families (Ford, Vostanis, Meltzer, & Goodman, 2007). Similar patterns of mental health disparities among foster children have been found throughout Europe (Holtan, Ronning, Handegard, & Sourander, 2005), Australia (Sawyer, Carbone, Searle, & Robinson, 2007), and Canada (Legault, Anawati, & Flynn, 2006).

Externalizing disorders appear to be one of the most common forms of psychopathology among foster children. For example, Garland et al. (2001) surveyed children receiving services within a number of public-care institutions (e.g., child welfare, juvenile justice, public school services for youths with serious emotional disturbances) and found that the most prevalent disorders were attention-deficit/hyperactivity disorder (ADHD) and disruptive behavior disorders (e.g., oppositional defiant and conduct disorder). The foster care portion of this larger sample comprised 426 children, of whom 38.7% displayed ADHD or a disruptive behavior disorder; overall, externalizing disorders accounted for a much higher percentage than did anxiety or mood disorders, which were present collectively in only 13.8% of the foster children.

While externalizing mental health disorders are more prevalent among foster children, rates of internalizing disorders also appear to be higher for foster children than for their community counterparts to a meaningful extent. For example, when 373 older foster children were interviewed for a study, the prevalence rates of major depression were revealed to be greater than those of a sample of working-class 18-year-old community youths. Depending on the early adversity the foster child had experienced prior to entering out-of-home care, the percentage of individuals suffering from major depression changed: 23% for physical abuse, 22% for physical neglect, and 26% for sexual abuse (McMillen et al., 2005).

These findings are congruent with those from other studies that have found an elevated risk for lifetime major depression in foster children compared with nonfoster children and an increase in suicidal ideation and attempts related to feelings of unimportance and inferiority within the child (e.g., Pilowsky & Wu, 2006). It should be noted, however, that not all data on internalizing disorders are consistent. Some studies have found no differences between scores of depression of foster children and published norms, relevant to the Children's Depression Inventory on children between ages 8 and 16 years (Allen, Combs-Orme, McCarter, & Grossman, 2000).

Trauma-related anxiety disorders are also common among foster children who had experienced some form of sexual abuse or multiple forms of abuses. A comparison between sexually abused, physically abused, and nonabused foster children revealed that more than 60% of sexually abused children exhibited posttraumatic stress disorder (PTSD) and that physically abused children had a higher prevalence for PTSD than did nonabused children, at a rate of one in five (Dubner & Motta, 1999). When compared with a community comparison sample, foster children who had experienced maltreatment, including

neglect, had 1.75 times the risk for manifesting PTSD (Widom, 1999).

Other problem domains include sexual behavior and eating difficulties (Tarren-Sweeney, 2006). For example, using the Assessment Checklist for Children, Tarren-Sweeney & Hazell (2006) found that approximately 33% of their sample of foster and kinship children ages 4–9 years exhibited age-inappropriate sexual behavior. Two prominent trends exist in terms of food-related difficulties as a result of early adversity: food maintenance syndrome and pica-type eating behavior. Tarren-Sweeney (2006) examined these patterns in a study of 347 preadolescent children and found that 24% displayed clinically significant eating difficulties. The eating difficulties tended to be associated with developmental profiles. For instance, those displaying food maintenance syndrome were comorbid with psychiatric disturbances, specifically, disruptive behaviors and affective problems, and pica-type eating behavior was associated with developmental problems ranging from intellectual disability to speech and reading problems (Tarren-Sweeney, 2006).

Attachment and Social Functioning

Research on foster care also provides support for the association between early adversity and problems with social functioning, especially in terms of caregiver attachment (Stovall-McClough & Dozier, 2004) and peer relationships (Leve, Fisher, & DeGarmo, 2007). Reactive attachment disorder and disinhibited attachment disorder are common forms of atypical attachment that have been observed when youths are exposed to early adversity. At the time of initial placement for foster children (ages 1–4 years), for example, Zeanah et al. (2004) found that 37% were diagnosed with reactive attachment disorder, 22% were diagnosed with disinhibited attachment disorder, and 17% were diagnosed with both disorders. An additional study showed similar findings. In a comparison between foster children and nonmaltreated, school-age children, higher rates of reactive attachment disorder were found among the foster children (Minnis, Everett, Pelosi, Dunn, & Knapp, 2006). One factor that was found to be associated with increased risk of developing reactive attachment disorder was increased numbers of placements for the foster child (Lehmann et al., 2013).

In addition to these general patterns of atypical social functioning, young foster children show a propensity to be indiscriminately friendly toward others, readily approaching unfamiliar individuals and showing little social reserve (Pears, Bruce, Fisher, & Kim, 2010). This pattern has also been observed among children reared in institutional settings (Gleason et al., 2014; Rutter et al., 2010); however, it is important to note that studies of both populations have shown that indiscriminate friendliness, while associated with problems in inhibitory control, is not correlated with attachment difficulties (Bruce, Tarullo, & Gunnar, 2009; Pears, Bruce, et al., 2010). Thus, as is discussed later in this chapter, this atypical pattern of behavior may be most accurately characterized as a neurobehavioral difficulty associated with social development than as an attachment problem.

A Canadian study examined the psychological adjustment of foster children, specifically, their anxious behavior and physical aggressiveness in the context of caregiver relationships (Legault et al., 2006). More permanent and higher quality caregiver relationships resulted in less frequent physical aggression, increased number of close friends, greater self-esteem, the use of approach coping strategies, and less frequent avoidant coping strategies and attachment behaviors.

Cognitive Functioning Deficits and Academic Adjustment

Foster children also show deficits in a variety of domains of cognitive functioning. More than half of foster children are estimated to have cognitive difficulties (Landsverk, Davis, Ganger, Newton, & Johnson, 1996). Many of these deficits have been found to be a direct result of early adversity, including early separation from the biological parent, multiple placements, neglect, and abuse. For example, Mueller et al. (2010) found that early adversity experiences were associated with altered cognitive ability when maltreated adopted children were compared with their typical adolescent counterparts on a change task experimental paradigm that tests one's ability to inhibit responses: the adopted children showed impaired cognitive control after having experienced early adversity.

Preschool-age foster children exhibit specific cognitive deficits, including poorer visuospatial processing, poorer memory skills, lower scores on intelligence tests, and less developed language capacities (Pears & Fisher, 2005a). Visuospatial processing was found to be associated with type of abuse and the number of maltreatment types: The ability to process visuospatial information increased with number of maltreatment types and decreased with neglect or emotional abuse. These unexpected patterns offer an early understanding of how the developing mind reacts to maltreatment and abuse.

Language is important to success in multiple realms of development because of its use as a tool for expression and communication (Stock & Fisher, 2006). In contrast, language deficits can lead to poor academic adjustment, which has been shown to increase mental health and behavioral problems, including internalizing and externalizing

problems (Halonen, Aunola, Ahonen, & Nurmi, 2006). Before children have the ability to read, their phonological awareness in kindergarten is one of the most predictive prereading skills. Pears, Heywood, Kim, and Fisher (2011) examined phonological awareness among foster children entering kindergarten: up to 54% scored below the 23rd percentile, indicating a risk for later reading difficulties and other academic challenges.

Poor academic adjustment is also a common problem among foster children. For example, when researchers looked at more than 11,000 second-grade children, they found that compared with community children, those in out-of-home placements showed a higher prevalence of school suspensions and experienced higher rates of poor academic achievement (Fantuzzo & Perlman, 2007; Mitic & Rimer, 2002).

Developmental Delays

The preceding review of social and cognitive functioning deficits in foster children clearly indicates that developmental delays are also very common among foster children. For example, one study compared prevalence rates of developmental delays between children in the general population and foster children and found a 4% to 10% rate in the general population and rates as high as 60% in foster children (Leslie, Gordon, Peoples, & Gist, 2002). When Klee, Kronstadt, and Zlotnick (1995) examined the psychomotor development of 125 children ages 0–3 years, they found that 50% of the foster children rated below the typical level of psychomotor development for their age group, compared with 13% in the normative sample.

Demographic and Race/Ethnicity Differences

Some noteworthy differences exist between male and female foster care alumni. Female foster care alumni are at not only heightened risk for multiple pregnancies, but are at higher risk than are their male counterparts for maltreating their children. Educational outcomes differ, as well. When Dworsky and DeCoursey (2009) examined a sample group of 4,590 pregnant or parenting foster care alumni from metropolitan Chicago, they found that only 44% of the females and 27% of the males possessed a high school diploma or graduate equivalent degree when they exited the program.

The race/ethnicity of foster families and children has been shown to be less influential in determining mental health outcomes among foster care alumni (Villegas & Pecora, 2012). For Caucasian, Hispanic/Latino, and African–American individuals who had experienced some form of foster care, ethnic background was not a strong predictor of whether mental health services would be needed later in life. However, gender, age of entrance into foster care, number of placements, and maltreatment before and while in foster care were factors associated with the eventual need for mental health services (Villegas & Pecora, 2012). It is noteworthy that there is relatively limited research in this area, however; this is a concern in part because of the overrepresentation of racial and ethnic minorities in foster care.

Long-Term Effects

Evidence suggests that the impact of early adversity on psychological and emotional well-being among foster children is not transitory and can persist well into adulthood. In a study in England, for instance, researchers found that adults who had spent time in foster care had twice the rates of mental health, drug, or alcohol problems than those with no histories of foster care (Viner & Taylor, 2005). Similarly, among a sample of 19,430 foster children ages 12–17 years, foster children were shown to have much higher rates of alcohol and illicit drug use (Pilowsky & Wu, 2006). The problems observed also extend to antisocial and criminal behavior. For example, among the NSCAW sample, arrests had occurred at more than four times the national rate for individuals ages 18–24 years (Administration for Children and Families, 2008). In addition, compared with their community peers, youths aging out of foster care have been shown to display higher rates of criminal and delinquent behaviors ranging from minor infractions to more serious crimes (Cusick & Courtney, 2007).

To summarize, the research suggests that foster children show alterations in development across many domains of mental health and well-being. There are few instances in which, when compared with nonmaltreated community children, foster children haven't been found to show disparities. This cumulative body of evidence supports the conclusion that early adverse experiences exert pervasive and enduring influences on typical development.

EARLY ADVERSITY HAS THE POTENTIAL TO ALTER BIOLOGICAL DEVELOPMENT AND TO INCREASE RISK FOR DISEASE

The notion discussed in the previous section—that early adversity affects typical mental development—has been a mainstay of the field of psychology dating back to the

early psychoanalysts. Similarly, there is a long tradition of research on the effects of stress on biological development dating back to the seminal work by Hans Selye (1936). Selye described a general adaptation syndrome in which the body goes through a series of stages in response to chronic stress, including alarm, resistance, and finally exhaustion. This helped explain the prevalence of illness and other negative sequelae in animals (and humans) exposed to chronic adversity. Although Selye's ideas have received considerable revision and clarification in the ensuing decades, many of the core ideas encompassed in his theory remain.

A vast animal literature about this topic shows the impact of stress on cognitive development and on neuroendocrine, immune, and metabolic systems (Levine, 2005). Much of this work has used paradigms that disrupt the early rearing environment of the species under investigation, most commonly through separating the offspring from its parent or by creating stress in the environment of the mother and her offspring. These studies have led to the fairly incontrovertible conclusion that stress experienced early in life has the potential to compromise the physiology of an organism at many levels.

Whereas research involving animals has provided an extensive and precise knowledge base regarding the timing, type, and duration of adverse experiences on typical development, the human literature about this topic is, understandably, considerably more limited because of the unfeasibility of exerting the degree of experimental control on specific dimensions of adversity that has been used in animal studies. However, as described in the next sections of this chapter, researchers have extensively documented the atypical physical, brain, and biological development in populations that have experienced early adversity.

Neuroendocrine Effects of Adversity

The primary neuroendocrine regulation system known to be affected by early adversity is the hypothalamic-pituitary-adrenal (HPA) axis, which is believed to contribute to a number of neurocognitive and physical health outcomes (Chrousos, 2009; Pechtel & Pizzagalli, 2011). In this system, physical or psychological stressors, including separation from a primary caregiver in infancy or social threat in late childhood, trigger a neuroendocrine cascade. Specifically, with sensory input and input from other areas of the brain indicating a disruption in homeostatic balance, corticotrophin releasing hormone, or CRH, is released in the hypothalamus. CRH is transported to the anterior pituitary, where it stimulates the release of adrenocorticophin releasing hormone, or ACTH; ACTH then enters the bloodstream and stimulates the release of glucocorticoids in the adrenal cortex. The release of these glucocorticoids (cortisol in humans, corticosterone in rodents) signals the widespread engagement of additional resources throughout the body to respond to environmental stressors, including increased metabolic rate and immune function (Chrousos, 2009; Hostinar, Sullivan, & Gunnar, 2014; Pechtel & Pizzagalli, 2011). In this way, cortisol released from the HPA axis plays a number of key roles in helping maintain a balance in response to perturbations (Chrousos, 2009). Under normative (nonmaltreating) environmental conditions, activation of the HPA axis in response to acute stressors is considered adaptive; however, environments with excessively high levels or chronic exposure are believed to reach harmful, *toxic* stress levels (Shonkoff, Garner, et al., 2012).

The HPA axis also exhibits a diurnal rhythmicity (Kirschbaum & Hellhammer, 1989). In humans, cortisol levels are very low during the night, begin to rise around the time of awakening, and reach their daily peak approximately 30 minutes after awakening. Levels then drop off fairly precipitously and continuously throughout the morning, and reach their nadir from bedtime through the night. Although this pattern is not established in infancy until children develop regular day/night sleep cycles, it does appear to remain fairly stable once established. One exception is that when individuals undergo periods of chronic stress (e.g., a health crisis, divorce, college exams), cortisol levels may fail to decrease, and instead, remain elevated throughout the day.

Research evidence has documented adversity-related alterations in the typical diurnal pattern of HPA-axis activity. Specifically, a *blunted* pattern is commonly observed in maltreated children, including foster children, that characteristically involves low morning cortisol levels that remain low throughout the day or a smaller decline across the day from morning to evening (Bruce, Fisher, Pears, & Levine, 2009; Trickett, Noll, Susman, Shenk, & Putnam, 2010). Although the specific mechanism for this blunted diurnal pattern, termed *hypocortisolism*, among foster children is not known, it may represent a down-regulation of the HPA-axis system as a resource-conservation mechanism in response to chronic early adversity (Fisher & Gunnar, 2010; Hostinar et al., 2014). Similarly dysregulated HPA-axis function has been observed in institutionally reared children (Carlson & Earls, 1997; Gunnar, Morison, Chisholm, & Schuder, 2001). Notably, improved environments, including adoption from institutional care or therapeutic foster care interventions, have been found to

normalize diurnal cortisol patterns in maltreated children or prevent further dysregulation from occurring (Fisher, Stoolmiller, Gunnar, & Burraston, 2007).

Substantial evidence from the animal literature suggests there are pathways through which dysregulated cortisol patterns may confer broader risk to the organism. Specifically, the function of brain regions dense with glucocorticoid receptors (e.g., prefrontal cortex, hippocampus, amygdala) are particularly compromised following acute and chronic stress exposure (Hostinar et al., 2014; Pechtel & Pizzagalli, 2011). Some evidence suggests that chronic stress and cortisol dysregulation relate to cellular atrophy in some of these regions (e.g., prefrontal cortex) and the opposite (i.e., increased cellular structure) in other regions, such as the amygdala (related to fear-based learning). These changes are theorized to contribute to a decreased capacity for adaptive homeostasis in the HPA-axis system and resulting stress sensitivity (Hostinar et al., 2014).

Although less established in the literature, the neuroendocrine regulation of the oxytocin hormone, which is involved in human bonding and social behavior, may also be altered by early adversity. This hormone is predominantly synthesized in a hormonal cascade similar to that described for the HPA axis. In this case, the cascade begins in the hypothalamus and proceeds through the pituitary and peripheral organs (e.g., uterus, testis, heart; Hostinar et al., 2014). Although there are no studies of oxytocin in foster children, inferential evidence can be obtained about the effects of early adversity on this hormone from related areas of the literature. For example, in comparison with nonadopted children, children who were adopted following early institutionalized care show lower levels of urinary oxytocin when interacting with their mothers (Wismer Fries, Shirtcliff, & Pollak, 2005). In addition, oxytocin levels in the cerebrospinal fluid of adult women with a history of maltreatment have been shown to be lower than those of controls with no such histories (Heim et al., 2008).

The Effects of Early Adversity on the Structure and Function of Brain Regions

A wide variety of brain regions important to basic and complex cognitive skills (e.g., self-regulation) appear particularly susceptible to environmental experiences because of their protracted course of development and stress-sensitive neurochemical properties (Berkman, Graham, & Fisher, 2012; Pechtel & Pizzagalli, 2011). Research evidence about the impacts of early adversity on these brain regions suggests alterations in the structural properties of the brain and functional correlates in neuroimaging and electrophysiological studies. It is important to note, however (as we present later in this chapter), that with a few noteworthy exceptions (e.g., Bruce et al., 2013), this research base is drawn from populations that are overrepresented in foster care, but in many cases it is not specific to research on samples of foster children.

A key developmental marker of healthy brain development is an increase in white-matter density and integrity, reflecting myelination and the insulation of neural pathways. Increased white-matter density and integrity, particularly originating from prefrontal brain regions, is believed to reflect the adaptive refinement of neural networks through heightened connectivity and integration within and between brain regions and circuits (Pechtel & Pizzagalli, 2011; Uddin, Supekar, Ryali, & Menon 2011). However, early adversity in the form of maltreatment has been found to alter white matter, with severe institutional neglect predicting whole-brain white-matter reductions and specific reductions in tracts within prefrontal brain regions and between prefrontal and temporal cortices (Hanson et al., 2013; McCrory, De Brito, & Viding, 2012). Children who have experienced maltreatment and show PTSD symptomatology, in contrast, have been shown to exhibit specific white-matter reductions in prefrontal brain regions but no whole-brain differences in white-matter integrity (DeBellis et al., 2002). The corpus callosum comprises the largest white-matter structure in the brain and has been found in all but one study of maltreated children to have adversity-associated reductions in white-matter integrity (McCrory et al., 2012). This cross-hemispheric brain structure is involved in a number of higher cognitive abilities (e.g., executive function, emotion). Atypical development of the corpus callosum has been theorized to contribute to the cognitive impairments found in maltreated children, although this association has yet to be established (McCrory et al., 2013).

Research evidence about the effects of early adversity on gray-matter volume in the cerebral cortex, which reflects neuronal density, is less consistent, with different studies reporting adversity-related increases or decreases in gray-matter volume (DeBellis et al., 2002; McCory et al., 2012). These discrepancies may result from the inverted U-shaped trajectory of gray matter over the course of development—specifically, early increases followed by a decrease in adolescence and relative stability in adulthood (Pechtel & Pizzagalli, 2011). Combined with developmental increases in white-matter density, these *cortical thinning* processes are believed to reflect the refinement of neural networks and the establishment of more efficient processing

that facilitates advanced cognitive skills (Padmanabhan, Geier, Ordaz, Teslovich, & Luna, 2011). Because of this nonlinear trajectory of gray-matter development, *altered* development could be reflected in multiple ways—for example, a lack of experience-related neuronal growth, resulting in reduced gray-matter volume, or insufficient gray-matter pruning, resulting in increased gray-matter volume. Interpreting the existing literature in this area is further hindered by the heterogeneity of maltreatment experiences, the differing sample age groups studied, and the differing timing of adversity across studies (McCrory et al., 2013).

The results for gray-matter integrity of noncortical brain regions are somewhat more consistent, with reductions in cerebellum gray-matter volume reported in multiple studies of children and adolescents with a history of maltreatment and adversity (McCrory et al., 2013; Pechtel & Pizzagalli, 2011; Teicher, Tomoda, & Andersen, 2006). Hippocampal-volume reduction is also associated with a history of adversity, although this difference does not appear to emerge until later adolescence or early adulthood. Although this reduction may be exacerbated by adversity-related high-risk behavior, such as alcohol abuse, findings from human and animal studies suggest that it also occurs as a consequence of early adversity itself. In rodent models, this has been posited to arise from alterations in expected prepubertal gray-matter overproduction and subsequent postpubertal pruning processes, resulting in a net deficit in hippocampal cells (Teicher et al., 2006).

Findings from research conducted during challenging cognitive tasks also provide evidence for the impacts of early adversity on the function of prefrontal and hippocampal brain regions. Such research uses functional MRI (fMRI) to measure regional blood-flow activity during performance of computer tasks, including protocols that assess the neural bases of inhibitory control (i.e., the ability to stop a planned motor response) and working memory (Bruce et al., 2013; Carrión, Haas, Garrett, Song, & Reiss, 2010; Mueller et al., 2010). In experimental paradigms involving inhibitory control, young maltreated adolescents in foster care were found to have less fMRI activation than did controls in prefrontal brain regions associated with inhibitory control (e.g., anterior cingulate cortex) and in visual processing brain regions (e.g., occipital cortex; Bruce et al., 2013). However, these findings somewhat contrast with the findings from another study of young adolescents with severe institutional neglect: these adolescents were found to have greater activation in prefrontal brain regions (e.g., inferior frontal cortex, anterior cingulate cortex, striatum) for inhibitory control versus non–inhibitory control trials (Mueller et al., 2010). Although both studies provide evidence that early adversity affects functionality in the neural substrates of advanced cognitive skills, the conflicting directionality of the findings has yet to be reconciled in the literature. Measures (fMRI) of brain activation during a working-memory task have also been examined in children and adolescents exhibiting PTSD symptomatology following early interpersonal trauma (e.g., physical abuse, sexual abuse, witnessing violence; Carrión et al., 2010). Such findings suggest that the participants who had experienced adversity had significantly less hippocampal activation during memory retrieval compared with participants who had not experienced adversity. This reduced activation was also found to be related to PTSD symptoms, particularly in the avoidance/numbing cluster, further strengthening the potential implications of hippocampus hypoactivation as a potential link to memory abnormalities associated with early adversity (Carrión et al., 2010).

Event-related potential (ERP) research has provided additional support for atypical functioning in prefrontal brain regions during challenging cognitive tasks. This research measures average electrophysiological activity at the scalp, which relates to specific task events and associated cognitive processes. Across samples facing early adversity (i.e., foster children and severely neglected institutionalized children), there is converging evidence that children exhibit slower executive attention–related ERP components that involve prefrontal attention processes (e.g., the N200; McDermott, Westerlund, Zeanah, Nelson, & Fox, 2012). This delayed neurocognitive response has been theorized to reflect a slower processing speed and has been associated with longer trial-reaction times. Early adversity has also been associated with reduced ERP responses related to attention and inhibitory control (e.g., the N200 and the P300), which have been theorized to reflect attention-regulation difficulties (Loman et al., 2013; McDermott et al., 2012). Although the aforementioned ERP components likely have multiple neural generators, prefrontal brain regions are critically implicated and theorized to coordinate activity across neural networks (Baumeister et al., 2014; Huster, Westerhausen, Pantev, & Konrad, 2010).

The growing body of ERP research findings also suggests that prefrontal brain regions (e.g., anterior cingulate cortex) in children who have experienced early adversity function atypically during tasks that require performance monitoring (Bruce, McDermott, Fisher, & Fox, 2009; McDermott et al., 2012). *Performance monitoring* refers to increased attention to errors in performance on a given

task and may include internal monitoring (internal awareness that an error has been made) and external monitoring (processing feedback that indicates the presence of an error). Specifically, during computerized inhibitory control tasks, children in regular foster care were shown to lack the expected ERP response following errors in performance versus correct trials. Notably, the adversity-related reduction in cognitive performance monitoring has been found for both internal and external monitoring processes. However, the children in therapeutic foster care (with additional intervention services) exhibited the expected exaggerated ERP response to errors for internal and external monitoring processes; this suggests that children who have experienced early adversity have the capacity for more normative cognitive processing in the presence of intervention and supports.

The neurocognitive processing of emotional stimuli has also been shown to differ among children with histories of adversity. Across a wide range of ages (e.g., 15 months to 9 years), ERP research findings indicate that adversity is associated with exaggerated, later stage attentional processing of angry stimuli, including angry (vs. happy) faces and voices (Curtis & Cicchetti, 2013; Shackman, Shackman, & Pollak, 2007). Research findings using fMRI have also shown an exaggerated right amygdala response to angry faces in maltreated children compared with controls (Dannlowski et al., 2012). Multiple contributing factors have been proposed to understand these findings, including increased exposure to anger in adverse environments and hypervigilance to threat (Curtis & Cicchetti, 2013; Shackman et al., 2007). Research in the early stages of attentional processing has also shown evidence for the increased processing of happy faces in maltreated children, which has been theorized to reflect the heightened processing of emotional stimuli as an adaptation to emotional stress (Curtis & Cicchetti, 2013; McCrory et al., 2013).

Other Physical Effects of Adversity

Beyond documenting the effects of early adversity on neurobiological regulatory systems, findings from research on foster care also indicate that some of the most basic functions are disrupted by perturbations to the early environment. For example, researchers have found that young foster children show signs of so-called *failure to thrive*, as indexed by a shorter stature and a smaller head circumference compared with that of typical children (Pears & Fisher, 2005a). As with the aforementioned study findings, these findings match those obtained in investigations of post–institutionally reared children and highlight the profound alterations that early adversity has on a child's physical, brain, and biological development.

The large-scale, population-based Adverse Childhood Experiences Study (ACES) has illuminated the general gradient between the cumulative number of adversity categories that an individual has suffered and the deleterious effects on many domains of adult health and well-being (Anda et al., 2006). In this study, the measure of adverse experiences included childhood maltreatment and general household dysfunction (e.g., adult in household with mental illness, incarceration, substance use problems, suicide, violence against the mother). The cumulative-risk approach used by the ACES investigators is particularly useful given that childhood adversity categories typically co-occur at rates as high as 80% to 98% (Dong et al., 2004; Pears, Kim, & Fisher, 2008).

A range of health problems has been found to be overrepresented in population-based survey data in samples of adults with four or more adversity categories (Felitti et al., 1998). They include heart disease, obesity, high blood pressure, allergies, arthritis, asthma, circulation problems, ulcers, chronic pain, and cancer. However, not all studies have found increased risk for every health problem (Chartier, Walker & Naimark, 2010; Felitti et al., 1998; Springer, Sheridan, Kuo, & Carnes, 2007).

A challenge in interpreting the causal links between childhood experiences and poor adult health in population-based studies is the fact that ACES also includes risk for adulthood-specific, health-threatening behavior (Arnow, 2004; Felitti et al., 1998; Springer et al., 2007). In addition, epidemiological research findings suggest that some of the negative physical-health outcomes associated with abuse (e.g., arthritis, obesity, cardiovascular health) may be associated with developmental exposure to harsh physical punishment, which does not meet severity criteria for maltreatment (Afifi, Mota, MacMillan, & Sareen, 2013). This suggests that some of the effects of early adversity among foster children and others may exist along a continuum of stressors with potential detrimental effects at levels even below *maltreatment* thresholds.

However, recent research findings also suggest multiple biological pathways that are perturbed in adulthood based on childhood maltreatment status. This research includes the effects of child maltreatment and physical health from clinical adult populations that are referred for specific medical problems. It also includes evidence from matched-cohort designs of children with substantiated maltreatment and community controls (Davis, Luecken, & Zautra, 2005; Widom, Czaja, Bentley, & Johnson, 2012).

One prospective study has followed children with a documented adversity history and community controls to adulthood, examining blood, vision, and respiratory biomarkers of health risk and controlling for a number of sociodemographic and lifestyle variables (Widom et al., 2012). This study found increased risk for diabetes (indexed by higher levels of poor glycemic-control blood levels), lung disease (indexed by poor peak airflow), and vision problems (indexed by an acuity test) in adults who experienced early adversity. The race and gender interactions suggested that women were at particular adversity-related risk for poor glycemic control and that White adults were at increased adversity-related risk for heart disease (as indexed by C-reactive protein). Other research on pubertal timing has highlighted the impacts of early adversity on developmental physical processes, with early neglect being associated with slowed pubertal development that later increased in boys; in contrast, sexual abuse was specifically associated with early pubertal timing for girls (Negriff, Blankson, & Trickett, 2014).

A specific focus on the biological bases of pain perception has been studied, given the diverse types of pathological presentations that include chronic pain (e.g., chronic pelvic pain, fibromyalgia, migraines) that are found to be overrepresented in samples with histories of adversity (Arnow, 2004; Davis et al., 2005; Tietjen et al., 2010; Walker et al., 1997; Walker et al., 1988). Evidence and theory suggest that a history of adversity may result in increased vulnerability to experiencing pain through stress-related hormonal processes (Arnow, 2004; Fisher, Gunnar, Dozier, Bruce, & Pears, 2006; Nicolson, Davis, Kruszewski, & Zauta, 2010). Research among adult women with fibromyalgia, a chronic pain condition without a known medical explanation, has shown that self-reported childhood maltreatment is associated with higher diurnal cortisol levels compared with women without maltreatment histories. This suggests that, although the dysregulated HPA-axis functioning may not be a contributing factor to fibromyalgia in all women, it may be a contributor or indicator of fibromyalgia risk in women who have experienced maltreatment.

Genetic Research Related to Adversity

Among the most noteworthy developments in recent years is the discovery of specific genetic vulnerabilities that may be responsible for poorer outcomes among some individuals who have experienced early adversity (Banny, Cicchetti, Rogosch, Oshri, & Crick, 2013; Caspi et al., 2002; Cutuli, Raby, Cicchetti, Englund, & Egeland, 2013). In this research, genetic vulnerabilities often interact with early environmental adversity (GxE interactions) to predict negative outcomes more likely to occur in the presence of early adversity. In the first study to document this effect, Caspi et al. (2002) found that among individuals who had experienced early adversity, carriers of a low activity MAOA-1 allele were at particular risk for antisocial behavior. Follow-up research has shown that this polymorphism is associated with an exaggerated neurocognitive response to threat and reduced activity in the brain regions involved in emotion regulation, suggesting a heightened vulnerability to aggressive or reactive behaviors (McCrory et al., 2012). Other notable studies have focused on Gene x Environment interactions of early adversity that predict later life depression based on polymorphisms of the serotonin transporter gene, which influences the availability of the serotonin neurotransmitter at neuronal synapses (Banny et al., 2013; Cutuli et al., 2013). Additional research has shown that genetic variations relevant to neuroendocrine stress response predict dysregulation of stress-related hormones (e.g., cortisol) in maltreated, but not in nonmaltreated, samples (Cicchetti, Rogosch, & Oshri, 2011).

Additional recent developments in the genetics literature include findings suggesting that early adversity may also affect the expression of specific genes (*epigenetic effects*), thereby modifying the blueprint for ontogeny provided by DNA (Essex et al., 2013). In rodent models, developmental exposure to maltreating caregivers can lead to changes in gene expressions related to neural growth, which is particularly important for prefrontal cortex development (Roth, Lubin, Funk, & Sweatt, 2009). The only study on early adversity to date in humans has shown support for epigenetic effects in adolescents related to maternal stress during the adolescent's infancy and paternal stress when the adolescent was preschool age. The implications of these effects have yet to be established, with some changes occurring in genes with plausible links to family stress (e.g., genes coding for cellular differentiation in the nervous system) and others in genes with no identified links (Essex et al., 2013). Increased cellular aging, as indexed by reduced telomere length, has also been reported among adults with a history of early adversity; however, the mechanisms contributing to increased cellular aging have yet to be established (Tyrka et al., 2010).

Summary

This large body of evidence across research among high-risk populations that include foster and maltreated

children suggests that early adversity contributes to profound changes in healthy biological, brain, and physical development. Recent genetic research findings suggest that certain phenotypes increase a child's vulnerability to the effects of adversity on outcomes such as depression and antisocial behavior. At the neuroendocrine level, early adversity is well documented to contribute to dysregulation of the HPA axis and atypical patterns of cortisol in the body. The effects of dysregulated cortisol production are strongly supported by animal models to contribute to a range of neurocognitive and physical health consequences, which are commonly overrepresented in samples with histories of early adversity. Evidence of atypical cognitive processing from fMRI and ERP methods also supports the findings from the animal literature of increased adversity-related deficits in brain regions with higher densities of glucocorticoid receptors. Given the widespread effects of early adversity on developing bodily systems, it is particularly promising that early intervention has been shown to ameliorate atypical development of neuroendocrine and cognitive-response monitoring processes. Ongoing research in the area is seeking a more in-depth description of the underlying mechanisms, which could advance the ability of interventions to improve outcomes for individuals with histories of early adversity.

THE TIMING AND DURATION OF ADVERSITY IS ASSOCIATED WITH DIFFERENTIAL BEHAVIORAL AND NEUROBIOLOGICAL OUTCOMES, WITH A GENERAL TREND OF LONGER LASTING ADVERSITY PRODUCING THE MOST PROFOUND EFFECTS

Although the animal literature contains extensive information about the timing and duration of effects of adversity on typical development, research with humans is much less suited for characterizing how such dimensions of adversity lead to alterations in key domains of functioning. However, research on foster care provides some information in this area. Consistent with findings from the institutional-rearing and international-adoption literatures, research findings about foster children indicate that increased time spent in adversity increases the likelihood for compromised outcomes. For example, children in the previously described NSCAW sample who lived in maltreating families longer (placed in foster care at older ages) showed more behavior problems than did those placed in care at younger ages (Burns et al., 2004). Perhaps what is most noteworthy about these results is that the effects of prolonged exposure to adversity appear to outweigh the effects of out-of-home placement. Other research on symptoms of serious psychopathology, such as borderline personality disorder, also suggests that the chronicity of adversity is particularly predictive of negative outcomes (Hecht, Cicchetti, Rogosch, & Crick, 2014). Moreover, research with a large cohort of public-school children has shown that earlier onset adversity is linked to increased academic problems (Fantuzzo, Pearlman, & Dobbins, 2011).

Although evidence across studies shows that the chronicity and earlier onset of adversity are related to more severe behavioral problems, research findings also suggest that the timing of certain types of maltreatment predicts distinct behavior problem trajectories (Keiley, Howe, Dodge, Bates, & Pettit, 2001; Manly, Kim, Rogosch, & Cicchetti, 2001). In particular, the severity of physical neglect in infancy has been related to later developing externalizing behavioral problems, whereas the severity of physical neglect in the preschool years has been related to later developing internalizing problems. In this same study, emotional abuse in infancy and physical abuse in the preschool years were related to externalizing problems. It is important to note that maltreatment in the school years contributed significant variance to behavioral problems after controlling for earlier maltreatment, suggesting that although earlier onset maltreatment might be the most harmful, later maltreatment also contributes to significant behavioral problems (Keiley et al., 2001). In growth models of behavioral problems, children who experienced later onset maltreatment have been shown to exhibit a more rapid increase in externalizing behavior despite having fewer behavioral problems at kindergarten entry.

Supportive evidence about the importance of the timing and duration of adversity can be derived from international studies such as The English and Romanian Adoptee (ERA) Project. The ERA Project investigated the development of Romanian children adopted into the United Kingdom in the early 1990s. The vast majority of the adoptees had experienced extreme early global deprivation up to age 42 months as a consequence of their early placement in Romanian institutions (Rutter et al., 2010). However, there was greater catch-up among children who were adopted prior to age 6 months (Rutter et al., 2010). Overall, the research in this area corroborates evidence from the animal literature and highlights the vulnerability of children to early and prolonged adversity.

In addition to the behavioral consequences associated with a longer duration of adversity, exaggerated adversity-related effects on brain development have been documented. Specifically, in a study of children with

maltreatment and PTSD, researchers found that smaller brain volume was associated with a longer duration of maltreatment and an earlier onset of PTSD-related trauma (DeBellis et al., 2002).

Relatively little research has been conducted about the effects of the timing of adversity on brain development, but findings from neuroimaging studies suggest that timing may be important given the differential development of specific brain regions across childhood (Pechtel & Pizzagalli, 2011). For example, in young adult females who experienced childhood sexual abuse, the abuse has been shown to predict different impacts on regional brain volume associated with timing of exposure (Andersen et al., 2008). Sexual abuse in very young children (ages 3–5 years) and early adolescence (ages 11–13 years) was shown to be associated with smaller hippocampal volume, whereas abuse in other age groups was shown to be associated with reduced volume in the corpus callosum (ages 9–10 years) and the prefrontal cortex (ages 11–13 years). Such changes are theorized to reflect the fact that brain regions may be differentially developing at distinct time points and, accordingly, may be differentially vulnerable based on the timing of maltreatment. However, as noted by Pechtel and Pizzagalli (2011), the specific mechanisms underlying such time-sensitive structural abnormalities have been minimally described despite extant theory related to the role of neurogenesis, myelination, and synaptic pruning.

The importance of timing has also been highlighted in a study investigating maltreatment-related declines in brain volume of the amygdala, thalamus, and caudate (Pechtel, Lyons-Ruth, Anderson, & Teicher, 2014). In early adulthood, participants (maltreated and control) were asked to recall specific maltreatment periods in their childhood to understand the importance of timing and severity on brain volume. Although the thalamus and caudate volumes were not different in the maltreated group, right amygdala volume was significantly larger in individuals who experienced childhood maltreatment, with larger volume associated with increased severity of maltreatment. Furthermore, a sensitive preadolescent period (ages 10–11 years) with even moderate maltreatment exposure contributed to increased right amygdala volume. The authors noted that the right (vs. left) amygdala exhibits a prolonged developmental trajectory and has been shown to be particularly sensitive to maternal prenatal stress (Pechtel et al., 2014). Furthermore, multiple fMRI studies have demonstrated maltreatment associated hyperreactivity of the amygdala to emotional stimuli (Dannlowski et al., 2012; van Harmelen et al., 2013). Based on animal studies, researchers have highlighted the potential significance of the preadolescent/prepuberty period for its increased neural pruning, but the mechanisms contributing to such a sensitive period are unknown (Pechtel et al., 2014).

Taken together, these results strongly suggest that the duration and severity of maltreatment are associated with increased aberrations from typical development. Theory suggests the potential importance of timing on different outcomes associated with the changing developmental processes of the body and brain (Pechtel & Pizzaglli, 2011). However, the evidence for such impacts in humans is just emerging. Multiple methodological challenges must be overcome to examine and understand the impacts of timing, including recruitment of sufficient sample sizes of at-risk children and the potential for regionally specific effects, which require the development of specific hypotheses to detect potential differences (Teicher & Samson, 2013).

NEGLECT IS A PARTICULAR CAUSE FOR CONCERN BECAUSE OF ITS PERVASIVENESS AND ITS PROPENSITY TO DISRUPT HEALTHY DEVELOPMENT AND EXERT A LASTING IMPACT ON HEALTH AND WELL-BEING

One of the lesser known characteristics of the foster care population, but one that has been the focus of research and public policy in recent years, is that many children are placed in out-of-home care because of neglect (e.g., failure to provide age-appropriate care, food, shelter, healthcare, supervision, or safety precautions) rather than physical and sexual abuse. Neglect is nearly ubiquitous among foster children—for example, more than 78% of foster children are estimated to be in care because of neglect alone, and nearly all those in care because of abuse have experienced neglect (U.S. Department of Health and Human Services, 2012). Moreover, neglect—even in the absence of other maltreatment—appears to represent a serious threat to the health and well-being of young children.

Neglect is an interesting phenomenon from a developmental perspective because it represents an omission of expected caregiving input rather than a commission of an act of physical or sexual violence toward the child. Because neglect is not an overt form of abuse and leaves no physical marks, the damage resulting from prolonged neglect may be more difficult to detect. However, as reviewed later, there is increasing evidence that neglect represents a threat to mental and physical development, which may become apparent in later years as the child experiences delays and is unable to keep pace with peers on key tasks of cognitive,

physical, or socioemotional development. The difficulty detecting neglect, especially among infants and toddlers who lack the language to describe their experiences, is one of neglect's most concerning qualities.

It is important to qualify any discussion of neglect by noting that neglect does not occur when a parent is unresponsive intermittently but otherwise consistent in providing care and promoting a loving environment. Intermittent inattentiveness is not cause for concern; rather, it may have the potential to promote independence in the child and increase the child's ability to self-soothe and problem solve. Similarly, variability in the attention given to the child by the parent has been shown to benefit the child. Such variability in an otherwise nurturing environment represents positive stress that has been shown to be beneficial to children as young as age 6 months (Tronick & Gianino, 1986).

One way to understand why neglect is so impactful is to consider the importance of adult–child interaction in development. Development in childhood is hierarchical in nature. Early skills develop out of consistent and nurturing interactions with caregivers, and these skills lead to later success and aptitude in academics, physical achievement, and control of the surrounding social environment (Shonkoff, Garner, et al., 2012). Neglect essentially represents the absence of evolutionarily expected environmental input.

Much of the research on the effects of neglect has not been specific to foster care; however, when compared with the general population, neglected children are clearly overrepresented in foster care. Moreover, neglect samples often contain many children currently in care or with a history of child welfare involvement. Research on samples of neglected children has consistently found that neglect is associated with numerous effects on development, health, and well-being (Horwitz, Widom, McLaughlin, & White, 2001). For example, the longitudinal Minnesota Mother–Child Project examined 267 children born to mothers who, for various reasons, were at risk for neglectful or psychologically reserved parenting, that is, *psychologically unavailable* mothers and *neglectful* mothers who failed to provide physical care and protection to their child. When these two groups of mothers were compared with other maltreatment groups, the neglected children performed the worst on the Bayley Scales of Infant Development from 9 to 24 months of age (Egeland & Sroufe, 1981; Hildyard & Wolfe, 2002). The neglected children also possessed more behavioral problems, including frustration and anger in problem solving. At age 48 months, the neglected children showed poor impulse control on an obstacle task and showed less creativity in problem solving. Neglected children's academic and cognitive abilities suffered as well (Gowen, Christy, & Sparling, 1993).

DeBellis et al. (2009) investigated the academic performance of neglected children and that of their nonneglected peers. The neglected children performed significantly lower on measures of intelligence. In addition, neglected children lacked aptitude in tasks that measure memory for faces, names, and narratives. Egeland and Sroufe (1981) examined the attachment behavior of 31 maltreated children and 33 nonmaltreated children, based on attachment theory. During feeding and play, all the children of mothers who lacked the basic skills in caring for their child were anxiously attached and in the avoidant attachment group at age 12 months. The authors further noted that following DHS intervention to remove the child from the home for some period of time, the mother was totally psychologically unavailable. Rutter et al. (2010) noted the co-occurrence of many symptoms of neglect and identified a specific behavioral phenotype among children who had experienced institutional deprivation (a severe form of neglect neglect) that included symptoms of quasi-autism, disinhibited attachment, cognitive impairment, and inattention/overactivity.

In institutional settings, neglect can be especially extreme (a condition referred to as *privation*). According to UNICEF, an estimated 1.5 million children in Central and Eastern Europe live in public care institutions, where it is typical for children to outnumber caregivers 15 to 1. In many contexts, caregivers work 8-hour shifts, meaning that the limited contact the child receives is provided by a changing "cast of characters." Research on children reared in institutional settings provides evidence that neglect affects neurobiological development. For example, Tottenham et al. (2010) examined the whole brain and limbic structures (amygdala and hippocampus) of children adopted following early institutional care versus a healthy comparison group. Measures used included indicators of emotion regulation, anxiety, and internalizing behavior. Results indicated that the later a child was adopted, the more psychiatric disturbances were associated with larger amygdala volumes, poorer emotion regulation, and increased anxiety.

The ability to recover from neglect varies depending on the specific experiences of the child and on genetic factors. The environment that the child enters after being exposed to neglectful conditions can benefit or hinder such recovery. The more stimulating the home and the more supportive the caregivers are, the better the child's chance to catch up with peers (Bradley & Caldwell, 1984). Foster care, when paired with supportive parenting programs,

offers a first step for promoting learning and development in neglected children.

TRANSITIONS AMONG PRIMARY CAREGIVERS ARE A SPECIFIC CLASS OF ADVERSE EXPERIENCE WORTHY OF ATTENTION BECAUSE THEY APPEAR TO NEGATIVELY AFFECT THE DEVELOPMENT OF KEY COGNITIVE AND BEHAVIORAL SKILLS NEEDED FOR SOCIAL AND ACADEMIC SUCCESS

Although the child–caregiver attachment system has been investigated extensively in the literature, it is most often assessed within the context of the child's relationship with permanent primary caregivers (e.g., biological or adoptive parents). In contrast, foster care research uniquely allows us to examine the pliability of the attachment system in children across multiple caregiver relationships. Indeed, within the context of foster care, transitions between caregivers are common: one to two thirds of foster placements disrupt within 12–24 months of placement, for various reasons (Wulczyn, Hislop, & Chen, 2007). In addition to uncontrollable child problem behavior, other variables appear to cause placement failures. In a study about this topic, Oosterman, Schuengel, Slot, Bullens, and Doreleijers (2007) conducted a meta-analysis of research involving more than 20,000 foster children. In addition to child problem behavior, the strongest predictors of placement failure were older age at placement, history of residential treatment, and number of prior placements. Similarly, Fisher, Burraston, and Pears (2005) found that placement instability essentially begets further instability. Placement transitions in foster care also result from administrative decisions (e.g., siblings subsequently being removed from the birth parents and placed into care). Moreover, even positive changes, such as reunification with birth parents or adoption, represent caregiver transitions.

Regardless of the cause, caregiver transitions appear to have the potential to compromise typical development. Rubin, O'Reilly, Luan, and Localio (2007) examined placement instability among NSCAW children and categorized the children according to whether or not they achieved a stable placement within 18 months in out-of-home care. They found that more than one quarter of the sample failed to achieve a stable placement and that placement instability predicted problem behavior, as assessed using the Child Behavior Checklist. Specifically, placement instability resulted in a 63% increase in problem behavior. In a second study, Chamberlain et al. (2006) found that the number of behavior problems was directly related to the number of placement disruptions.

Placement disruptions have also been shown to contribute to foster child inhibitory-control difficulties. Pears, Bruce, Fisher, and Kim (2010) reported that among a sample of foster preschoolers, the number of unique placements a child had experienced was significantly correlated with inhibitory control problems. These inhibitory control problems were noted as being part of a more general set of difficulties with self-regulation that included indiscriminate friendliness. Similarly, Lewis, Dozier, Ackerman, and Sepulveda-Kozakowski (2007) examined inhibitory control in a sample of foster children who were adopted following care, including children with and without a history of placement instability. They found that the children with a history of placement instability (vs. that of the comparison group) performed more poorly on a measure of inhibitory control derived from a day/night Stroop task and were rated as more oppositional (although inhibitory control did not mediate the association between placement instability and oppositional behavior).

To summarize, research on foster children provides evidence that experiencing caregiver transitions has the potential to disrupt healthy child development. In particular, the literature suggests that such transitions are associated with an increased likelihood for disruptive behavior and inhibitory-control difficulties. These findings provide evidence that this particular form of adversity may interfere with the development of regions of the prefrontal cortex involved in executive functioning, suggesting that policy and programming designed to mitigate risks for foster children (and others) should seek to prevent or reduce the number of caregiver transitions that children experience.

THE COMBINED EFFECTS OF PRENATAL STRESS (ESPECIALLY PRENATAL SUBSTANCE EXPOSURE) AND EARLY ADVERSITY ON NEUROBEHAVIORAL DEVELOPMENT ARE ADDITIVE AND PRODUCE WORSE OUTCOMES THAN PRENATAL STRESS OR EARLY ADVERSITY ALONE

Although research on foster children and other samples experiencing early neglect/deprivation provides a strong case for the cumulative effects of adversity on typical development, one noteworthy aspect of this evidence base is that it focuses almost exclusively on experiences that occur after the birth of the child. In reality, for many

foster children, adversity begins at conception, continues throughout pregnancy, and is ongoing antenatally. An extensive literature involving animal models and humans documents the effects of prenatal adversity (particularly substance use) on biobehavioral development (Thompson, Levitt, & Stanwood, 2009). However, to be consistent with the natural ecology of foster children (and many other high-risk populations), modeling *the combined effects of prenatal and early adversity* is a necessary addition to examining separately the effects of either developmental period. Interestingly, relatively limited research has been conducted in this area.

Foster Care as a Context for Prenatal Substance Exposure

Foster care provides an excellent context for examining the combined effects of prenatal substance exposure and early adversity. Estimates are that between 43% and 79% of the parents of foster children meet criteria for a substance use disorder (Besinger, Garland, Litrownik, & Landsverk, 1999; Young, Boles, & Otero, 2007). Also, 80% to 90% of cases of neglect reported to child welfare involve parental substance use disorder (Dunn et al., 2002). Thus, it is likely that for many foster children, parental substance use occurred at least intermittently if not throughout pregnancy. Indeed, evidence for this exists in the literature. For example, in a study of 204 infants placed in family foster care at ages 0–15 months, prenatal substance exposure was verified for 61.7% and suspected for 16.7% of the infants (McNichol, 1999). Similarly, in a foster care population in Washington state, the rate of fetal alcohol syndrome was 10–15 times greater than in the general population (Astley, Stachowiak, Clarren, & Clausen, 2002).

In response to the recognized prevalence rates of prenatal substance exposure and the risks associated with such exposure, 19 states and the District of Columbia have implemented mandatory reporting procedures at birth for prenatally exposed infants, and 12 states and the District of Columbia define *prenatal exposure* as child abuse or neglect (Child Welfare Information Gateway, 2011). Perhaps owing to the vigilant use of these indicators of prenatal exposure at the birth of a child, these infants are some of the youngest foster children. For example, McNichol (1999) found that infants with verified prenatal substance exposure (verified by maternal self-report or toxicology tests at birth) were placed in foster care at a significantly earlier mean age (3.8 months) than were infants with suspected prenatal exposure (5.6 months) and infants with no suspected exposure (5.9 months). Further, nearly half of the prenatally exposed infants were placed in care within 1 month of birth. Similarly, in a study of high-risk mother–infant dyads recruited at birth, Eiden, Foote, and Schuetze (2007) found that 19.1% of the infants prenatally exposed to cocaine entered foster care within 1–2 months of birth. Prenatally exposed infants are also likely to be exposed to postnatal parental substance use and its attendant risk for neglect (Dunn et al., 2002) and primary caregiver transitions (Bauer et al., 2011). They also have a high propensity to be placed in foster care, where they often experience further placement transitions (Smith, Johnson, Pears, Fisher, & DeGarmo, 2007).

Methodological Challenges to Research on Prenatal Substance Exposure

Before considering the combined influences of prenatal and early adversity on foster children, we briefly review prenatal substance exposure and its major short- and long-term effects. The majority of research on prenatal exposure has considered the effects of alcohol, tobacco, cocaine, methamphetamine, marijuana, and opiates on the developing fetus. Epidemiological evidence suggests that alcohol (10%) and tobacco (16.7%) are the most common substances consumed by pregnant women (Substance Abuse and Mental Health Services Administration, 2009). There are a number of challenges to definitively predicting the impact of prenatal exposure on infant outcomes. First, the quantity, frequency, and timing of prenatal substance use vary across women, and drug effects on fetal development vary by stage of gestation, with more significant teratogenic effects being observed during the embryonic stage (particularly in the case of alcohol) and more subtle effects being observed during the fetal period (Behnke, Smith, Committee on Substance Abuse, & Committee on Fetus and Newborn, 2013). Moreover, some pregnant women eliminate substance use when they learn of their pregnancy, (although this may not occur until well into the pregnancy, whereas others never desist from substance use [Massey et al., 2011]). Rates of prenatal substance use also vary by age group, with past-month alcohol and illicit drug use levels being higher for pregnant teenagers ages 15–17 years, compared with adults ages 18–25 years (Substance Abuse and Mental Health Services Administration, n.d.).

Efforts to disentangle the effects of prenatal substance exposure on biobehavioral development are complicated by a number of issues. First, the reality is that most prenatal substance exposure involves multiple substances (Lester, Andreozzi, & Appiah, 2004). In spite of the fact that the literature reports many studies that are designed to investigate the effects of a specific substance (e.g., alcohol,

cocaine) on the fetus, a great many of the individuals in the samples that have been gathered are polysubstance exposed. There are advantages and disadvantages of this methodological strategy. On the positive side, polysubstance exposure appears to be something of a reality for many women who use alcohol, tobacco, and illicit drugs during pregnancy. Moreover, some studies have attempted to control for the effects of substances that are not the focus of the investigation by using statistical covariation. Nevertheless, it is not clear that the extant knowledge base involving humans provides a clear picture of the effects of specific substances on development.

Although it is difficult to find nationally representative statistics for polysubstance exposure, several studies highlight this phenomenon as it manifests in high-risk and child welfare–involved families. In the Infant Development, Environment, and Lifestyle (IDEAL) longitudinal study of prenatal methamphetamine exposure, women who used methamphetamine (vs. those who did not) consumed significantly more tobacco (71% vs. 25%), alcohol (49% vs. 16%), and cannabis (43% vs. 8%) during pregnancy (Derauf et al., 2007). Among women referred to a perinatal addiction outpatient clinic in the United Kingdom, 49% were polysubstance users of at least two of the following drugs: heroin, cocaine, alcohol, cannabis, and methamphetamine (Mayet, Groshkova, Morgan, MacCormack, & Strang, 2008). In a study of a 3-year home visitation intervention for mothers with alcohol or other drug problems during pregnancy ($N = 458$), the women used tobacco (90%), alcohol (73%), cocaine (63%), cannabis (63%), and methamphetamine (42%; Grant et al., 2011). Despite the prevalence of prenatal polysubstance exposure, the mechanisms by which multiple substances interact to influence fetal development are not yet understood (Lester et al., 2004).

A related issue that complicates research in this area is that prenatal substance exposure is likely to co-occur with many other known stressors. For example, prenatal nutrition may be inadequate for many of these infants. Poverty, domestic violence or other relationship stress, and other environmental stressors may also be present. These variables may represent confounds in the assessment of prenatal exposure.

Developmental Outcomes of Prenatal Substance Exposure

In spite of the limitations in the research methodology, research on prenatal exposure has yielded a considerable amount of important information. In general, the adverse effects of prenatal substance use are attributed to alterations in the development of the fetal brain and autonomic nervous system. This is a logical supposition, inasmuch as substances used by the mother cross the placenta, where they may exert specific or individual effects (Behnke et al., 2013; Lester et al. 2004). In their model of the developmental effects of prenatal substance exposure, Lester and colleagues (2004) proposed that immediate drug effects emerge in early infancy (before the postnatal environment becomes influential) and may be transient or long lasting. For instance, tobacco use has twice the impact on infant birth weight compared with illicit drug use (Bailey, McCook, Hodge, & McGrady, 2012). However, by age 24 months, few studies find effects of fetal tobacco exposure on physical growth (Behnke et al., 2013). As an example of a longer lasting immediate drug effect among prenatally exposed (cocaine) children, high neonatal arousal and stress (an immediate drug effect on neonatal neurobehavior) have been indirectly associated with increased problem behavior at ages 3 and 7 years via difficult temperament at age 4 months (Lester et al., 2009).

Lester and colleagues (2004) argued that in addition to immediate drug effects, latent drug effects can be observed later in development in the context of brain and behavior effects specific to older children. For instance, a recent meta-analysis revealed a significant association between any binge alcohol exposure (≥ 4 or ≥ 5 drinks per occasion) during pregnancy and negative child cognition outcomes between ages 6 months and 14 years (Flak et al., 2014). These researchers also observed a significant, detrimental association between moderate prenatal alcohol exposure ("up to 6 drinks per week, including some individuals who consumed at least 3 drinks per week," p. 215) and child behavior between ages 9 months and 5 years. During the transition to adolescence, prenatally exposed youths demonstrate an especially pronounced vulnerability to substance use. For example, in a prospective longitudinal study, Cornelius, Goldschmidt, and Day (2012) found that prenatal exposure to cigarette smoking at all three trimesters predicted earlier child smoking experimentation at age 10, heavier smoking at age 14, and higher rates of smoking and addiction to nicotine at age 22, all while accounting for prenatal exposure to other drugs. Parallel outcomes have been observed among adolescents prenatally exposed to alcohol (Behnke et al., 2013).

Developmental Outcomes of Prenatal Exposure Among Children With Foster Care Histories

Prenatally exposed foster children tend to demonstrate more latent drug effects than do their prenatally exposed

peers in stable living arrangements, suggesting that prenatal effects are compounded by subsequent experiences. For example, in a prospective longitudinal study from birth, prenatally exposed 6-year-olds (n = 169) self-reported more symptoms of oppositional defiant disorder and ADHD than did nonexposed children (n = 153; Linares Singer et al., 2006). Further, prenatally exposed children in adoptive or foster care (n = 36) self-reported significantly more externalizing symptoms than did nonexposed children (n = 153) and prenatally exposed children living in maternal or relative care (n = 133; Linares Singer et al., 2006). Notably, the sample in the studies by Linares and colleagues was specifically selected for prenatal cocaine exposure.

Several prospective longitudinal studies from birth have followed prenatally exposed children with a foster care history into adolescence. In one study of prenatally exposed versus nonexposed adopted children (some adopted from foster care and others from private agencies or other means), the prenatally exposed adolescents exhibited significantly more externalizing problem behavior, according to parent reports 14 years postadoption (Crea, Barth, Guo, & Brooks, 2008). In another prospective longitudinal study, pregnant women considered to be at risk for prenatal substance use were recruited at the child's birth (Min, Minnes, Yoon, Short, & Singer, 2014). Behavioral adjustment at ages 12 and 15 years was compared between subsamples of prenatally exposed (cocaine) and nonexposed youths. Controlling for covariates, including prenatal exposure to alcohol, tobacco, and cannabis, prenatal exposure was associated with more externalizing behavior problems at ages 12 and 15 years and with more attention problems at age 15 years. Consistent with findings from Linares et al. (2006), the prenatally exposed adolescents in nonkinship foster or adoptive care (23% of the prenatally exposed adolescents) reported significantly more externalizing and attention problems than did nonexposed adolescents in nonkinship foster or adoptive care (4.5% of the nonexposed adolescents) at ages 12 and 15 years (Min et al., 2014).

Behavioral maladjustment in prenatally exposed (cocaine) adolescents in nonkinship foster or adoptive care occurred despite these caregivers having higher educational attainment and less substance use than biological/relative caregivers of prenatally exposed youths had (Min et al., 2014). There are several possible explanations for this finding. In keeping with the developmental model proposed by Lester and colleagues (2004), the heightened behavioral maladjustment of prenatally exposed (cocaine) adolescents in foster or adoptive care could reflect latent effects of prenatal cocaine exposure on fetal nervous-system development. In addition, prenatally exposed youth may have endured more severe or persistent early adversity than did their nonexposed peers. This heightened early adversity, in turn, may have contributed to their entry into foster care and to their long-term biobehavioral development. Taken together, the findings from these studies of children with foster care histories illustrate the importance of understanding the effects of prenatal substance exposure in the context of the child's early caregiving environment.

The Combined Effects of Prenatal Substance Exposure and Early Adversity

Beyond understanding the immediate and latent effects of specific drugs, it is important to identify risk and protective factors in the postnatal caregiving environment that moderate prenatally exposed children's developmental outcomes (Lester et al., 2004). Research on the combined effects of prenatal and early adversity is in its early stages. Commonly, studies that account for the postnatal environment in their analyses have conceptualized the environment as a variable that must be controlled to isolate the independent effects of prenatal exposure to a specific substance. These studies are frequently motivated by behavioral-teratology questions. However, a few studies have considered the independent, mediated, and moderated effects of prenatal exposure and early adversity on developmental outcomes from infancy into adolescence. Research findings about aspects of the postnatal environment that mitigate prenatal-exposure effects on child outcomes suggest important directions for future research and prevention in this area. In the remainder of this section, we provide a representative summary of existing evidence about the combined effects of prenatal exposure and early adversity in samples of children recruited on the basis of prenatal exposure—some that included children with histories of foster care and some that focus exclusively on foster children.

Independent Effects of Prenatal Exposure and Early Adversity

Lambert et al. (2013) examined the effects of prenatal exposure and other demographic and environmental risk factors on risk-taking behavior among 963 adolescents in the Maternal Lifestyle Study, a multisite, longitudinal cohort study that examined prenatal exposure effects in a sample that included 433 prenatally exposed (cocaine) infants and 530 nonexposed infants. Children in this landmark study, many of whom had contact with the child

welfare system or a history of placement in foster care, have been followed from birth through the transition to adulthood, with multiple waves of data collection. The assessment includes developmental and behavioral indicators of adjustment and measures of neurobiological functioning. Analyses of this data set have revealed that prenatal cocaine exposure, caregiver socioeconomic status (SES), and male child gender predicted increased odds of being arrested by age 15 years. In contrast, prenatal exposure to cocaine, alcohol, tobacco, or cannabis did not predict increased odds of adolescent alcohol, tobacco, or marijuana use. Rather, other demographic or environmental variables, such as having friends who used each drug, predicted adolescent substance use behaviors. For instance, caregiver abuse, number of caregiver changes, and having friends who used alcohol predicted increased odds of alcohol use at age 15 years. In the case of sexual risk-taking behavior at age 15 years, only prenatal exposure to cocaine or cannabis was predictive. Taken together, community violence, low parental involvement, male child gender, and other postnatal demographic and environmental factors contributed more to the prediction of sexual risk-taking behavior than did prenatal exposure (Lambert et al., 2013). Using data from the same study, Conradt et al. (2014) found that prenatal polysubstance exposure and early adversity did not relate to physiological correlates of behavioral and emotional problems in early childhood or adolescence. However, prenatal polysubstance exposure and early adversity related (differently for males and females) to neurobehavioral outcomes at age 13 years that were associated with risk-taking behavior at age 16 years.

Additional information about the combined effects of prenatal substance exposure and early adversity—specifically among foster children—can be derived from a Norwegian study. This prospective, longitudinal investigation of children prenatally exposed to opiates and other substances examined the effects of prenatal exposure on cognitive development at age 4.5 years (Moe, 2002). The sample for this study was considerably smaller than that of the aforementioned study by Lester and colleagues (2009). It consisted of 64 children who were prenatally exposed and 58 in the comparison group. Of the prenatally exposed group, 79.7% were diagnosed with a neonatal abstinence syndrome (i.e., withdrawal) and 84.6% were placed in foster care during infancy. The foster caregivers were recruited specially to provide care for at-risk infants, enabling the researchers to examine the effects of prenatal exposure under conditions of minimal postnatal risk. There was a significant interaction between male child gender and prenatal substance exposure such that boys in the prenatal-exposure group demonstrated the lowest general cognitive ability and the lowest perceptual, memory, and motor scores on the McCarthy Scales of General Ability. For the whole sample, prenatal exposure, foster-caregiver SES, gestational age, and mental development at age 1 year were independently associated with lower perceptual performance at age 4.5 years. However, prenatal exposure was not associated with general cognitive ability when these postnatal predictors were added to the model. Rather, only parental SES and mental development at age 1 year predicted general cognitive ability scores. It appears that, especially for girls, specialized foster care may have been protective of the effects of prenatal exposure on general cognitive ability. However, more research on larger samples is necessary to adequately understand the gender effects that were observed.

Early Adversity as a Mediator of the Effects of Prenatal Substance Exposure

In addition to the previously described work that has examined the separate effects of prenatal exposure and early adversity, several studies have examined early adversity as a mediator of the association between prenatal exposure and neurobehavioral disinhibition in childhood and adolescence. Mediation assumes that the developmental consequences of prenatal exposure are partly explained by the adverse postnatal conditions typically associated with maternal substance use during pregnancy. In two studies on this subject (Abar et al., 2012; Fisher et al., 2011), early adversity was assessed as a summative risk index that measures the presence of postnatal parental substance use, chronic poverty, primary caregiver changes, community violence, sexual/physical abuse, and other risk factors.

Using data from the Maternal Lifestyle Study, Fisher et al. (2011) examined the emergence and growth of a phenotype termed *neurobehavioral disinhibition* across the transition to adolescence among prenatally polysubstance-exposed youths who experienced early adversity. The neurobehavioral disinhibition construct included a composite measure of behavioral dysregulation and a composite measure of executive-function difficulties. They found that behavioral dysregulation at age 8/9 years predicted growth in executive function difficulties from age 8/9 years to age 13/14 years. Prenatal polysubstance exposure predicted the onset and growth of neurobehavioral disinhibition across adolescence. In the case of behavioral dysregulation, prenatal exposure directly predicted growth of neurobehavioral disinhibition across

adolescence. In the case of executive function difficulties, prenatal exposure was indirectly related to growth in these difficulties through early adversity. Specifically, prenatal polysubstance exposure was related to early adversity, early adversity was related to behavioral dysregulation at age 8/9 years, and behavioral dysregulation at age 8/9 years was related to growth in executive function difficulties across the transition to adolescence. Fisher et al. noted that prenatally exposed youths who enter adolescence with behavior problems may be particularly likely to experience executive function difficulties.

Abar et al. (2012) obtained similar findings among younger prenatally exposed children in the Infant Development, Environment, and Lifestyle study of prenatal methamphetamine exposure. In this study, prenatal methamphetamine exposure was indirectly associated with behavioral/emotional control problems at age 5 years and executive function deficits at age 6.5 years through early adversity experienced from birth to age 3 years. That is, children prenatally exposed to methamphetamine were likely to be exposed to early adversity, which was then associated with increases in behavioral/emotional control problems and executive function deficits. Prenatal exposure was not related to these neurobehavioral outcomes when early adversity was included in the model.

Postnatal Risk and Protective Factors That Moderate the Effects of Prenatal Substance Exposure

Among samples recruited on the basis of prenatal exposure, converging evidence suggests that postnatal family and community adversity can exacerbate the association between prenatal exposure and child outcomes. For example, a study by Lester et al. (2010) found that, at age 11 years, adolescents prenatally exposed to cocaine demonstrated lower elevations in cortisol in response to a laboratory stressor, controlling for prenatal and postnatal drug exposures. Exposure to parental domestic violence between ages 1 month and 11 years also predicted blunted cortisol reactivity to stress. In addition, domestic violence exposure acted as a moderator: Children prenatally exposed to cocaine who also witnessed parental domestic violence were more likely to exhibit blunted cortisol reactivity than were nonexposed children who witnessed domestic violence.

This finding was replicated in a study by Fisher, Kim, Bruce, and Pears (2012): among foster children with prenatal substance exposure, those who had experienced more maltreatment showed significantly lower cortisol elevations in response to a laboratory stressor. Together, these findings suggest that the vulnerability of the HPA axis to environmental adversity may begin during the fetal period and extend through early childhood.

In addition to neuroendocrine effects, there is evidence that combined prenatal and early adversity affect behavioral adjustment. For example, Bada et al. (2012) examined growth in behavior problems from ages 5 to 15 years among prenatally exposed (cocaine or opiate) youths in the Maternal Lifestyle Study. They also evaluated child, family, and community risk and protective factors that could moderate the effects of prenatal exposure on growth in child problem behavior across childhood and into adolescence. The risk factors included caregiver psychopathology, child abuse, male child gender, and postnatal exposure; the protective factors included caregiver involvement, family resources, and child resilience. The number of risk factors (total = 13) and protective factors (total = 9) were summed to create risk and protective indices, respectively. In addition to assessing the impact of risk and protective factors scored in this cumulative way, Bada et al. examined the combination of levels (high vs. low) of risk and protective indices. At child age 5 years, prenatal exposure (vs. nonexposure) was associated with increased externalizing problem behavior. Important to note, a high-risk index combined with a low-protective index contributed to the already-significant effects of prenatal exposure on behavior problems. In addition, among the prenatally exposed children, who had significantly higher total behavior problems at age 5 years, high or low risk in the presence of a high-protective versus low-protective index contributed to greater declines in total behavior problems throughout the study period.

Similarly, in a small sample of 38 children younger than age 16 years who were placed in foster care because of prenatal alcohol exposure, Koponen, Kalland, and Autti-Rämö (2009) examined the role of the caregiving environment in child behavioral outcomes. In this investigation, 82% of children were prenatally exposed to alcohol only; the other children were exposed to other drugs as well. The majority of the children in the sample met diagnostic criteria for fetal alcohol syndrome (58%) or fetal alcohol effects (24%). Compared with children exposed to fewer traumatic experiences as reported by social workers and foster caregivers, the children exposed to three or more traumatic experiences demonstrated more attentional and emotional problems. Conversely, entry into foster care before age 3 years appeared to be a protective factor in that fewer of these children demonstrated attentional and emotional problems than did the children placed at later ages. Age at entry into foster care and number of traumatic experiences were strongly correlated ($r = 0.67$), suggesting

that early entry into foster care protects children from experiencing further traumatic events in the family of origin. The protective effect of conventional foster care is particularly noteworthy, given that the foster caregivers in this sample reported problems of their own during the child's placement (e.g., economic problems = 37%, family violence = 11%). Although it is not possible from this study to determine the extent to which aspects of foster care were protective of prenatal exposure effects, per se, it is clear from these findings that the postnatal environment is an important contributor to behavioral outcomes among children with a history of foster care resulting from prenatal exposure.

Additional, albeit preliminary, evidence that a positive early environment can offset the adverse effects of prenatal exposure can be found in a nonexperimental study of 22 prenatally exposed infants in a specialized early foster care program (D'Angiulli & Sullivan, 2010). The Safe Babies Program was designed to provide foster caregivers with education and support in caring for prenatally exposed infants. The program recruited "experienced and highly qualified foster parents," including "people with relevant professional qualifications in social work, pediatric medicine, and nursing in addition to their experience as foster parents" (p. 461). Infants for whom parental substance use during pregnancy was the main factor for court-ordered foster care were placed in care before age 24 months. The authors compared the developmental outcomes, including basal salivary cortisol, between full-term and preterm infants enrolled in the program. Compared with full-term infants, preterm infants were in the norm on all developmental domains (assessed with the Battelle Developmental Inventory) except fine motor skills. The preterm and full-term foster infants scored within two standard deviations of the mean on all developmental domains, suggesting no developmental delays. The infants' circadian cortisol rhythms were consistent with typical infant patterns and did not differ between preterm and full-term infants when number of months in foster care was included as a covariate in the analysis. It is important to acknowledge the limitations in this study from a methodological perspective. Confidence in the interpretation of these findings will be increased with the inclusion of a comparison group that does not receive the specialized foster care intervention.

Although the knowledge base in this area is still emerging, the body of research presented here suggests important opportunities for prevention and intervention scientists working with foster families. Although postnatal interventions would not necessarily protect prenatally exposed infants from the immediate neurobehavioral effects of prenatal exposure at birth, such interventions could help mitigate the long-term, or latent, effects of prenatal exposure. Interventions that support and enhance the caregiving capacity of foster caregivers will be particularly relevant in this regard (Healey, Fisher, van Scoyoc, & Relling, 2013). Many important questions remain, the answers to which will help refine existing intervention strategies. For example, it is not clear which dimensions of early adversity are the most detrimental and the most protective of child outcomes among prenatally exposed children. It is also uncertain how the timing of exposure to prenatal and postnatal adversity contributes to child outcomes. Finally, although the general rule is that earlier is better for intervention to offset the effects of postnatal adversity, more research is needed to determine how early in the child's development postnatal protective influences are needed to positively affect outcomes.

In sum, research on foster children and other prenatally exposed populations provides evidence that prenatal adversity represents an independent set of influences over and above the risks conferred by early postnatal adversity, and specifically that it negatively affects behavioral and biological development. Moreover, research suggests that the combined effects of prenatal and early postnatal adversity are worse than that of either alone. This is particularly germane to research on foster children because of the epidemiological evidence that the two may co-occur frequently among children in out-of-home care. Finally, a small but important evidence base suggests that just as a poor postnatal environment may exacerbate the effects of prenatal exposure, a good environment—one that may occur in the context of both conventional foster care and therapeutic foster care—has the potential to mitigate or offset prenatal exposure effects. However, because of the paucity of research in this area, more investigations are needed to replicate and extend the results obtained thus far.

RESILIENCE (I.E., TYPICAL DEVELOPMENT IN THE FACE OF ADVERSITY) IS EVIDENT IN ALL SAMPLES OF FOSTER CHILDREN (ALTHOUGH WHAT CONTRIBUTES TO IT IS NOT WELL UNDERSTOOD)

To this point in our discussion of research on foster care, we have focused largely on conclusions that can be drawn about the associations between early adversity and atypical development. However, it is equally important to consider two corollaries of this research: first, that some atypical

outcomes may be adaptive to the environmental circumstances of early adversity and foster care and second, that although atypical development is in general associated with adversity, it is far from ubiquitous; rather, typical development can and does occur even under conditions of significant adversity. That these issues are sometimes underemphasized or obscured in studies of foster children is not surprising. Although our culture does tend to celebrate the extraordinary instances in which individuals achieve great success amidst traumatic and neglectful childhoods, the prevalence and magnitude of problems observed among foster children may be more salient to researchers and other observers than the less frequent positive outcomes. Moreover, there may be concern that emphasizing positive outcomes could lead to less support from policy makers and the general public for programs that support this population.

Nevertheless, there is remarkably consistent empirical evidence that not all foster children fare poorly. Clearly, as we discuss later, some foster children manage to circumvent some or most of the expected negative outcomes. This line of investigation falls into the domain of resilience research, which has been a topic of considerable scientific interest in recent years (Rutter, 2006). The question of what might lead some individuals to emerge from early adversity relatively unscathed or even strengthened while others experience lasting effect has been a matter of considerable speculation (DuMont, Widom, & Czaja, 2007). Cultural models are often invoked with respect to the idea that some individuals' innate strength of character enables them to be successful even in the most difficult times (Masten, 2001). However, the science of resilience is considerably more developed and nuanced than that. In the scientific study of resilience in the general population, emphasis has been placed upon defining the individual/environmental variables most associated with positive outcomes, including personality characteristics (Flores, Cicchetti, & Rogosch, 2005), genetic polymorphisms (Rutter, 2003), strong caregiver relationships (Flores et al., 2005), and supportive parenting (Forgatch & DeGarmo, 1999).

There are several sources of evidence that resilient outcomes in the face of adversity are possible among foster children (Samuels & Pryce, 2008). Ironically, one source of evidence comes from the same sources of data that have been used to document the disparities of foster children. For example, in two earlier sections of this chapter, we highlighted the prevalence of poor psychological, developmental, and cognitive functioning and alterations in key domains of neurobiological development among foster children. However, these problems are by no means universal. One concrete example of the prevalence of resilient outcomes can be drawn from research on altered cortisol levels in foster children. This research has found that dysregulated diurnal cortisol-level patterns occur approximately three times as often in foster children than in the general population—a finding that may lead to the conclusion that this pattern is exhibited by most foster children. However, examination of the prevalence rates of foster children's diurnal HPA dysregulation reveals a different perspective: In two different samples, the low morning cortisol "blunted" pattern has been observed in only about 30% of the foster children (Bruce, Fisher, et al., 2009; Dozier et al., 2006). In other words, about 70% of foster children show typical patterns of diurnal cortisol production.

Moreover, although we tend to characterize low morning cortisol and blunted diurnal patterns as dysregulated, the fact that this pattern is associated with neglect in foster care and institutionalized samples (Carlson & Earls, 1997) suggests that it may be an adaptive response designed to conserve metabolic and other biological activity in the context of a nonresponsive rearing environment. Put another way, what we perceive from the perspective of typical development as dysregulated may be a strategy designed by nature to increase the likelihood of survival under adverse circumstances. In that sense, although we still may consider low morning cortisol to be atypical in the general population, it may be less appropriate to view it as pathological.

Corroborating evidence of resilience following early adversity can be found in the numerous studies of the catch-up that occurs among adopted children. Much of this work is focused not on foster care samples but on children who have experienced institutional rearing (Rutter, 1998). Notably, some of these children also experience foster care or multiple family placements before adoption, although the separate and additive effects of institutional and foster care have not been investigated.

In a remarkable meta-analysis that included a synopsis of more than 270 studies with a total of more than 230,000 adopted and nonadopted children and their parents, van IJzendoorn and Juffer (2006) found strong evidence for developmental catch-up in physical and emotional/psychological domains, especially for children adopted early. Although catch-up was often incomplete relative to nonadopted peers, the adopted children consistently fared far better than children who stayed in institutions. Interestingly, Croft, O'Connor, Keaveney, Groothues, and Rutter (2001) found that

catch-up in postinstitutionalized adoptees was associated with longitudinal improvements in the quality of the parent–child relationship.

The literature about specific predictors of resilience in foster children is surprisingly sparse. Healey and Fisher (2011) found that favorable outcomes, such as emotion regulation and academic adjustment in middle childhood, were more likely in foster children who during the preschool years had typical developmental status, particularly with respect to attention and executive functioning and who lacked environmental stress in early-childhood foster care.

Several studies have examined the nature of foster children's experiences while in care that may be associated with resilient outcomes. For example, a longitudinal investigation involving more than 3,000 children younger than age 12 years found factors that may improve placement stability, which is associated with positive outcomes, among foster children (Koh, Rolock, Cross, & Eblen-Manning, 2014). The factors contributing to foster care stability included the caregiver's dedication to the child's legal permanence, placement with a relative caregiver, and the absence of child mental health problems.

Kinship care also seems to be a protective factor for foster children (Farineau & McWey, 2011; Leathers, Spielfogel, Gleeson, & Nancy, 2012). For example, in a NSCAW subsample, long-term foster adolescents placed in kinship care were shown to have the lowest delinquency scores compared with other long-term foster adolescents (Farineau & McWey, 2011).

Kinship care may also help reduce the potential for the child to develop psychosocial problems. Landsverk et al. (1996) found psychosocial problems to be significantly higher for foster children in nonrelative (vs. kinship) placements, with foster children experiencing emotional and behavioral problems more frequently than kinship children (59.9% vs. 31.6%, respectively). This trend was also true for developmental and learning problems (24.2% vs. 15.8%, respectively). Finally, the foster children were also at higher risk for developing multiple types of problems and delays (28.0% vs. 14.5%, respectively).

Clearly, more research on the predictors of foster child resilience is needed. It is plausible that much of the research on resilience in the general population might apply to foster children as well. Given the availability of existing datasets in which to explore such issues by means of secondary analyses (e.g., NSCAW), this is an area in which progress may be readily achievable. In sum, it is clear that although foster and adoptive children may face increased risk for numerous negative outcomes, many display very high rates of resilience, especially when removed from circumstances of ongoing adversity and placed in stable, supportive, family-based care.

FAMILY-BASED CARE (INCLUDING FOSTER CARE) IS, AS A GENERAL RULE, BETTER THAN INSTITUTIONAL CARE

It is important to note that the foster care system is often maligned, in part because of the proliferation of research documenting atypical development and poor adjustment among foster children and to negative public perceptions about the foster care system. However, as was originally noted by Chapin (1926) and other early researchers and social activists, in spite of all its limitations, foster care allows children to be reared in a family setting. This appears to have significant advantages over institutional care and provides evidence of the central importance of family-based care to health development. Evidence about the advantages of foster care over institutional care can be derived from studies that have compared groups of children living in these different conditions by using the same measures of health and well-being. In this section, we review research on family-based care as an alternative to institutional care.

Child Care in Institutions

First-hand observations of institutional care for infants and young children describe conditions of profound deprivation. At a postwar United States institution, for example, infants ages 4 days to 24 months spent most of their time in cribs and rarely ventured outside the institution (Provence & Lipton, 1962). The younger group of infants ages 4 days to 8 months experienced the following:

> [They] shared the time and attention of the attendant with seven to nine other infants in the same age range for the eight-hour period of the day when she was present. For the remaining sixteen hours of the day there was no person in the nursery except at feeding time when an attendant who also had similar duties in other nurseries heated formulas, propped bottles, and changed diapers. Her presence could lead to no more than the briefest of contacts because she had twenty-five to thirty other babies for whom she must do the same before it was time to start over again. During an eight-hour day, five days a week . . . [the infant's] contact with [the attendant] was mainly in being taken from his crib to the work area once daily for bathing and dressing, and subsequently three or four times for a diaper change. (p. 27)

As is illustrated in this excerpt, the caregivers interacted with the children to fulfill only the most basic instrumental needs, such as feeding, diapering, and bathing. These interactions offered few opportunities for social engagement: Infants younger than age 8 months were fed by a "propped bottle" rested against padding in their crib, and older infants were spoon-fed for 6–8 minutes each while caregivers talked amongst themselves (Provence & Lipton, 1962). The caregiving staff "seemed to like the babies" and "gave as much of themselves as they could" in overworked conditions (p. 29), but shifting staff schedules and turnover meant that many infants were not regularly assigned to the same caregivers. Strict routines for feeding, diapering, and bathing, along with a paucity of adult supervision, meant that each infant "had very few experiences in having the adult respond to his needs (e.g., the discomfort of hunger) at the time he expresses them." (p. 19). Perhaps not surprisingly, Provence and Lipton noted "an almost startling quietness" in the nursery (p. 89), an indication that the infants learned to not seek adult attention under either playful or distressed conditions.

Based on this brief depiction, it is clear why Nelson, Fox, and Zeanah (2014) argued that institutionalization "represents a form of neglect, albeit a very extreme form" (p. 306) and that children in contemporary institutional care "lack supervision and structure, necessary social interaction and emotion regulation, cognitive and language stimulation, access to adequate nutrition, and so on" (p. 306–307). Echoing the postwar findings of Provence and Lipton (1962), observations of a Romanian institution in the 1990s found that children had limited opportunities to interact socially with caregivers (Nelson et al., 2014). They had long stretches of unstructured playtime, in which the caregivers mostly chatted amongst themselves, ignoring the large number of children wandering aimlessly. Over the course of a day, a child would likely have contact with multiple adults, which precluded consistency or the opportunity for sustained interaction. In a given week, a child could have come in contact with 17 different caregivers, three housekeepers, four nurses, two educators, one physician, one psychologist, and one physical therapist (Nelson et al., 2014; pp. 34–35). Although the conditions of institutional care vary widely within and across countries, the institutions studied by Nelson et al. in Bucharest shared a routinized daily schedule, a high child:caregiver ratio, and staff with little formal training in child development.

By contrast, foster caregiving typically involves one or two primary caregivers—extended family members, if possible—who have, under ideal circumstances, made an investment to provide personalized care for the child. Natural variability in caregiving quality across foster caregivers notwithstanding, children living in foster care can reasonably expect that their primary caregivers will respond to their basic needs. A major question is the extent to which typical development can occur in the absence of a relationship with a primary caregiver.

A Comparison of Foster and Institutional Care: The Bucharest Early Intervention Project

Although research in the twentieth century has demonstrated that children raised in institutions show impairments across a variety of developmental domains, the inferences that can be drawn from these studies are necessarily limited by a lack of an experimental control (Zeanah et al., 2003). Without random assignment, it remains possible that infants who are abandoned to institutions began life with more severe disadvantages than noninstitutionalized children or that the more-advantaged infants get adopted from institutions, leaving behind their most disadvantaged peers. As a result, sample bias (vs. institutionalization itself) could explain the detrimental outcomes found among this population.

In 2000, a landmark, randomized controlled longitudinal study was launched that investigated foster care as an alternative to institutional care: the Bucharest Early Intervention Project (BEIP; Nelson et al., 2014). The BEIP is remarkable because the circumstances in Romania at the time when the study began allowed the researchers to randomly assign children to ongoing institutional care (n = 67) or to family-based foster care (n = 69; Zeanah et al., 2003). Although the foster families received some training (Smyke, Zeanah, Fox, & Nelson, 2009), the conditions did not allow for foster care to be enhanced in terms of ongoing support and treatment for the children. Thus, this study represents a scientifically rigorous comparison of institutional versus family-based rearing development. The BEIP results provide remarkably consistent evidence that institutionally raised children fare worse than foster children across numerous domains in which foster children show atypical development, including emotional, psychological, physical, and neurobiological development.

The BEIP assessed children at baseline (before age 31 months) and at ages 30 months, 42 months, 54 months, and 8 years. Some children were as young as age 6 months when the intervention began. At the first assessment, some of the children had as many as 24 months of the intervention, while the older children had a few months or less. In addition to the two randomly assigned groups, a third group of

72 noninstitutionalized, matched community comparison children who lived with their biological parents was also assessed at each study wave. This permitted researchers to evaluate developmental catch-up among the foster children (Zeanah et al., 2003).

Over the course of the study, some of the institutionalized children were adopted or entered foster care. Analyses were conducted on an *intent-to-treat* basis, such that (for example) a proportion of children in the institutionalized group at age 8 years were living in family-based care (Nelson et al., 2014). Thus, the findings that are reviewed in the next sections represent conservative estimates of the effects of institutionalization on child outcomes.

Cognition and Language

The children who remained in institutional care until age 8 years demonstrated significant declines and delays in all domains of cognition, including intellectual function, executive function, memory, and language (Nelson et al., 2014). On measures of intellectual function, the children placed in foster care demonstrated higher mean IQ scores on the Bayley Scales (at 42 months) and on the Wechsler Preschool and Primary Scale of Intelligence (at 54 months) than did their institutionalized peers (Nelson et al., 2007). The lesser time the children spend on institutional care, the better their IQ performance. Specifically, children needed to have been assigned to foster care before age 24 months to outperform their institutionalized peers on the intelligence measures. The intervention effects on IQ were not as strong at age 8 months as at ages 42 and 52 months, an indication (perhaps) of the modest gains in IQ among institutionalized children who were placed in newly designated government foster homes between the 54-month and 8-year assessments (Fox, Almas, Degnan, Nelson, & Zeanah, 2011).

In some cognitive domains, foster children's capacities were superior to institutionalized children's but below those of their community peers. Despite their advantages in IQ over institutionalized children, foster children's IQ scores were lower than the community control children's on all Wechsler Intelligence Scale for Children subscales at age 8 years (Fox et al., 2011). Similarly, on assessment of inhibitory control at age 54 months, the foster children scored higher than the institutionalized children did but lower than the community comparison group did (Nelson et al., 2014).

In the case of other executive-function skills measured with the Cambridge Automated Neuropsychological Test and Battery at age 8 years, the institutionalized children performed worse than the community comparison children on visual memory and executive functioning tasks (Bos, Fox, Zeanah, & Nelson, 2009). The foster children and institutionalized children assigned to ongoing institutional care performed equivalently on all memory and executive-functioning domains except spatial working memory. After controlling for birth weight, head circumference, and duration of time spent in the institution during infancy, spatial working memory performance favored the foster group.

In the BEIP, language assessments across time indicated that the foster care intervention remediated the severe language deficits associated with ongoing institutional care, if placement occurred early enough. Compared with the institutionalized children, the foster children demonstrated better expressive and receptive language skills at ages 30 and 42 months (Windsor et al., 2011). The language-development benefits continued for foster children through the 8-year assessment (Windsor, Moraru, Nelson, Fox, & Zeanah, 2013).

Socioemotional Development

Given the profound absence of emotionally salient, consistent, and contingent social interaction with caregivers in the institutions, the BEIP investigators anticipated that the institutionalized children would show detriments in attachment to caregivers and in the experience and expression of emotion in social contexts. Indeed, foster children (vs. institutionalized children) expressed more joy during Laboratory Temperament Assessment Battery (Goldsmith & Rothbart, 1999) tasks at ages 30 and 42 months and exhibited more improvements in positive emotion during this period (Ghera et al., 2009). Notably, foster children showed even more positive emotion and attention to tasks at age 42 months (Ghera et al., 2009). Institutionalized children demonstrated low levels of attention to the positive emotion-eliciting tasks at ages 30 and 42 months (Ghera et al., 2009). The lower levels of attention and positive emotion expression among the institutionalized children care may relate to disruptions in the neural circuitry involved in emotion processing (Parker & Nelson, 2005). By contrast, the recovery observed among foster children provides evidence for the relative plasticity of neural circuits that support positive affect (Ghera et al., 2009).

The disruption of attachment in institutionalized children was severe. At the baseline assessment, investigators assessed attachment behaviors in the community comparison sample and a subset of 95 institutionalized children ages 12–31 months who had spent an average of 90% of their lives in institutional care (Zeanah,

Smyke, Koga, Carlson, & Bucharest Early Intervention Project Core Group, 2005). The Strange Situation Procedure (Ainsworth, Blehar, Waters, & Wall, 1978) was administered with these institutionalized infants and their preferred caregiver (if none could be identified, it was the caregiver who worked with the child most regularly). In addition to deriving a categorical attachment classification from the Strange Situation Procedure, a continuous, 5-point rating of attachment behavior was assigned by two experts (Zeanah et al., 2005). Compared with the community children, who were classified as 74% secure and 22% disorganized, the institutionalized children were classified as 18% secure, 65% disorganized, and 12.6% *unclassified*, a rare designation meaning that there were too few attachment behaviors to assign a child to any group (Zeanah et al., 2005). Using the continuous rating scale, investigators confirmed that 65% of institutionalized children exhibited "anomalous behaviors only minimally related to attachment" (Nelson et al., 2014, p. 244). In addition, 9.5% of the institutionalized children "had no discernible attachment behaviors whatsoever" (Nelson et al., 2014, p. 244).

At 42 months of age, BEIP intervention effects on attachment and social behaviors among foster children were substantial. Secure attachment at age 42 months was exhibited by 18% of institutionalized children, 65% of community children, and 49% of foster children (Nelson et al., 2014). Foster children also showed significantly fewer signs of an emotionally withdrawn and inhibited type of reactive attachment disorder than did institutionalized children; levels of this subtype were comparable between foster and community children after age 30 months (Smyke et al., 2012). Regarding timing effects, secure attachment at age 42 months was more prevalent among children assigned to foster care at or before age 24 months than among those placed later (Smyke, Zeanah, Fox, Nelson, & Guthrie, 2010). Similarly, children assigned to foster care at or before age 20 months were rated by teachers as significantly more socially skilled with peers at age 8 years than were those placed later (Almas et al., 2012).

Psychopathology

The impact of severe psychosocial deprivation on the development of psychopathology in institutionalized children was predictably detrimental. At age 54 months, 53.2% and 27.0% of institutionalized children were diagnosed with psychiatric and behavioral disorders, respectively, compared with 22.0% and 6.8% of community children (Nelson et al., 2014). In the case of ADHD, institutionalized children in the BEIP study demonstrated more symptoms of inattention and impulsivity at age 8 years than did community children (McLaughlin et al., 2014). This effect of early psychosocial deprivation on ADHD symptoms was mediated by reductions in cortical thickness in several regions of the prefrontal, parietal, and temporal cortices (McLaughlin et al., 2014).

Foster care tended to improve mental health outcomes when compared with institutional care, but with several qualifications. First, at age 54 months, foster children had fewer internalizing, but not externalizing, disorders than did institutionalized children (Zeanah et al., 2009). Second, this was true only for foster girls (Zeanah et al., 2009). The effect of foster care on internalizing disorders in girls was mediated by secure attachment at age 42 months (Nelson et al., 2014). Nelson et al. identified a number of other psychobiological moderators of BEIP intervention effects. A particularly important finding to note is that the timing of assignment to foster care did not moderate the effect of intervention on psychopathology. Even children who entered foster care relatively late were protected from the effects of early deprivation on anxiety and depression (Zeanah et al., 2009).

The Caregiving Conditions Necessary for Typical Development

Findings from the BEIP and related longitudinal research on internationally adopted children (Rutter, Kumsta, Schlotz, & Sonuga-Barke, 2012) point to specific developmental domains that have more or less plasticity in response to early deprivation. These studies provide many insights: We highlight only a few here, along with their implications for intervention with children exposed to early adversity.

First, it appears that children can form attachments with primary caregivers even after accumulated early experiences with institutional caregivers who, because of their context, were by definition not able to provide sufficiently responsive or emotionally salient interaction. Clearly, this is an area in which earlier intervention is better. In the BEIP, catch-up in attachment security was significantly more common among foster children placed before age 24 months than among children placed later. A meta-analysis of research on adopted children found an even more stringent age cut-off of 12 months, by which children must be adopted to catch up to the attachment security of their nonadopted peers (van IJzendoorn & Juffer, 2006). In turn, secure attachment was associated with a range of short- and long-term psychosocial benefits for foster and adopted children. These findings suggest that the earlier a

child with unstable living arrangements can be placed with a primary caregiver, the better.

Second, in terms of other domains of development, the timing of placement into foster care was important for some but not for others. For instance, attachment security, IQ, language skills, electroencephalogram measures, stereotypies, and other domains were sensitive to the timing at which children began to live in family-based care, with earlier placement generally being more beneficial (Bos, Zeanah, Smyke, Fox, & Nelson, 2010; Zeanah, Gunnar, McCall, Kreppner, & Fox, 2011). Interestingly, family-based care was protective of anxiety and depression no matter what age children were assigned to foster care (Zeanah et al., 2009), though this finding must be interpreted with caution: No child was older than age 3 years when placed into family-based care. It is possible that adoption at a later age may not be protective in terms of internalizing disorders. Nevertheless, this finding highlights the influence of the family caregiving environment on difficulties that are often attributed to inherited biological predispositions.

Third, family-based care was beneficial for BEIP children's cognitive development (Nelson et al., 2007) but did not protect them from difficulties with executive functioning, inattention, and hyperactivity (Bos et al., 2009; McLaughlin et al., 2014). In their longitudinal study of adopted children, the ERA team also found that inattention/hyperactivity was part of a constellation of difficulties, persistent into adolescence, labeled as *deprivation-specific psychological patterns* (Kreppner et al., 2010; Kumsta et al., 2010). Institutionalized children may have experienced more adverse prenatal experiences that detrimentally influenced neurodevelopment prior to children's entrance into the orphanages. Regardless, these findings suggest important targets for intervention.

To mitigate the executive function deficits associated with early deprivation, ordinary caregiving provided by foster and adoptive families may have to be enhanced or supplemented with specific interventions designed to improve the functioning of children's neural systems and attendant behaviors (Fisher & Gunnar, 2010; Gunnar, 2010). Nevertheless, the results of the BEIP are critically important because they indicate that typical development seems to require, as a basic condition, the presence of a primary caregiver. Although the most optimal arrangement may be a permanent biological or adoptive parent, it is not always possible to quickly resolve issues of permanency. Within this context, the evidence base is strong that foster care appears to enhance current and future health and well-being more than does institutional care.

FAMILY-BASED INTERVENTIONS THAT CAN MITIGATE THE EFFECTS OF EARLY ADVERSITY

If a general conclusion of foster care research is that temporary placement in family-based care falls somewhere in the continuum between conditions that promote optimal development care and institutional care, then a related question is how to shift the location on the continuum represented by foster care in a positive direction through interventions. This is a key question from a public policy standpoint and from a scientific perspective inasmuch as it relates to questions about the malleability or plasticity of the biobehavioral systems negatively affected by early adversity. There is a fairly extensive literature in this area, although much of this work has not used randomized experimental designs. A recent systematic review using the Cochrane Collaboration's criteria (Turner & Macdonald, 2011) noted that only five studies met the criteria for an evidence-based program for foster families. Further, a study by the Office of Victims of Crimes suggested that only 1 of 24 mental health interventions for children who had been abused is effective (Saunders, Berliner, & Hanson, 2004).

Foster care families have unique needs that determine which interventions are likely to remediate the effects of early adversity on healthy development. First, because foster children have been exposed to neglectful or abusive parenting prior to their entry into care, in any foster care intervention the caregiver receiving the intervention services does not have a shared history with the child. Further, the foster caregiver may already have a set of parenting skills that are generally effective. Second, because of their maltreatment histories, foster children are more likely to exhibit constellations of behavioral, neurobiological, and relationship vulnerabilities that pose unique challenges to caregivers. Thus, standard parenting intervention programs might not be sufficient or appropriate for improving child outcomes. Third, children enter foster care at varying ages and have likely experienced multiple prior caregiving situations. This may lead foster children to enter care with their own set of expectations and demands based on their histories.

Leve et al. (2012) conducted a systematic review of intervention programs that have been tested with foster families and shown to improve child outcomes. The interventions included in the review met the following criteria: evaluated using a randomized, controlled trial; produced at least one positive outcome; randomized at the level of the individual; and included at least 15 children per group. Eight interventions met these criteria. We describe seven of those interventions (the eighth—BEIP—was described

in an earlier section of this chapter), along with two others (meeting these criteria) that were published after the Leve et al. review. Five of these interventions emanated from the same research group at the Oregon Social Learning Center (OSLC) and are reviewed together, followed in developmental order by four evidence-based programs from other research groups. (Please note that the lead author of this chapter is one of the developers of several of the OSLC interventions.)

Treatment Foster Care Oregon for Adolescents (TFCO-A)

TFCO-A, the first intervention developed by the Oregon group, consists of a multicomponent program that involves individual placement with a specialized foster family for adolescents being removed from their homes (Chamberlain, 2003). Typically, TFCO-A adolescents have maltreatment histories and serious, chronic problems with delinquency. In TFCO-A, adolescents are placed in community homes where the foster caregivers are intensively trained, supervised, and supported to provide positive adult support and mentoring, close supervision, and consistent limit setting. TFCO-A placements typically last 6–9 months and involve coordinated interventions at home, with peers, in educational settings, and with the adolescent's long-term placement resource. The results from TFCO-A trials in the United States indicate its effectiveness in reducing arrest rates and deviant peer affiliations for boys and girls; placement disruptions and parenting for boys; and pregnancy rates, depressive symptoms, psychotic symptoms, and school engagement for girls (Chamberlain & Reid, 1998; Harold et al., 2013; Kerr, Leve, & Chamberlain, 2009; Leve, Fisher, & Chamberlain, 2009; Poulton et al., 2014). For example, between baseline and a 12-month follow-up, the TFCO-A adolescents had spent 53 (boys) and 22 (girls) days in lockup (e.g., a detention facility) versus 129 and 56 days, respectively, for the control adolescents. In addition, long-term effects have been found on drug use at 7 years postintervention (Rhoades, Leve, Harold, Kim, & Chamberlain, 2014). Several international replications of TFCO-A have shown positive results. For example, a trial in Sweden indicated significant reductions in youth-reported externalizing and internalizing behavior (Westermark, Hansson, & Olsson, 2010).

Multidimensional Treatment Foster Care for Preschoolers (TFCO-P)

TFCO-P is a downward extension of TFCO-A for preschool-age foster children. It uses a behavior-management approach and trains, supervises, and supports foster caregivers to provide positive adult support and consistent limit setting. This support and training occurs through weekly parenting groups, individual therapy, family therapy, and 24/7 on-call support and typically lasts 6–9 months. Similar to TFCO-A, it also coordinates with the child's biological parents, with the assumption that the end goal is reunification. The randomized trial of TFCO-P showed that the intervention improved child attachment behavior: TFCO-P children demonstrated increased secure behavior and decreased avoidant behavior relative to children in regular foster care (Fisher & Kim, 2007). TFCO-P also improved stress–response systems, preventing blunted diurnal cortisol patterns among the intervention children (Fisher et al., 2007) and reducing caregiver stress (Fisher & Stoolmiller, 2008). Further, TFCO-P improved placement stability outcomes across a 2-year period and mitigated the risk of influence of multiple prior foster placements on subsequent placement failures (Fisher et al., 2005). Compared with the TFCO-P children, the control children (in regular foster care) were 3.6 times more likely to experience a permanent placement failure.

Kids in Transition to School (KITS)

KITS evolved from the TFCO-P intervention as a short-term, readily scalable intervention focused on school readiness and improved school functioning for foster children (Pears, Fisher, & Bronz, 2007; Pears, Fisher, Heywood, & Bronz, 2007). The KITS intervention occurs in two phases: a school readiness phase (2 months before kindergarten entry) focused on preparing children and caregivers for school and a transition/maintenance phase (first 2 months of kindergarten) focused on supporting a positive transition to school. The intervention includes a group-based program for the children (24 sessions) focused on promoting early literacy and socioemotional skills and a parent-based program (8 sessions) focused on promoting caregiver involvement in early literacy and school. Compared with regular foster care services, KITS has been shown to increase foster children's early literacy and self-regulatory skills (Pears et al., 2013) and to reduce child oppositional and aggressive behavior in the classroom (Pears, Kim, & Fisher, 2012).

Keeping Foster Parents Trained and Supported (KEEP-SAFE)

KEEP-SAFE shares the foster–caregiver component of the TFCO programs described earlier but, like KITS,

was designed to be a less intensive intervention for foster families with school-age children. In the randomized trial of KEEP-SAFE, foster caregivers receiving a new placement were randomly assigned to regular foster care services or to the KEEP-SAFE parenting intervention (Chamberlain et al., 2008). The KEEP-SAFE intervention lasts 16 weeks and includes foster caregiver meetings with 8–10 foster caregivers that are focused on training, supervision, and support for applying behavior management strategies. KEEP-SAFE has been shown to effectively reduce child problem behavior. These child behavior problem reductions were associated with intervention-driven improvements in parenting (Chamberlain, Price, Reid, & Landsverk, 2008). Similar to TFCO-P, KEEP-SAFE also improved placement stability: KEEP-SAFE mitigated the risk-enhancing effects of prior multiple placements (Price et al., 2008), and the KEEP-SAFE children were more likely to be reunified with their biologic parents or permanently placed with relatives or an adoptive family (17% of the KEEP-SAFE children vs. 9% of the control children).

Middle School Success (MSS)

The final intervention originating from the OSLC team is MSS, a derivative of KEEP-SAFE that targets youths exiting primary school (Chamberlain, Leve, & Smith, 2006). MSS includes foster–caregiver and youth components in the summer prior to middle-school entry (six sessions) and through the first year of middle school (weekly). The parenting sessions were group based and behavior-management oriented; the youth sessions were group based (summer) and individually based (school year) and were oriented toward skill building. Relative to the children in regular foster care, the MSS children exhibited decreased externalizing and internalizing problems at the 6-, 12-, and 24-month follow-ups (Kim & Leve, 2011; Smith, Leve, & Chamberlain, 2011). MSS also resulted in increased prosocial behavior and fewer placement changes at the 12-month follow-up, reduced substance use and health-risking sexual behavior at the 36-month follow-up (Kim & Leve, 2011), and improved decision making at the 5-year follow-up (Weller, Leve, Kim, Bhimji, & Fisher, 2015).

Attachment and Biobehavioral Catch-Up (ABC)

ABC is one of three interventions shown to be effective during early childhood (BEIP and TFCO-P being the other two). It is a 10-session intervention designed to help caregivers facilitate healthy regulation of foster child behavior and stress responses by teaching foster caregivers to be highly responsive to child emotions and to increase their provision of nurturing care and promotion of attachment security during early childhood (Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008). The results of a randomized trial of ABC indicated that the intervention children were more often secure and less often disorganized in their attachments to caregivers than were the control children: 52% (vs. 33%) exhibited secure attachment and 32% (vs. 57%) exhibited disorganized attachment approximately 1 month after the intervention (Bernard et al., 2012). ABC has also shown success in normalizing foster child stress responses (i.e., cortisol reactivity) relative to the control children, which indicates the plasticity of their neurobiological systems and the capacity for recovery. Overall, the ABC findings parallel the TFCO-P effects on attachment and stress responsivity but extend downward developmentally to the infant and toddler period.

The Incredible Years

The Incredible Years is an effective intervention for at-risk children and children with conduct problems that was modified for foster families with school-age children (Reid, Webster-Stratton, & Hammond, 2003; Webster-Stratton, Reid, & Hammond, 2001). The modified Incredible Years intervention incorporates a coparenting component between foster and biological caregivers to expand their knowledge of each other and their child, practice open communication, and negotiate interparental conflict regarding topics such as family visitation, family routines, and discipline (Linares, Montalto, Li, & Oza, 2006). The results suggest that Incredible Years improves foster caregivers' positive discipline and coparenting skills.

Fostering Individualized Assistance Program (FIAP)

The FIAP is focused on wrapping services around the child according to their individual and family needs, with the goal of improving placement stability and reducing behavioral and emotional problems (Clark et al., 1994). The FIAP has four components, including a strengths-based assessment, life-domain planning, clinical case management, and follow-along supports and services. The FIAP children were shown to exhibit fewer attention, withdrawal, and total problems at an 18-month follow-up (assessed via caregiver report; Clark et al., 1994). In addition, the FIAP children had fewer runaways and spent less time incarcerated. Increased placement stability has been found for older FIAP children only (Clark et al., 1998).

Fostering Healthy Futures (FHF)

FHF was designed for maltreated foster children ages 9–11 years (Taussig, Culhane, & Hettleman, 2007). The program promotes child well-being by identifying and addressing mental health issues, preventing adolescent risk behaviors, and promoting competence. The intervention consists of 90-minute therapeutic skills groups for the children over 30 weeks during the school year, combined with one-on-one mentoring (2–4 hours/week) with a graduate student. FHF has been shown to reduce child mental health problems and reduce symptoms of dissociation 6 months postintervention (Taussig & Culhane, 2010). In addition, the FHF children reported better quality of life immediately following the intervention, and fewer FHF youths had received recent mental health therapy 6 months postintervention (Taussig & Culhane, 2010). Finally, the FHF youths were 71% less likely to be placed in residential treatment 1 year postintervention (Taussig, Culhane, Garrido, & Knudtson, 2012).

Limitations of Existing Foster Care Interventions

Although the nine interventions reviewed in the preceding sections offer promise for improving outcomes for foster children, there are limitations in the work to date. First, there is a lack of long-term follow-up data: five studies do not have published follow-up data beyond a 12-month follow-up period (ABC, Incredible Years, KEEP, KITS, and FPF), and only three have published effects beyond 24 months (TFCO-A, BEIP, and MSS), making it difficult to know whether the observed effects sustain across development. In at least one of these interventions (Incredible Years), the effects dissipated quickly: 3 months after the intervention ended, only the positive discipline effect remained. Further, the length of time between intervention completion and the outcome assessment was often unclear from the published work. For example, the ABC samples had a wide child age range; therefore, the outcome assessment was delayed if the child was younger at the start of the study. In addition, some children in all of the studies experienced one or more placement changes prior to the outcome assessment. Together, these limitations cast doubt about whether the foster children who benefited from intervention will exhibit healthy adjustment later in development. Long-term follow-up studies are needed to better evaluate whether initial effects of such interventions are maintained over time.

Second, the effects found across studies did not consistently generalize to other measures. For example, the FIAP effects on child mental health were present for caregiver reports but not for youth reports, and delinquency outcomes in TFCO-A were present for girls using days-in-locked-settings data but not using self-reported delinquency data. The effects were also sometimes specific to subpopulations (e.g., one gender, older children; FIAP and TFCO-A) or to one set of hypothesized outcome constructs but not to another set (MSS and FIAP). Given these inconsistent findings and the generally small effect sizes (and the failure to report effect sizes in many published reports), there is room for refinement. Efforts to identify patterns of behavior among nonresponders might yield useful insights into how effective interventions could be modified or adapted to further remediate the negative effects of early adversity.

Summary

In summary, at least nine interventions for foster families have been tested using randomized trial designs at the individual level and have been shown to be effective in improving one or more outcomes for foster children. The results from most of these studies have shown small to moderate effect sizes that decrease over time. TFCO-A is an exception to this pattern, as is BEIP, reviewed in an earlier section of this review.

Although these interventions vary in content and target age, they converged around several domains, including being developmentally specific, aiming to reduce known risk factors and promote resilience, and emphasizing the mediating role of parenting in linking early adversity with child outcomes. Of note, the positive effects of the interventions varied based on the developmental period of the children receiving the services. For example, two of the interventions reviewed here (TFCO-P, ABC) and BEIP reviewed in an earlier section showed positive effects on parent–child attachment relations and child neurobiological development in early childhood. Conversely, nearly all the middle-childhood and adolescent interventions showed positive effects on behavior problems (TFCO-A, KEEP, MSS, and FIAP), but only MSS had documented effects on an aspect of neurobiological functioning (decision making; Weller et al., 2015). Whether this is a function of the respective assessment measures in each study or a function of reduced neural plasticity across development is a question for future research. Taken together, however, the results of the interventions reviewed here provide strong evidence that the domains of functioning affected by early adversity in foster children appear to remain, at least to some degree, pliable throughout development.

CONCLUSIONS, TRANSLATIONAL IMPLICATIONS, AND DIRECTIONS FOR FUTURE RESEARCH

In any comprehensive, complex review of the literature, it can be challenging to synopsize points into a manageable set of conclusions. However, if such an effort is to prove useful—not only for summarizing the current state of a scientific knowledge base but also for pointing to directions for future research—a parsimonious perspective on the field is necessary. Several main inferences on typical and atypical development can be made from the foster care literature:

First, foster care research adds to the general understanding about the effects of early adversity on development and to specific studies documenting that early adversity effects (beginning prenatally) are cumulative, with those occurring earlier and for longer periods having the greatest impact. This research replicates and extends the findings in other areas (including research on animals and humans) with respect to the pervasive impact of early adversity on typical development. In particular, it highlights that development can get off course from not only traumatic events that occur in the life of the child, but also the absence of expected environmental input in the form of nurturing and responsive care (i.e., neglect). One disclaimer is that when considering the tendency for there to be poorer outcomes for foster children, it is important to bear in mind that foster care is typically an outcome of adversity rather than the cause of poor adjustment, although certain experiences in foster care can exacerbate the impact of early adversity.

Foster care research further makes clear that the disruptions to typical development emanating from early adversity may affect broad and interrelated domains of psychological and biological functioning. Of particular note is the finding that early neglect appears to disrupt the development of neuroendocrine systems that play a critical role in maintaining homeostatic balance in the presence of stress. This may help explain the vulnerability to future stress that has been observed among individuals exposed to early adversity. In addition to neuroendocrine effects, early adversity appears to affect the structure, function, and possibly the connectivity among crucial brain regions that underlie key capacities such as executive functions and threat detection.

One of the unique aspects of foster care research with respect to elucidating the effects of early adversity on child development is that it enables us to understand the effects of specific dimensions of adversity on particular underlying neurobiological systems. The aforementioned results related to the effects of placement transitions on executive functioning are one example of this. One important future direction for foster care research is to continue to explore the impact of specific types of early adversity that occur more commonly in foster care. For example, children who experience prenatal ethanol exposure and subsequently spend their early years in a succession of foster homes with different caregivers might be examined in comparison with those remaining with their biological parents and those adopted at birth. This would allow for a much more precise understanding of the combined effects of prenatal teratogenic exposure and early adversity than currently exists. It will be especially important for work in this area to be multilevel in nature, thereby continuing to contribute to the translational knowledge base that exists with respect to the psychological and biological effects of adversity.

Second, foster care research provides conclusive evidence that, despite the health risks posed by early adversity, typical development can occur under less than optimal rearing conditions. On average, foster children fare poorly on many measures of well-being. However, as is nearly ubiquitous in studies of foster children, some individuals' development appears relatively on course despite significant early adversity. From an evolutionary perspective, our ability to survive as a species would certainly have been reduced were this not the case, but it can still be easy to overlook this phenomenon given the extent to which the risks associated with being in foster care (or other forms of adversity) are highlighted in the literature and media. Historically, such positive outcomes have been vaguely attributed to defined concepts of innate resilience. Research in this area poses methodological challenges; however, it is important that future investigations focus on better understanding the variables, especially those that are malleable, that increase the likelihood of typical development following early adversity. Such variables may exist at many levels. Thus, research will do well to focus on the constitutional and environmental influences on resilience and on the complex interrelations among these influences.

Third, foster care research suggests that, when early adversity leads development off course, subsequent improvements in environmental conditions have the potential to realign trajectories positively. Further, although early intervention seems to produce positive change, environmental improvements later in development can have a positive impact.

These intervention studies do more than inform foster care policy. Studies of this nature provide proof of concept

about the plasticity of behavior and biology—even in the context of deterministic life circumstances. Several disclaimers are necessary, however, in this area. First, not all children whose development is compromised by early adversity respond to interventions. In particular, it appears that as adverse experiences accumulate—especially in the context of combined prenatal and early adversity—they may limit the plasticity of these systems. In addition, genetic factors are likely to play a role. Because most research on interventions has been focused on detecting main effects, the knowledge base in this area is limited and more work is needed to better understand the variables associated with recovery from the effects of early adversity. Second, it is important to point out that the foster care intervention research on biological plasticity following adversity is quite limited and focuses primarily on the HPA axis. Moreover, at this point, the biological evidence comes only from studies of infants and young foster children. It is not clear at present whether the same plasticity can be observed in other biological systems or in older foster children.

Several additional issues warrant attention with respect to what foster care intervention research can tell us about typical and atypical development. First, although the ability to mitigate the effects of early adversity is evident in this research, the specific intervention mechanisms at work are far less well understood. The existing evidence-based interventions for foster children typically consist of multiple components that focus on the child and caregiver. Although the interventions are theory based, the existing studies provide only limited information about whether the interventions effectively target the domains hypothesized to be most necessary to affect outcomes. With numerous intervention components, it may be that some produce more of an impact than others do. However, because studies evaluating these interventions are quite costly and take many years to conduct, the ability to deconstruct interventions and test the impact of their individual and combined components is limited.

A related issue is to examine for whom interventions are most effective. There is no question that the development of a scientific knowledge base within the foster care literature showing that the effects of early adversity can be mitigated is a major accomplishment. Yet we know that these interventions are not universally effective and that it may be possible to identify certain phenotypes that are more or less likely to respond to existing interventions. Work in this area is fundamentally translational in nature because it reciprocally informs our understanding of how to best support foster children and our understanding of issues related to individual differences in neural and behavioral plasticity.

In this chapter, we have attempted to characterize the foster care research literature as it pertains to typical and atypical development. Although many of the conclusions should create ongoing concern and motivate continued efforts to reduce adversity in all children, there is also reason for optimism, both in terms of the clear ability of some children to overcome adversity and in terms of the extant knowledge base about how to facilitate positive outcomes. The ongoing research in this area will likely continue to inform this topic; as such, future updates of this discussion are warranted.

Our chapter concerns developmental psychopathology and autobiographical memory development. We especially focus on links among child maltreatment, trauma-related psychopathology, and memory. Our main tenet is that memory development can be influenced by childhood trauma (child maltreatment being the main type of trauma we discuss) and by the emotion regulation problems and trauma-related psychopathology that may result from that trauma. More specifically, we contend that children and adults with child maltreatment histories, like individuals without such histories, often have particularly accurate memories for trauma-related life events. In fact, histories of trauma may heighten memory for trauma-related information. However, individual differences also exist, leading at times to autobiographical memory deficits in a subset of individuals who experienced childhood maltreatment. Of importance, these deficits do not appear to be directly related to child maltreatment per se but instead are predicted by certain emotion regulation strategies that are associated with trauma-related psychopathology.

This chapter provides a selective review of research relevant to our thesis. We begin by presenting a conceptual framework for considering empirical findings. Based

on a developmental psychopathology perspective, we then ground the reader in theories and research on typical development of memory and emotion regulation processes. Effects of child maltreatment, particularly in relation to trauma-related psychopathology in children and adults, are then described, with a special focus on post-traumatic stress disorder (PTSD), dissociation, and depression. This is followed by a brief discussion of the psychophysiology and neurobiology of trauma as related to autobiographical memory development. Then, we describe theories that provide potential reasons why child abuse victims may have particularly accurate memories of trauma-related information, followed by a review of theories pertaining to why a subset of child maltreatment victims show impaired memory. Next, we present our autobiographical memory development model that places emotion regulation at the forefront of understanding individual differences in autobiographical memory in relation to psychopathology. Afterward, we review research findings with regard to child maltreatment and memory development. We conclude with comments on the translation of this research into practice and on future research needs. Although some ideas we mention in this chapter include elements of speculation, we hope that this review will stimulate future theory and research.

CONCEPTUAL FRAMEWORK

Goodman, Quas, and Ogle (2010) proposed a conceptual framework for thinking about maltreatment and memory, a framework that we expand and then rely upon in the present paper. The framework is largely heuristic, but it helps us in organizing and interpreting relevant theory and empirical research. Our original conceptualization included two dimensions along which studies vary. The first dimension concerns the type of stimulus or to-be-remembered information, and the second concerns the life experiences and background of the participant in question. For simplicity, these dimensions can be represented by a 2 (type of stimulus) × 2 (childhood background) factorial classification scheme. However, given growing evidence regarding the important roles of emotion regulation and related psychopathology in memory, we expand on the conceptualization here to better incorporate emotion regulation/psychopathology. Specifically, we propose a 2 (type of stimulus) × 3 (childhood background/emotion regulation strategy) factorial classification scheme.

Considering first the type-of-stimulus dimension, in many studies, the to-be-remembered stimulus is fairly neutral or even mildly positive (e.g., stories, brief interactions with an adult; Goodman, 1980; Quas et al., 2007). But in other studies, the to-be-remembered information is distressing or trauma related (e.g., stressful medical procedures, anogenital examinations, trauma narratives; Lanious et al., 2006; McWilliams, Goodman, Lyons, Newton, & Avila-Mora, 2014; Merritt, Ornstein, & Spicker, 1994; Saywitz, Goodman, Nicholas, & Moan, 1991). This difference in stimulus type can have a profound effect on memory (Christianson, 1992), regardless of the childhood history of the person under study.

The second dimension that we originally proposed concerns participants' backgrounds: that is, whether or not they experienced childhood trauma or have a history of maltreatment. In most memory studies, the participants do not have any known histories of trauma. Yet, as reviewed here, individuals with trauma histories may remember at least some kinds of information with greater clarity than do those without such histories. Moreover, chronic trauma, as experienced by many child maltreatment victims, has physiological and possibly neurological consequences that may affect memory. For such reasons, it is important to differentiate between children with and without trauma histories.

However, given current research, we now propose a third factor, specifically emotion regulation tendencies and related psychopathology. We add this factor as a third type of the second dimension because considerable research points to emotion regulation and associated psychopathology as affecting memory, especially for negative information, but also at times for positive information. And, especially with regard to memory error, it likely is not only the experience of trauma or child maltreatment that matters but also more specifically how that experience affects psychological functioning related to certain types of emotion regulation. In extreme cases, emotion regulation problems may lead to psychopathology, both being subsequent to trauma exposure. Stated another way, the psychological sequelae of childhood trauma will have effects on memory over and above a history of traumatic experiences in childhood. The inclusion of the third factor (emotion regulation/psychopathology) helps us to distinguish effects of trauma from the effects of the consequences of the trauma. Note that when Bremner, Shoebe, and Kilhstrom (2000) compared memory functioning in women with no known abuse histories, women with child sexual abuse histories but no symptoms of posttraumatic stress disorder (PTSD), and women with both child sexual abuse histories and current PTSD, it was only the latter group that showed elevated memory monitoring problems.

This pattern points to possible effects of psychopathology, not of abuse history per se.

Thus, we now expand our second dimension to have three (rather than just two) categories (Table 13.1): (1) typical development (e.g., no significant childhood adversity/no maltreatment or childhood trauma history), with normative emotion regulation strategies; (2) childhood trauma/maltreatment history, with *hyperarousal* emotion regulation tendencies; and (3) childhood trauma/maltreatment history, with *hypoarousal* emotion regulation tendencies. Regarding the first group, by *typical* development, we mean individuals (children or adults) who have not experienced child maltreatment or other serious childhood adversity. This group is usually represented by a nonmaltreated control group in studies on effects of child maltreatment. In attachment theory terms, this group would include a large percentage of securely attached individuals (those who score low in attachment anxiety and low in attachment avoidance). The second group represents a subset of child maltreatment (or child trauma) victims, specifically ones who respond to their adverse childhood experiences with hyperarousal emotion regulation strategies. Individuals who evince reexperiencing and hypervigilance symptoms of PTSD subsequent to child maltreatment would fall in this category. In attachment theory terms, this group would include a large percentage of attachment anxious individuals (individuals who score high in attachment anxiety but low in attachment avoidance). The third group also represents a subset of child maltreatment or child trauma victims, but in this case ones who respond to their adverse childhood experiences with hypoarousal emotion regulation strategies. Individuals who evince avoidance symptoms of PTSD subsequent to child maltreatment would fall in this category. In attachment theory terms, this group would include a large percentage of attachment avoidant individuals (individuals who score low in attachment anxiety but high in attachment avoidance).

TABLE 13.1 Hypothesized Developmental Psychopathology Model of the Effects of Childhood Adversity on Memory

	Type of remembered stimulus[1]	
	Positive/neutral	Negative/traumatic
Maltreated—hyperarousal (including anxiety problems)	−	+
Maltreated—hypoarousal (including avoidance problems)	−	−
Nonabused (controls, typically developing)	0	+

[1]A minus sign (−) indicates less complete or less accurate memory. A plus (+) sign indicates especially vivid or particularly accurate memory. A zero (0) indicates typical memory performance.

Accordingly, when considering the memory development research, it is important to eliminate confusion between, for example, the mundane versus traumatic nature of the stimulus and the background and emotional functioning of the participants. In some studies, the to-be-remembered information is so negatively valenced and high in arousal as to be described as traumatic, but the participants may have no known trauma histories (e.g., Goodman et al., 1997; Merritt et al., 1994). In other studies, the memories under examination may be for neutral or mildly positive information (e.g., fun interactions with adults), but the participants have child maltreatment histories and have reacted to their maltreatment with hyperarousal or hypoarousal emotion regulation tendencies and resulting psychopathology (e.g., Harris et al., in press; McWilliams, Harris, & Goodman, 2014).

Unfortunately, researchers in many studies do not differentiate between child trauma histories and emotion regulation strategies or trauma-related psychopathology, making the aforementioned distinctions impossible to determine and making a comprehensive review of all cells of our classification scheme difficult. Types of childhood emotion regulations strategies should, however, be kept in mind in reading this paper, even when studies do not permit refined analysis separating child maltreatment history and different resulting emotion regulation strategies or trauma-related psychopathology. Given the limited research on some cells and given the significance of certain cells within our classification scheme for understanding the links among child maltreatment, trauma-related psychopathology, and memory, a majority of our review, as well as our main tenets, focuses on the following subset of cells: (1) stimuli are neutral or positive and participants do not have maltreatment or childhood trauma histories; (2) stimuli are positive and participants have maltreatment histories or experienced other childhood traumas; and (3) the stimuli are negative (stressful or trauma related), and the participants have child maltreatment histories or experienced other childhood traumas. When relevant, though, findings from studies falling in the other classification cells are mentioned as well. Also of importance, we differentiate between hyperarousal and hypoarousal emotion regulation strategies and memory performance as possible.

OVERVIEW OF MEMORY DEVELOPMENT

The first cell in our classification scheme concerns typical memory development, in the absence of known child

maltreatment or childhood trauma, and in the absence of trauma-related psychopathology. An understanding of how trauma (such as child maltreatment), or the psychopathology resulting from such, affects memory first requires an understanding of how memory develops under normal conditions. At its most basic level, memory consists of three stages: encoding (i.e., entrance of information into the memory system); storage (i.e., the embedding and upkeep of encoded memory); and retrieval (i.e., accessing stored memories; Alexander et al., 2002; Gordon, Baker-Ward, & Ornstein, 2001). Despite the simplicity of this model, human memory development involves fascinating and complex processes and changes. In this first section, we discuss theories of memory development and relevant empirical findings on the progression of memory functioning across childhood, with a particular focus on autobiographical memory.

Theories of Memory Development

In an important but limited sense, memory development begins in the womb, even before we take our first breaths. Using a habituation paradigm, it can be demonstrated that fetuses remember vibroacoustic stimulations across 10-minute spans beginning at 30 weeks gestational age. By 34 weeks gestational age, fetuses can remember these stimulations over a 4-week period (Dirix, Nijhuis, Jongsma, & Hornstra, 2009). However, habituation is such a basic form of memory that it is evident even in single cell organisms like the amoeba. One should *not* infer from demonstrations such as this that, for humans, prenatal and birth experiences enter consciously accessible autobiographical memory.

Fortunately, theorists have clarified types of memory that have evolved phylogenetically, as well as ontogenetically, in typically developing individuals. These theories refine what is meant by the more general term "memory." The most famous theory in this regard is Endel Tulving's (1985) monohierarchical multimemory systems model. According to this theory, lower organisms and human infants evince procedural memory, such as demonstrated by human fetuses in the vibroacoustic-stimulation habituation task studied by Dirix et al. (2009), mentioned previously. This form of implicit memory is anoetic; that is, such memories are not consciously retrievable. Thus, for the individual, such memories are, in effect, not known, at least not consciously, but instead are primarily expressed behaviorally. Stimulus-response learning, motor memory (e.g., remembering how to aptly turn the corner while riding a bicycle), and habituation are examples of procedural memories. Procedural memories give our memory system a start, and later in development, procedural memories can co-exist with consciously accessible ones.

With brain development, a second form of memory, called semantic memory, emerges, according to Tulving's theory. Such memory is of general knowledge, such as concepts and facts. It is explicit, in the sense that such information can be retrieved into consciousness. However, this type of consciousness is noetic and does not involve consciously recollecting the *context* in which information was learned. It is therefore not autobiographical. We may know that George Washington was the first president of the United States, but not remember when or how we learned this fact. That is, we have lost the memory for the *context* in which the information was engraved in our minds. According to Tulving, young children (up to about 5 or 6 years of age) have procedural and semantic memory. Thus, young children can remember facts and have generalized event representations (e.g., scripts such as what typically occurs at a restaurant, at school, or at bedtime), but not episodic memory.

In Tulving's theory, episodic memory is the most phylogenetically and ontogenetically advanced form of memory. This form of memory permits mental time travel, such that true recollection of unique autobiographical experiences can occur, including the context in which the event happened. Thus, episodic memory permits one of us (GG) to remember (and mentally travel back to the moment of) hearing the news, while sitting in her junior high school home room class, that President John F. Kennedy had been shot, and that she cried and looked over at a classmate from a conservative Republican family, to see if he was, too. Autobiographical memory is a type of episodic memory. (In the previous example, it would also likely be called a flashbulb memory; Brown & Kulik, 1977.) Although Tulving believes that children do not develop episodic memory until about 6 years of age, this view is hotly contested by many developmental psychologists (e.g., Bauer, 2005). A related distinction has been made between familiarity (knowing) and recollection (Jacoby, 1991; Yonelinas, 2002; see Lindsay, Kelley, Yonelinas, & Roediger, 2014), with the idea that familiarity is a fast automatic process whereas recollection is a slower, more deliberative process that emerges in its more adult form around 8 or 9 years of age (e.g., Ghetti & Angelini, 2008; Holliday, 2003).

Although Tulving's theory provides a useful, developmental framework for considering changes in memory during childhood, his ideas regarding memory systems have been challenged in numerous ways. For example, Roediger, Weldon, and Challis (1989) argued for a unitary memory

system in which memory processes but not memory systems vary (see also Burianova, McIntosh, & Grady, 2010). Based on her extensive developmental research, Rovee-Collier (1997) provided empirical support for a unitary memory system beginning in infancy. Moreover, in elicited imitation experiments, older infants and toddlers arguably evidence episodic memory (Bauer, 2014; Bauer, Wenner, Dropik, & Wewerka, 2000; Lukowski et al., 2005; Meltzoff, 1995). Even certain lower animals, such as a subset of birds (e.g., scrub jays), can be shown to have episodic-like memory (Clayton, Salwiczek, & Dickinson, 2007).

These critiques of Tulving's theory are consistent with an alternative formulation, specifically that memory is more associationist in nature. The associationist approach has a long history in philosophy and psychology (e.g., Locke, 1948/1690). In this approach, memory consists of associative networks. With age and experience, the networks become more elaborated (e.g., more intricate, detailed, and connected to other semantic nodes), spreading activation within and across the associative networks becomes faster, and activation becomes more automatic (Howe, 2011). Also according to this approach, semantic networks form our knowledge base, and various encoding, storage, and retrieval processes act on the associative networks. Emotional information is remembered well in large part because it is distinctive. Associationist theories have the advantage of parsimony and considerable scope, but are less developmental in nature, given their emphasis on quantitative growth rather than qualitative changes in memory.

Fuzzy trace theory (FTT) is an alternative theoretical framework for understanding memory development (Brainerd & Reyna, 2001, 2002). According to FTT, children rely more on verbatim memory than do adults, who rely more on gist memory. That is, Fuzzy Trace Theory suggests that young children tend to encode and remember surface features of events (Gordon, et al., 2001; Reyna & Brainerd, 1995). With development, however, individuals increasingly encode and remember the gist (i.e., the semantic/conceptual meaning) of information as well as considerable detail. Although gist memory is said to be less specific than verbatim memory, the former tends to be retained longer. Thus, according to this theory, younger children's memories decay more quickly than those of older children and adults.

Finally, two theories are of particular importance for the development of autobiographical memory. The sociocultural theory, offered by Katherine Nelson and Robyn Fivush (2004), takes inspiration from Vygotsky's ideas (e.g., children's internalization of the mental tools provided by parents) and Nelson's training in developmental psycholinguistics. According to this view, by about 20 months of age, children have the rudimentary language skills to recall small fragments of memory about very recent events. On their own, these very young children cannot structure retrieval of memory for recall; they need an adult's help to communicate memories. However, by 2 years of age, children can recall past events and remember events over relatively long periods of time (Fivush & Hamond, 1989), and by 2.5 to 3 years of age, children can verbally recall prior experiences with some level of coherency (Eisenberg, 1985; Fivush, Gray, & Fromhoff, 1987; Fivush & Schwarzmueller, 1998).

A core and unique part of Nelson and Fivush's proposal is that autobiographical memory emerges, based in important part, on parent–child discussion of past events. Through such discussions, children learn how to structure memory reports and place events on an autobiographical timeline. Individual differences in how children learn this structure, though, also exist. Parents who engage in elaborative discussions with their young children, as opposed to parents who use a more repetitive discussion style, have children who develop earlier and more complete autobiographical memories (Fivush, Haden, & Reese, 2006). Thus, according to Nelson and Fivush, social communication and language play key roles in the development of autobiographical memory.

The last theory of note, the Personalization Theory, was articulated by Howe and Courage (1997). They proposed that autobiographical memory requires development of the self-system, as indexed, for example, by young children's abilities to recognize themselves in the mirror. Without a sense of self, children cannot retain autobiographical information. According to this view, even in the first year of life, children remember previous events but such information does not become autobiographical and is eventually forgotten or inaccessible. Starting between 18 and 24 months of age, an internal representation of the self emerges. This representation provides a knowledge structure around which personally experienced events are organized and retained in memory. In support of their theory, these authors note that the ability to retain autobiographical memories after the age of two is correlated with self-recognition (Courage & Howe, 2010). Subsequent increases in autobiographical memory are explained by a larger knowledge base, greater automaticity of processing, and more developed mnemonic strategy implementation.

Overall, these theories, including those that take a decidedly developmental approach, focus on typically developing children. The theories were not explicitly designed to explain such important topics as memory for

traumatic experiences, effects of acute or chronic child maltreatment on memory, or effects of the onset and continuation of psychopathology in childhood (but see Howe, 2011). It is important nonetheless to keep normal memory development in mind when considering diverse developmental trajectories that may occur as a result of trauma exposure and any subsequent psychopathology. These normal memory frameworks inform theories of developmental psychopathology and memory, and, as such, it is critical to have a sense of the progression of normal memory development.

Empirical Studies of Typical Memory Development

Developmental researchers typically contend that a newborn's brain is not mature enough to consolidate explicit memories that last for years. Whereas some debate children's abilities to develop early episodic memories, many researchers have shown that children have long-term nonverbal memories in infancy (e.g., Bauer, 2005; Fagan, 1970; Meltzoff, 1988; Rovee-Collier, 1999; Rovee-Collier & Cuevas, 2009). These memories, however, tend to have limited retrievability and considerable fragility.

Moreover, many of these early memories cannot be accessed later in life (e.g., older childhood and adulthood), a phenomenon known as infantile amnesia (Courage & Howe, 2010; Reese, 2002, 2009; Peterson, 2002). There are individual differences in the age at which infantile amnesia occurs, and some adults can recall events that date back to when they were 2 years old (Usher & Neisser, 1993). A number of memory development researchers have called for a conceptualization of infantile amnesia as a memory development process, rather than a barrier (Peterson, 2002). According to some authorities, the problem is one of retrieval rather than of complete forgetting (Rovee-Collier, 1997). Despite the fact that we still do not have a definitive explanation for infantile amnesia, we do know that our memory abilities continue to improve throughout childhood and adolescence.

Although even young children can retain an impressive amount of information, overall autobiographical memory performance, including accuracy, number of details recalled, and length of time that self-relevant memories are retained, increases with age (Bauer & Fivush, 2013; Farrar & Goodman, 1992; Gordon, Baker-Ward, & Ornstein, 2001; Howe, 2011). Older children perform better on memory tasks, on average, than younger children—and adults perform better still (Goodman & Reed, 1986; Hudson, 1990). Research links developmental increases in autobiographical memory with social interactions, including parent–child attachment or reminiscing, language abilities, and metacognitive skills (Bauer & Fivush, 2013; Bjorklund, 2011: Chae, Goodman, & Edelstein, 2011; Courage & Howe, 2010; Peterson, 2002). Developmental increases in memory abilities have a number of potential causes. For example, they may be due to increased automaticity (Howe, 2011; Reese, 2009), increased knowledge base (Chi, 1978), increased or improved use of memory strategies (Beuhring & Kee, 1987; Bjorklund, 2011), brain development (Ghetti & Bunge, 2012)—and, most likely, a combination of these factors.

An important driver of development of autobiographical memory concerns increased knowledge about the event or situation to be remembered (Chi, 1978; Mandler, 1984; Nelson, 1986). Repeated events are stored in memory as schemas, or scripts, which are unified sets of mental expectations (organized knowledge bases) about sequences of events that largely play out in the same, routine way each time. School days, medical or dental exams, bedtime routines, and holiday traditions are all examples of events for which a person may have a scripted memory (e.g., First, I put on my PJs, then I brush my teeth, and then I get into bed). Older children and adults tend to have more established scripts than younger children (Nelson, 1986). Information about familiar or well-understood events can be more easily encoded as well as retrieved partially due to the existence of these scripts. As children get older, their knowledge base expands, which likely explains in part their corresponding expansion in memory. (See Brubacher, Roberts, & Powell, 2012, for interviewing children about unique vs. repeated events.)

However, older children's increased script knowledge, and greater ability to use gist memory traces, does not necessarily result in improved memory in all instances. Myles-Worsley et al. (1986) followed children from preschool through third grade and found that the use of scripts for recall can also have drawbacks. Specifically, although the older children remembered more details about the general school-day script, they also misremembered more details about sequences of events that had occurred in school several years before.

Relevant to the development of knowledge base and gist processing, research using the Deese-Roediger-McDermott (DRM) paradigm has revealed reverse developmental trends, where adults and older children often perform worse than younger children (Brainerd, Reyna, & Ceci, 2008). The DRM paradigm requires participants to attempt to remember semantically related lists of words (e.g., dream, pillow, night, bed ...) that are all highly associated with a critical lure (e.g., sleep), which is a word

that does not appear in the list (Roediger, McDermott, & Robinson, 1998: Read, 1996; Otgaar, Peters, & Howe, 2012). Adults frequently create false memories of having heard the critical lure when, in fact, it was never presented (e.g., Gallo, 2006; Roediger et al., 1998). Whereas adults are highly likely to fall for the critical lure on DRM tasks (presumably due to greater gist processing based on their expanded knowledge base), children are much less susceptible to the illusion, at least given the length and types of lists that have been traditionally studied (Brainerd, Reyna, & Forrest, 2002; but see Ghetti, Qin, & Goodman, 2002). This is especially true when young children do not recognize the list items' conceptual relations as readily as do older children and adults or because the lists exceed younger children's working memory capacities (Ghetti et al., 2002). In any case, such reverse developmental trends can also be demonstrated at times in autobiographical memory tasks that rely heavily on knowledge-based inferences (Brainerd et al., 2008).

In summary, a great deal is known about normal memory development, at least for lists of words, everyday routine events, and some aspects of autobiographical memory. We consider typical memory development for stressful events later in this chapter.

EMOTION REGULATION AND MEMORY

Another key concept in our review concerns emotion regulation. We contend that emotion regulation plays an important role both in the expression of psychopathology and in memory functioning and development (see also Richards & Gross, 2000, 2006). A useful starting point is for us to define what we mean by emotion regulation and briefly review how it develops, and what problems in it may arise. Emotion regulation is defined as the "internal and external processes involved in initiating, maintaining, and modulating the occurrence, intensity, and expression of emotions" (Thompson, 1994, p. 27). Precursors to contemporary emotion regulation theories include psychoanalytic theory (Freud, 1909/1995) and classic models of stress and coping (Gross, 1998; Lazarus, 1966). For example, psychoanalytic theories emphasize several types of anxiety regulation, termed ego defenses, which generally focus on avoiding situations that are anxiety-inducing and suppressing the expression of impulses that could result in elevated levels of anxiety (Freud, 1909/1995). For contemporary emotion regulation researchers, the focus has widened to include both conscious and unconscious processes that increase or decrease the experience or expression of either positive or negative emotions (Mayer & Salovey, 1995; Parrott, 1992; Thompson & Goodman, 2010).

Emotion regulation initially develops fairly slowly across development, with advances continuing into adolescence and beyond (Calkins & Bell, 1999; Zeman & Shipman, 1997). In early childhood, emotion regulation largely takes the form of extrinsic, behavioral regulation strategies aimed at reducing negative sensations and increasing positive feelings (Zeman et al., 2006). With age, children begin utilizing more effortful and planful regulation strategies (Lazarus & Folkman, 1984), gain more nuanced understanding of when and how to control emotions (Thompson & Goodman, 2010), and rely more on mentalistic or cognitive tactics (e.g., attentional redirection, cognitive reappraisal) in place of behavioral (e.g., seeking social support, avoidance) strategies.

When considering the role that experiential factors play in children's emerging emotional regulation, caretakers (e.g., parents) serve as particularly important influences, and what children learn from their parents about emotion regulation has long-lasting implications for development (Morris et al., 2011). Parents indirectly influence children's emotion regulation strategies through children's observational learning of their parents' emotional displays (Parke, 1994). Children of parents who display wide ranges of emotions learn a variety of emotional responses in relation to situations that evoke those responses (Denham et al., 1997). Perhaps more evident are the direct effects of parents: Parents who help their children verbally label emotions and empathize with or validate children's emotions have children with more successful emotion regulation strategies. Likewise, parents who actively help children problem solve when dealing with negative emotions (Gottman et al., 1997) have children who tend toward more optimal emotion regulation strategies, such as cognitive reappraisal and seeking social support (Eisenberg & Fabes, 1994). In contrast, parents who react punitively to children's emotions have children who tend toward less optimal emotion regulation strategies, such as avoidance or escape. Parental minimization of children's emotions is also associated with children's greater use of avoidant emotion regulation strategies (Eisenberg, Fabes, Carlo, & Karbon, 1992).

Emotion regulation, in many ways, is intimately tied to children's attachment system. Indeed, Bowlby's (1980) attachment theory has recently been conceptualized in terms of individual differences in emotion regulation strategies (Mikulincer & Shaver, 2007). As Shaver and Mikulincer (2007) noted, "Bowlby (1973, 1980) characterized the stable individual differences in emotion regulation that emerge from prolonged reliance on

particular 'attachment figures,' people who provide either adequate or inadequate protection, safety, support, and guidance concerning emotions and emotion regulation" (p. 446). Research suggests that attachment is best described by the intersection of two orthogonal dimensions, anxiety and avoidance (Fraley & Waller, 1998; Mikulincer & Shaver, 2007; Shaver & Mikulincer, 2003). On the one hand, individuals scoring high on the avoidance dimension are characterized by chronic emotion regulation attempts to deactivate or inhibit attachment-system activation (Edelstein & Shaver, 2004; Fraley, Davis, & Shaver, 1998). To regulate their emotions, these individuals tend to minimize expressions of distress and attempt to hypoactivate their attachment needs (Dozier & Kobak, 1992; Fraley & Shaver, 1997). High scores on the anxiety dimension, on the other hand, appear to reflect hyperactivation of the attachment system, which can also be viewed as an emotion regulation strategy (Cassidy, 2000). Highly anxious individuals are hypervigilant to attachment figures and attachment-related concerns (e.g., Mikulincer, Birnbaum, Woddis, & Nachmias, 2000; Mikulincer, Gillath, & Shaver, 2002) and become easily distressed by separations from attachment figures (Feeney & Noller, 1992; Fraley & Shaver, 1998). These attachment tendencies and the underlying emotion regulation strategies are believed to emerge in childhood and exist across the life span. They can, as well, be combined to delineate the classic attachment styles: Secure adults and secure infants are those who score low on both anxiety and avoidance, dismissing avoidant adults and avoidant infants score low on anxiety and high on avoidance, fearful avoidant adults and disorganized infants score high on both dimensions, and preoccupied adults and anxious-ambivalent infants score low on avoidance and high on anxiety.

We have proposed that emotion regulation strategies, including those associated with the attachment system, are particularly useful in understanding individual differences in autobiographical memory development (Chae, Goodman, & Edelstein, 2010; Goodman, Quas, & Ogle, 2010). Children's mental processing of negative events is especially likely to activate emotion regulation strategies, including the strategies that parents, in effect, impose when dealing with their children's emotions and emotional memories, and strategies that children observationally learn from their parents. For children who themselves are more securely attached, or who have more attachment secure parents, emotion regulation, including that enhanced by the parents' likely support, may facilitate children's attentiveness, storage, rehearsal, or retrieval of negative information. In contrast, children who are more attachment avoidant or have more attachment avoidant parents may demonstrate limited attentional, storage, rehearsal, and/or retrieval processing of negative information, focusing instead on self-protection, their own internal states, and avoidant coping, that is, on the types of emotion regulation strategies that they have learned to use directly or have observed. Children with greater attachment anxiety or with more attachment anxious parents may become fixated on negative emotional information, either ruminating or dwelling on the details of the information without an adequate strategy for alleviating discomfort.

Parental attachment is also associated with parent–child discussion of events, including those that are negatively valenced. For example, more securely attached parents engage in conversations that are more elaborate and emotionally open (Raikes & Thompson, 2008). Such conversations may, in effect, teach children how to interpret and respond to emotional events. Such conversations, as well, help children understand their own emotions and emotion regulation efforts. Parents who self-report as more, rather than less, anxiously attached engage in more explanatory and detailed conversations with their children about stressful information, but also introduce more misinformation (McWilliams, 2014). The latter tendencies may serve to focus children's attention on emotional information but not help children understand that information or regulate their own responses, and may also lead to confusion in children about specific event details. Consistent with Nelson and Fivush's autobiographical memory development theory, such discussions, and the ensuing regulation strategies in children, can affect children's memory (e.g., Reese, 2009; but see Principe, DiPuppo, & Gammel, 2013).

We have also proposed that emotion regulation strategies are characteristic of certain trauma-related psychopathologies, leading to associations of symptoms of such disorders with memory performance. We turn to a multilevel consideration of this proposal next, starting with the effects of maltreatment, including on trauma-related psychopathology symptoms; then briefly describing the psychophysiology of trauma and stress, and relevant neuroscience discoveries; and then delving more deeply into memory for positive and negative events and child trauma research.

EFFECTS OF CHILD MALTREATMENT

Childhood maltreatment, such as physical, emotional, or sexual abuse, can have far-reaching negative effects on development (Cicchetti & Toth, 2005) and increase the

lifetime risk of trauma-related psychopathology, including PTSD, dissociation, and depression (Alley et al., 2015; Berntsen et al., 2012; Eisen et al., 2007; Leeson & Nixon, 2011; Macfie, Cicchetti, & Toth, 2001; Widom, Dumont, & Czaja, 2007). Many effects of childhood trauma, moreover, have biological underpinning or expressions. Accordingly, consideration of behavioral manifestations of the consequences of maltreatment should be accompanied by an evaluation of physiological and neurological concomitants. Moreover, it is always important to keep in mind that child victims are often polyvictimized, such that they experience multiple forms of maltreatment (e.g., neglect and physical abuse). This results in cumulative adversity, increasing the risk of trauma-related psychopathology (e.g., Finkelhor, Ormrod, Turner, & Holt, 2009), emotional dysregulation, and altered physiological response proclivities.

These trauma-related psychopathologies are associated with emotion dysregulation (Shields & Cicchetti, 1998), some of which likely affect autobiographical memory. As mentioned earlier, emotion regulation refers to the approaches taken by an individual to deal with arousing emotions, such as attempting to avoid thinking about traumatic experiences as a means to reduce negative feelings (Bowlby, 1980; Gross & Thompson, 2007; Shields & Cicchetti, 1998; Shipman & Zeman, 2001). It is perhaps not surprising that maltreated children often demonstrate substantial deficits in effective emotion regulation. In maltreating families, there is often a lack of modeling and support; an absence of positive affect; the presence of harsh discipline and negative control; inconsistent discipline; and a lack of parental sensitivity (Shipman & Zeman, 1999, 2001). Maltreating parents also appear to be less understanding of their children's emotional displays and have fewer strategies for effectively helping their children regulate emotions in arousing situations. All of this may lead to emotion regulation problems in maltreated children (Kim & Cicchetti, 2010; Main & George, 1985; Maughan & Cicchetti, 2002; Pears & Fisher, 2005; Robinson et al., 2008), several of which at their extreme manifest in psychopathology. Next we focus on three particularly relevant forms of trauma-related psychopathology.

Trauma-Related Psychopathology

PTSD

After experiencing a traumatic event, a subset of individuals will evince post-traumatic symptoms, and some of these symptoms will be so severe, debilitating, and persistent as to warrant a diagnosis of PTSD. This disorder is characterized by anxiety and memory problems, for example, involuntary intrusions (i.e., flashbacks) of traumatic memories and avoidance of reminders of the precipitating trauma (e.g., Rubin, Bernsten, & Johansen, 2008). Approximately a third of maltreatment victims are diagnosed with PTSD at some point in their lifetime, and many more have elevated levels of PTSD symptoms (Vranceanu, Hobfoll, & Johnson, 2007; Widom, 1999). A child maltreatment history, especially having endured multiple forms of maltreatment, increases the chance of evincing PTSD symptoms (e.g., Bernsten et al., 2012; Finkelhor, Turner, Hamby, & Ormrod, 2011; Finkelhor et al., 2009; Perry & Azad, 1999; Silva et al., 2000; Vranceanu et al., 2007; Widom et al., 2007). As explained by Alley et al. (2015), "The involuntary intrusion of memories may reflect the evolutionarily based need to remember traumatic events in vivid detail so as to avoid the events in the future. The avoidance component of PTSD can be viewed as an (unsuccessful) emotion regulation strategy to limit the processing and memory (including involuntary memory) of traumatic experiences" (pp. 86–87).

Dissociative Tendencies

Individuals who have suffered childhood trauma, including child maltreatment, are also at risk of heightened dissociative tendencies (e.g., Eisen, Goodman, Qin, Davis, & Crayton, 2007; Putnam, 1997). Dissociation is typically conceived as occurring on a continuum from mild detachment to more severe detachment from physical and emotional experience. In the mild form, dissociation is considered a normal process. However, when extreme, it can take the form of a dissociative disorder. These disorders are characterized by a wide range of irregularities in the typically integrated functions of memory, consciousness, and identity, and can result in amnesia, depersonalization, and general confusion (Eisen & Lynn, 2001). Child maltreatment victims may use dissociation to escape negative affect by preventing potentially distressing memories of childhood from reaching cognitive awareness (Becker-Blease, Freyd, & Pears, 2004; Hulette, Fisher, Kim, Ganger, & Landsverk, 2008). Dissociation can therefore also be viewed as an avoidant emotion regulation strategy (but see Giesbrecht, Lynn, Lilienfeld, & Merckelbach, 2008).

Depression

Depression is one of the most commonly diagnosed psychological disorders, and it is often comorbid with PTSD and dissociation. Depression can result from many causes and is not specific to a history of childhood abuse. However,

childhood maltreatment consistently emerges in research as a predictive factor, with younger age at onset of maltreatment being associated with a greater likelihood of depressive symptoms (Jaffee et al., 2002; Kaplow & Widom, 2007; Toth, Manly, & Cicchetti, 1992; Widom et al., 2007). Problems in interpersonal functioning and poor emotion regulation further contribute to and are worsened by depression (Kim & Cicchetti, 2010; Levendosky, Okun, & Parker, 1995). As discussed in greater detail later in this chapter, Williams et al. (2007) found that adult depression that is related to childhood trauma is associated with overgeneral memory, that is, lack of specific recall of events, which Williams and colleagues attribute to avoidance of autobiographical memories. Such avoidance likely reflects an emotion regulation strategy aimed at countering the distress that can arise from remembering negative childhood experiences. Avoidance has been identified as a contributor to depression (e.g., Leventhal, 2008).

Summary

In summary, there are clear reasons to suspect that autobiographical memory for traumatic, stressful, or emotional events is affected by emotion regulation strategies associated with trauma-related psychopathologies, such as PTSD, dissociation, and depression, which are often comorbidly expressed. Before developing this theme further, we turn to consideration of relevant psychophysiology and neuroscience research.

Maltreatment and Psychophysiology

As mentioned, consequences of maltreatment and other childhood traumas are not simply evident in behavioral and emotion regulatory outcomes. Consequences to physiological responses, particularly those that are sensitive to stress exposure, also emerge. Moreover, disruptions or alterations in physiological stress responses themselves have implications for psychopathology, emotion regulation tendencies, and memory. A multilevel approach that takes into account the different domains of consequences and their reciprocal influences is necessary to understand more fully the complexity of the associations among maltreatment, psychopathology, emotion regulation, and memory.

As a starting point to understanding how maltreatment affects physiological response tendencies, it is necessary to describe briefly what is typically meant by physiological reactivity in childhood, a phrase routinely used to describe children's physiological response proclivities. Interest in biological and neurological stress responsive systems in human functioning and behavior has exploded during the past several decades, with a sizeable amount of this work focusing on explaining when and why physiological responses influence social-emotional, cognitive, and mnemonic processes (Hertzman & Boyce, 2010; Lupien, McEwen, Gunnar, & Heim, 2009; McEwen, 1998; Obradović, 2012; Taylor, Lerner, Sage, Lehman, & Seeman, 2004).

A majority of this work has, as well, focused on specific stress-responsive physiological systems, and how those systems' responses may be altered as a result of trauma exposure, including that due to childhood maltreatment. Systems that have received the largest amount of attention in stress-related research, especially in children, include the locus coeruleus-norepinephrine system or autonomic nervous system (ANS) and the corticotrophin releasing hormone system, more commonly referred to as the hypothalamic-pituitary adrenal (HPA) axis.

Regardless of a history of maltreatment, exposure to stress leads to a host of biological (and behavioral) responses. These responses are necessary, allowing an organism to respond quickly to the stressor. They involve an array of neural structures and target organs, and include preparatory, immediate, and post-exposure biological alterations that foster adaptation to and recovery from the stressor (Chrousos & Gold, 1992; McEwen, 1998; Sapolsky, Romero, & Munck, 2000; Weiner, 1992). Of note, however, the nature and consequence of these responses vary depending on whether the responses emerge as a result of exposure to an acute or unanticipated, single, and short-lasting stressor, or exposure to chronic or repeated threats or stressors (Chrouros & Gold, 1992; Kemeny, 2003; Lupien et al., 2009; McGaugh, 2002; Sapolsky, Romero, & Munck, 2000; Pearlin, Menaghan, Lieberman, & Mullan, 1981). Responses to acute stressors, for instance, are considered both biologically adaptive and appropriate. However, when stressors are chronic or repeated, these acute responses cannot be sustained. Instead, modifications gradually occur. These modifications confer increased risk for a range of adverse physical and mental health outcomes (Essex et al., 2002; Taylor et al., 2004). In addition, exposure to chronic stress can alter subsequent physiological responses to short-term stressors. It is precisely this latter type of exposure and situation that may be particularly common in maltreated children. For them, repeated exposure to maltreatment (rather than a single incident) is often the norm. This likely leads to altered physiological reactivity overall, which then affects the children's (and later adults') ability to mount

a response to novel, acute, and unanticipated challenges. Consideration of the effects of physiological arousal on memory ideally takes into account the type of event that induced the arousal as well as any history of prior stress exposure, and the potential consequences of that exposure on multiple levels of responses and behaviors.

Briefly, regarding the most commonly studied stress-responsive systems, the first is the ANS. Following exposure to a short-term, often unanticipated stressor, both the sympathetic and parasympathetic branches change rapidly. The sympathetic system (SNS) is most closely associated with the classic fight-or-flight response, which prepares an individual for any immediate actions that may be necessary (Berntson, Cacioppo, & Quigley, 1991; Cannon, 1932; Stratakis & Chrousos, 1995).The parasympathetic branch (PNS) may withdraw its regulatory influence, in what is called parasympathetic withdrawal, thereby allowing energy to be diverted in case action is necessary (Berntson, Cacioppo, & Quigley, 1993; Porges, 2007). Once the threat has been eliminated, the PNS then returns to its regulatory function, slowing sympathetic responses and restoring homeostatic control of end-organ functions (Berntson et al., 1993; Kapa, Venkatachalam, & Asirvatham, 2010; Porges, 2007).

The other stress-response system is the HPA axis. It has received the most consistent and widespread attention across studies of physiological stress responses and reactivity (Chrousos, 2009; Dickerson & Kemeny, 2004; Hostinar & Gunnar, 2013). When confronted with a threat, the hypothalamus releases corticotropin-releasing hormone (CRH), which stimulates the release of adrenocorticotropic hormone (ACTH) via the anterior pituitary hormone. ACTH then signals the adrenal cortex to release cortisol, the primary glucocorticoid (GC) in humans (Sapolsky et al., 2000). This heightened cortisol in turn motivates a range of slower-onset excitatory as well as suppressive functions on stress-responses throughout the body.

Our description of stress responses of the ANS and HPA axis focuses, for the most part, on how these systems typically respond to short-term stressors. However, the types of stressors to which many maltreated children are exposed are rarely short-term and may be more appropriately labeled as traumatic. The stressors are also often chronic and unpredictable, which, as mentioned, can lead to long-lasting alterations in how these systems function in general and how they respond to acute stress (Tarullo & Gunnar, 2006; Van Voorhees & Scarpa, 2004). In fact, many different types of chronically adverse environments have been shown to influence both children's general level of arousal when not exposed to stress (i.e., their baseline physiological functioning) as well as their physiological reactivity to acutely stressful events. These environments include not only maltreatment, but also exposure to family conflict, extreme poverty, living in foster care, and premature birth (Erath, El-Sheikh, & Cummings, 2009; Erath, El-Sheikh, Hinnant, & Cummings, 2011; Fisher, Kim, Bruce, & Pears, 2011; Gordis, Ganger, Susman, & Trickett, 2008; Harkness, Stewart, & Wynne-Edwards, 2011; Koss et al., 2013; MacMillan et al., 2009; Ouellet-Morin et al., 2011; Pollak, Vardi, Putzer Bechner, & Curtin; 2005; Scheeringa, Zeanah, Myers, & Putnam, 2004; Sturge-Apple, Davies, Cicchetti, & Manning, 2012). What is important to note about the results across studies is that the directions of the alterations at times vary. Some results are suggestive of hyper-responsiveness, while many other results are suggestive of the opposite, hypo-responsiveness.

A few studies have examined differences in ANS reactivity between children exposed versus not exposed to chronic stress, like maltreatment and family violence. Pollak et al. (2005), for instance, found that physically abused children showed larger SNS reactions to acute, emotionally provocative social stimuli containing expressions of anger and hostility than did nonabused children. Scheeringa et al. (2004) uncovered somewhat similar results in an investigation of young children who had versus had not experienced serious traumas (including both chronic trauma, such as exposure to domestic violence, and singular trauma, such as automobile accidents). This study is of special interest because it concerned memory. Children were asked to recall a pleasant and negative prior experience while their heart rate and PNS responses were monitored. The trauma-exposed children who exhibited high levels of PTSD symptoms exhibited greater arousal (per heart rate and PNS withdrawal) when recounting the negative compared with positive event. The non-trauma exposed children and trauma exposed children without PTSD either responded with decreased arousal or no change in arousal when recounting the negative versus positive prior experience. Other studies, in contrast, have found evidence for hypo-reactivity of the ANS in children growing up in high conflict families and adolescents who have suffered sexual abuse (e.g., Erath et al., 2009, 2011; Gordis et al., 2008).

Unlike the rather small body of work that has examined ANS reactivity in stress-exposed children, a much larger literature exists concerning how chronic stress alters HPA axis functioning, again as mentioned both in response to acute stressors or challenges and in terms of baseline levels of arousal when not exposed to stress, including across

the day (Gunnar & Quevedo, 2007; see Tarullo & Gunnar, 2006; Van Voorhees & Scarpa, 2004, for review). With regard to reactivity, a few studies have reported heightened HPA reactivity in maltreated relative to nonmaltreated children (Harkness, Stewart, & Wynne-Edwards, 2011). Many more, though, have revealed blunted or dampened responses in maltreated and other chronic-stress exposed children (Fisher, Kim, Bruce, & Pears, 2011; Gunnar et al., 2009; Koss et al., 2013; MacMillan et al., 2009; Ouellet-Morin et al., 2011; Sturge-Apple, Davies, Cicchetti, & Manning, 2012).

In terms of atypical basal levels of HPA axis functioning, first, maltreated children seem to have lower baseline levels of HPA axis activation than do non-maltreated children, particularly when morning basal levels are examined (Alink, Cicchetti, Kim, & Rogosch, 2012; King et al., 2001; Loman & Gunnar, 2010). Second, maltreated and other chronically stressed children have been shown to have a flatter rhythm of HPA functioning throughout the day than nonstressed children (Carlson & Earls, 1997; Cicchetti et al., 2010; Dozier et al., 2006; Fisher, Stoolmiller, Gunnar, & Burraston, 2007; Pfeffer, Altemus, Heo, & Jiang, 2007). Of relevance to multilevel approaches to understanding maltreatment, psychopathology, and memory, Cicchetti et al. (2010) found that it was primarily maltreated children who also presented with high depressive or internalizing symptoms who exhibited a flattened HPA axis diurnal response pattern and low morning basal levels of HPA axis activation. Similar findings (i.e., flattened diurnal patterns and low morning basal levels of cortisol) have been reported in studies of children with PTSD following the loss of a parent in the 9/11 attacks (Pfeffer, Altemus, Heo, & Jiang, 2007). Together, research suggests that maltreated children likely have dysregulated patterns of physiological response tendencies relative to nonmaltreated children. This dysregulation is evident in reactions to acute stress in both the ANS and HPA axis, as well as in daily functioning, that is, in basal levels, of the HPA axis. Of note, this dysregulation is reflected at times in heightened reactivity, particularly in younger children who have endured maltreatment or other forms of traumas that induce PTSD symptoms. At other times, and possibly more often in older children and those exposed to chronic, though perhaps slightly lower levels of stress (e.g., harsh parenting), this dysregulation is reflected via dampened physiological reactivity to laboratory stressors, a reduction in diurnal variability of cortisol levels across the day, and lower basal levels of cortisol (but see Bugenthal, Martorell, & Barraza, 2002). This pattern of some children reacting with hyperreactivity and others with hyporeactivity is consistent with our theme of these being important individual differences in children's reactions to trauma, including child maltreatment.

Maltreatment and Neuroscience

As with psychophysiology, there is a growing interest on how trauma may affect neurobiological development and, in turn, how that may affect memory development. Neuroimaging studies of the functional neuroanatomy of autobiographical memory among adults reveal that a core network of left-lateralized regions are involved, including the medial and ventrolateral prefrontal, medial and lateral temporal and retrosplenial/posterior cingulate cortices, the temporoparietal junction, and the cerebellum (Addis, Roberts, & Schacter, 2011; Conway, Pleydell-Pearce, Whitecross, & Sharpe, 2002; Maguire, 2001; Svoboda, McKinnon, & Levine, 2006). In particular, the formation of new autobiographical memories involves the medial temporal lobe, a structure that includes the hippocampus. In addition to these core areas, imaging studies examining the role of emotion and autobiographical memory indicate the additional recruitment of right hemisphere regions (Winston, Strange, O'Doherty, & Dolan, 2002), including regions attributed to emotional processing, such as the amygdala (Greenberg et al., 2005; McGaugh, 2002), the insular cortex (Critchley, Wiens, Rotshtein, Ohman, & Dolan, 2004), and the orbitofrontal cortex (Rolls, 2002).

Studies relevant to the functional neural development of this core network, in the context of autobiographical memory have begun (see Ghetti, DeMaster, Yonelinas, & Bunge, 2010; Wendelken et al., 2014). Insight can also be gained from research on the physical development of these regions and from research on the adverse effects of trauma on brain development. Although portions of the medial temporal lobe mature relatively early in development (Seress & Abrahám, 2008, for review), other core areas, such as the prefrontal cortex and dentate gyrus, undergo a much more protracted period of development (Bourgeois, 2001; Sowell, Trauner, Gamst, & Jernigan, 2002). Recent research suggests that, although volumetric changes to the hippocampus appear to be limited or absent after the first few years of life (Gogtay et al., 2006), the microstructure of the hippocampus may continue to mature well into middle childhood (Gogtay et al., 2006; Insausti et al., 2010). Moreover, the connections between core structures develop gradually with increasing age (e.g., Lebel & Beaulieu, 2011; Menon, Boyett-Anderson, & Reiss, 2005; Ofen et al., 2007; Schneider, Il'yasov, Hennig, & Martin, 2004). This protracted period of neural development entails a degree of

vulnerability to these core structures, both directly and indirectly. Trauma and/or prolonged stress may disrupt brain development and the neurobiological systems that affect brain maturation and function (Watts-English, Fortson, Gibler, Hopper, & DeBellis, 2006). Because of the prolonged development of some of the core structures that support autobiographical memory, the timing of when trauma occurs may have differential consequences for brain development and function, and subsequently for the development of autobiographical memory (Andersen et al., 2008; Teicher et al., 2003; Teicher et al., 2004; Teicher, Tomodoa, & Andersen, 2006).

Imaging studies of children and adults with a history of trauma, adversity, and/or neglect suggest that trauma-related stress, particularly among those with PTSD symptoms, may adversely affect the volume and function of various brain regions, including some of the core brain structures of the autobiographical memory network such as the hippocampus (Behen et al., 2009; DeBellis et al., 2002; Bremner et al., 2003; Hansen et al., 2010; Tomoda et al., 2009; Tupler & DeBellis, 2006). In general, the decreases in hippocampal volume that have been observed among adults with trauma-related PTSD have generally not been observed among maltreated children (Watts-English et al., 2006; but see Andersen et al., 2008; Teicher et al., 2012). It is possible that the adverse effects of trauma on the hippocampus are not evident until later in development after prolonged exposure to glucocorticoids (Bremner et al., 2003, but see Gilbertson et al., 2002). There is, however, some indication that the hippocampi of children with PTSD symptoms may not function typically (DeBellis, Hooper, Woolley, & Shenk, 2010; Carrion et al., 2010). Garrett et al. (2012), for instance, found that children with posttraumatic stress symptoms showed significantly greater activation in response to emotional facial expressions than did controls in several brain regions, including the amygdala, hippocampus, medial prefrontal cortex, insula, and ventrolateral prefrontal cortex, as well as evincing less activation than controls in the dorsolateral prefrontal cortex.

Dysregulation of the major neurobiological stress response systems, which contribute to and control physiological reactivity (e.g., HPA axis), as a result of trauma may also contribute to alterations in brain structure and metabolic function. Vulnerable brain regions include the amygdala, hippocampus, and prefrontal cortex (Alink, Cicchetti, Kim, & Rogosch, 2012; Chugani et al., 2001; DeBellis, 2005; Hariri & Holmes, 2006; McGowan et al., 2009; Sapolsky, 2000; Van Gaalen, Stenzel-Poore, Holsboer, & Steckler, 2002). Richert et al. (2006) found that children with PTSD symptoms showed a significantly larger volume of gray matter in the middle-inferior and ventral regions of the PFC than did control children. Moreover, decreased volume of gray matter in the dorsal PFC was correlated with increased functional impairment scores. It is difficult to draw clear causal inferences from such studies, however.

Effects of maltreatment, trauma, and psychopathology on the amygdala and hippocampus are of particular importance for memory. However, it is crucial that any evaluation of relevant studies take into account resultant psychopathology. When this is done, it is often the psychopathology rather than maltreatment per se that seems to have the effect. For example, in Bremner et al.'s (2003) research, adults with child maltreatment histories showed reduced hippocampal size, but only in the presence of PTSD. In a longitudinal study of adolescents, Whittle et al. (2013) reported that maltreatment was indirectly associated, through psychopathology, with retarded growth of the left hippocampus and accelerated growth of the left amygdala over time. The authors concluded that psychopathology was a mechanism through which child maltreatment affected brain development, a conclusion consistent with increasing evidence that psychological traumatization is associated with amygdala size and connectivity. For example, Nooner et al. (2013) studied adolescents' self-report of trauma symptoms in relation to functional connectivity of the amygdala. Even mild trauma symptoms seemed to affect brain networks associated with the amygdala. Traumatization may also increase over time, further affecting brain functioning. Herringa et al. (2013) examined brain connectivity in 64 adolescents in a community sample. Childhood maltreatment appeared to alter the regulatory capacity of the brain's fear circuit, leading to increased internalizing symptoms by late adolescence.

Bremner (1999) proposed two distinct acute neurological responses to trauma: hyperarousal and dissociative reponses. These responses are consistent with our proposal that hyperarousal and hypoarousal emotion regulation following maltreatment may both affect memory. Functional magnetic resonance imaging (fMRI) studies have found evidence compatible with Bremner's thesis. Lanius and her colleagues (e.g., Lanius, Bluhm, Lanius, & Pain, 2006) read trauma narratives to soldiers while the soldiers were in the scanner. Relevant to limbic regions, Lanius et al. (2010) reported that a small percentage of the soldiers with PTSD responded with hypoarousal and dissociative distancing; whereas a remaining larger percentage responded with hyperarousal (including flashbacks and other intrusive symptoms). Overall, PTSD patients with a dissociative response to trauma narratives activate neuronal circuitry differently from PTSD patients with a hyperarousal

response. These two reactions are reminiscent of the two dimensions that underlie attachment orientations: attachment anxiety (hyperactivation of the attachment system) and attachment avoidance (hypoactivtaion of the attachment system), and, as will be discussed later, the reactions have implications for individual differences in memory for trauma.

Recently, researchers have uncovered direct relations between activation of the attachment system and brain responses. Normally, secure attachments may help modulate children's emotion regulation, as reflected in amygdala activity and connectivity. Primary caregivers often play a vital role in helping children regulate their emotions. Gee et al. (2014), for instance, examined the effects of caregivers on 4- to 17-year-olds' amygdala regulation. In an emotion identification task, children (but not teenagers) exhibited more mature amygdala-prefrontal connectivity in the presence of maternal stimuli (pictures of their mothers). For maltreated children, who may lack adequate parental succor, caregiver emotional comfort that supports affect regulation via suppression of amygdala activity may occur all too infrequently, whereas fear circuits may be activated chronically. Future research should examine hyperactivation versus hypoactivation of brain circuitry in children as a function of attachment, emotion regulation, and maltreatment history.

In summary, maturation of the core autobiographical memory network varies by neural region, with some core structures maturing early in development and others maturing later. The effect of trauma on brain development and function, therefore, may depend, in part, on the timing and duration of the trauma. Moreover, the dysregulation of neurobiological stress systems may further contribute to alterations in brain structure and function. Neuroscience research indicates two distinct patterns of reactions to trauma, one of hyperarousal and one of hypoarousal. These two patterns may correspond to emotion regulation strategies (e.g., anxiety and avoidance, in attachment theory terms), although additional research is needed to complete our understanding of relations among brain development, emotion regulation, trauma-related psychopathology, and autobiographical memory development.

THEORIES OF TRAUMA AND MEMORY

A number of important theories are relevant to the study of memory in traumatized children. Some of these theories predict that children who suffer trauma will evince particularly accurate memory for negative autobiographical experiences, whereas others predict an impairment in these memories. We first discuss theories that argue for more robust memory and then discuss theories that argue for diminished memory.

Theories of Robust Memory for Negative and Traumatic Experiences

Several basic memory mechanisms and influences underlie theories that propose better memory for trauma-related information, including among traumatized children. For example, the following have been linked empirically to heightened memory for negative and traumatic experiences: arousal combined with negative valence, distinctiveness, knowledge base and expertise, self-schema processing, elaboration, and rehearsal (e.g., see Bjorklund, 2011; Howe, 2006; Howe & Otgaar, 2013; Kensinger, Garoff-Eaton, & Schacter, 2006; McWilliams, Narr, Goodman, Ruiz, & Mendoza, 2013). Traumatic events are likely to leave robust memories because these events are bolstered by activation of neural circuits and structures, such as by the amygdala, specifically evolved to ensure enduring memory for survival threats (Alley et al., 2015; Cordon, Melinder, Goodman, & Edelstein, 2013; Nairne, 2010). Several of the theories of trauma and memory utilize (implicitly or explicitly) such basic memory process notions, but add an analysis specific to traumatic experiences. To provide a sense of relevant theories that propose enhanced memory for negative and traumatic events, we review several theoretical models next.

Christianson's Model

In an important paper, Christianson (1992) reviewed extant research that focused on memory for negative information, which he defined in terms of new, unexpected, and potentially threatening events. The experiments he reviewed were largely laboratory studies, available at that time, concerning adults' memory for one time negatively valenced and highly arousing events or images. He concluded that during stressful or traumatic experiences, attention is riveted to the main stressor (e.g., the snake about to bite, the gun that just appeared in a bank robber's hand), whereas attention to peripheral details is reduced. As a result, memory for the central details of an emotional event should be particularly robust, which was supported by empirical studies even in the laboratory, in contrast to memory for peripheral details, which should be poorer. A two-process model was proposed in which there is first an early, fast, and automatic preattentive process that helps ensure attention to and

encoding of threat information. A second, slower process then takes place that involves evaluation, memory rehearsal, and the like, ensuring consolidation of memory. Christianson's model did not concern individuals with trauma histories or psychopathology. However, it is possible that the acute focus on trauma-related information that Christianson proposed can become, in the face of chronic trauma, hypervigilance to trauma-related experiences, resulting in particularly robust memory for traumatic events (Alexander et al., 2005; Alley et al., 2015; Goodman et al., 2010).

Foa's Fear Network Theory

Foa and her colleagues proposed that traumatized individuals (e.g., those who evince symptoms of PTSD) have fear networks (i.e., semantic/episodic networks of associates) that store trauma-related information and guide both attention and memory. These fear networks result in an overfocus on trauma cues that signal threat to safety or serve as reminders of past threats (Foa, Feske, Murdock, Kozak, & McCarthy, 1991). Accordingly, people who develop PTSD or other anxiety disorders form hyperactivated mental networks of fear-related information. Indeed, this heightened sensitivity to threat cues has been observed in traumatized children and adults (e.g., Dubner & Motta, 1999; McNally et al., 1998; Pollak & Tolley-Schell, 2003). This hypervigilance to threat cues and an elaborated semantic network would be expected to lead to particularly accurate memory for such information.

Survival Processing

Nairne (2010), a cognitive psychologist who is attuned to evolutionary considerations, recently proposed Survival Processing Theory. His framework rests on the idea that humans evolved to prioritize survival-related information with adaptive significance. Given that many traumatic experiences are relevant to current survival as well as to survival in our ancestral past, such experiences should be prioritized in attention and memory. In a series of experiments, Nairne and his colleagues have shown that information that is processed for its survival relevance is remembered better than the same information processed in other ways (Nairne, Pandeirada, & Thompson, 2008; Otgaar, Smeets, & van Bergen, 2010). In regard to traumatized children and adults with chronic threat experiences, survival processing may be activated repeatedly. One would predict, based on Nairne's theory, that such activation should lead to particularly robust memory for traumatic, survival-relevant experiences, with chronic survival processing possibly resulting in even greater attention to and memory for such information.

Theories of Impaired Memory for Negative and Traumatic Experiences

In contrast to the aforementioned theories, several other theories predict inaccurate or incomplete autobiographical memory of trauma experiences. A number of basic cognitive processes can also be brought to bear to predict that traumatized individuals will have holes in their memories or provide inaccurate reports.

Dissociation and Repression

Theories that rely on the notions of dissociation and repression are quite controversial, in part, because they are difficult to test scientifically (e.g., Giesbrecht et al., 2008; Loftus, 1993; Rubin et al., 2008). Nevertheless, such theories try to explain why memories for traumatic experiences can be inaccurate or even lost from conscious access. Van der Kolk and Fisler (1995) proposed that traumatic memories are dissociated and encoded as sensory fragments without cohesion, resulting in incomplete memory traces (see also Putnam, 1997). Freudian theory (Freud, 1909/1995; see also Terr, 1991) serves as a basis for contending that traumatic memories are lost from consciousness due to repression, that is, motivation to avoid reliving the content of painful memories especially those involving self-blame. Although these theories are controversial, there is some support for at least part of their theses. For example, Goodman et al. (2003) found that dissociation predicted lack of memory for childhood sexual abuse. That said, there is also evidence that traumatic memories are particularly coherent and not disjointed (Bernsten et al., 2011; Rubin, 2005). In any case, it is of interest that implicit in these theories is the notion of avoidance of painful memory as an emotion regulation strategy.

Orienting Versus Defensive Responses

Deffenbacher, Bornstein, Penrod, and McGorty (2004) argued that less stressful events are remembered with greater accuracy than are more stressful events. The researchers theorized that less stressful events involve orienting responses (activation mode of processing), whereas highly stressful (e.g., life threatening) events give rise to defensive responses (arousal mode of processing). We interpret defensive responses as a type of emotion regulation strategy put into play when a highly aroused person tries to avoid processing the information, precluding formation of a detailed memory. Much of the research that Deffenbacher et al. (2004) relied upon included individuals who likely score high in avoidant emotion regulation strategies

and who may have a history of exposure to negative events. For instance, eyewitness identification was examined among military personnel (e.g., Morgan et al., 2004), many of whom may have attachment avoidant tendencies to start with. Deffenbacher et al. rightly mention that individual differences likely play an important role in memory for stressful and traumatic events.

Overinterpretation Theory

Windmann and Krüger (1998) proposed a theory that focuses on how trauma can lead to overinterpretation of neutral events as trauma related, resulting in commission errors on memory tasks. Specifically, according to the theory, for the sake of survival, all people are predisposed to be hypervigilant to traumatic material. This is presumably because the amygdala is adapted to respond to such information to help us survive. However, it is further proposed that people who are traumatized overinterpret neutral stimuli as trauma related, which in turn results in commission errors, likely reflecting biased interpretations combined with poor memory monitoring. A signal detection theory approach is needed in research to test this theory, yet such an approach is uncommon in the relevant literature. However, evidence consistent with Windmann and Krüger's theory comes from Pollak et al. (2002) who found that child physical abuse victims exhibited a liberal response bias when perceiving facial expressions of possible anger (but see Pollak & Sinha 2002). Moreover, compared to adults without PTSD, those with PTSD produce more commission errors (e.g., intrusion of unrelated or nonlist words) on DRM false memory tasks, indicating less-rigorous memory monitoring (Bremner et al., 2000; Zoellner et al., 2000).

Proposed Model

We recently proposed a model that sheds light on the contradictory theories and empirical findings concerning child maltreatment and autobiographical memory development. This model reviewed below features emotion regulation in autobiographical memory development especially in relation to memory for negative information (Chae, Goodman, & Edelstein, 2011; Goodman & Melinder, 2007).

In our model, we reinterpret notions such as dissociation and repression as types of emotion regulation strategies. An advantage of considering emotion regulation, over, for example, the concepts of dissociation and repression, is that the former can be more readily measured with psychological instruments and is consistent with several current conceptualizations of coping, emotional competence, and attachment theory (Compas, 1998; Lazarus & Folkman, 1984; Shaver & Mikulincer, 2007; Thompson 1994). Experimental manipulation of emotion regulation results in differential effects on memory (Richards & Gross 2006).

Consistent with Christianson's (1992), Nairne et al.'s (2008), and Windmann and Krüger's (1998) theories, we have proposed that people typically have particularly accurate memories for negative information (e.g., negatively valenced and high arousal events). Based on evolutionary, psychophysiology, and neural (e.g., amygdala) mechanisms, our brains are adapted to prioritize processing of and memory for survival-relevant information. Negative experiences are well retained in memory, because individuals need to recount, consider, and reflect on their pasts to avoid encountering dangerous situations again. Episodic rather than just semantic memory provides humans with a more refined ability than seen in other species to avoid danger through autobiographical memory and therefore to survive. Our reading of the empirical evidence also leads us to agree with Foa et al.'s (1991) formulation of fear networks that underlie traumatized children and adults becoming hypervigilant to trauma and threat cues.

However, consistent with Deffenbacher et al.'s (2004) and Windman and Krüger's (1998) formulations, we also propose that memories may be less robust or less accurate in certain individuals. We interpret their theories and the empirical evidence in terms of emotion regulation strategies. Specifically, there appears to be a subgroup of individuals who are motivated not to think about negative experiences and to employ defensive processes that may dampen, inhibit, or distort trauma memories, which include trying not to think about the trauma, not talking about it with other people, and not rehearsing the information. It is not clear whether such avoidant strategies result in lost memory, but it is likely that they can weaken memories of traumatic events, and perhaps this amounts to lost memory in some cases. Moreover, traumatization can also lead to the overinterpretation of ambiguous situations (including what others might consider positive interpersonal interactions) as trauma related and can lead to poor memory monitoring, consistent with Windman and Krüger's insights. Our ideas are also related to attachment theory, as articulated by Bowlby (1980). As proposed by Shaver and Mikulincer (2007), attachment theory can be interpreted in terms of emotion regulation.

From an evolutionary perspective, the emergence of autobiographical memory has adaptive value; that is, it helps children and adults survive (Chae et al., 2011). For infants and children, survival is highly dependent on

protective caregivers. Threats activate the child's attachment system, ordinarily motivating the child to seek protection from parents. Many negative events are thus attachment related. Children learn to look to their main caretakers (e.g., parents) for both protection from and understanding of such events.

Earlier, we mentioned basic assumptions of attachment theory and of our framework. Here we elaborate on our model, as an example of how emotion regulation affects memory. Attachment styles and associated internal working models likely act as affective and cognitive filters that *regulate emotion* and influence attention to, processing of, and memory for distressing information. Avoidantly attached children whose requests for emotional or physical care have been unattended or rejected may regulate their processing of negative attachment-related information to prevent negative affect associated with memories of attachment loss. When such avoidant (defensive) strategies are activated and negative or otherwise distressing information is not processed, the attachment system remains unactivated. This then eliminates or at least reduces psychological distress, but at the same time it adversely affects memory. Bowlby (1973) referred to this process as defensive exclusion. If these avoidant defenses break down, emotion regulation is disrupted, also adversely affecting memory. In contrast, securely attached children who have developed expectations of responsive and supportive others, and of a worthwhile and loved self, may cope with stress in a nondefensive way, confronting, attending to, and thinking coherently about negative experiences. This would then be more likely to result in accurate and complete autobiographical memory (Alley et al., 2015; Chae et al., 2011).

Parents' own attachment styles should also relate to children's memory of events. Parents' attachment may affect their behaviors toward their children relevant to distressing situations (e.g., preparing their children for stressful events, as possible; providing support or comfort; helping their children process the event afterward). Avoidant parents express that after stressful events they take little time to comfort children and are more likely than secure parents to tell children to just forget about the event and move on, whereas secure parents are more likely to discuss negative life experiences openly and provide children with emotion regulation strategies and understanding that facilitate coherent, accurate memories (Goodman et al., 1997; Jones, Cassidy, & Shaver, 2015). Therefore, children's own and their parents' own attachment orientations result in individual differences in memories of stressful and negative experiences. As verified by studies of adult attachment, the early interactions with parents contribute to emotion regulation strategies that may follow individuals into adulthood (Mikulincer & Shaver, 2007). These strategies thus can influence autobiographical memory in childhood and in adulthood.

We have proposed that this model is helpful for understanding autobiographical memory development in traumatized children, including those who have suffered maltreatment (Alley et al., 2015: Chae et al., 2011). Experiencing repeated adverse childhood events when coupled with avoidant attachment tendencies may result in defensive coping and avoidant emotion-regulation strategies; these then influence later memory duration, detail, distortion, and retrieval style, as well as generating or aggravating psychopathology, such as PTSD (Maughan & Cicchetti, 2002; Mikulincer, Shaver, & Solomon, 2015; Ogle, Rubin, & Siegler, 2014; Williams et al., 2007).

EMPIRICAL STUDIES OF MEMORY IN TRAUMATIZED CHILDREN AND MEMORY FOR STRESSFUL EVENTS IN TYPICAL DEVELOPMENT

Children who experience trauma, such as child maltreatment, especially if at an early age, are at risk of exhibiting delays and nonoptimal developmental trajectories in a number of ways that can affect memory. For example, they may show deficits in performance on verbal recall, attention, and working memory tasks (Bücker et al., 2012). Compared with nontrauma-exposed children, they often score lower on intelligence tests, achieve more limited academic success, and evince disciplinary problems (e.g., Eckenrode, Laird, & Doris, 1993; Eisen et al., 2007; Toth et al., 2011). However, of importance, these deficits may reflect a redirection of cognitive resources, rather than a decrease in overall abilities (Ayoub et al., 2006).

Attention and Encoding in Traumatized Children

Encoding a stimulus is the first step in forming a memory (Gordon et al., 2001). Poor attention to a stimulus during the encoding phase can lead to reduced recall and recognition memory down the line, as well as source-monitoring errors (Naveh-Benjamin, Guez, & Marom, 2003). Contrariwise, intensified attention ordinarily produces particularly detailed and robust memory. Thus, differences in attentional processes (perhaps due to trauma or psychopathology) could provide an explanation for the memory differences in traumatized versus nontraumatized children.

A heightened sensitivity to threat and anger cues, which may optimize encoding of such information, has been observed in maltreated children. Compared with nonmaltreated children, children who have suffered maltreatment show a marked hypervigilance to negative cues (Cicchetti & Ng, 2014; Toth et al., 2011) and a corresponding attentional focus on negative input (Ayoub et al., 2006; Pollak, 2008). For instance, in a selective attention task, physically abused children compared with nonmaltreated children were slower to disengage from angry faces (Pollak & Tolley-Schell, 2003). In addition, among traumatized individuals with PTSD, an increased Stroop interference effect was uncovered for trauma-related material compared with neutral words (e.g., Dubner & Motta, 1999). Such an attentional bias may lead to accurate memory for traumatic or negative information and impaired memory for neutral or positive information (Moradi, Taghavi, Neshat-Doost, Yule, & Dalgleish, 1999, 2000).

Furthermore, a study of 7- to 12-year-olds, some of whom had suffered abuse and some of whom had not, revealed that children who were abused overattended to visual and auditory anger cues (Shackman, Shackman, & Pollak, 2007). The effect was particularly pronounced for visual anger cues when the anger was displayed by the children's abusive mothers, suggesting that this hypervigilance arises in part from familiarity effects and in part as an adaptive response to help maltreated children be vigilant to future threats and violence. For auditory anger cues, although abused children were more attentive to them than nonabused controls, there was not a significant difference between responses to their mothers versus response to cues from strangers, possibly because auditory attention to anger may be more involuntary, or may occur before the child recognizes who the angry party is.

This deployment of additional attention to negative input has a number of potential causes, ones that may have a cumulative effect (Pollak & Tolley-Schell, 2003; Shackman et al., 2007). Children who are maltreated may have learned to attend more to negative situations, such as their abusive parents' anger, because the children associate negative situations with danger, as implied previously. In addition, given that maltreated children attend more to other unfamiliar negative cues than control children, it may also be that maltreated children's attention is caught more by these negative cues. Finally, it may be that maltreated children's attention is related to their attempts at emotion regulation (Toth et al., 2011).

There is also evidence that attentional differences may be due to psychopathology. Children with mood and anxiety disorders, that may or may not be related to maltreatment, show biases for information congruent with the emotional states linked to the disorders (Hankin, Gibb, Abela, & Flory, 2010). For example, youth experiencing depression pay greater attention to sad faces than to happy, neutral, or angry faces. Depressed youth show this preference in comparison to control groups, as well as to youth with anxiety disorders. Conversely, anxious youth pay more attention to angry faces, and youth experiencing comorbid depression and anxiety disorders pay significantly more attention to both sad and angry faces (Hankin et al., 2010). Attentional control, which adults and even children use to some degree to inhibit their attention to irrelevant stimuli and allot attention to important target information (Roderer, Krebs, Schmid, & Roebers, 2012), allows people to extract the most important to-be-remembered information from an event, likely affecting memory. However, given a history of abuse or psychopathology, this selective attention could also bias retention. Rather than there being memory deficits in children and adults who have experienced these problems, it may be that their attentional biases are focused on areas of understandable concern to them (e.g., concerns for safety and for self-esteem, aka, "respect"), and thus what information is encoded and remembered may vary from that of individuals without such concerns. Interpretations can also affect encoding and subsequent memory: Toth et al. (2011) proposed that abused compared with nonabused children are more likely to misinterpret ambiguous actions as negative and have better memories for aggressive stimuli.

It is important to point out, however, that whereas stress at encoding may enhance memory, stress at retrieval may impair it. Although the following study did not include traumatized children, it makes an important contribution by disentangling effects of stress at encoding and stress at retrieval. Specifically, Quas and Lench (2007) examined children's memory for a fear-inducing video clip. The researchers measured the children's physiological stress responses both while the children watched the video (during encoding) and when the children returned to be interviewed a week later (during retrieval). Measuring stress level independently at these two points allows one to separate out the effect of stress on encoding versus retrieval. Additionally, during recall, children were interviewed by either an unsupportive interviewer, increasing the children's stress during that phase, or a supportive interviewer, decreasing their stress during that phase. Children who demonstrated higher levels of stress (based on measured increases in heart rate) during the encoding stage produced fewer incorrect responses when asked to

remember the video. Somewhat conversely, children who were more stressed at retrieval and were questioned by an unsupportive interviewer were more inaccurate in their recall (Quas & Lench, 2007). These findings suggest that stress at encoding may actually be beneficial for memory whereas stress at retrieval may be detrimental.

Basic Associative Memory and Psychopathology

Basic associative memory is a cornerstone of memory development. It is thus of considerable interest to determine if children with trauma histories perform similarly to children without such histories on basic associative memory tasks. As described earlier, the DRM task taps associative memory while at the same time examining false memory for semantic associates. Specifically, as detailed previously, it analyzes whether participants falsely remember that a critical lure was present in a list of semantically related words (Goodman et al., 2011). Recognizing the potential tie between memory of the critical lure and false memory, researchers have utilized the DRM task to see if maltreated compared with nonmaltreated youth show different patterns of memory, when tested either by recall or recognition tests. DRM list studies have thus far not uncovered significant differences in maltreated and nonmaltreated children's false memory of critical lures (Goodman et al., 2011; Howe, Cicchetti, Toth, & Cerrito, 2004; Howe, Toth, & Cicchetti, 2011).

In an important early and relevant study of maltreated children's DRM memory performance, Howe et al. (2004) tested 5- to 12-year-old maltreated children and nonmaltreated controls on the DRM task using standard DRM lists. There were no significant differences in DRM false memory as a function of maltreatment status. Lower socioeconomic status rather than maltreatment predicted memory (see also Howe, Toth, & Cicchetti, 2011). In a related study, Goodman et al. (2011) presented sexually abused adolescents and adults and age-matched nonsexually abused controls with trauma-related DRM lists (e.g., lists with words relevant to such trauma-related topics as sex, rape, fondle), positive lists, negative lists, and neutral lists. Participants with compared to those without child sexual abuse histories did not reveal a difference in recall of the critical lures, regardless of the nature of the DRM list. All participants, however, were more likely to falsely recall the critical lure for child sexual abuse lists and negative lists than for positive lists (Goodman et al., 2011). This pattern could result if the negative lists had tighter semantic associates generally, such that participants were more likely to make associative connections to the nonpresented but highly associated critical lures when the DRM lists were negative.

Despite the similarity in DRM performance for maltreated and nonmaltreated populations generally, researchers have uncovered differences in DRM recall as a function of psychopathology (Goodman et al., 2011; Howe, et al., 2004; Howe, Toth, & Cicchetti, 2011). Goodman et al. (2011) found that adolescents who experienced sexual assault and who also scored high in PTSD symptomology more often falsely recalled the critical lure compared with nonsexually abused individuals and those with child sexual abuse histories who did not score as high in PTSD symptomology. These results are in line with findings showing that maltreated children's tendencies toward memory problems are related to higher levels of psychopathologies.

Memory for Neutral and Positive Events

As mentioned previously, maltreated compared with nonmaltreated children tend to focus on negative input (Ayoub et al., 2006; Pollak, 2008). One could predict that maltreated children's memory would be particularly accurate for negative information, but perhaps less so for positive information, given lack of attention or distorted interpretations of the latter (e.g., Windmann & Krüger, 1998). In two separate studies with maltreated 3- to 6-year-olds, Ayoub et al. (2006) administered the Mean and Nice Interactions Scales. The Mean and Nice Interaction Scales consist of 17 stories with varying interactions, nice, mean, or nice/mean, between either a child and his or her peer (Peer Version) or a child and his or her caretaker (Adult-Child Version). Each story increases in complexity. Children are then asked to recall the story. Recall was coded both for accuracy and complexity of the recalled story, regardless of accuracy. Ayoub et al. (2006) found that, prior to approximately three and a half years of age, maltreated youth had higher recall scores than nonmaltreated youth. After three and a half years of age, however, this difference reversed and maltreated children recalled fewer stories than nonmaltreated children. In further analyzing why these maltreated youth scored lower in overall recall, the researchers discovered that the maltreated youth scored lower primarily on the nice and nice/mean stories. Both maltreated and nonmaltreated youth recalled mean stories at a statistically similar level (Ayoub et al., 2006). Thus, it was not a difference in overall ability to recall that caused the resulting score differences but a difference in recall as it relates to positive stories. Goodman et al. (2010) also found that children with maltreatment histories compared

with those without such histories obtained lower scores in answering specific questions about a positive interaction with a researcher.

Do memory deficits in maltreated children for positive information continue into older elementary age and adolescence, and are the deficits a function of maltreatment or associated psychopathology? McWilliams et al. (2014) asked 9- to 15-year-olds to watch a film clip of a domestic argument or a happy family scene. Approximately half of the children per film clip had maltreatment histories. The children's memory for the film clip was then tested (with IQ scores statistically controlled). Neither a history of maltreatment nor trauma-related psychopathology scores predicted memory for the negative film (the domestic argument). In contrast, higher levels of trauma-related psychopathology (e.g., PTSD, dissociation, depression) were associated with a higher proportion of commission errors in memory about the positive family interaction (see also Young & Widom, 2014).

Building on the previous theme, Chae and colleagues (2011) reported that trauma-related psychopathology, not maltreatment status, predicted memory for a fun interaction, a beanbag game, that occurred during children's stay at a child abuse evaluation center (Chae, Goodman, Eisen, & Qin, 2011). Several days after the children took part in the beanbag game, participants were interviewed, with open-ended, specific, and misleading questions, about the interaction. No significant differences in memory or suggestibility were found between maltreated and nonmaltreated participants, regardless of the children's age. Memory differences were, however, revealed for children with certain symptoms of psychopathology. For instance, although the children's PTSD diagnosis was unrelated to memory accuracy, increased levels of dissociative symptoms were associated with decreased memory performance in children who reported high levels of trauma symptomology. Thus, overall, maltreated children with higher levels of dissociative tendencies and higher trauma symptomology did not perform as well as maltreated children with lower levels of dissociative tendencies and fewer trauma symptoms. It was unclear, however, if the memory errors were due to actual memory deficits or response biases in answering the questions.

Further research is needed to determine if child maltreatment or trauma-related psychopathology is associated with deficient memory performance for positive and neutral events, but not for comparable negative events. Studies such as those previously indicate this as a possible avenue for additional research.

Memory for Stressful and Traumatic Events in Typical Development

Before reviewing research on maltreated children's memory for stressful and traumatic events, it is important to consider typical memory performance in this regard. We do so here rather than earlier as these studies directly set the stage for scientific investigations with child maltreatment samples. The contexts of these studies vary, with some research on children's memory for stressful and traumatic information performed in the laboratory and others taking advantage of stressful or traumatic events that occur in naturalistic contexts.

It is reasonable to ask whether laboratory studies can ever truly recreate the trauma of a highly stressful experience, and whether laboratory-based work is ecologically valid and thus applicable to trauma memories generally (Christianson, 1992; Deffenbacher et al., 2004). Deffenbacher et al. (2004) suggested that the stress experienced under laboratory conditions is fundamentally different from traumatizing or life threatening experiences, such that in the laboratory, stress is actually in the form of arousal, but during life threatening events, a more defensive activation response occurs. The researchers theorized that during a truly threatening situation the defensive activation mode of response is dominant and that this mode leads to impaired memory (but see McKinnon et al., 2015). As noted by Christianson (1992), however, researchers have been quite successful in creating and invoking stressed and emotional reactions in laboratory settings, such as staging crimes and exposing participants to highly distressing photographs. Moreover, a growing number of studies of memory for naturally occurring stressful events, such as invasive medical procedures, although not exactly laboratory based, can still have the advantage of a controlled event that can be documented by researchers, permitting scientific study (e.g., Goodman et al., 1997; Peterson, 2012). These situations arguably provide researchers with data comparable to that obtained from other real-world stressful scenarios while still abiding by ethical requirements.

Research on Stressful Events in Children without Maltreatment Histories

As we articulated earlier, it is important to differentiate, on the one hand, the stressful or traumatic nature of the stimulus or event, and, on the other hand, the traumatic background of the participant. A number of studies have examined memory for traumatic events in children who

have no known histories of prior trauma or maltreatment. Thus, researchers have analyzed these children's memory for traumatic natural occurrences or disasters, such as serious accidents (Peterson, 2012), stressful medical procedures (e.g., Goodman et al., 1991, 1997; Merritt et al., 1994), hurricane-induced floods (Sales, Fivush, Parker, & Bahrick, 2005), and tornadoes (Ackil, Van Abbema, & Bauer, 2003; Bauer, Burch, Van Abbema, & Ackil, 2007). In these studies, children who had personally experienced the event showed detailed and long-standing memories for what happened. Although the researchers' conclusions as to the impact of the distress on the children's memories and the level of recall about the event vary (Goodman et al., 1991; Sales, Fivush, Parker, & Bahrick, 2005), a number of researchers find a positive relation between the stressfulness of the event and the children's later recall. For instance, Ackil et al. (2003) reported that children who had experienced a tornado provided longer and more complete narratives about the traumatic tornado event than nontraumatic events. This relation between the traumatic event and heightened recall persisted over time, in this study across 6 months.

Other researchers have considered how children remember medical procedures, including highly stressful ones (Burgwyn-Bailes, Baker-Ward, Gordon & Ornstein, 2001; Goodman et al., 1997). Goodman et al. (1997) examined children's memory for and suggestibility about a voiding cystourethrogram fluoroscopy (VCUG). Here, the correlation between the stressfulness of the event and children's memory accuracy was related to parental attachment orientations. Thus, whether stress has a negative effect may not be due just to the stressfulness of the event itself but also to the children's background and the context surrounding the distress. Chae et al. (2014) similarly found that children's memory of an inoculation was better for children who had more positive parental representations than children who had less positive parental representations. These findings implicate an important role for parental influence and emotion regulation strategies.

Physiological Stress Responses and Typical Memory

During a stressful event, as mentioned, numerous stress-responsive physiological reactions occur. Such responses, even in children, help them prepare for, respond to, and adapt following stress exposure. These responses, as well, have important implications for attention, encoding, storage, and retrieval of information from memory. To determine a course of action following threat exposure, for example, it is necessary to attend directly to that threat, a process mediated by SNS activation and PNS withdrawal. Enhanced attention should increase encoding. Likewise, high concentrations of glucocorticoid and other relevant receptors that bind to glucocorticoids (Roozendaal et al., 2009) are located in the amygdala and hippocampus, neural regions heavily implicated in attention, encoding, and consolidation, especially of emotional information. Accordingly, when the HPA axis responds to stress exposure, glucocorticoid levels increase, which should, as a result of the activated neural receptors, enhance memory.

An impressive body of scientific work has documented the aforementioned set of links, that is, between physiological response and memory processes, including encoding, consolidation, and declarative memory. A majority of this work has examined memory in adult humans and non-human animals (McGaugh & Roozendaal, 2002; Roozendaal, McEwen, & Chattarji, 2009; Wolf, 2009), but some studies have investigated memory in children.

In adults, tight experimental control has led to well-designed investigations that allow for causal conclusions about the *effects* of physiological arousal on memory. In many studies, stress is induced via a laboratory procedure, such as the Trier social stress test (TSST), which involves giving a surprise speech and solving arithmetic problems in front of a small audience. In other studies, stress is induced via a pharmacological manipulation, such as giving adults a synthetic form of cortisol (e.g., hydrocortisol acetate, dexamethasone). During or after the stress induction procedure (or the completion of a nonarousing control task), participants are exposed to to-be-remembered material, such as pictures, words, stories, or faces depicting emotional or neutral expressions, and not, as described next, autobiographical information (e.g., Cahill & Alkire, 2003; Cahill & McGaugh, 1995; Flint, Bunsey, & Riccio, 2007; Gold & van Buskirk, 1975; Putman, van Honk, Kessels, Mulder, & Koppescharr, 2004; Kirschbaum, Wolf, May, Wippich, & Hellhammer, 1996; Smeets, Otgaar, Candel, & Wolf, 2008; Smeets et al., 2009). Findings from studies using these types of experimental designs typically reveal that greater arousal, as indexed via activation of the SNS and HPA axis, or via heart rate (a peripheral measure of ANS activation) at or near the time of encoding, enhances memory (Cohen & Waters, 1985; Lang, Newhagen, & Reeves, 1996; Vrana, Cuthbert, & Lang, 1989; for reviews, see Wolf, 2008, 2009). These effects are particularly pronounced when memory for emotional (primarily negative) information is tested. When stress manipulations are implemented at retrieval, greater physiological arousal,

especially of the HPA axis, inhibits adults' memory (e.g., Wolf, 2009).

In studies with children, the methodologies have diverged substantially from those with adults. First, in developmental studies, of primary interest has been how the amount of stress children experience during a threatening experience relates to their later memory of that experience. Thus, of importance, the to-be-remembered information is the stress-inducing event, thereby tapping autobiographical memory. Second, in many studies with children, stress exposure is not experimentally manipulated; rather all children experience the same event, and individual differences in the magnitude of children's responses to that event are compared with the accuracy and completeness of their memory. Although results from developmental studies are not as consistent as those observed in studies with adults, a number of studies have revealed similar patterns, specifically with regard to arousal at encoding: Physiological arousal is associated with better memory in children, as often observed in adults. For example, Quas and Lench (2007) exposed 5-year-olds to a fear-inducing video while the children's heart rates were monitored. After a week delay, memory for the video was tested. Larger increases in heart rate to the video predicted subsequently better memory for it. Quas et al. (2006) uncovered similar results in a study of children's memory for a fire alarm incident. Specifically, 4- to 8-year-olds' SNS and PNS reactivity was monitored while the children completed a series of laboratory tasks and experienced a brief fire alarm. When asked, shortly afterward, to describe what happened during the alarm, greater SNS-driven arousal was related to better recall. Greater PNS withdrawal, however, was associated with poorer recall, although only in older aged children. When Quas and colleagues (2011, 2012) exposed children, adolescents, and adults to a modified version of the TSST and later tested their memory for details of what occurred, greater HPA axis reactivity during the TSST predicted enhanced recall. This pattern, again, was remarkably similar to that observed in adults (but see Bugental et al., 1992; Chen, Zeltzer, Craske, & Katz, 2000; Merritt et al., 1994; Quas et al., 2014).

Two other developmental findings are important to consider in relation to emotion regulation and memory. One is that, for children, a supportive retrieval context can affect the memory patterns uncovered. Specifically, hints from several investigations suggest that the emotional context at retrieval may influence the type of information that children are able or willing to report about a prior stressful event (Klemfuss, Milojevich, Yim, Rush, & Quas, 2013; Rush et al., 2014). The other is that, while physiological arousal at encoding is often associated with better memory, including in children, among the small number of studies that have tested arousal at retrieval and memory, findings generally reveal negative effects (Nathanson & Saywitz, 2003; Quesada et al., 2012), especially when the interviewer is behaving in a nonsupportive manner (Quas & Lench, 2007). The latter effect, as well, points to the potential significance of emotion regulation at retrieval, especially when children are being asked to recount negative information.

To summarize, research with adults consistently reveals beneficial effects on memory of physiological arousal at encoding and negative effects on memory of such arousal at retrieval, especially when arousal is indexed by HPA axis activation, with these effects emerging largely as a result of changes in levels of circulating cortisol activating neural regions (e.g., in the limbic system) heavily implicated in attention, emotional processing, encoding, and consolidation of information. In children, greater physiological arousal at encoding is at times associated with enhanced memory for stressful to-be-remembered experiences, although few studies have utilized the types of tight experimental manipulations of stress and content of to-be-remembered information as that employed in studies with adults, which would enable clearer interpretation of findings and causal conclusions to be drawn. Greater physiological arousal at retrieval is often predictive of poorer memory in children, or perhaps a reduced willingness to answer questions correctly.

Memory for Stressful and Traumatic Events in Child Maltreatment Victims

Recognizing that differences in the traumatic nature of information to be recalled can affect memory performance, as can the traumatic nature of the children's personal histories, researchers have analyzed maltreated children's recall of traumatic events that the children personally experienced (e.g., Greenhoot, McCloskey, & Glisky, 2005; Melinder, Baugerud, Ovenstad, & Goodman, 2013). Although any discussion of memory for traumatic events requires an acknowledgment of the potential effect stress may have on motivation to report what occurred and other possible effects of distress on retrieval of memories, there is evidence within research on child maltreatment victims' recall of traumatic events that stress benefits recall. Moreover, although some participants fail to reveal prior documented abuse histories (Greenhoot et al., 2005), researchers have found that, when maltreated individuals do reveal prior abuse, they are relatively accurate in remembering the traumatic event (Alexander et al., 2005).

For instance, Alexander et al. (2005) interviewed older children and young adults about sexual abuse they experienced over a decade previously. Overall, the victims demonstrated fairly accurate recall of the abuse (accuracy was determined based on comparisons of the later reports to details in the original case files). However, and as was hypothesized, individual differences in psychopathology significantly predicted to the victims' recall. Individuals who reported their prior sexual abuse as their most traumatic experience and who revealed higher PTSD symptomology had better recall for their prior documented abuse experiences. Individuals with higher frequency of abuse, however, had higher rates of omission in their recall of their prior assaults. There are a number of potential explanations for this difference. First, as the authors note, this may be due in part to schematization of the memory where individuals who have experienced a higher frequency of abuse have generalized these memories due to the events' reoccurrence. Second, this decreased recall may not be an issue of the participants' inability to recall the events but, instead, of participants' hesitancy to report their abuse, particularly where this abuse has occurred quite frequently.

Maltreated children's memory for traumatic events other than the abuse also shows little in the way of consistent relations to the prior maltreatment. Two related studies, for instance, examined maltreated and nonmaltreated children's memory of an anogenital examination (Eisen et al., 2002) and/or venipuncture (i.e., blood draw; Eisen et al., 2007). In both studies, maltreatment status overall was unrelated to children's memory performance. However, in the 2007 study that included memory for an anogenital examination and venipuncture, the sexual and physical abuse victims actually performed better than others on a few of the memory measures. Of interest, sexual abuse and physical abuse victims actually had the fewest omission errors as to abuse-related questions.

Both Eisen et al. (2002) and Eisen et al. (2007) also found relations between certain psychopathologies and children's memory. In the Eisen et al. (2002) study, the children's GAF (psychological functioning/adjustment) ratings predicted the errors in memory interviews. Surprisingly, dissociation did not predict memory errors in this study. However, in the Eisen et al. (2007) project, the researchers found that dissociation was predictive of memory performance when one considered the level of children's physiological stress about the event and their self-reported trauma symptoms. Specifically, highly stressed children with higher dissociation and trauma symptom scores produced the most memory errors and were the most suggestible of the children tested. For the latter study, no connection between PTSD diagnosis and memory was found.

Research analyzing traumatized children's memory for stressful events thus reveals similar patterns to that found in memory for nonstressful events. Maltreatment itself appears to play a role in memory for trauma-related information in terms of enhancing memory when the type of trauma fits the type of event to be remembered, perhaps due to biased attention and/or greater knowledge (as seen for the sexually abused children in the Eisen et al., 2007, study). Further memory differences between abused and nonabused children seem to be primarily associated with factors such as emotion regulation and psychopathology. That said, the previously outlined research does not specifically reveal the source of these differences.

Maltreatment, Physiological Reactivity, and Memory

As reviewed earlier in this chapter, physiological reactivity and basal arousal vary between maltreated and nonmaltreated children. Given that reactivity has implications for memory, multi-level models of trauma, psychopathology, and memory should consider the extent to which possible differences between maltreated and nonmaltreated children's memory are linked to underlying variations between the groups in physiological responsivity. Precisely how these effects may play out is difficult to ascertain, and little research has actually examined these complex links.

When considering the links among maltreatment, reactivity, and memory, one possibility is that, following stress exposure, maltreated children will exhibit poorer memory for emotionally laden information than nonmaltreated children. This possibility stems from evidence that chronic exposure to maltreatment often reduces children's physiological reactivity, and evidence that heightened physiological reactivity near encoding, particularly of the HPA axis, enhances memory, theoretically as a result of activation of neural regions (e.g., the hippocampus) heavily involved in memory encoding and transfer of information to long-term storage. As such, maltreated children's hypothesized poor memory under stress would not be due to active attempts to avoid emotional information or potential difficulty understanding emotional events, but instead, would be due to reduced activation of memory-dependent neural regions implicated in basic memory processes.

Despite this possibility, as already mentioned, studies have not revealed differences between maltreated (or other stress-exposed groups) and nonmaltreated children in arousal and memory, including between stress-exposed

and nonexposed children. Nor have studies found any links between arousal and memory in maltreated children specifically. For instance, in an investigation described earlier, Scheeringa et al. (2004) collected heart rate and PNS responses in young children who had and had not been exposed to traumas while they were recounting prior experiences. The researchers coded children's descriptions for accuracy and compared the children's accuracy to their physiological responses. No significant differences were uncovered in any of the groups (traumatized with and without PTSD, nontraumatized) in physiological responses between children who were more versus less accurate in their memory reports. Likewise, Eisen et al. (2007) did not find any significant associations between maltreated children's heart rate while undergoing an anogenital medical exam that occurred while they were in-patients in an evaluation facility and their later memory for the exam.

However, studies have rarely measured maltreated children's HPA axis responses in relation to memory (but see Eisen et al., 2007). In adults, consistent evidence has been uncovered linking physiological reactivity (especially as driven by the HPA axis) and memory. The evidence for this link is stronger when memory for well-validated material is tested rather than when memory for prior personal experiences, including autobiographical memory, is tested, though in the studies with adults, none has relied on a traumatized (e.g., formerly maltreated in childhood) sample or compared performance between traumatized and nontraumatized adults. Future research is needed to examine, in a much more comprehensive manner, whether the effects of stress on memory vary between maltreated and nonmaltreated children, or between other samples of trauma-exposed individuals and nontrauma-exposed individuals. If any such difference emerges, it will be critical as well to test whether differences in physiological reactivity explain or simply correlate with evident trends.

A few other studies have examined how chronic stress and concomitant physiological dysregulation relate to general cognitive and memory abilities, as compared with autobiographical memories. Chronically high and low levels of cortisol have been linked to deficits in cognitive functioning and to poor performance on standardized memory tasks (Blair, Granger, & Razza, 2005; Cicchetti et al. 2010; Lupien, King, Meaney, & McEwen, 2001). For instance, in young children enrolled in a preschool program for low-income families as well as young children who spent (in infancy) a longer time in neonatal intensive care units, higher baseline cortisol levels predict poorer performance on cognitive measures (Blair, Granger, & Razza, 2005; Bugental et al., 2010). (Note: steroid [cortisol] inoculations are often given to women in preterm labor to develop the neonates' lungs, which while meant to help premature infants survive may also have long term effects on their HPA axis function and mental health; e.g., Kahlife et al., 2013.) At the same time, particularly low levels of cortisol, at least among chronically neglected or emotionally abused children, are related to more errors on a declarative memory task (Cicchetti et al., 2010). These studies are largely correlational, however, and thus causal inference is precluded. Moreover, the extent to which these outcomes relate to children's autobiographical and episodic memory is not entirely clear. Thus, although maltreated children may exhibit dysregulated physiological responses and may evidence cognitive deficits on certain standardized tests of memory, it is not known from extant research whether or why these deficits would spread to autobiographical and episodic memory and how these may relate to psychopathology.

Maltreatment and Overgeneral Memory

Psychopathology and childhood adversity seem to influence individuals' reporting of their autobiographical memories, sometimes with striking, but not fully understood, effects. Here, we discuss one specific autobiographical memory propensity that has been associated with childhood trauma, overgeneral memory (OGM), as an example of how emotion regulation and psychopathology may affect memory. This area of study also reveals complexities in pinpointing effects and even in replicating findings.

Williams and Broadbent discovered OGM while studying autobiographical memory in suicidal versus nondepressed adults. When asked to recount specific autobiographical memories in response to cue words, adults who had recently attempted suicide (i.e., parasuicidal) showed a pattern of retrieval deficits (Williams & Broadbent, 1986). Rather than retrieving specific memories, which are defined as memories for events that lasted one day or less and happened at a particular time and place (e.g., Having lunch with my friend on Saturday), the parasuicidal adults, as compared with a control group, provided general categorical memories (e.g., Every time I have lunch with my friend) or extended memories (e.g., My trip to England last year). Follow-up studies have repeatedly supported the presence of OGM in depressed patients (e.g., Brittlebank, Scott, Williams, & Ferrier, 1993; Swales, Williams, & Wood, 2001; Valentino, Toth, & Cicchetti, 2009). In both currently depressed people and those who were previously but are not currently depressed, OGM is

predictive of future recurrence of depression, increased feelings of hopelessness, poorer social relations, and impaired social problem-solving (Brittlebank et al., 1993; Sumner et al., 2010; Swales et al., 2001).

Further research has shown links between other psychopathologies and OGM. McNally, Lasko, Macklin, and Pitman (1995) found OGM in Vietnam veterans with PTSD, a link that has subsequently been shown in other samples of people experiencing PTSD (Schonfeld, Ehlers, Bollinghaus, & Rief, 2007). OGM has also been linked to borderline personality disorder, acute stress disorder, suicidality without depressive history, and early life trauma, in particular child abuse (Swales et al., 2001).

Several studies of OGM in depressed, traumatized, and PTSD individuals have uncovered their particular difficulty in retrieving specific positive memories. However, some studies have found that these populations do not have any more trouble than control groups at retrieving negative memories (Brittlebank et al., 1993; McNally et al., 1995; Swales et al., 2001, but see Williams, 2006). This pattern is reminiscent of that described earlier in which trauma-related psychopathy subsequent to maltreatment was associated with memory deficits for positive but not negative autobiographical experiences.

Williams (2006) proposed the CaRFAX (Capture and Rumination, Functional Avoidance, and Executive Control Dysfunction) model to explain OGM. Capture and Rumination refers to the way people who evince OGM tend to have certain negative memories or thoughts that capture their attention, as well as their mental and emotional resources. It was proposed that this step then leads to Functional Avoidance: a conscious attempt by the individuals to evade the negative feelings associated with particular specific memories so as to regulate arousal and affect, an emotion regulation process, resulting in truncated retrieval. Finally, the CaRFAX model proposes that individuals with OMG experience Executive Control Dysfunction, which helps explain the necessity of the avoidant strategies: The distress and other problems caused by their psychopathologies may leave people with reduced executive control, so that avoiding capture by distressing thoughts is much harder. Overall, OGM appears to reflect a maladaptive emotional regulation strategy related to traumatic events or thoughts that is difficult for people with histories of childhood adversity to overcome, at least under the conditions of timed tests (Bunnell & Greenhoot, 2012; Goodman et al., 2010).

Given the high rates of comorbidity between many of these disorders and the intercorrelated variables (e.g., childhood trauma and later depressed mood) involved, it is difficult to determine precisely how the various factors contribute to OGM, and under what conditions OGM is likely to arise. Of special interest, there have been conflicting findings as to whether OGM is primarily predicted by psychopathology, often depression, or instead by a prior childhood trauma, such as child sexual abuse (e.g., Kuyken & Brewin, 1995; Orbach, Lamb, Sternberg, Williams, & Dawud-Noursi, 2001; see Valentino, Toth, & Cicchetti, 2009, for a review). A 2010 meta-analysis by Sumner, Griffith, and Mineka found small but significant predictive values for OGM of depression, solidifying a link between depression and overgeneral memories, particularly in present clinical samples. However, many studies have also uncovered evidence that childhood trauma history is related to OGM (Aglan et al., 2010; Kuyken & Brewin, 1995; McNally et al., 2006; Valentino et al., 2009).

Valentino et al. (2009) suggest that this split in the literature may be due in part to the difficulty in measuring the amount of trauma that a person has experienced during his or her life, and how severe his or her traumas have been. In analyzing OGM in groups of abused, neglected, and maltreated children, Valentino et al. (2009) reported that the children in the abuse group had higher levels of OGM than the children in the neglected or nonmaltreated groups. The neglect and nonmaltreatment groups did not differ significantly in OGM. It was postulated that, although the neglected and abused children had all experienced maltreatment, the abused children suffered specific events and memories in ways that neglected children did not, and thus the neglected children would not have memories that they needed to avoid in the same way as the abused group. Valentino (2011) also suggests that the timing and severity of traumatic events may result in later OGM and psychopathologies. Of note, in Valentino et al.'s (2009) study, OGM was not mediated by depression in the abused sample, suggesting that trauma leads to OGM regardless of depression.

In a study by Stange, Hamlat, Hamilton, Abramson, and Alloy (2013), the researchers found that in Caucasian adolescents with OGM, emotional maltreatment predicted increases in depression more than it did for African American adolescents with OGM. Early differences in socialization may put groups at different levels of risk based on their upbringing. Caucasian parents tend to talk to their children about specific past events more than African American parents do, so there is a possibility that OGM is less predictive of future psychopathology in an African American sample just based on these varying styles of socialization. If nonspecific memory is already in place as a normal style of memory development instead

of a protective strategy, we would not expect it to have the same outcome as in a group that is more inclined toward specific memories normally. These variations have been noted and explored in other ethnic groups as well (see Valentino, 2011, for a review). Further research is necessary to determine what role ethnicity, psychopathology, and prior trauma play in resulting OGM.

Moreover, discrepancies in the OGM literature might be explained by considering the two responses to childhood trauma discussed earlier in this chapter, specifically a hyperarousal and hypoarousal response (Harris et al., in press). One would expect that use of functional avoidance as an emotion regulation strategy would be associated with a hypoarousal response to trauma, for example, perhaps to a general avoidant coping tendency (e.g., Bunnell & Greenhoot, 2012). In contrast, a hyperarousal response to trauma might well lead to specific memory retrieval rather than OGM (see Ogle et al., 2008, for review).

Translational Issues

As is evident from our review, multiple practical implications emerge when attempting to understand how well maltreated children, particularly those who exhibit significant impairments in emotion regulation, can remember and recount prior experiences, including those experiences that were and were not stressful or traumatic. Two domains, though, stand out as being especially important, with the understanding that what children remember about prior experiences, how they communicate those memories, and the effects of those memories on the children's current and ongoing functioning are all intertwined.

The first domain within which the research must be translated and understood is that involving clinical interventions and treatments for maltreated and trauma-exposed children. Clinicians and therapists are routinely faced with the need to interact with and solicit information from children about not only the children's experiences, but also their thoughts and interpretations of those experiences. Clinicians need to be aware of when trauma and stress may affect children's reporting of their experiences, and when it may not. That is, stress and trauma may not affect children's overall memory, but may instead shape the content of what is recalled (Howe, 2011; Klemfuss et al., 2013) and how children come to understand their experiences. Clinicians also, though, need to be well versed in the different ways memory may be affected. Moreover, as we outlined early in this chapter, it is incredibly useful to distinguish the type of information being recalled, or as we described, the type of stimulus (traumatic or not); children's backgrounds (maltreated or not) in relation to children's type of emotion regulation and psychopathology. Within this factorial design, which cell one is considering may shape the interpretations and conclusions that can be drawn about children's memory reports. Which cell, as well, likely shapes how children talk about and recount specific experiences. Accordingly, knowing which cell is being targeted can help clinicians guide their questions and interpret children's responses.

The second domain is the legal system. Children who suffer or witness maltreatment or other traumatic events are often interviewed by child protection and legal authorities (e.g., social workers, law enforcement officers, attorneys, judges) about both positive and negative events in their lives. It is vital that such authorities become aware of the many factors that can affect children's accuracy and completeness of report. Children with trauma backgrounds who have experienced or witnessed crime may attempt to regulate their emotions by truncating recall, yet child forensic interview protocols largely require free recall reports. Because relatively few studies have been conducted on the accuracy of maltreated and traumatized children's memory, there is still much to learn to ensure interview protocols used in child forensic interview centers optimally tap traumatized children's abilities and willingness to report their memories and resist false suggestions.

Conclusions and Future Directions

Whereas differences in memory between children who have experienced trauma and those who have not have been detected, the research thus far primarily supports a hypothesis that individual differences in psychopathology and emotion regulation, more so than maltreatment per se, play important roles. Maltreated children often show comparable memory performance to that of nonmaltreated children (Goodman et al., 2011; Howe, Toth, & Cicchetti, 2011; Howe et al., 2004). Additionally, child maltreatment history and resulting psychopathology do not necessarily result in memory deficits but may in fact improve retention, particularly for trauma-related events. For instance, individuals who evince PTSD symptomology have particularly accurate recall for the events that they report are highly traumatic (Alexander et al., 2005; McKinnon et al., 2015). Despite these general patterns, additional research is necessary in a number of areas.

First, additional research is needed into the effects of individual differences on children's memories for negative versus positive information, distinguishing between valence and arousal (Kensinger et al., 2006). Traumatized

children as a group, compared with children without trauma histories, have a number of characteristics that potentially could result in memory deficits or memory advantages, such as their attachment orientation, attentional focus, and emotion regulation tendencies. Whereas in this paper, we have argued that individual differences in emotion regulation and psychopathology, and not as much in trauma background itself, predict important aspects of memory error and performance, additional research is needed to support or refute this hypothesis. Research is also needed to explain protective factors that may exist that preserve memory functioning in spite of trauma. Such investigations should include longitudinal research on children's memories for traumatic events and positive events.

Second, although attachment orientations have been repeatedly shown to relate to memory accuracy and completeness for stressful and/or attachment-related events (Edelstein et al., 2005), further research is needed into the exact mechanisms involved, such as parental representations (Valentino et al., 2008) and parent–child communication (McWilliams, 2014) that may result in memory differences. In addition, neuroscience studies that show hyperarousal compared with hypoarousal (e.g., in PTSD response to trauma narratives) would profit from attention to the roles of attachment orientations of research participants, considering the separable dimensions of attachment anxiety and attachment avoidance. Overall, several discrepancies in the trauma and memory research literature may be resolved, at least in part, by considering the distinction between a hyperarousal and hypoarousal response.

Third, additional research is needed on how to bolster and improve children's memory even in the face of psychopathology, including how to increase resistance to false suggestion and reduce memory monitoring errors. For instance, Lyon and Dorado (2008) showed that when maltreated children take a truth-telling oath, their rates of true disclosures increased. These small social contracts and changes in approach can perhaps make a large difference in the way maltreated children recall their memories to others. Such changes have the potential to make a difference in the legal arena and can help alleviate the concerns raised regarding the types of suggestibility that can lead to memory errors. In the study of trauma and memory, socioemotional and cognitive factors must both be considered to understand and improve children's memory reports.

Finally, the burgeoning field of research analyzing the connections between neuroscience, psychophysiology, and children's memory continues to be a necessary area of focus. As noted previously, this includes research into whether, and if so how, neurobiological effects of trauma influence the developmental trajectory of maltreated children's memory functioning. A richer understanding of these phenomena can help practitioners provide better services to traumatized children and adults who are asked to recall their pasts.

INTRODUCTION

Few abilities are as important for success in contemporary societies as the ability to exercise self-control. Conversely, few developmental difficulties generate as much controversy and concern in our society as problems with inattention and impulsivity.

Self-control and self-regulation (defined momentarily) develop, and go awry, via the synergistic interplay of multiple psychological, neural, behavioral, and social systems, including bottom-up reactive processes (i.e., behavioral inhibition and approach, in turn directly influencing arousal regulation), top-down effortful control or executive functions, language development, and dynamic interaction with socialization processes (e.g., parent–child relationships and learning opportunities) in infancy, preschool, and the school-age years. In the prior edition of this volume, my coauthors and I (Nigg, Hinshaw, & Huang-Pollack, 2006) emphasized the interplay of socialization and interior dynamics of the child's cognitive, language, and emotional development in the gradual unfolding of self-regulation, as well as in the breakdowns that emerge into attention-deficit/hyperactivity disorder (ADHD) (APA, 2013).

This chapter therefore takes a somewhat different tack. It does not recapitulate the review of socialization and the role of language. Instead, after noting basic framing concepts similar to those described by Nigg et al., including an updated account of clinical features and history, it elaborates a two-process conceptualization of self-control of attention and impulse. This chapter is therefore entirely

[1]Color versions of Figures 14.1, 14.2, 14.4, 14.5, 14.6, 14.11 and 14.13 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

updated from the prior edition of this handbook. It outlines how this basic model can be used both to understand disorders like ADHD and to guide new research.

In the process, the chapter considers the formal constructs of attention and impulse control, outlining their development, and pointing out illustrative recent findings related to ADHD that help the reader understand normal and abnormal development of these abilities. The review is selective and heuristic, highlighting recent developments, selecting classic findings, and pointing readers to meta-analyses and comprehensive recent reviews on key component literatures for further study.

Developmental changes are notable throughout the life span, including infancy and young adulthood (Nigg et al., 2005) and old age (Hasher & Zacks, 1988; Zacks & Hasher, 1994). However, data on ADHD in later life are sparse; normative cognitive aging is beyond the scope of this chapter and well reviewed elsewhere (Park, 2012; Spreng, Wojtowicz, & Grady, 2010). This chapter therefore largely bypasses discussion of cognitive decline of attention or impulse control in later adulthood.

Throughout, in keeping with the developmental psychopathology perspective of multiple levels of analysis (Cicchetti & Dawson, 2002), the essay considers multiple perspectives. While emphasizing the psychological and neural levels of analysis, careful note is taken of considerations relevant to the genetic and socialization contexts, all with an eye on development.

Self-Regulation and ADHD

In the normative domain, one can invoke the concept of *self-control* (implying *deliberate* control or regulation of thoughts, behavior, and emotions) or the even broader domain of *self-regulation,* encompassing both deliberate self-control and involuntary regulatory processes related to attention, mental ideation, behavior, and emotion. Because in most research the two constructs are not operationally distinguished, the text herein refers to self-regulation except when the data clearly pertain only to self-control. The wide array of positive and negative life outcomes that are related to self-regulatory abilities includes physical health, mental health disorders, substance abuse, academic achievement, school readiness, learning, peer relations, development of conscience, resilience to adversity, and even mortality and longevity (Blair & Razza, 2007; Calkins & Keane, 2009; Clausen, 1993; Gorenstein & Newman, 1980; Iacono, Malone, & McGue, 2008; Kern, 2008; Krueger et al., 2002; Krueger, Markon, Patrick, & Iacono, 2005; Moffitt et al., 2011; Nigg, 2006a; Wood, Rijsdijk, Asherson, & Kuntsi, 2009; Young et al., 2009). The importance of adaptive and maladaptive self-regulation and its relevance to life outcome therefore is compelling.

In the maladaptive domain, self-regulation broadly defined is so fundamental that it influences almost all psychopathology to some extent, from depression, to aggression, to ADHD (Rudolph, Troop-Gordon, & Llewellyn, 2013). This includes poor regulation of attention, planning, foresight, and working memory (inattention) and poor regulation of decision making, motor response, speech, and emotional expression (impulsivity). Mirsky and Duncan (2001) listed 17 psychiatric and neurological conditions associated with disordered attention, including schizophrenia, autism, fetal alcohol syndrome, closed-head injury, and narcolepsy. Crucially, however, the term *attention* connotes multiple functions; not all such functions are equally affected across these various conditions.

Impulse control likewise is multiply defined and multicomponential (Nigg, 2000; Whiteside & Lynam, 2003) and appears in a range of conditions, of which ADHD may be the most prominent but is hardly the sole exemplar. Antisocial behaviors (including conduct problems and psychopathy), eating disorders, personality disorders (notably borderline personality disorder and antisocial personality disorder), substance abuse disorders, tic disorders, obsessive-compulsive disorder, bipolar disorder, and pathological gambling are only some of the psychopathologies readily associated with serious maldevelopment of impulse control (Coles, 1997). Many of these are syndromes primarily observed in adulthood, and their relation to childhood impulsivity is largely unstudied. Nonetheless, clearly the correspondence is not one-to-one between the topic of disorders of attention and impulse control and the clinical syndrome of ADHD.

Indeed, this fundamental quality of underlying shared dimensionality is part of the reason that there is extensive overlap between ADHD and aggression and some overlap between ADHD and mood problems such as irritability (Shaw, Stringaris, Nigg, & Leibenluft, 2014), as well as to a lesser extent mood disorders like depression. That is, the ability to regulate impulse and attention is related to fundamental human capabilities that cut across descriptive categories of psychopathology. To constrain the scope of discussion, however, and because aggression and mood problems are discussed in other chapters, this chapter's emphasis is ADHD, a syndrome which is paradigmatic of problems in the domain of self-regulation. Readers may bear in mind that the underlying regulatory abilities discussed herein are likely related across conditions other than ADHD.

At the same time, ADHD affords certain unique considerations. Most salient is the perspective taken in *DSM-5*

(APA, 2013), that ADHD is a neurodevelopmental condition. It is thought to have developmental roots in early in childhood and perhaps even in infancy (Auerbach et al., 2004; Sullivan et al., 2015). Thus, the maturational processes of self regulation are of central importance. In early precursive form, preschooler problems with self-regulation and early school age problems with inattention and impulsivity (as well as hyperactivity), which typically co-occur with irritability, are a risk factor for development of persistent aggression, mood regulation, or depression (although, importantly, this is not the only route to depression). While the picture for girls is somewhat more complex, most boys with conduct disorder also previously had ADHD, and the combination of ADHD and conduct disorder is a primary route to drug addiction and alcoholism. Thus, shared neurobiological mechanisms are expected in ADHD, conduct disorder, and drug addiction. The Psychiatric Genetics Consortium pooled genome-wide data (from arrays that assess hundreds of thousands of common variants called single-nucleotide repeats or SNPs) with a sample of some 30,000 individuals from one of five psychiatric disorders, including ADHD. Risk genes were identified that tended to be common across disorders (Smoller et al., 2013), although there was some nonoverlap for ADHD with the other disorders. Among child disorders, many neuropsychological findings seen in ADHD are seen in other disorders also, though sometimes with variations that support partial distinctions among conditions (Seguin, Parent, Tremblay, & Zelazo, 2009).

As might be expected from these intersections, many proposals for the psychological and neurobiological mechanisms involved in ADHD have been offered in the contemporary period (Barkley, 1997; Berger & Posner, 2000; Casey, Tottenham, & Fossella, 2002; Castellanos & Tannock, 2002; Douglas, 1972, 1999; Newman & Wallace, 1993; Nigg, 2001; Nigg, Swanson, & Hinshaw, 1997; Nigg, 2006; Sagvolden, Johansen, Aase, & Russell, 2005; Satterfield & Dawson, 1971; Sergeant, Oosterlaan, & van der Meere, 1999; Zentall & Zentall, 1983). Many are similar to what could be hypothesized for other disorders of impulse control. This nonspecificity is not belabored herein but should be borne in mind while considering genetic and neural findings in relation to inattention and hyperactivity-impulsivity or in relation to ADHD.

Overall, then, it is important to recognize that psychopathological categories exist in relation to underlying dimensions of liability, and also that they exist to some degree on a developmental continuum. Figure 14.1 shows one empirical estimate of how ADHD fits in with common types of psychopathology. It shows that hyperactivity-impulsivity tends to correlate strongly with oppositional defiance and conduct problems. Note, however, that even though inattention is placed on the externalizing factor in the figure, it is equally correlated with depression/anxiety symptoms. Also note that this helpful study by Lahey et al. (2008) did not consider the correlation of ADHD with learning disorders, autism, motor delays, or other neurodevelopmental conditions.

Few studies have done so. One study to consider this question, however, found that ADHD clustered strongly with ODD but also with autistic symptoms, motor coordination, and reading problems and that sibling cross

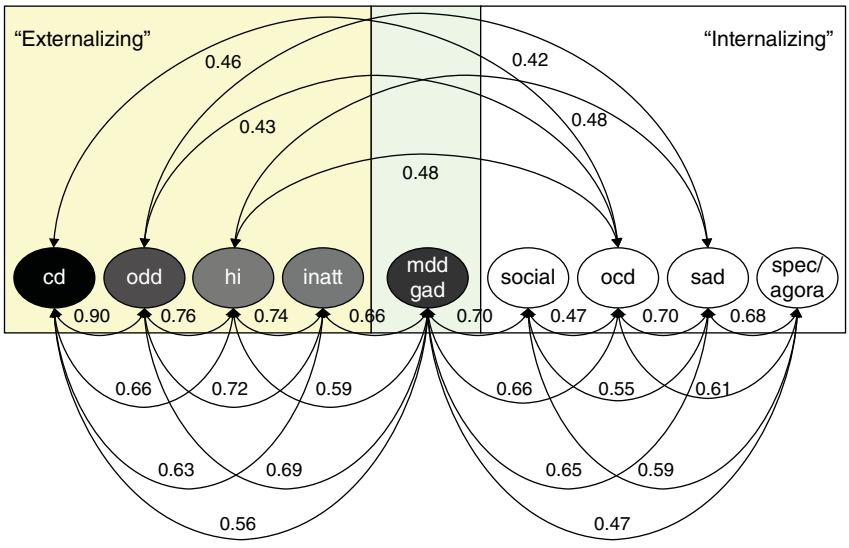

Figure 14.1 Correlations among child disorders. See footnote 1. *Source:* Reprinted with permission from Lahey, B. B., Rathouz, P. J., Van Hulle, C., Urbano, R. C., Krueger, R. F., Applegate, B., … Waldman, I. D. (2008). Testing structural models of *DSM-IV* symptoms of common forms of child and adolescent psychopathology. *Journal of Abnormal Child Psychology, 36*, page 196.

correlations loaded better for autistic, motor, and reading problems than behavior problems (Couto et al., 2009). Indeed, when one considers the overlap among symptoms of these disorders, it is striking that ADHD symptoms have a substantial phenotype overlap with motor delays (Fliers et al., 2009; Piek, Pitcher, & Hay, 1999; Pitcher, Piek, & Hay, 2003; Rasmussen & Gillberg, 2000); phenotypic overlap with autism spectrum disorders, (ASD) in that 50% of children with ASD are hyperactive and about 20% of children with ADHD have sufficient social oddity to raise questions about ASD overlap (Matson, Rieske, & Williams, 2013; Reiersen, Constantino, & Todd, 2008); have shared heritability with autism (Lichtenstein, Carlstrom, Rastam, Gillberg, & Anckarsater, 2010; Musser et al., 2014; Rommelse, Franke, Geurts, Hartman, & Buitelaar, 2010); and have cognitive problems including lower average IQ (Nigg, Willcutt, Doyle, & Sonuga-Barke, 2005) and learning disabilities (Willcutt et al., 2010), with which there is again genetic overlap (Couto, et al., 2009; Loo et al., 2004; Willcutt et al., 2002). Additionally, ADHD is associated with early appearing alterations in neural development (Castellanos et al., 2002; Shaw et al., 2007). These early brain alterations are not fully explained by differences in the structure of the genome (Castellanos et al., 2003) and so are due at least in part to either stochastic epigenetic changes or environmental influences on gene expression. While interesting neural signatures have been linked to callous-unemotional (psychopathic) traits (Breeden, Cardinate, Lozier, VanMeter, & Marsh, 2015), it is relatively difficult to demonstrate similar magnitude developmental brain changes in children with ODD or CD who do not also have ADHD. This is in part because such children are rare. A typical developmental progression is from ADHD (often accompanied by significant irritability early in life) to ADHD+ODD, and then to ADHD+CD; from there emanates one pathway to substance use disorders (Molina & Pelham, 2014). While many children with ADHD do not have ODD and many with ODD do not develop CD, most children with ODD also have ADHD, and nearly all children with conduct disorder, at least among boys, previously had ODD and ADHD.

The idea of a neurodevelopmental disorder is important for another reason: whereas ADHD is in part an extreme of a dimension of poor self-regulation, it is not only this. Substantial evidence indicates that ADHD also arises in relation to subtle neural injuries or developmental perturbations pre- and perinatally. These include prenatal teratogenic exposure, maternal severe emotional stress during pregnancy, low birth weight, or premature birth, particularly when other developmental conditions such as motor coordination problems or ASD symptoms, co-occur (Gillberg, 2003; Linnet et al., 2003; Nijmeijer et al., 2010; Owens & Hinshaw, 2013; Pearsall-Jones, Piek, Rigoli, Martin, & Levy, 2009; Sato, Aotani, Hattori, & Funato, 2004; Whitaker et al., 2011; Thapar et al., 2013). A caveat is that pre- and perinatal effects on outcome are difficult to detect after middle childhood (Wagner, Schmidt, Lemery-Chalfant, Leavitt, & Goldsmith, 2009) and are not necessarily causal. For example, maternal smoking in pregnancy seems to be largely a proxy for genetic risk, operating via gene-environment correlations (D'Onofrio et al., 2008; Obel et al., 2011; Thapar et al., 2009).

Even so, the weight of evidence indicates that in some instances ADHD is associated with poor self-control in the same way that a closed head injury is associated with poor self-control—that is, as a consequence of a subtle neural injury rather than as normal variation on a trait (Whitaker, et al., 2011). Thus, multiple etiological pathways must be borne in mind. In all, developmental paths to clinically significant inattention and impulse control problems are highly likely to involve both *equifinality*, meaning that several causal routes are contributory to ADHD, and *multifinality*, whereby early risks for ADHD may yield substantially divergent outcomes contingent on socialization and contextual processes (Cicchetti & Rogosch, 1996; Hinshaw, 1999).

Initial Comments on Etiological and Developmental Process

In the preschool years, the attainment of self-regulation, including arousal regulation, emotion, and attentional control, depends on socialization. It therefore is inherently an interpersonal process influenced by a complex interplay of child temperament (reactivity, presumably related to genetic and prenatal effects) and parent responsivity (Cecil, Barker, Jaffee, & Viding, 2012; Kim & Kochanska, 2012; Troxel, Trentacosta, Forbes, & Campbell, 2013; Ursache, Blair, Stifter, & Voegtline, 2013). In particular, family processes may be a primary mediator for the expression, over time, of the genetic mechanisms reflected in the substantial heritability estimates of these behavior problems, particularly in early life. School and community expectations for behavioral control also cannot be overlooked in considering the societal context of these problems.

Indeed, the contexts of children's development have changed rapidly in the past one hundred years in numerous ways beyond compulsory schooling. Diets have changed so much in the last century in the northern and western hemispheres that what most people in those societies

now eat has ceased to resemble the recent evolutionary diet, with complex effects on health that are still debated (Turner & Thompson, 2013; Walter & Ley, 2011). Hundreds of synthetic neurotoxins have flooded children's environments worldwide, including food, water, and air, with poorly understood consequences (Canfield, Gendle, & Cory-Slechta, 2004; Koger, Schettler, & Weiss, 2005; Lanphear, 2015; Nigg, 2006; Rice, 2000). In the last decade alone, the pace of technological change has been dramatic, continuing to change children's interpersonal and peer-relations throughout much of the world, through screen media exposure and social networking technology (Christakis et al., 2013; Sigman, 2012; Spies Shapiro & Margolin, 2013; Tandon, Zhou, Lozano, & Christakis, 2011). Political strife, upheaval, and violence have remained unfortunate realities for children in much of the world, often with substantial but poorly studied effects on the development of attention, self-control, and with them socialization, conscience, and interpersonal health (Betancourt et al., 2013; Betancourt et al., 2012). The meaning of ADHD in these varying contexts requires careful reflection, which this essay cannot fully address.

In the first world populations in which it has been primarily studied, ADHD (or its symptom domains) is highly heritable (Chang, Lichtenstein, Asherson, & Larsson, 2013; Kan et al., 2013). How do contextual and environmental pressures intersect with genetic effects? At times contextual forces are doubtless so powerful as to largely overpower genetic effects (e.g., an entire village of children forced to be child soldiers; Betancourt, et al., 2013). At other times, developmental contexts are sufficiently within the expectable limits for adequate development that genetic effects on individual variation are substantial. In short, when it comes to the complex behavioral picture of inattention and impulsivity, genetic effects are relevant, yet not directly causal or deterministic. Instead, two basic principles must be considered.

The first basic principal is that genetic and other child-specific mechanisms that influence individual differences in the expression of given traits or conditions (e.g., ADHD) do so within the context of effects on the entire population. For instance, individual differences in height are highly heritable, but the secular trends over the past century regarding substantially increased stature in the population at large (in developed and developing nations) are the result of environmental factors, such as more available calories. In the same way, population-wide changes in environment that influence level of a trait can contribute to children's attentional and regulatory problems regardless of heritability estimates within that population.

The second principle is that heritability estimates for nonmetabolic, multifactorial disease are better understood as heritability of liability than as heritability of disease. Put another way, genes likely influence susceptibility to psychiatric illness, while experiential events actualize that liability to varying degrees. This principle holds of liability even for infectious disease; heritability is substantial for tuberculosis, for instance (Fine, 1981) due to inheritance of vulnerability and protective qualities. Although specific considerations pertain to infectious disease, the same principle holds for behavior. This has been demonstrated in animal studies dramatically for some time. For example, Cairns and colleagues (Cairns, 1996) showed that in rodent populations bred to have nonoverlapping levels of stranger aggression, rearing in different socialization contexts fully eliminated this genetic effect in a single generation. This picture has helped drive strong interest in gene by environment (G×E) interactions, a theme later in this review.

Societal Context of Discussion: Medicalization, Controversies, Scientific Change

The clinical syndrome of ADHD and its treatment with medication has generated periodic and sustained controversy and social criticism for nearly half a century. This controversy requires comment to frame the current discussion. These societal discussions are provoked in part by ongoing secular increases in the numbers of children being identified with ADHD in the United States (Perou et al., 2013), although it should be noted that evidence of an actual increase in prevalence (as distinct from case identification), at least over the past two decades, is scant (Erskine et al., 2013). Western nations have also seen renewed concern about diversion of stimulant medication for nonprescription use for performance enhancement, leading to unintended health problems for users, which seizes media attention (Substance Abuse and Mental Health Services Administration, 2013; Tavernise, 2013). Clear data on the actual extent of such misuse, and whether it is related to rates of prescribing, is difficult to come by but nonetheless has become a significant concern in its own right (Kaye & Darke, 2012; Wilens et al., 2008; Weyandt et al., 2014).

Sociologists point out that *medicalization* occurs when a problem falls under the purview of the medical profession. For example, American society has seen the medicalization of pregnancy and birth, drinking problems, and other processes and conditions (Barsky & Borus, 1995; Conrad, 1992). The medicalization of attentional problems and hyperactivity, as well as disruptive behavior more generally, has long spurred critics to ask whether ADHD is a

valid psychiatric disorder (Searight & McLaren, 1998). It has also long sparked concern that rising medication rates may indicate an important shortage of other needed psychological or educational interventions for children (Safer & Krager, 1992) or that social control is being served rather than mental health (Menzies, 1997). The extreme forms of such criticism sometimes expressed are difficult to reconcile with the wealth of biological correlates of ADHD, from reliably reduced brain size (Castellanos, et al., 2002) from age 4 on, slower maturation of the cortical mantle (Shaw, Greenstein, et al., 2006), elevated levels of lead in their blood (Nigg, Nikolas, Knottnerus, Cavanagh, & Friderici, 2010), more family members with ADHD (Stawicki, Nigg, & von Eye, 2006), and differences in genotype (Banaschewski, Becker, Scherag, Franke, & Coghill, 2010).

The issue to which critics may be trying to allude is that biological markers are not sufficient for clinical diagnosis in ADHD or, indeed, in psychiatry generally. Diagnosis relies on clinical judgment about behavioral symptoms. That judgment is only as good as the skill of the clinician and the quality of the evidence base upon which she relies. The ontological status of ADHD as a real condition with a definable biological process or marker that can be measured in all or nearly all cases of the disease (like it presumably can in cancer or infectious disease) is still some distance off and may never occur. It is likely that if such diagnostic biomarkers are ever identified, they will not apply to all individuals currently diagnosed with ADHD.

Indeed, for all complex diseases (hypertension, obesity, diabetes, cancer, and psychiatric conditions) the ability to identify a single biological cause is likely to be possible only when we can differentiate subgroups (as in breast cancer recently, for example). Complex disease is inherently characterized by probabilistic prediction based on risk factors that predict morbidity and mortality. ADHD conveys considerable morbidity risk (Nigg, 2013a), and thus examination of probabilistic diagnostic categories remains useful and important.

Whether these biological arguments will take a new turn remains difficult to say. It is striking that the past decade has seen a sea change in available scientific tools: the field now has access to affordable and powerful genetic assays, new tools for integrated systems biology, more refined imaging measures that assay the entire brain and its organization instead of just regions of interest, internet based large scale data collection, and ever more powerful computers that all enable the era of big data to come to bear on the study of human development and behavior. Most of these tools are only beginning to influence our understanding of ADHD, but it can be anticipated that they will do so to an increasing, if incremental, extent. With these considerations in mind, the discussion now turns directly to the syndrome of ADHD.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER: BACKGROUND

The changes in conceptual definition of and treatment rates for ADHD over the years are one contributor to controversy about its status and meaning. It therefore is helpful to briefly review key historical aspects. More detailed historical background is provided by Nigg, Hinshaw & Huang Pollock (2006), Taylor (2011) and Nigg and Barkley (Nigg & Barkley, 2014), from whom I borrow liberally to set a contemporary context.

History

Well before current conceptual models began to be developed, educators and clinicians began to notice clinical-level manifestations of inattention, impulsivity, and dysregulated behavior in school-age children. Description of disorders of attention first appeared in the medical literature a little over two hundred years ago. As noted by Barkley and Peters (2012), Weikart (in 1770 or 1775) described adults and children who were inattentive, distractible, impersistent, overactive and impulsive, reminiscent of today's description of ADHD. As detailed by Taylor (2011), Crichton (1798) described patients with extreme mental restlessness.

The first American record comes from the physician Benjamin Rush, often credited as the founder of American psychiatry, who in his pioneering textbook in 1812 mentioned a syndrome involving inability to focus attention (Rush, 1812). Other references occurred in Europe periodically during that century. Interest picked up considerably, however, in first part of the 20th century, perhaps in relation to the implementation of compulsory education in the 19th century. By 1908, the term minimal brain damage had entered the medical lexicon (Taylor, 2011) to represent a group of children displaying substantial ADHD-like behavioral disturbances yet without evidence of gross brain damage.

Following the worldwide influenza epidemic during and after World War I, some children developed encephalitis, and it was noted that many survivors of this infection developed significant problems in attentional deployment, regulation of impulses, and general behavioral control, leading to the term minimal brain damage syndrome, a

term later softened to minimal brain dysfunction, or MBD (e.g., Strauss, 1947). By the 1960s, the boundaries of MBD had become far too over inclusive (Clements & Peters, 1962; Wender, 1971), and the term began to fall into disfavor.

Others were calling for narrower and more descriptive appellations. Laufer and Denhoff (Laufer & Denhoff, 1957) described a hyperkinetic disorder of childhood, focusing more specifically on dysregulated motor behavior. The second edition of the *DSM* (APA, 1968) adopted this narrower conception and nomenclature.

An empirical tradition was also expanding, in which parent and teacher ratings of child problems were subjected to factor analyses in an attempt to discern identifiable, empirically supported syndromes of psychopathology (Quay, 1972; Achenbach, 1966; Achenbach & Edelbrock, 1978). Factors labeled hyperactivity and immaturity emerged in such dimensionalized accounts of child problem behavior. Indeed, prior to *DSM-III* (APA 1980), ADHD was identified by extreme scores on these newly emerging ratings scales such as the Conners Teacher rating scale (Achenbach & Edelbrock, 1978; Conners, 1969; Pelham, Fabiano, & Massetti, 2005).

Based largely on the research of Douglas and colleagues (Douglas, 1972), in the 1970s and 1980s researchers in North America began to conceptualize the core deficit of children considered hyperkinetic as related to dysregulated attention and impulse control rather than motor overactivity per se. By *DSM-III* (APA, 1980), in the United States the condition had been renamed attention deficit disorder, which was posited to consist of a subtype with hyperactivity and a second, albeit undefined, subtype without hyperactivity. Meanwhile, in Europe the World Health Organization *ICD-9* (*World Health Organization, 1978*) continued to refer to hyperkinesis and to use a more restrictive definition that excluded many children with comorbid conditions who were still included in the *DSM* definition.

The empirical tradition continued, with efforts to develop empirically based taxonomies of children that included dimensions related to hyperactivity and inattention (Achenbach & Edelbrock, 1983). By this time, stimulant medication treatments, which had originated decades earlier with the pioneering work of Bradley (1937), were generating controversy (Sroufe & Stewart, 1973), a theme that continued (Jacobvitz, Sroufe, Stewart, & Leffert, 1990; Safer & Krager, 1992) and persists, as noted earlier.

Renamed attention-deficit/hyperactivity disorder for *DSM-III-R, DSM-IV,* and *DSM-5* (American Psychiatric Association, 1987, 1994, 2013), the condition's core subtypes were expanded in *DSM-IV* to three: a Predominantly Inattentive type (similar to the *DSM-III* notion of attention deficit disorder without hyperactivity), a predominantly hyperactive-impulsive type (unprecedented in previous nomenclatures), and a Combined type in which both symptom clusters were clinically salient. In *DSM-5* (APA, 2013), the structure of ADHD was largely unchanged although the subtypes were downgraded to presentations with text explaining their temporal instability.

Legislative changes in the early 1990s yielded the inclusion of ADHD as a potential trigger for special education services in public schools, while pharmaceutical companies began direct-to-consumer advertising, all increasing the salience of ADHD to families and clinicians. Prescription rates for stimulants, as for other psychotropic medications used with youth, doubled in the United States in the 1980s, repeated that in the 1990s (Safer & Krager, 1992; Safer & Zito, 1999; Zito et al., 2003), and continue to climb. Meanwhile, major clinical trials evidenced the efficacy of stimulant pharmacologic treatment for ADHD, if implemented carefully and with thorough monitoring, with combined medication-behavioral treatments yielding the highest likelihood of clinically meaningful improvement (Conners et al., 2001; MTA Cooperative Group, 1999). However, subsequent long term follow up studies indicate that the long term outcomes of brief intensive treatment were little altered (Molina et al., 2009), leading to an increased sense of the need to more fully understand pathophysiology and etiology.

Prospective longitudinal investigations were showing that ADHD was a condition likely to persist into adolescence in a majority of cases and to continue to yield impairment into adulthood in a substantial percentage (Mannuzza & Klein, 2000). Those findings led to the blossoming of research on ADHD in adults and the gradual recognition of the unique issues in establishing validity of the construct in adults, reflecting recognition of a research and clinical domain in ADHD that had been underway for a generation (Wood, Reimherr, Wender, & Johnson, 1976).

Thus, ADHD has for some time now been recognized as a condition that is not restricted to childhood or even adolescence. Yet the ongoing recognition of ADHD in adolescents and adults has in some ways exacerbated questions about the boundaries of normality when it comes to inattention and disorganization, as a harried, over-scheduled workforce and a student population driven by increasing competitive performance demands seeks relief and help.

In general, ADHD is currently understood as a clinically useful, statistically informative but not biologically meaningful cut point on a continuous dimension of behavior in the population (Larsson, Anckarsater, Rastam, Chang, & Lichtenstein, 2012; Levy, Hay, McStephen,

Wood, & Waldman, 1997; Levy, McStephen, & Hay, 2001; Willcutt, Pennington, & DeFries, 2000). It is provocative to consider whether this dimension we call ADHD in fact contains meaningful subconfigurations, which hew better to biological domains and that might isolate biologically more meaningful populations. That question is taken up in this chapter's concluding sections.

Clinical Features and Issues for ADHD

DSM-5 (APA, 2013) requires six of nine possible symptoms of inattention-disorganization or 6/9 symptoms of hyperactivity-impulsivity to be present for at least 6 months and to have onset prior to age 12 years. They must cause substantial interference in functioning and substantial features have to be present in more than one setting (e.g., home and school). The World Health Organization's *ICD-10 (World Health Organization, 1992)* is expected to be updated with an 11th edition in 2017 or 2018, shortly after this volume is published, but likely will not have identical criteria to *DSM-5*, reflecting ongoing differences in how this syndrome is viewed in Europe and the United States. However, because most research on ADHD uses a *DSM* or else a dimensional perspective, the present chapter refers to ADHD without differentiating potential distinctions with hyperkinetic disorder in the *ICD*. The prevalence of ADHD worldwide is estimated by recent meta-analyses to be between 2.5% (Erskine, et al., 2013) using fairly conservative criteria, to about 5% using slightly broader criteria (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007; Willcutt, 2012), with a male preponderance on the order of 2.5:1 in community samples. A handful of key issues with the clinical construct are important to note.

The diagnosis of ADHD requires not only above-threshold numbers of symptoms but also (1) the early onset of these symptoms, (2) their developmental extremity (a key point, given that problems of inattention and impulsivity are ubiquitous in young children), (3) their cross-situational display (i.e., at home, at school, and often in the peer group or work setting), and (4) the requirement that they yield functional impairment. These guidelines have strong empirical support. Thus, assessment requires, at a minimum, the taking of a careful history; reports from multiple adult informants with well-normed rating instruments; differential diagnostic procedures to distinguish ADHD from either normal developmental variation or a host of medical and psychiatric conditions that feature inattention and impulse control problems in their presentation; and, when possible, direct observation of the child in family and school contexts. Considering functional adjustment in multiple domains can assist with treatment tailoring (Pelham et al., 2005).

Willcutt et al. (2012) provided a thorough review of the empirical data regarding symptom dimensions and clinical subtypes, which yielded several important conclusions. First, a two-factor structure underlying the constituent symptomatology, corresponding to inattentive-disorganized and hyperactive-impulsive symptom domains, is valid and useful psychometrically. Both areas can be reliably measured by parent and teacher rating scale instruments. They show divergent validity, with inattentive behaviors uniquely associated with academic problems and hyperactive/impulsive behaviors aggregating with disruptive tendencies in school and home settings. (Factor analyses actually show that a three factor model, separating impulsivity from hyperactivity, fits slightly better but because the fit is excellent for two factors, this more parsimonious solution is preferred for most uses). Thus, the underlying dimensions of ADHD show considerable psychometric viability.

Second, however, the *DSM-IV* subtypes (nearly identical to the *DSM-5* presentation) had significant validity problems. For this reason, they were downgraded to presentations in *DSM-5*. These problems included lack of longitudinal stability (one type easily becomes another over time), lack of differential treatment response; and lack of differential clinical or cognitive correlates beyond those that are already attributable to the distinction between the inattentive and hyperactive symptom domains. However, almost no data have examined genetic or neuroimaging findings on putative subtypes or dimensions differentially. Family studies asking whether ADHD subtypes breed true have been mixed; one meta-analysis found a small but statistically significant familial separation of the combined and inattentive types (Stawicki, et al., 2006). Meantime, behavioral genetic analyses suggest that the HI type, unlike the others, is not heritable (Willcutt, et al., 2000); its validity in school-age children is doubtful (Willcutt, et al., 2012).

ADHD is heterogeneous and some form of subtyping is likely to eventually be useful, but this will probably entail revision if not overhaul of the existing presentations. In part, there remains considerable concern in the field about how to describe a group of children who appear inattentive and underactive, sometimes referred to as children with sluggish cognitive tempo (Barkley, 2013; Moruzzi, Rijsdijk, & Battaglia, 2013). Many of these children are likely included in the ADHD inattentive presentation, but some experts suspect they have a distinct syndrome unlike other children in that presentation grouping. A better subtyping

scheme would reflect neurobiological variation better, and might also yield superior clinical stability and prediction.

The *DSM-5* criteria provide some parenthetical examples pertaining to adults, but probably are still inadequate to capture the syndrome in adulthood. The hyperactive-impulsive symptom cluster is likely to be particularly salient during the preschool and grade school years but fades in frequency and intensity by adolescence. On the other hand, the inattentive-disorganized symptom cluster, which becomes most recognizable with the advent of formal schooling, is more stable throughout adolescence (Hart, Lahey, Loeber, Applegate, & Frick, 1995) and may present as serious problems with self-organization and executive functioning in adulthood that are not fully captured in the current symptom list. Further, the range of impulsivity in adults is likely far more complex than captured in the three impulsivity items in *DSM-5*, as is noted in my discussion of impulsivity later. An established literature suggests empirical bases for refining the conception in adults (Achenbach, 1991; Conners, Erhardt, & Sparrow, 1999; Kessler et al., 2010), but this literature has not yet reached sufficient critical mass to overcome the advantages to the diagnostic nomenclature of retaining similar symptoms across age for ADHD.

New impairments unique to adolescents and adults must be considered including risky sex, drug experimentation, driving accidents, problems with employment, and marital conflict (Barkley, Fischer, Smallish, & Fletcher, 2004; Nigg, 2013a). A final complexity unique to the condition in adults concerns the potential for misdiagnosis in relation to Axis II psychopathology, or, in other words, the possibility that ADHD may develop into an enduring maladaptive personality style or trait by adulthood (Kernberg & Yeomans, 2013).

ETIOLOGIES

Genetics

Family studies established long ago that ADHD breeds true, with a twofold to fourfold increased risk among first-degree relatives see (Stawicki et al., 2006). How much of this familial similarity is due to genes versus common family experiences? Numerous twin and a few adoption studies from North America, Western Europe, and Oceania have established that at least in those cultures, and primarily relying on parent ratings, substantial portions of liability are carried by genetic variation, with a heritability coefficient, averaged across many studies, exceeding .8 (Boomsma, Cacioppo, Muthen, Asparouhov, & Clark, 2007; Chang, et al., 2013; Grant et al., 2007; Kan, et al., 2013). Heritability estimates are lower, however, when teacher ratings and self-ratings are examined (Merwood et al., 2013), due to the fact that each twin has a different informant (Kan, van Beijsterveldt, Bartels, & Boomsma, 2014). Yet the heritability of a latent variable for shared parent and teacher agreement was .78 in one study (Derks, Hudziak, Van Beijsterveldt, Dolan, & Boomsma, 2006). Relatively few studies have examined twin concordance of ADHD diagnoses derived from full clinical evaluation or the combining of parent and teacher input on symptoms and impairment.

The variation in results for teacher vs. parent ratings raises questions of rater bias (known as contrast effects) as an influence on heritability estimates. Contrast bias (parents emphasizing differences more in DZ than MZ twins) inflates heritability estimates of activity level in preschoolers (Basque, Martel, Leduc, & Cantin, 2008). Such effects in ADHD ratings appear to depend on what rating scale is used. Reitveld et al. (2011) reported on a longitudinal study of a large sample of twins in Europe, with maternal CBCL ratings at four age points (3, 7, 10, and 12 years). Even with rater contrast effects controlled, heritability was above .7 at each age. Simonoff et al. (2011) confirmed maternal contrast effects but also noted biases in teacher ratings due to twin confusion (known as correlated errors), especially for MZ twins. In other words, many twins have the same teacher, and teachers have more difficulty keeping MZ twins straight in their minds. When these effects were accounted for, heritability was between .6 and .7 in developed nations. Inattention-disorganization and hyperactivity-impulsivity have partially distinct genetic influences (Nikolas & Burt, 2010), underscoring the importance of considering this two-domain structure in any statements about ADHD's etiology.

Nonshared environmental effects account for the remainder of variance in ADHD liability, which distinguishes it from conduct disorder (Burt, 2010). Thus, conduct disorder seems to have a greater component of shared environment than ADHD. This is consistent with a developmental model in which ADHD, a condition influenced by early genetic and nonshared environmental effects, gives rise via family and peer socialization processes to conduct disorder (Snyder, Schrepferman, Bullard, McEachern, & Patterson, 2012).

In response to these findings of high heritability for ADHD, researchers aggressively pursued molecular genetic studies during the period from the late 1990s to now. Some reflections on approaches to molecular genetic studies are in order to aid readers in evaluating his body of work.

In taking a molecular approach, one must consider the conceptual genetic model of the trait or disorder being studied. While this was largely guesswork in the case of psychopathology a decade ago, Figure 14.2 (Hindorff, Gillanders, & Manolio, 2011; Manolio et al., 2009) illustrates one general analysis that is influential in psychiatric and medical genetics of complex disease today. It shows that the magnitude of genetic effect on disease for individual genes grows smaller in a near logarithmic function as one proceeds from rare genes causing genetically simple diseases to common genes acting in concert to influence complex disease.

In the case of ADHD, the most common approach to studying molecular correlates in the past two decades was, from the viewpoint of this model, rather limited. The idea was to look for large effects in candidate genes using common gene variants. These were candidate genes because they were believed for theoretical reasons to be of interest, such as dopamine receptor genes. One early meta-analysis of that literature concluded that six genes have common markers that had been statistically associated with ADHD to date: dopamine transporter (DAT1), dopamine D4 and D5 receptors (DRD4, DRD5), serotonin transporter (5HTTPLR), HTR1B, and SNAP25 (Gizer et al., 2008). However, these in combination account for only 1% of phenotypic variance in ADHD and thus are not clinically useful, and their effects, in terms of our Figure 14.2, are small, with odds ratios around 1.1 (i.e., far too small to be of clinical interest, but potentially adding clues to pathophysiology overall, in conjunction with one another).

A second approach also assumes that ADHD is a product of common variants (the common disease + common variant model), but takes an agnostic approach to which genes are involved. The approach therefore scans the entire genome, called a genome-wide association (or linkage) study or GWAS. With this approach searches are conducted across hundreds of thousands of common markers (usually a particular type of marker called single nucleotide repeat or SNP) distributed across the genome. Somewhat to the surprise and disappointment of many scientists, genome-wide scans generally failed to identify important new genes in ADHD. However, when we consider Figure 14.2, in retrospect this result is not especially surprising. The model in Figure 14.2 predicts that the effects of individual variants are quite small. In GWAS, thousands of statistical tests are required, resulting in low statistical power to detect these small effects. Indeed, individual markers have not been seen reliably for most complex diseases or traits until sample sizes have reached into the range from 10,000 to 30,000 samples. Yet most studies of ADHD used only a few hundred to a few thousand samples.

Nonetheless, a few interesting findings emerged from GWAS of ADHD so far. Novel candidates may warrant follow up, including one that is under a genome-wide significant linkage peak in a meta-analysis, cadherin 13 (CDH13) (Lasky-Su et al., 2008). This gene is expressed in nicotinic receptors and involved in neurite outgrowth (Canino & Alegria, 2008). Further, specific genetic effects, particularly related to central nervous system development, are shared across several major psychiatric disorders (PGC,

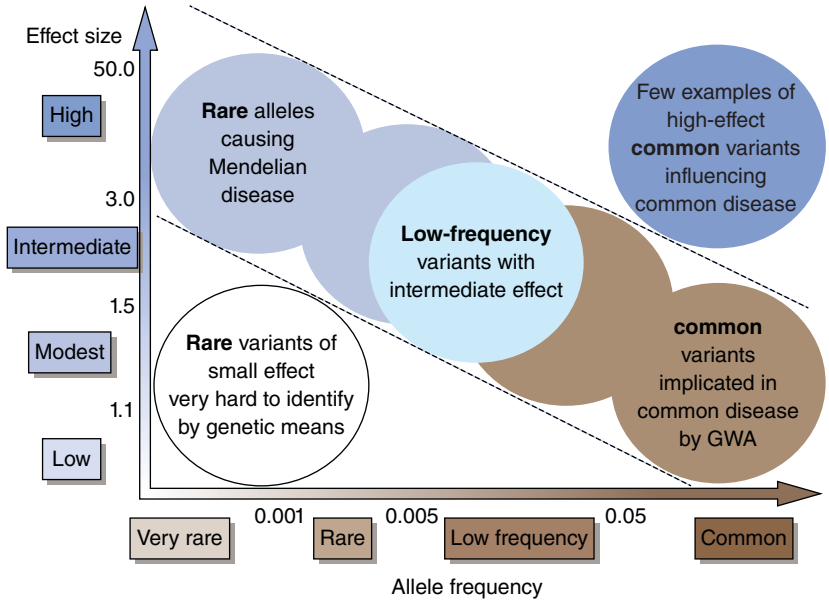

Figure 14.2 Molecular genetic meta-model. See footnote 1. *Source:* Reprinted with permission from T. A. Manolio, F. S. Collins, N. J. Cox, D. B. Goldstein, L. A. Hindorff, D. J. Hunter, . . . P. M. Visscher (2009) Finding the missing heritability of complex diseases, *Nature, 461*(7265), page 749.

2013; Lotan et al., 2014) although ADHD does not fully share in this overlap (Smoller, et al., 2013).

Perhaps most interesting at the present juncture are analytic methods that manage to sum up the effects of all the variants on a chip, whether or not they are initially significant (for description of these methods, see Wray et al., 2014). This approach reveals that when all the common variants are taken into account, in aggregate they account for about 25% of the genetic variance in ADHD (PGC, 2013). Insights regarding molecular genetic overlap of ADHD with other traits and disorders are accordingly now possible and beginning to emerge at a rapid pace as of this writing (Hamshere et al., 2013; Martin, Hamshere, Stergiakouli, O'Donovan, & Thapar, 2015).

These polygenetic analyses confirm that common variants are important, but underscore that they do not act primarily via single gene effects but rather act in concert. That is, they likely operate in ADHD via their joint involvement in biological and metabolic systems. Those systems must now be described (next paragraph). Second, as corollary, other kinds of gene effects not due to common variants are carrying much, perhaps the majority, of the genetic variation in ADHD.

To build on the first of these hard-earned realizations, about the aggregate activity of common variants, will require organizing common gene variants into their chemical and physiological groupings, called gene-based pathways. This approach tests for significant association with an over- or underexpressed pathway and thus has more power than searches for individual markers. A small number of handful studies have attempted this approach with ADHD. Results, while preliminary, are intriguing, linking ADHD to gene pathways involved in synaptic transmission, nicotinic receptors (already one of the biochemical theories of ADHD), neuritic growth, and CNS development (Bralten et al., 2013; Cristino et al., 2014; Hammerschlag et al., 2014; Poelmans, Pauls, Buitelaar, & Franke, 2011; Stergiakouli et al., 2012; Yang et al., 2013). Whether these specific findings will reproduce remains to be seen, but it is likely that more gene-pathway-based approaches will be fruitful in the near future and will eventually converge on new insights.

To build on the related insight, about effects of noncommon variants, requires still another approach. Here, a different model is assumed. As also illustrated in Figure 14.2, instead of a common disease + common variant model, one now adopts a common disease + rare variant model. Here the assumption is that numerous distinct, but individually rare, genetic events are all giving rise to the same syndrome. The goal is to discover some of these rare structural variants, in hopes of gleaning new insights into pathophysiology that may apply to the syndrome more broadly.

Many of these are rare copy number variants (meaning the only difference in the allele is that a given nucleotide sequence is repeated too many times). They can be found by re-analyzing GWAS data. These studies are beginning to emerge on a regular basis and implicate genes involved in neural development, suggesting the beginnings of genetic clues to pathophysiology. Studies of this type are emerging at a steady pace (Elia et al., 2010, 2011; Jacob et al., 2013; Jarick et al., 2014; Lionel et al., 2011; Martin, Hamshere, Stergiakouli, O'Donovan, & Thapar, 2014; Williams et al., 2010). It has been hypothesized that 10–15% of the genetic variation in ADHD may be due to these CNVs. To date, work has been limited because only fairly large variants could be seen to date. As the ability to see smaller perturbations in the genome emerges, more findings in this area will emerge.

Still other rare variants can be discovered by looking within family pedigrees and sequencing exomal regions of the genome (nonsynonymous variants) or by sequencing the entire genome. Both methodologies are on the cusp of widespread application. Novel rare variants are expected, and likely to be discovered, in the process, but each will pertain only to a small fraction of the population with ADHD. If enough are discovered that have large effects, clinicians can test for them, but the real payoff may be in determining their pathophysiological activity to discover more about how ADHD develops in the brain more generally.

Last but far from least, the unexplained genetic variation in attention deficits, impulsivity, and dysregulation may be due to gene × environment interaction or epigenetic effects. This idea is of central importance and the implications are substantial from a multilevel, developmental psychopathology perspective.

Gene–Environment Effects

In the past decade, studies of gene–environment (G×E) effects have become standard in research on development, developmental psychopathology, and clinical disorders. Ever more sophisticated process models are now available, and G×E is approaching the level of a new paradigm for behavioral studies generally, with entire special issues of major clinical and scientific psychopathology journals devoted to G×E in the last couple of years (Nigg, 2013a, 2013b).

The still emerging literature on GxE effects on inattention, impulsivity, activity, or ADHD is promising. An early review (Nigg, Nikolas, & Burt, 2010) indicated reliable and consistent interactions of psychosocial distress measures and genotype for particular candidate genes, notably serotonin transporter and dopamine transporter. Subsequent

work continues to generally support this picture using a range of measures of psychosocial stress and expanding to other candidate genes (Berry, Deater-Deckard, McCartney, Wang, & Petrill, 2013; Elmore, Nigg, Friderici, Jernigan, & Nikolas, 2015; Li & Lee, 2012, 2013; Riva, Marino, Giorda, Molteni, & Nobile, 2015; Sanchez-Mora et al., 2015; van der Meer et al., 2014; van der Meer et al., 2015). However, these studies have generally relied on one or two candidate genetic markers in relation to selected measures of the environment. The hazards of such studies are many. In particular, (1) the environmental measures may be influenced by unmeasured genes and (2) if the allele frequencies are sub-optimal or environmental measures not properly scaled, statistical artifact can easily result (Eaves et al., 2000). Nonetheless, the general picture is that GxE effects are gaining considerable support as a key mechanism in ADHD etiology.

While better modeling will be needed to identify particular genes and particular environments and how they interact, the general approach already shows that larger genetic effects can be seen when looking within different environments. Now, with the existence of G×E established in specific instances and widely accepted conceptually, a particularly salient question for the G×E effect in the development of ADHD as well as normative self-control and self-regulation concerns the nature of the interplay. The idea that different forms of interaction exist and can be distinguished was first proposed over two decades ago by Aiken and West (1991), and has now been rediscovered in the area of G×E for a range of child characteristics (Belsky, Pluess, & Widaman, 2013; Pluess & Belsky, 2011). Figure 14.3, adapted from a recent paper in this genre, illustrates the central question.

The top panel of Figure 14.3 schematizes a vulnerability model. In some environments, genetic risk is not activated, but in other environments it is. This model, consistent with a classic diathesis stress model, has long been the best, if underutilized, general model in psychopathology. The bottom panel illustrates an alternative, which is called a susceptibility or plasticity effect. Here, the clinical genotype is actually a genotype that is maximally responsive to the environment. The genotype confers not vulnerability but *responsivity*. Under negative environments, one sees the typical poor outcome for the risk genotype. But in advantageous environments, the same genotype can have a superior outcome to the alternative genotype.

Numerous hazards accrue to attempting to statistically distinguish these effects. To name just one obvious one, the top panel, extended to infinity, would presumably

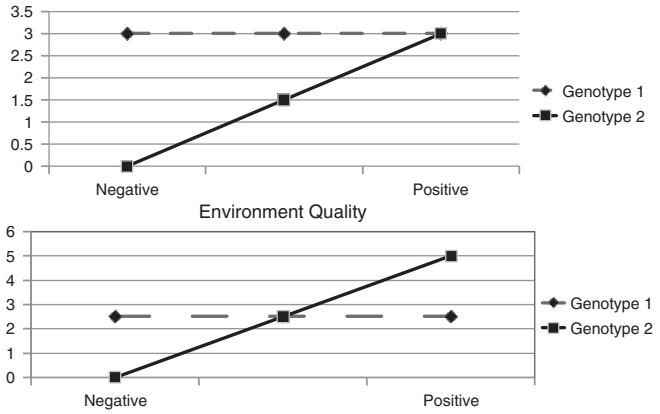

Figure 14.3 Vulnerability versus susceptibility models of G×E effect. *Source:* Adapted with permission from J. Belsky, M. Pluess, & K. F. Widaman, (2013) Confirmatory and competitive evaluation of alternative gene–environment interaction hypotheses, *Journal of Child Psychology and Psychiatry, 25*, page 1136.

eventually show the cross over pattern. However, at a practical level, this and other problems may be addressed with appropriate scaling, consideration of range, and other methods. Now, empirical studies have begun to distinguish plasticity from vulnerability effects in the area of parenting, temperament, and outcomes related in self-regulation of attention and impulse in early childhood (Kochanska & Kim, 2013b; Kochanska, Kim, Barry, & Philibert, 2011).

Further, recent years have seen exciting developments in epigenetics, that is, the recognition that experience can alter the genome—and thus the phenotype—sometimes dramatically. This represents at least one mechanism by which G×E can occur. Epigenetic modification occurs in several ways; one well-known way is through DNA methylation, which entails modification of chromatin, the material in which DNA is housed, to alter gene expression. That is, the expression of much of human variation may not depend only on DNA structure but on the regulatory markings that control whether and how a gene is expressed. Because these mechanisms remain speculative for ADHD, attention, and impulsivity, I do not elaborate further here. However, epigenetic mechanisms may prove extremely important in understanding human behavioral and cognitive development so I return to them later when considering future directions.

These two insights (the importance of G×E and the importance of epigenetic effects) have sparked a renaissance in studies of environmental contributions to ADHD (as well as several other psychiatric conditions) that is changing the face of research in the second decade of

the twenty-first century and may potentially also change the face of clinical practice in the decades that follow. Therefore, the role of the environment in the development of self-regulation, self-control, and ADHD is likely to be much more important than was widely believed ten or twenty years ago. However, this will be a modified understanding from even earlier days when ADHD was assumed to be entirely environmental. Instead of looking at environmental main effects, the field will undertake more specification of for whom (genetically) environments are exerting their effects on development and how (by modifying gene expression) they are doing it.

When it comes to the environmental effects, they must be considered at multiple levels of analysis and stages of development. We can consider the prenatal environment, where maternal diet and maternal stress likely exert influences on the developing fetus. We also can consider the early socialization environment. One interesting gap in our knowledge concerns very early socialization influences on later ADHD. The belief has been that disrupted parenting and discordant parent–child interactions result from, rather than cause, temperamentally mediated child noncompliance and impulsivity. This assumption is well supported by existing data, although problematic parent–child relationships may well be significant maintaining and exacerbating factors related to ADHD, yielding reciprocal, transactional chains of influence in conjunction with the child's core symptomatology (Hinshaw, 1999; Johnston & Mash, 2001). However, nearly all of the studies that support that view were conducted with children beyond the toddler years. Essentially nothing is known about the role of parent–child interchanges in the first year or two of life in ADHD.

ATTENTION AND IMPULSE CONTROL IN DEVELOPMENT: DUAL-PROCESS PERSPECTIVE

In thinking about how attention and impulse control develop, a heuristic model is helpful to organize the vast array of ideas and information available. Here one can gain considerable insight from a fundamental and ubiquitous approach in psychology, known as a hierarchical two-process model. Later it will be noted that more than two processes are involved ADHD. Nonetheless, while this is not a formal model, it provides substantial help with conceptualizing and organizing work in this field.

TABLE 14.1 Type 1 and Type 2 Regulation and Commonly Used Terminology

Type 1	Type 2
Reactive	Effortful
Automatic	Deliberate
Fast	Slow
Incentive motivated	Goal motivated
Hot	Cool
Bottom-up	Top-down
Develop early	Develop late

Two-process models must include the following elements: (1) type 1 process, (2) type 2 process, and (3) resource capacity or motivation[2] that influence the decision set points for which process will engage—in this case, the set point at which Process 2 is invoked to override Process 1. Models of this general nature, with varying specifics, are found historically in the ADHD literature (Nigg, 2001; Nigg, 2000b; Sergeant, et al., 1999; Sonuga-Barke, 2005; Sonuga-Barke, Dalen, Daley, & Remington, 2002), in theories of personality and temperament that relate to self-regulation (Block & Block, 1980) and are in concert with cognitive and social psychology models dating back over 30 years, as several excellent reviews attest (Evans, 2008; Evans & Frankish, 2009; Evans & Stanovich, 2013; Kahneman, 2011).

The perspective herein builds on earlier work by the author and collaborators (Nigg & Casey, 2005; Nigg, 2001, 2000b, 2006), complemented by related work by others (e.g., Sonuga-Barke, 1998; 2002), introduces some modifications in light of recent work in cognition (Evans & Stanovich, 2013), and uses this to describe a heuristic model that can usefully guide thinking both on ADHD and on the overall idea of self-regulation of attention and impulse and its development. From this perspective, the developmental psychopathology story is organized as it relates to disturbances in self-regulation and to ADHD.

The model has two distinct processes; they can be thought of as two aspects of a single system or as two systems (while experts in fact debate this last nuance, for present purposes either view is acceptable). These are termed type 1 and type 2 processes and heuristically summarized by their common appellations in Table 14.1.

Type 1 processes provide automatic handling of routine information, emergency reaction, and alert us to salient and unexpected information. Type 1 processing is the pre-

[2]The capacity or motivation aspect is also part of the model if it is recast as a single-process models with two aspects (Kruglanaski, 2012).

sumed default: most behavior is automatic, presumably to conserve the organism's energy. Type 2 processes override stimulus-triggered responses and allow us to regulate our focus and our action in response. How does the mind determine whether to follow type 1 processing or to invoke the more costly and resource-intensive type 2 processing? This determination must take into account both the incentive value of the problem (motivation) and overall available resources (energy, arousal, and intellectual or working memory capacity). Therefore, the model must also include capacity or resource constraints that influence relative involvement of type 2 processes in a given situation.

Proposals for what goes wrong in ADHD invariably invoke a breakdown in type I, type 2, or resource-capacity domains (or combinations thereof) to explain the syndrome. A critical question for theory of ADHD is, therefore, this: does regulatory failure occur because the type 2 process, once invoked, was ineffective? If so, was this ineffectiveness due to insufficient capacity or resources or to some other problem? Or does failure occur because the type 1 process failed to function properly and did not invoke the type 2 process in the first place? Theories of ADHD can be grouped according to which of these scenarios they emphasize.

Type 1 Process

Type 1 regulation is characterized by relatively automatic or autonomous processing. It is stimulus driven, rapid, occurs without intent or volition, and requires minimal working memory resources or application of attentional control. As conceived in relation to attention and impulse control, it is implemented primarily in posterior and subcortical neural networks, although functionally connected frontal brain areas can also be involved. It can interrupt deliberate activity, or be suppressed by it, but it is distinguishable from deliberate mental activity. An example of type 1 regulation is when behavior is automatically interrupted in response to a surprising sound or a frightening event (an example of subcortical activation sending involuntary signals into the attentional sphere and interrupting working memory and motor programs; (Gray, 1982; Gray & McNaughton, 1996; Kagan, Reznick, & Snidman, 1987), or when attention is automatically captured by a sudden movement (an example of a ventral attention network sending signals to the cognitive control system). In each case, attention automatically reorients to the new event, and other behavioral routines are interrupted. Thus, when she notices something anxiety provoking, a child may direct her attention to the concerning event or person—reallocating and narrowing the focus of attention (Derryberry & Tucker, 1994).

An important principal in a dual-process account of self-regulation or ADHD entails the intersection of emotion and cognition (Nigg & Casey, 2005). In many psychology writings, type 1 processing is associated with relatively more affective response and type 2 with relatively less affective response and more cognitive processing or reasoning. While that summary has some value, readers are encouraged to think integratively about how emotion and cognition interplay in the moment-to-moment regulation of behavior. That is, emotion-free cognition and cognition-free emotion do not really occur. Rather, we are referring to the relative strength of emotional arousal.

Put another way, the incentives that shape attention can be sufficiently immediate as to triggering "hot" type 1 processing, or sufficiently distal as to require "cool" or type 2 strategic processing to attain them. Thus, even though attention is usually viewed as a cognitive process, it is just as often (if not always, to some degree) motivated by incentive concerns. These same incentives can also influence impulse control, leading either to a very strong impulse to action (e.g., excitement from an imminent reward) or to inhibiting some or all behavior (e.g., confrontation with an anxiety-provoking or unfamiliar situation). Such motivated responses are often relatively spontaneous, and they are relatively more automatic than the more deliberate responding characteristic of effortful control. In short, the type 1 response, often called the prepotent response in ADHD theories, can arise for multiple reasons—emotional salience (fear or excitement, which are associated heuristically with limbic circuits, in particular the amygdala), overlearning (associative or implicit learning, which can be associated in part with striatal structures), or response set (multiple prior instances of an overpracticed response). In each case, the response is activated without intent. It has become, or always been, automatized.

An interesting possibility, though largely bypassed here, is whether children with ADHD have difficulty automatizing behavior (Huang-Pollock & Karalunas, 2010). That is, in ADHD self-regulation may remain excessively dependent on type 2 process when it should not, hurting overall regulatory efficiency and causing effortful tasks to be overwhelming. An analogy would be poor readers for whom each word is effortfully sounded out rather than effortlessly recognized.

Type 2 Process

Type 2 regulation is characterized by demand on working memory or attentional resources, is experienced

subjectively as effortful or deliberate, is controlled, and is capacity limited. Its outcome is not automatic, but flexible (see thoughtful discussion by (Thompson, 2013). An example of such regulation is when I consciously bite my tongue to avoid interrupting a long-winded colleague so as to keep a New Years' resolution to be more patient. It is implemented to an important extent in prefrontal cortex, although it also involves the anterior cingulate cortex, and several other cortical and subcortical brain areas become involved due to their functional connection to prefrontal cortex. It serves to prime, bias, direct, or suppress the type 1 processes. This suppression is hypothesized to be implemented neurally by exertion of inhibitory projections backward to parietal cortex and downward, particularly via frontal-limbic-thalamic and frontal-striatal-thalamic and cortical-subcortical neural circuits.

Type 2 processing can be linked with productive concepts from the study of preschool temperament that refer to *effortful control*—the ability to delay or interrupt task-inappropriate behavior (Rothbart & Bates, 1998), or to assign positive motivation to a required task (Kochanska, et al., 2011). Effortful control shows longitudinal stability, with high scores for this ability associated with development of adaptive behaviors (Kochanska, Murray, & Coy, 1997; Kochanska, Murray, & Harlan, 2000), it also was helpful associations to developmental psychopathology, which help us integrate multiple literatures. Thus, excessively *high* control is associated with internalizing problems, while *low* control is associated with externalizing behavior problems over the preschool years (Murray & Kochanska, 2002).

Type 2 processing often requires working memory, and so is related with the idea of executive functioning, which has been a common neuropsychological approach to conceptualizing ADHD. It is widely agreed both that executive functioning is central to understanding attention and impulse control and that it is an underspecified construct (Pennington & Ozonoff, 1996; Zelazo et al., 2003). In a neuropsychological framework, executive function refers to strategic or relatively deliberate regulation of response to context and maintenance of behavior in relation to goals (Pennington & Ozonoff, 1996). While often supplanted by the more contemporary term cognitive control, the concept of executive function has additional connotations. It seems to reflect several component operations of which working memory is one; other important abilities include the capacity to temporally sequence information (Castellanos & Tannock, 2002; Fuster, 1997)—part of a broad but not a narrow conception of working memory (Baddeley, 2012), the ability to suppress prepotent responses whether or not information is being held in working memory, and the ability to shift set. Numerous proposals for how to componentialize executive functions testify to its historical under-specification as well as its substantial heuristic utility (Barkley, 1997; Dempster, 1993; Engle, 2002; Friedman & Miyake, 2004; Logan, Cowan, & Davis, 1984; Lyon & Krasnegor, 1996; Mirsky & Duncan, 2001; Miyake et al., 2000; Monsell & Driver, 1998; Nigg, 2000b; Pennington & Ozonoff, 1996). This reflection on executive function also underscores the close relationship of the neural bases of deliberate control of attention and impulse (as well as the regulation of emotion) (Nigg & Casey, 2005; Posner & Rothbart, 2000).

With regard to impulse control, similar frontal-subcortical neural circuits are implicated in suppressing responses (Casey, et al., 2002). For example, suppressing inappropriate motor response during complex behavior appears to involve the dorsolateral prefrontal cortex, at least in young children (Diamond, Prevor, Callender, & Druin, 1997), as well as the orbitoprefrontal cortex (Aron, Fletcher, Bullmore, Sahakian, & Robbins, 2003; Posner & DiGirolamo, 1998) and the subcortical connections to each. Indeed, the subcortical and striatal structures to which these prefrontal regions are connected may be crucial in the actual suppression of a response (Kimberg & Farah, 1998) at least in certain contexts (Nigg & Casey, 2005). A developmentally oriented process conception of executive functioning emphasizes deliberate problem-solving steps, such as representing and manipulating the problem in working memory (planning), carrying out an intended action rather than a competing action, and detecting mismatch to expected results or success (Zelazo et al., 2003). Those functions likewise have clear relevance to attention and impulse control and all refer to type 2 regulatory processing.

Development, Socialization, and the Two-Process Model

The development of these neural and behavioral systems is in constant interplay with the child's interpersonal world as elaborated in more detail by us in the second edition of this handbook (Nigg, Hinshaw, & Huang-Pollock, 2006) via mechanisms like parenting attunement, verbalization of affect, and subsequent routinization, limit setting, and other activities, all of which operate in complex interchange with child reactivity and control to shape consolidation of self-regulation (Choe, Olson, & Sameroff, 2013; Kochanska & Kim, 2013a, 2013b; Koenig, Barry, & Kochanska, 2010). Neural development and self-regulation cannot develop apart from the early

parent–child relationship. Indeed for the first few months of life the mother provides the type 2 processing for the child and is the child's regulatory system in many respects. Scaffolding by caregivers in the early rearing environment, the modulation of stress, and the success of early learning all emerge as important in the early developmental consolidation of both type 1 but particularly type 2 self-regulation (Barry, Kochanska, & Philibert, 2008; Cecil et al., 2012; Kochanska & Kim, 2013b; Koenig, et al., 2010). Furthermore, it is likely that the aforementioned gene × environment interactions affect how parenting and child temperament interplay (Rothbart & Posner, 2005; Sheese, Rothbart, Voelker, & Posner, 2012). In short, while the current essay elaborates the within-child components of cognition and self-control, readers should be cognizant that interactions and transactions between within-child factors and environmental influences are crucial in any complete account of how self-regulation, inattention, or impulsivity develop. The transactional account is constrained in this chapter due to space, not due to its developmental importance.

Type 1 processes mature more rapidly than type 2 processes, commensurate with the brain's developmental maturation from rostral to caudal and the importance of prefrontal cortex in the implementation of advanced type 2 processing. Thus, behavior of young children is relatively less governed by type 2 processing than behavior of adults. Behavior of toddlers reflects relatively more precursive type 2 or effortful self-regulation than behavior of infants.

Infants allocate their attention (and their motor responses) simply on the basis of stimulus response and reflex response, which are largely midbrain-mediated processes that correspond to the reflexive attentional mechanisms discussed earlier. However, by later in infancy, sometime in the 1st year of life, children begin to respond to cues for incentives by directing their attention and making motor responses such as approaching a potential reward or withdrawing from a potentially distressing signal (Rothbart & Rueda, 2005). These latter responses correspond to affectively based type 1 allocation of attention and control of behavior. By the beginning of the toddler period, roughly about the age of 14 months, infants can be observed to deliberately turn their attention away from upsetting material, exemplifying a precursor to deliberate regulation of behavior and affect by executive control, and thus the beginnings of self-control (Rothbart & Bates, 1998).

In the toddler years, type 2 control of attention and impulse, in the guise of effortful control, develops rapidly. By about 30 months of age, children can begin to inhibit stimulus-driven motor response (Diamond et al., 1997; Rothbart & Posner, 2005). For example, by this age, they can engage in interference control, go/no go, and stopping tasks (Diamond et al., 1997). Diamond and colleagues documented a steady development in the ability to inhibit competing, stimulus-driven motor responses by ages 3, 4, and 5 years; similar work is reported by Zelazo and colleagues (2003).

In middle childhood, many aspects of type 1 regulation mature, while type 2 regulation continues to develop. Huang-Pollock, Carr, and Nigg (2002) compared children in second through sixth grades on a computerized selection task evaluating two kinds of attentional selection. Late selection was progressively more mature in the older groups. Even sixth-graders were still well below adult level capabilities, although they were notably better than fourth graders. In contrast, early perceptual selection was essentially fully mature, at adult levels, even in the second-graders (Huang-Pollock et al., 2002). Similarly, Reuda et al. (2004) examined exogenous orienting (type 1), alerting (arousal) and strategic orienting (type 2). The exogenous orienting was essentially fully developed by the 6–9-year-old age period. All of these data are consistent with the proposition that relatively automatic type 1 processes develop earlier and complete their development at a much younger age than do cognitively demanding type 2 processes.

This general pattern of development mirrors the nonlinear and dynamic development of the brain systems involved. In particular, the cortical mantel develops in a partial caudal-rostral gradient, but with a peripheral-to central tendency, so that the most anterior and posterior portions of the cortex mature first, followed by regions of prefrontal cortex. In addition, myelination as well as pruning of neural circuits to improve their specialization and efficiency proceed all the way into early adulthood (Benes, 2001).

In adolescence, the picture becomes more complex because cortical and subcortical brain regions and their supported capabilities are maturing in nonlinear, dynamic fashion. Thus, important changes in type 2 processes and regulation occur during adolescence. Here some aspects of controlled attention reach adult levels, but many aspects of impulse control do not. In particular, it is interesting that cool executive function or response control without strong emotional or incentive content improves in linear fashion and reaches adult levels by about 20 years of age (Hare et al., 2008). However, when hot decision making is involved (imminent emotional information and in particular, social cues of emotional salience), then adolescents have more failures than children or adults

(Casey & Caudle, 2013; Casey et al., 2011). Thus, adolescents have a unique impulsivity around socially heightened reward or reward-salient cues that will alter the risk profile for those with ADHD or with propensity to impulse control disorder. At the same time, in adolescence demands for cognitive control increase (e.g., multiple class schedules in high school) that require more executive functioning; those who are weak in this area may start to see more clinical impairment. Hyperactivity normatively levels off in adolescence (an ADHD adolescent does not run around the room, the way a 6 year old with ADHD does).

In turn, as the child matures in the social context, the strength of this two-process self-regulation system is likely to influence the child's capacities to be normally socialized by average expectable parenting and peer environments (Cicchetti & Lynch, 1995) and achieve adequate socialization adaptively in adverse or suboptimal caregiving environments. The import here is that if a child has very strong reactive processes (e.g., extremely strong negative affect), these may interfere with development of effortful control, in turn further weakening ability to regulate the reactive affects. Conversely, weak effortful control as an early temperamental characteristic could lead to difficulty with affect regulation as part of a two-way mutual influence process. This formulation may help to explain why executive and affective difficulties so often co-occur in children with disruptive behavior problems and ADHD.

Additional Considerations

Hierarchy Model of Complexity

This last point highlights that type 2 processes are not all unitary, but rather exist on a hierarchy of complexity. Representing a stimulus-response association is less abstract than remembering that the association only applies in certain contexts, that is, a meta rule. Likewise, considering an action's consequences in the next few minutes or hours is not the same operation, nor does it rely on the same neural bases, as considering consequences over much longer time periods. It can be argued that in the brain a rostral-caudal control gradient organizes type 2 or control processes, with the most anterior aspects of PFC involved in the most abstract (meta-rule, or time duration) control tasks and operations (Badre & D'Esposito, 2009). Because anterior PFC projects unidirectionally to premotor cortex, as well as bidirectionally with dorsal and ventral lateral prefrontal cortex as well as medial prefrontal cortex (Petrides & Pandya, 2007), it is anatomically reasonable to consider top-down control operations to be involved in both motor and attentional control. This becomes important later when considering recent advances in neuroimaging of ADHD.

Functional Linkage of Attention and Impulse Control

Both for expository purposes and functionally, the elements of attention and impulse control can be understood as partially distinct. They do not always operate in perfect tandem; they may develop at different rates and they can be measured in distinct ways. In particular, attention can regulate mental processes, even when no motor behavior occurs. While one can speak of cognitive impulsivity (e.g., racing thoughts in hypomania, or inability to suppress thoughts in ADHD), to avoid confusion, regulation of mental contents is treated here under the purview of attention. The term *impulsive* is reserved for overt motor responses and to decision making that results in an associated motor, vocal, or overt emotional response.

Yet this separation of attention and impulse control should not be overstated. Attention and impulse control are closely related both functionally and developmentally. This is important because it is tempting to link problems in regulation of impulse with faulty type 1 processing and problems in regulation of attention with faulty type 2 processing. While doing so can be helpful in some respects, it is a misleading simplification in terms of development or neural function. Attention can regulate impulse and impulse can capture attention. As noted earlier, for a young infant attention is captured involuntarily by an attractive object and she reaches for it automatically (type 1 process). Soon thereafter, a toddler can deliberately look away from a tempting but forbidden object, using attention to regulate impulse as well as emotional arousal (type 2 process). Thus, from early infancy on, attention assists with self-regulation and impulse control (including emotion regulation, behavioral control, and cognitive control) (Pollak & Tolley-Schell, 2004; Rothbart & Rueda, 2005).

Functionally, some kinds of individual variation in impulsivity can be seen as variation in stylistic features of type 2 processing, that is, simply preferences for reflective or nonreflective decision making. Other kinds of individual variation in impulsive decision making are not so easily seen as part of type 2 process, but rather as type 1 process (e.g., intensity of response to incentive). Further, in day-to-day behavior attention and impulse often act in concert or in tension. Both can be influenced, for example, by sensory reflex response. Likewise, both are influenced by strong affective arousal. In the case of strong anxiety (signal of *possible* threat) or fear (*actual* threat), attention is captured and existing impulses are suppressed and replaced by impulses related to the anxiety or fear

(e.g., impulse to flee). In the case of strong excitement due to potential reward, attention is captured and impulses are activated toward the incentive. Likewise, as noted before, the neural systems that support certain attentional skills are closely related to those that support control of motor responses, or impulses (Calkins & Fox, 2002). Further, one can easily think of intersections that do not easily map on to a discrete process model. If the keys are locked in the car because I got distracted as I quickly slammed the door, which impulse control process is faulty? Or is the impulsive action actually an instance of inattention?

Summary Comments About Two-Process Model

An essential qualification is that both attention and impulsivity are multicomponential—neither is a unitary construct, and so neither can be summarily described in terms of the two-process model without further differentiation. The subcomponents of attention, as well as of impulse control, develop dynamically, at different rates, integrating in different ways at different points in development, all reflecting the dynamic nature of neural maturation. In what ensues these component operations and their partially distinct neurobiology are noted. This is done via a taxonomic approach to the various functional domains at hand, as the discussion outlines the different types of regulation and their components relate them to development and to psychopathology.

Therefore, having outlined a fundamental heuristic model, and described the potential to locate developmental breakdowns in a handful of key processes, the essay can now consider in more depth the elements of attention and the elements of impulsivity *per se* and how they might develop or go awry in development.

ATTENTION: CONCEPTUAL FRAMEWORK AND KEY ADHD-RELATED EFFECTS

Definition

By classic definitions, attention refers to the facilitated processing of one source of information over another, although broad usages of the term can include capacity pool (Engle, 2002), as well as response readiness, arousal, regulation (Taylor, 1995), and other abilities (Mirsky & Duncan, 2001). With regard to mechanisms, as outlined by Yantis (1998), attentional selection can be based on spatial location (Eriksen & Hoffman, 1972), object features (Treisman & Gelade, 1980; Wolf, 1998), timing (Shapiro & Raymond, 1994), movement, or other object characteristics (Kahneman & Henik, 1981). Attentional selection is influenced by two overarching component functions, underscoring a dual-process theme: (1) bottom-up stimulus-driven processes that are relatively automatic and relatively early developing, and (2) top-down goal-driven processes that are strategic, relatively deliberate, related to the concept of executive control, and later developing. Consistent with the overarching framework used here, it has long been recognized that these two types of processes interact continuously, each placing constraints on the other (Schneider & Shiffrin, 1977). Researchers attempt to isolate these two influences in varying ways, depending on part on the age of the child. At the same time, as noted, often overlooked in the purely cognitive approaches to attention is the role of affective motivation in attentional allocation (Nigg & Casey, 2005; Pennington, 2002). Another limitation to this general formulation occurs in very early infancy. While one might see a semblance of exogenous versus endogenous attention in infants, top-down control supported by prefrontal cortex is not possible for very young infants. Their attention is governed by multiple processes, but these do not map neatly onto the two-process model.

However, even without considering emotion or infant development, the complexity of the cognitive component of attention alone has led to a massive literature that cannot be adequately captured in less than book length (de Fockert, 2013; Posner, 2004; Srinivasan, Thorpe, & Nunez, 2013). Highlighted here are certain aspects of attention that have been particularly influential in studies of attentional disorders and ADHD, that may be of most interest to students, or that suggest directions for the future.

Visual attention is the most well-understood modality of attention and therefore most often examined in developmental psychopathology. While not all aspects of visual attention generalize to auditory attention, a useful understanding of the principles of attention can be gained by considering results of visual attention studies and so they are the focus here.

Attention in the Brain

Turning to the brain, one recent perspective suggests six relevant and partially dissociable functional neural networks involved in attention. Figure 14.4 illustrates four of these putative cortical brain networks as recently synthesized from task-based and resting state functional brain imaging literature (Power et al., 2011) and consolidated recently by Petersen and Posner (2012) in an update of their earlier influential model of attention (Posner & Petersen, 1990).

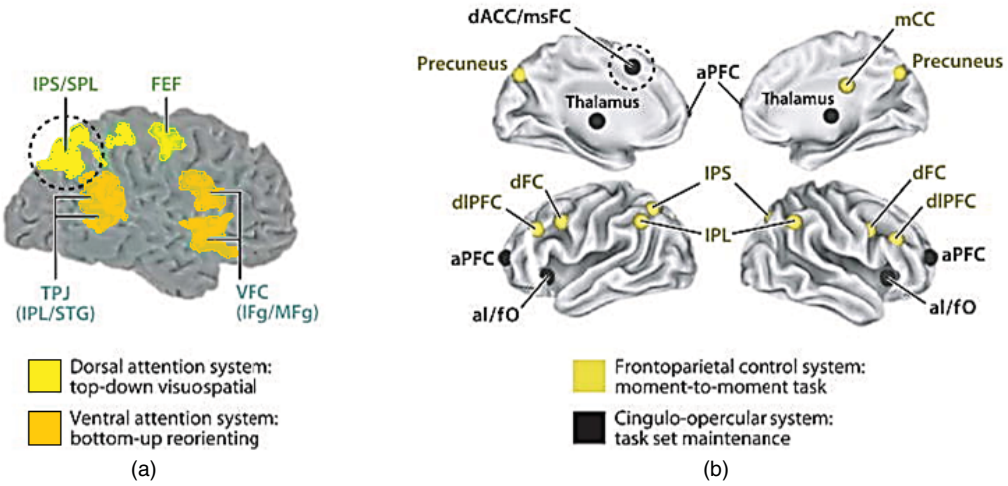

Figure 14.4 Brain attention networks. Panel a: Attention networks. The dorsal attention network = interparietal sulcus (IPS), frontal eye fields (FEF); it is associated with strategic direction of attention. The vental attention network includes temporal-parietal junction (TPJ), inferior frontal gyrus (IFG). It is associated with bottom-up capture of attention. Panel b: Executive control networks involved in higher order attentional allocation and control on task. Frontoparietal network includes dorsolateral PFC (dlpfc), IPS, medial cingulate (mCC); cingulo-opercular network includes dorsal anterior cingulate (dACC), anterior pole (aPFC), fronto-operculum (Al/fO), and thalamus as well as regions of striatum not shown. These canonical networks are inferred from functional connectivity as well as task based functional MRI data. For detailed discussion see Petersen & Posner (2012). See footnote 1. *Source:* Figure adapted with permission from Petersen, S. E., & Posner, M. I. (2012). The attention system of the human brain: 20 years after. *Annual Review of Neuroscience, 35*, page 76.

Panel (a) depicts two now well-recognized networks for the orienting of visual attention (Corbetta & Shulman, 2002). A dorsal frontoparietal network is engaged during top-down control of attention or goal-directed attention. It includes the frontal eye fields and interparietal sulcus (IPS). A ventral frontoparietal network is engaged during stimulus (or bottom-up) capture of attention and includes the temporoparietal junction (TPJ), the supramarginal gyrus, and inferior frontal gyus[3] (Chica, Bartolomeo, & Lupianez, 2013; Corbetta & Shulman, 2002; Thiebaut de Schotten et al., 2011). Note that while these two networks are well defined, an entire network does not inevitably activate in lock-step during all attentional tasks. For example, in the ventral network, TPJ and inferior frontal gyrus activation can be dissociated based on whether a novel stimulus is expected or unexpected (Shulman et al., 2009). Further, the top-down control of visual versus auditory attention likely share some features of attention (Petersen & Posner, 2012) but also differ somewhat anatomically with regard to perceptual signals. For example, while both involve middle and inferior frontal gyrus, the frontal eye fields are not as involved in auditory task control (Braga, Wilson, Sharp, Wise, & Leech, 2013). It is crucial to add that additional circuits or loci not shown here are engaged in attention, particularly when attention is motivated. These would include subcortical and basal ganglia brain regions as well as network-specific thalamic nuclei depending on the nature of the visual stimulus. Thus, the focus on cortical networks here is only part of the brain's overall engagement in attention.

The map to type 1 and type 2 processing for these two particular circuits is helpful yet rather incomplete. While most conceptions grant some degree of strategic control of attention to the dorsal network in the sense of endogenous orienting, the orienting systems are primarily involved in allocation of attention, but not more difficult control tasks like suppressing interference, handling response conflict, or complex working memory tasks. For these types of challenges we must invoke additional neural networks.

Experts disagree as to whether executive control is handled by one or two neural networks (Botvinick, Braver, Barch, Carter, & Cohen, 2001; Petersen & Posner, 2012), but these perspectives do not dramatically change the story here. The perspective that argues for two such networks (Dosenbach, Fair, Cohen, Schlaggar, & Petersen, 2008; Petersen & Posner, 2012) proposes the following.

[3]Some renderings include the frontal operculum (Chica et al., 2013, as cited in text), but here I follow the version provided by Petersen and Posner (2012), who suggested differentiating the ventral network more fully from the fronto-opercular network.

As depicted in Figure 14.4, panel (b), there are two putative networks involved in executive functioning. In keeping with our model of hierarchical control in prefrontal cortex, these executive (or task-control) circuits are engaged when *complex* attentional strategies are needed. The frontal-parietal-task control network (depicted in yellow), which is more anterior to the dorsal attention network, includes the dorsolateral prefrontal cortex. Petersen and Posner (2012) propose that it is involved in initial task evaluation and engagement, although the hierarchical model described earlier might amend this to propose that it is engaged in working memory and other control tasks that do not require multi-level switching or context processing. The cingulo-opercular network (in black) includes the remaining regions usually associated with executive control including the lateral frontal pole, dorsal anterior cingulate, dorsolateral anterior prefrontal cortex, and anterior insula. Petersen and Posner (2012) proposed that it is involved in maintaining effort on a task and suppressing competing information. It may also be engaged in particularly difficult task switching paradigms, according to the hierarchical model. In other words, depending on task complexity, abstraction, and duration, type 2 processes or attention allocation will involve both the dorsal attention and one or both executive control networks.

Two other networks are important that are not shown in Figure 14.4. A so-called *default mode network* is also involved; it includes the posterior cingulate cortex, the ventromedial prefrontal cortex, lateral inferior parietal lobes, and medial temporal structures. Its functions are still debated, but it activates when task control is relaxed and de-activates when task control is engaged. Yet it also is active in many other task situations, so it may be important to some tasks such as determining the relative focus on internal and external stimuli, in retrieving autobiographical information, or in integrating recent experiences (Spreng, 2012). The posterior cingulate cortex in particular may be involved in regulating consistency of responding (Leech & Sharp, 2013) and so may be relevant to resource allocation and response variability, as discussed in subsequent sections. Notably, the default mode network appears to have altered connectivity in ADHD as well as other disorders (Fair et al., 2012). The final network is an alerting (or, in some conceptions, arousal) network, which is discussed subsequently under the section heading, *capacity*.

This multi-network model helps us heuristically think about the ADHD clinical picture. For example, a common clinical observation in ADHD is that the child cannot focus on their homework or on what they are being told to do (weak controlled attention), but they can focus for hours on an engaging videogame (attentional capture) while being unable to disengage from it upon instruction (weak controlled attention). Thus, the two-process/three-network model helps us resolve the superficial paradox of situational-specific attentional focus in children.

Brain Imaging, Attention, and ADHD

What do brain imaging and cognitive studies tell us about the integrity of attentional processes and their neural supports in ADHD? Numerous MRI findings have provided consistent evidence that at the group level, neural regions and networks associated with type 2 attention processes are altered in function or development in groups of children with ADHD (Bush, 2010; Durston, van Belle, & de Zeeuw, 2011; Rubia, 2011). Key findings from MRI studies of the brain in recent years are noted here, with an emphasis on meta-analytic findings when available. Then, studies of attention itself (not of brain function), conducted in the laboratory under controlled conditions, are considered in relation to ADHD.

Functional MRI studies are quite interesting in regard to the two-process model and the circuits just described. A meta-analysis (Cortese et al., 2012) covering data through 2011 identified 55 relevant functional MRI studies with a total of 741 ADHD and 801 comparison subjects. That meta-analysis unfortunately was quite limited in that it did not report effect sizes. However, it did conclude that ADHD was associated with abnormal (mostly hypoactivation) response in multiple brain nodes that are part of distinct brain circuits. While it relied on canonical networks suggested from a study of 1,000 adults (Yeo et al., 2011), these are similar to those described in Figure 14.4. Cortese et al. concluded that in addition to frontal-striatal circuitry, in children there was abnormal hypoactivation in the ventral attention network, while in adults there was abnormal hypoactivation in the dorsal attention network. These results were not explained by either comorbid conditions or treatment history. In addition, they highlighted that findings in a smaller number of studies related to hyperactivation of the default network as well as sensory networks (vision) and hypoactivation of motor networks that need further exploration. Again, it is important to point out that the method used in this analysis relied on so-called functional networks that are being explored in the brain using MRI; these are confined to cortical networks and do not represent thalamic, limbic, or other subcortical components of these and other networks in the brain.

A second meta-analysis took a different approach, enabling consideration of subcortical areas and thus filling

in a gap from the preceding study (Hart, Radua, Nakao, Mataix-Cols, & Rubia, 2013). They selected studies using task-based MRI that the authors considered to be measures of attention including divided attention tasks (e.g., oddball), sustained attention (e.g., continuous performance test), and flexible attention (e.g., mental rotation). The results are reproduced in part in Figure 14.5. They further highlight the role of breakdown in attention-related neural circuits in cortical areas, as well as bringing to bear the important subcortical components of attention control. The figure depicts that ADHD is associated with regional hypoactivation during attention tasks in key nodes of the frontoparietal task control network (notably, dorsolateral prefrontal cortex) and associated subcortical components of thalamo-cortical-striatal neural loops involved in cognitive control, including putamen, caudate, and portions of the thalamus. It also shows altered activation in the insula and inferior parietal lobe, in the precuneous, and increased activation in the left cuneus and right cerebellum.

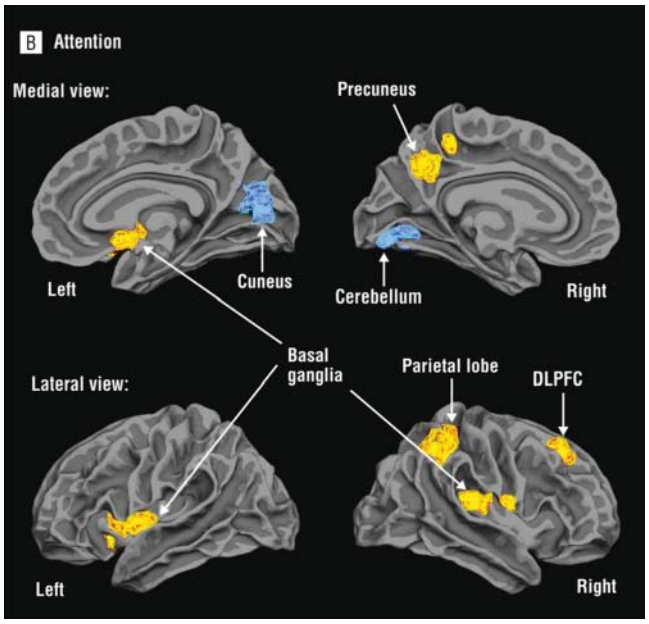

Figure 14.5 Altered brain activation during attention tasks in ADHD. ADHD associated on attention tasks with decreased activation in the right dorsolateral prefrontal cortex (DLPFC), left putamen and globus pallidus, right posterior thalamus (pulvinar) and caudate tail extending into the posterior insula, in the right inferior parietal lobe, and in the precuneus and superior temporal lobe. Increased activation in the left cuneus and in the right cerebellum. See footnote 1. *Source:* Adapted with permission from H. Hart, J. Radua, T. Nakao, D. Mataix-Cols, & K. Rubia (2013), Meta-analysis of functional magnetic resonance imaging studies of inhibition and attention in attention-deficit/hyperactivity disorder: Exploring task-specific, stimulant medication, and age effects, *Journal of the American Medical Association Psychiatry, 70*(2), page 191.

Whenever we consider breakdowns in neural systems, we must recognize that they may be disrupted via their interconnecting pathways rather than their modular loci. For example the distributed loci of the dorsal and ventral attention networks are thought to be connected via long fiber connections that lie along the longitudinal fasciculus (Chica et al., 2013) and that speculatively may participate in connecting the distributed regions of these attentional networks. However, note that these fibers may also form connections for the executive control network (the fourth network shown earlier in Figure 14.4). Integrity of these long fiber connections can be queried using a different MRI technique called *diffusion tensor imaging* or DTI. DTI uses the molecular spin of ions to gauge direction of water or fluid flow in the brain; that flow tends to be directional where axons are well developed and diffuse where they are less developed. Leaving aside here several complexities in interpreting that signal, from a simplified point of view we can consider the degree of directional water flow as an index of axonal integrity at the level of white matter microstructure. Several studies have taken this approach with ADHD.

A meta-analysis is again helpful, pooling multiple studies of diffusion tensor signal (measuring white matter development) in ADHD children and adults. Although the collective database remains small (9 studies, 173 ADHD and 169 control participants from 5 to 49 years of age), one consistent finding in research on ADHD in the past decade has been alterations in white matter microstructure along the superior longitudinal fasciculus (van Ewijk, Heslenfeld, Zwiers, Buitelaar, & Oosterlaan, 2012). Figure 14.6 reproduces their key results. Findings that held across the pooled data are highlighted with blue coloring available online. Note the second column in the figure, showing effects for the right anterior corona radiata. This was the largest cluster found, and as the authors noted probably incudes parts of the superior longitudinal fasciculus, implicating altered development of fibers that support top-down control of attention via either the dorsal attention network or the frontal-parietal task control network. It was notable that there were stronger effects in younger children (Nagel et al., 2011), suggesting the potential to use this technique to map development of ADHD.

Laboratory Tests, Attention, and ADHD: Type 1 Attention

Laboratory tests of attention are illuminating but the literature is vast. Type 1 attentional regulation can be studied via experiments to assess reflexive orienting and perceptual selection, among others. Other experiments have tapped

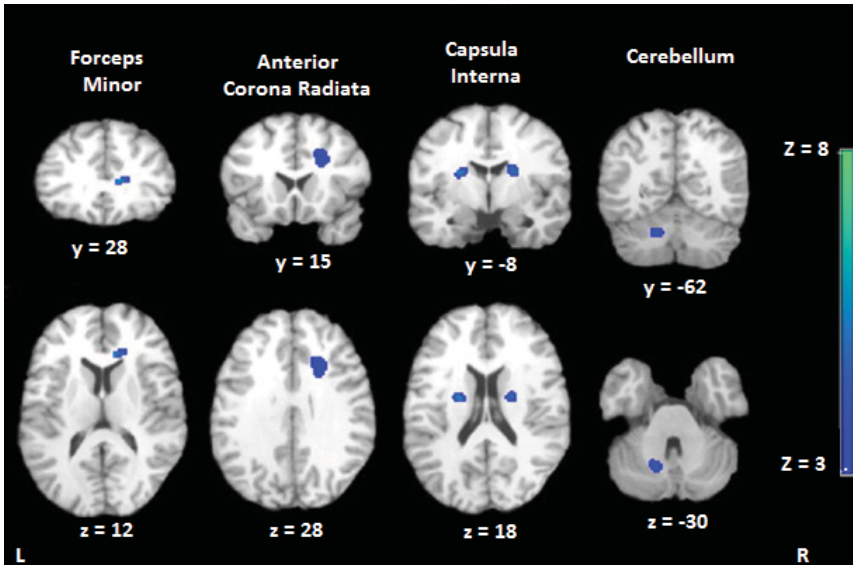

Figure 14.6 Figure 6: White matter microstructure and ADHD. Meta-analysis results for fractional anisotropy effects ADHD versus non-ADHD (all effects $z > 3$, $p < .05$ corrected). Top row: Coronal view. Bottom row: Axial few. L = Left, R = Right. See footnote 1. *Source:* Reprinted with permission from H. van Ewijk, D. J. Heslenfeld, M. P. Zwiers, J. K. Buitelaar, & J. Oosterlaan, (2012) Diffusion tensor imaging in attention deficit/hyperactivity disorder: A systematic review and meta-analysis, *Neuroscience & Biobehavioral Reviews, 36*, page 110.

type 2 attentional processes via strategic attentional orienting, late stage selection, task switching, working memory, and interference control tasks. Note that when it comes to type 2 processes, most of the ADHD-related literature involves tasks that engage the frontal-parietal network as well as the dorsal attention network, so clear conclusions isolating their involvement is difficult in both MRI and cognitive studies. Nonetheless, we can make several observations.

Perhaps the most fundamental type 1 process is orienting to an unexpected stimulus, called exogenous orienting and also sometimes referred to as covert orienting because it is nondeliberate and can occur without eye movement (Carrasco, 2011). A literature has examined ADHD on basic computerized visual orienting tasks to test this function, while a few studies have added ERP recordings as well. With regard to the basic orienting to a stimulus or cue, one early meta-analysis concluded that the salience network was operating normally in ADHD (Huang-Pollock & Nigg, 2003). However, the studies reviewed there failed to carefully distinguish unwarned alerting, an important function of attentional capture albeit one dependent on the state of arousal or capacity as much as on type 1 process per se. Studies using ERP to examine the early processing of cues seem to suggest that when failures are observed in exogenous orienting, they are best understood as driven by failures in alerting or failures in arousal (capacity) rather than in the targeted ventral system *per se* (Ortega, Lopez, Carrasco, Anllo-Vento, & Aboitiz, 2013). In particular, when confronted with unwarned targets, amplitude of ERP response (here, the negative signal at 100 ms or N-1 component) is weaker in ADHD than non-ADHD. Children with ADHD also under-respond to warning cues (here, the contingent negative variation or CNV signal) on ERP studies of orienting (Benikos & Johnstone, 2009). These findings can be interpreted either as failure of capacity or state readiness (arousal) or else failure of the salience network per se, although the cited authors tended to favor the former explanation. In an effort to sort out this ambiguity, Huang Pollock et al. (2006) combined results from a continuous performance task and an endogenous cueing or orienting task. They, too, concluded that exogenous orienting was spared but that alertness (arousal or capacity) was impaired. A similar conclusion was reached when alerting and endogenous orienting were isolated by task design in a study of adults with ADHD (Oberlin, Alford, & Marrocco, 2005).

Other task designs also seem to converge with this picture. With regard to selection, historically the data have argued against a perceptual selection (type 1 selection process) problem in ADHD (Berman, Douglas, & Barr, 1999; McIntyre, Blackwell, & Denton, 1978; Sergeant & van der Meere, 1988; Sharma, Halperin, Newcorn, & Wolf, 1991). A review of automatic versus effortful visual search concluded that children with ADHD have normal automatic (type I) visual search processes (Mullane & Klein,

2008). Many such investigations lacked systematic control of perceptual load in addition to other limitations, (see critique by Douglas, 1999). The issue of load in particular was a potentially important gap in light of subsequent theories of load and selection (Lavie, 1995). Yet, even when our group controlled perceptual load more systematically using newer paradigms, perceptual selection problems were not detected in ADHD-C (Huang-Pollock, et al., 2002). All of these findings suggest that, despite imaging findings, at the performance level it is difficult to identify marked problems in the ventral attention system itself—unless one attributes failures of alertness, arousal, or energy to the ventral network. I suggest that a resource capacity limitation in ADHD magnifies any weakness in the ventral attention system and is most parsimoniously understood as a capacity problem rather than a ventral attention problem.

In the face of evidence that type 1 processing of attention is not primarily involved in ADHD, theorists have suggested that the posterior attention network may be a mechanism in children in a *subgroup* with a refined ADHD inattentive type who are not hyperactive (Goodyear & Hynd, 1992; Milich, Balentine, & Lynam, 2001). Very few data address this possibility formally.

Yet there has been substantial concern in the nosology literature that the ADHD inattentive subtype (now presentation) may not be well-specified. In particular, it may be that items tapping sluggish cognitive tempo (a tendency of a child to be spacy, underactive rather than overactive, and have low energy) are important to recognize when defining a subgroup with purely inattentive forms of ADHD (Carlson & Mann, 2002; McBurnett, Pfiffner, & Frick, 2001). Indeed, in *DSM-IV* and *DSM-5*, the inattentive type/presentation includes children who are overactive (but just below the threshold for ADHD combined) plus children who are clearly underactive. The latter group may be those most affected by a posterior attention system dysfunction (Milich et al., 2001). An interesting possibility is that subgroups, based either on phenotype or genotype, show type 1 attention problems. Bellgrove et al. (2009) reported that genotype moderated deficits on an endogenous orienting task. Three other studies looked at children who were defined as inattentive without any hyperactivity—that is, a more restrictive definition than that provided by the *DSM-IV* subtypes or the *DSM-5* presentations.

Carr et al. (2010) used a relatively novel task called the attentional blink, in which rapidly presented stimuli cause an involuntary "blindness" to ensuing stimuli after a relevant target is presented. The idea is that for a couple of hundred milliseconds after detecting a target, attention lapses while the stimulus is verified and stored in memory. The "blink" is thought to reflect an automatic filtering mechanism. It was generally normal in ADHD but abnormal in the subgroup with pure inattention. This could reflect a type 1 process failure or a capacity failure. Goth Owens et al. (2010) used simple speed of output tasks, and found that speed was slower in the group with pure inattention. This result could suggest an energy deficit (capacity) unique to that group. A third study (Derefinko et al., 2008), similarly defining an inattentive type without any activity elevation, also saw alterations in cognition in this group that could reflect either type 1 processing or else capacity differences.

Laboratory Tests, Attention, and ADHD: Type 2 Attention

The most heavily studied domain of attention in ADHD is controlled attention, broadly defined. These studies include both strategic allocation of visual attention (the narrow definition confined to the dorsal attention network) and studies of task control (involving increasingly anterior portions of prefrontal cortex in the frontoparietal network). Numerous reviews and meta-analyses have demonstrated that compared with typically developing individuals, children and adults with ADHD have, as a group, worse performance on laboratory measures of cognitive control and executive functioning (Alderson, Kasper, Hudec, & Patros, 2013; Kasper, Alderson, & Hudec, 2012).

A key question concerns whether we can fractionate or isolate component abilities in relation to ADHD. As noted earlier, functional MRI studies of cognitive control in normal adults suggest that increasingly complex control tasks involve more anterior portions of frontal cortex. Recall the Badre and D'Esposito (2009) see "hierarchical model". Let us now consider it in more detail. Those authors suggested that dorsal premotor cortex (approximately Brodman's area 6) is involved in response selection, stimulus-response rule execution, and similar single-rule learning tasks. The premotor cortex and caudal prefrontal cortex (approximately area 8) engages when tasks are somewhat more complex, such as response-sequence selection, sequence categorization, and stimulus-response rule learning. Still more complex tasks involve the mid-dorsolateral prefrontal cortex (approximately areas 9/46), including task switching and maintaining cross-temporal contingencies. Finally, the most abstract tasks involve the frontal pole (area 10), including episodic goal monitoring and shifting from internal to external attention. Thus, by this perspective there is some potential value in isolating ADHD dysfunction if scientists could isolate what level of abstraction and what

modules in prefrontal cortex might be especially vulnerable to breakdown when individuals have symptoms of ADHD.

Without getting this specific, neuropsychological models have accordingly often suggested various fractionations of executive functions such as the distinction between working memory, set shifting, interference control (late selection and strategic orienting), and planning (e.g., Friedman & Miyake, 2004; Mirsky & Duncan, 2001; Miyake & Friedman, 2012; Miyake et al., 2000; Pennington & Ozonoff, 1996; Redick, Calvo, Gay, & Engle, 2011; Unsworth, Redick, Heitz, Broadway, & Engle, 2009). Despite this effort, cognitive and neuropsychological studies of ADHD have not yet established this level of precision, for two reasons. One reason is that the tasks used in ADHD studies remain too noisy to isolate neural circuits or psychological functions within the type 2 domain. The other is that individuals with ADHD are highly variable in their responding—itself an interesting observation discussed in the section on resource *capacity* below.

Nonetheless, attempts are beginning. For example, Rubia (2011) reviewed a series of studies from her laboratory that suggest that tasks of sustained and controlled attention differ in which portions of prefrontal cortex are differentially activated in ADHD versus control children, with the latter task type moving activation deficits closer to the frontal pole. More work of this nature that focuses specifically on effect sizes and on individual variation will set the stage for better clinical prediction.

The prior citations also suggest empirical and conceptual distinctions between inhibition, shifting, and working memory/updating. Working memory has been perhaps the most well operationalized aspect of controlled attention (Conway et al., 2005; Redick & Engle, 2011; Unsworth & Engle, 2007), even though a very wide range of measures have been labeled as working memory in studies of ADHD that sometimes confound short term storage with working memory. Working memory is theorized to have distinct elements. The first element, commonly referred to as the central executive (Baddeley & Hitch, 1994) or working memory capacity, is viewed as a domain general ability that essentially taps the same construct as the frontoparietal task network discussed earlier (Engle, 2002; Engle, 2001). It involves the ability to protect and manipulate information in mind, and likely depends in part on dorsolateral-prefrontal cortex (Kane & Engle, 2002). The second element entails domain-specific, short-term memory modules for temporarily holding information. The most common division of these is into the visual sketch pad (visual working memory) and the phonological loop (speech-based information or verbal working memory; (Baddeley & Hitch, 1994). Nearly three dozen experimental studies have looked at working memory and related abilities (short term memory, planning) in ADHD. These are most interpretable if sorted into verbal versus spatial domains. Meta-analytic data suggest that averaging across ages and tasks, children with ADHD differ from controls by about 0.7 standard deviations in terms of working memory (Kasper et al., 2012). However, this effect size may more than double when the focus is on tasks that have high memory load (e.g., dual task designs) and studies of younger children (e.g., age 8 years of age). The significant cognitive developmental shifts that occur from 5 to 8 years of age may be a period when children, particularly boys, with ADHD tend to lag their peers and fail to make a rapid consolidation of type 2 attentional processes (Kasper et al., 2012). A working memory weakness in ADHD also persists into adulthood (Alderson et al., 2013).

Higher level type 2 processing is often operationalized in tasks that are referred to as interference control (Barkley, 1997; Berger & Posner, 2000). The most classic such task is the Stroop task (MacLeod, 1991). One must name the ink color of color-words (e.g., the word red printed in green ink); reading the word is more automatic than naming the color, so interference results. Both qualitative (Nigg, 2001) and quantitative reviews (Homack & Riccio, 2004; van Mourik, Oosterlaan, & Sergeant, 2005) have concluded that Stroop interference is at most minimally impaired in ADHD. However, the null findings probably reflect methodological problems with the paper-and-pencil version of the Stroop task, which consistently reveal slow naming speed but not an additional interference effect (Nigg, 2001). Subsequent investigations have been somewhat more confirming of ADHD problems when using computerized interference control tasks, which prevent response strategy effects to which the paper stimuli had been vulnerable and also provide more precise timing measures (Assef, Capovilla, & Capovilla, 2007; Bush et al., 1999; Carter, Krener, Chaderjian, Northcutt, & Wolfe, 1995; Jonkman et al., 1999, but see Huang-Pollock, Nigg, & Carr, 2005).

Numerous other multicomponent tasks, including widely used clinical measures like the Trailmaking and Wisconsin Card Sort test, show modest effect size differences between children with ADHD and typically developing children (Willcutt et al., 2005). More contemporary studies of, for example, task switching that can truly tap the higher order control that engages the frontal pole and the task-control network, are needed to

clarify this picture. Some studies have begun to do so. For example task switching designs all induce a response set and then measure reaction times when the primary response set must be changed; they can monitor dual-task performance (performance cost of doing two things at once) or switching costs (see Pashler, 1998). Application of these more refined paradigms to ADHD has begun. Initial studies provide some evidence of rapid, controlled shifting deficits (Cepeda, Cepeda, & Kramer, 2000; Hollingsworth, McAuliffe, & Knowlton, 2001; Oosterlaan & Sergeant, 1998; Perchet, Revol, Fourneret, Mauguiere, & Garcia-Larrea, 2001; Rauch, Gold, & Schmitt, 2012; Schachar, Tannock, Marriott, & Logan, 1995), but studies to date are too few and varying in method to allow firm conclusions about whether the magnitude of the effect is larger here than for simpler control tasks, as the hierarchical model of frontal lobe activity and task complexity would predict.

Summary

Evidence for a problem in type 2 attention in ADHD exists from a wide range of neuropsychological investigations, although such deficits not large enough for clinical application as ADHD is currently defined. Newer, more refined measures of cognitive selection and working memory that capitalize on reliable reaction time measures that truly tap the complex attention implemented in the most anterior neural networks are likely to be most helpful in future evaluations.

Resource Capacity Limits and ADHD

Problems in energetic or resource state have been one central proposal for an ADHD mechanism (van der Meere, Börger, & Wierseman, 2010). Yet the definition of energetic state or capacity has been elusive in the literature. It can refer to effort pool, energy, arousal, attentional capacity, or motivation. Yet these are quite distinct constructs in terms of the intellectual traditions from which they derive and hence their connotations. An arousal perspective is adopted here, while briefly noting other approaches.

Arousal

Arousal is undeniably important to effective adaption; someone who is too lethargic cannot accomplish much, nor can someone who is panicked. Extreme lapses in the arousal function are salient in such medical conditions as epilepsy and narcolepsy. Arousal is to some extent involuntary—at a certain point, we fall asleep no matter how much we want to stay awake, or panic no matter how much we want to stay calm. Yet it also has some degree of voluntary regulation—by strategic planning we can relax a bit, by effort we can overcome our fatigue and continue on a boring task when weary. The classic Yerkes-Dodson curve describes optimal performance under optimal arousal. Developmentally, arousal is an important characteristic even in infants and is considered perhaps the earliest hallmark of self-regulation (Olson, 2002). Crucially, regulation of arousal from very early in life is heavily dependent on caregiver responsiveness. For example, a large body of literature notes the difficulty in arousal regulation experienced by children with insecure attachments to their parents when in stressful situations, and some evidence suggests that this relation is not merely temperament driven but is at least in part a reflection of the quality of the parent–child interaction (Olson, 2002; Schore, 1994). Similarly, early sleep regulation is partly temperamental and partly related to parental monitoring (Dahl, 1996; Peirano, Algarin, & Uauy, 2003). Whether these different examples of arousal are all addressing the same underlying processes is an open question but they clearly moderate other attention and impulse control operations. However, arousal has suffered historically from under-specification particularly in terms of neurobiology.

One influential integration comes from the same model guiding the discussion of attention herein from Posner and Petersen (Petersen & Posner, 2012; Posner & Petersen, 1990). They proposed that an arousal system, which they call *alerting*, is responsible for establishing and maintaining an alert state suitable to task demands and preferences. In this perspective, *vigilance* depends on a network of neural structures that include the noradrenergic system originating in the locus coeruleus, the cholinergic system of the basal forebrain, the intralaminar thalamic nuclei, the right prefrontal cortex (Parasuraman, Warm, & See, 1998; Posner & Petersen, 1990; Rothbart, Derryberry, & Posner, 1994), and the ascending reticular activating system ((Mirsky & Duncan, 2001) the latter is related to wakefulness). Peterson and Posner (1990) noted two distinct functions. The first was phasic *alerting* to a stimulus (Berger & Posner (2000); called arousal by Pribram & McGuinness, (1975), and stabilize by Mirsky & Duncan, (2001)). The second was tonic sustaining of attention to the stimulus, called *vigilance* (Posner & Peterson, 1990) or *sustained attention* (Mirsky & Duncan, 2001).

Posner and Peterson (1990) proposed that arousal (alerting) is a right brain lateralized process of activation by noradrenergic neurons. It responds to stimulus input

and prepares to take advantage of new information by enhancing the signal:noise ratio for novelty detection. Classic theories of ADHD emphasize a deficit in cortical arousal (Satterfield, Cantwell, & Satterfield, 1974; Zentall & Zentall, 1983) or, concomitantly, disruption in ascending noradrenergic neural systems that facilitate signal:noise detection (McCracken, 1991). A line of ongoing work in the EEG theta:beta ratio requires integration here and also relies on an arousal framework.

A revision of this model by Aston Jones and Cohen (Aston-Jones & Cohen, 2005) is integrated into Peterson and Posner's (2012) more recent summation. This perspective retains much of the earlier idea but formulates the functioning of the ascending NE system from the locus coeruleus in terms of allocation of attention or focus to a single task (efficient) versus a diffuse (exploratory) framework. The tonic-phasic terminology is retained but its function is clarified in computational terms. In this perspective, ascending NE systems are involved via projections to frontal and parietal cortices in bottom-up optimization of behavioral performance by influencing responsivity (a gain parameter) in those cortical systems. Meantime, downward projections from PFC can regulate the NE system, helping to explain how top-down cognitive control can be involved in deliberate regulation of arousal and task efficiency. The *phasic* activity is important in this efficient mode, as phasic NE firing is associated with task-relevant responses. The *tonic* mode is important to maintain general alertness, but when tonic activity is high and phasic activity is low, the person is distractible and aroused; when both are low, the person is drowsy and not alert. That proposal is obviously of interest for hypotheses about ADHD neurobiology.

Arousal can be assessed in several different ways as listed in Table 14.2. Performance on a sustained task of detecting rare targets (continuous performance test) yields a signal detection parameter *d*-prime (d'). Reaction time variability on two choice decision tasks can be decomposed into indicators of a gain parameter (interpreted as arousal here for simplicity, although some experts would not agree) and of a decision set point parameter, which may be analogous to the CPT log-beta parameter that is sometimes seen as index of activation or tonic firing (Sergeant et al., 1999). EEG and ERP components may also be informative.

TABLE 14.2 Arousal-Related Concepts

	Arousal	Vigilance
Other terms	Phasic alerting	Tonic vigilance
NE system	Phasic	Tonic
Behavior balance	Task focus efficiency	Distractible if no phasic exploration
Measure (putative)	*d*-prime (d')	log beta
	RT variability-gain	RT decision parameter
	Theta-beta ratio	Event modulation
	CNV	

While slow reaction times (RT) seem like an obvious indicator of low arousal, the pattern of *reaction time variability* may be even better. A careful analysis of the reaction time literature actually shows that reaction times are not consistently impaired in ADHD (Huang-Pollock & Nigg, 2003; Kofler et al., 2013) so much as a consistent pattern of high within-individual variability of responding (Leth-Steensen, Elbaz, & Douglas, 2000). To determine whether variability is an index of arousal/alertness or of something else requires fractionation of the RT signal. RT may vary over seconds, minutes, hours, days, or weeks or even years and each of these may be of some informational value in understanding psychopathology (Ram & Gerstorf, 2009).

The past decade's literature has seen considerable interest in reaction time (RT) variability as a key marker in ADHD (Epstein et al., 2011) as well as other conditions. However, the main focus of ADHD research has been on fluctuations that occur from minute to minute or second to second. Within this framework, several methods for decomposing RT variability have been proposed to try to isolate cognitive functions that are relevant.

One advantage of RT variability is it can be retrieved from almost any study that includes reaction time as a primary measure. Taking advantage of this, a recent meta-analysis was able to pull RT variability data from over 300 studies to gauge effect sizes in ADHD (Kofler et al., 2013). This review made several important conclusions. First, children with ADHD do not have deficits in terms of slow RT after taking into account RT variability, but they continue to have deficits in RT variability after accounting for slow RT. Second, the effect size for simple RT variability ($d = .76$) is similar to other effect sizes for measures of controlled attention or arousal in the literature, suggesting that RT variability is not a more sensitive measure of ADHD than other cognitive measures touted as key deficits. Interestingly, the effect was slightly larger in children with ADHD than other clinical disorders (differential $d = .25$), although the effect in ADHD tended to be smaller in adolescents and adults than in children.

It also appears that from the perspective of subdomains of ADHD, RT variability is heritable and shares genetic variance with symptoms of inattention (Kuntsi et al., 2013). Yet RT variability can be affected not just by arousal (reflecting, perhaps, phasic NE firing), but also by

decision making strategy (e.g., cautious or reckless), and attention (distraction) (reflecting, perhaps tonic NE firing). Therefore, clarifying what drives the effect is needed. Three different methods are extant in the literature relevant to ADHD.

One approach decomposes the RT distribution within each participant using Fourier transformation into variation at different hertz, in line with the idea that the nervous system also oscillates at several hertz simultaneously (Wang, 2010). One proposal is that ADHD variability is occurring at slow wave forms, equivalent to an occasional *lapse* of attention every several seconds (Mairena et al., 2012). This could conform to claims that malfunction of the default mode network in the brain is dysfunctional (Sonuga-Barke & Castellanos, 2007). A careful review of relevant literature disproved that particular formulation as seen in RT data; children with ADHD have variable responding at all frequencies studied so far (Karalunas, Huang-Pollock, & Nigg, 2013), but more examination of both attentional lapses and oscillation cycles using physiological measures may be informative.

The second approach is to separate the Gaussian and ex-Gaussian components of the reaction time distribution (Leth-Steensen, et al., 2000). This approach is depicted in Figure 14.7. It shows that the approach decomposes the distribution into the mean and standard deviation of the normally distributed portion, and then a function called *tau* that reflects the mean and standard deviation of the non-Gaussian portion of the reaction time distribution. If this is done for each individual, then these three parameters can be separately assessed using regular statistical approaches. This method suggests ADHD deficits in *tau* but there has been controversy over what *tau* means psychologically. Deficits in *tau* are consistent with a deficit in arousal, but alternative interpretations are possible.

A third approach is called the diffusion model (Ratcliff, 2006; Ratcliff & McKoon, 2008). Here an information-processing paradigm is used. The model decomposes (1) a gain parameter (v) (rate of information processing), (2) a decision boundary parameter (conservative versus hasty decision making, conceptually related to the log-beta parameter in signal detection analysis), which could be indicative of tonic NE firing as explained earlier, and (3) nondecision processes that add to the overall processing time. The diffusion model has an important advantage in that it takes into account accuracy as well as reaction time, and so can accommodate speed–accuracy tradeoffs that bedevil other methods. The model is explained in Figure 14.8. However, note that as presented here, it assumes a two-choice reaction time task and so is applied to a more specific kind of task challenge than the ex-Gaussian model. This model has only recently been applied to ADHD. The first such study on a sizable sample (Karalunas, Huang-Pollock, & Nigg, 2012) suggested that the ADHD effect on both the reaction time and the reaction time variability was accounted for by the information gain parameter. This is very important because it locates an ADHD deficit not in perception or motor speed but in cognitive processing, and because it simplifies a multicomponent analysis of RT and RT

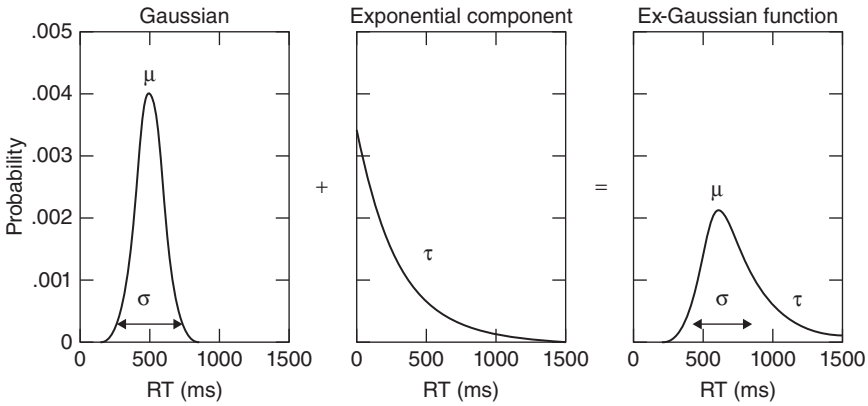

Figure 14.7 Ex-Gaussian decomposition of reaction time components. Reaction time distributions are usually positively skewed (third display on right), rendering a standard statistical analysis suspect. One solution is decomposing the distribution components. Left panel: μ reflects the mean of the normal (Gaussian) portion of the distribution, and σ captures the standard deviation of the normal portion of the distribution. Middle panel: τ reflects both the mean and standard deviation of the exponential portion of the distribution. Right panel: combining these describes the skewed distribution. *Source:* Used with permission and adapted from Karalunas, S. L., Geurts, H. M., Konrad, K., Bender, S., & Nigg, J. T. (2014). Annual Research Review: Reaction time variability in ADHD and autism spectrum disorders: measurement and mechanisms of a proposed trans-diagnostic phenotype. *Journal of Child Psychology and Psychiatry, and allied disciplines, 55*, page 707.

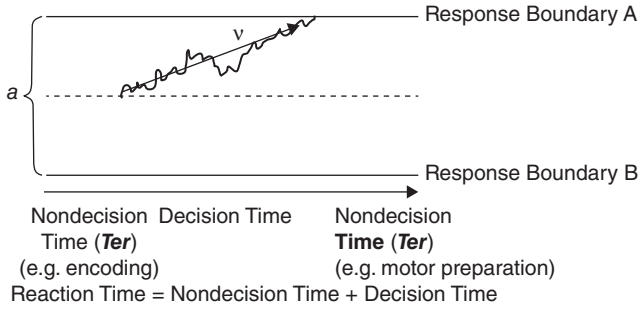

Figure 14.8 Diffusion decomposition of reaction time components. Drift rate (v) = rate at which information accumulates as reflected by the average slope of the line. It is determined by speed of information processing and noise (represented by the hypothetical jagged deviations from the average slope). Larger values of v indicate faster processing. Boundary separation (a) = conservativeness of the response criterion with wider separations indicating more conservative responding. Nondecision time (*Ter*) includes all nondecision processes, such as stimulus encoding and motor preparation. *Source:* Reprinted with permission from Karalunas, S. L., & Huang-Pollock, C. L. (2013). Integrating impairments in reaction time and executive function using a diffusion model framework. *Journal of Abnormal Child Psychology, 41*, page 839.

variability. If that result holds, it can likely be interpreted best as a weakness in capacity or arousal.

Other evidence is also consistent with this interpretation of RT variability in ADHD. Historically, the most widely used task for ADHD has been the continuous performance task (CPT). As noted earlier, a signal detection analysis can decompose the accuracy data to examine sensitivity to signal versus noise (most often used is one called *d*-prime or *d'*) see Table 14.2 in conjunction with decision bias (conservative or risky, for which one index is called log-β) (Lachman & Butterfield, 1979). It has been known for some time that ADHD is associated with poor signal detection (Losier, McGrath, & Klein, 1996).This finding can be interpreted as evidence of an arousal dysfunction.

Caveats to the arousal interpretation, however, were pointed out by van der Meere and colleagues (Sergeant, et al., 1999; van der Meere, 2002). They noted that most studies to that time (e.g., with the CPT) failed to consider *event rate* and that (1) failure to find sustained attention deficits on fast-event rate CPT tasks contradicts an arousal dysfunction hypothesis and thus (2) many of the performance data may in fact reflect a problem in activation (see later discussion). Moreover, (3) strategy effects (e.g., speed-for-accuracy trade-off) were often overlooked.

To address this criticism, a recent meta-analysis of 47 CPT studies considered both a signal detection approach (*d'*) and diffusion model to account for speed accuracy trade-offs (Huang-Pollock, Karalunas, Tam, & Moore, 2012) and also considered event rate variation across studies as well as estimating measurement artifacts. This thoroughly done analysis concluded that ADHD is associated with a deficit in *d'* of $d = .98$ (when seen from a signal detection lens), and in the information gain parameter $d = .75$ (seen from a diffusion modeling lens). Thus, these two approaches appear to converge in support of a deficit in capacity, likely in arousal although the arousal–activation distinction remains to be considered and is taken up again in the next section.

Another line of work related to low arousal in ADHD comes from EEG recordings. Among the first efforts to use contemporary definitions of ADHD and viable EEG methods was conducted by Satterfield and colleagues (Satterfield et al., 1974; Satterfield & Dawson, 1971). Recent electrophysiological work has often, though not unequivocally, been supportive (Brandeis et al., 1998; Monastra e al., 1999; Silberstein et al., 1998). The frequency or power spectrum of the EEG can serve as a central nervous system indicator of arousal (Minkwitz et al., 2011). Higher power in fast frequencies (e.g., the beta band) is seen as high arousal, while higher power in slow frequencies (e.g., theta band) is interpreted as low arousal (Arns, Conners, & Kraemer, 2012; Pizzagalli, 2007). The theta:beta ratio is often used to quantify arousal, although this interpretation has been questioned.

A salient finding in ADHD entails an excess theta:beta ratio, or excess relative slow wave activity. The literature on theta-beta ratio and ADHD has been meta-analyzed three times with different results. Boutros et al. (2005), using fairly liberal criteria for study inclusion, estimated an ADHD effect size of $d = .70$ for absolute theta power and of $d = 1.07$ for relative theta power. Snyder and Hall (2006) concluded that the theta:beta ratio was a startling 3.08; however that calculation was flawed by failure to use a pooled standard deviation when comparing group effects, as is considered best practice in meta-analyses (Borenstein, Hedges, Higgins, & Rothstein, 2009). Further, some studies with very large effects have had flawed methods, comparing their clinical group to norm groups obtained years earlier as noted by Arns et al. (2013). Arns et al. (2013) were more conservative, selecting a homogenous group of studies with similar protocols. They arrived at an effect size estimate of $d = .62$. They also noted a linear trend of decreasing effect sizes over time as additional studies are conducted. Thus, it appears that the EEG theta:beta measure performs similarly to other measures in differentiating ADHD from non-ADHD youth. Arns et al. concluded by emphasizing the potential prognostic value of the theta:beta ratio, which may help predict treatment response.

Activation

A complication for readers of the ADHD literature is that the concept of tonic vigilance is related in some models to still another older concept, that of activation (Pribram & McGuinness, 1975), a term itself often used in differing ways in the ADHD literature and in the developmental and temperament literature. The lack of isomorphism in handling activation across theories is related to distinct historical streams of thought (Strelau, 1994). One stream, exemplified by Gray (1982), arose from research on temperament and learning theory reaching back through the work of Eysenck to Pavlov's early conceptions of learning, in which activation was closely related to reward responding and thus to motivation. The second stream, exemplified by Posner and Peterson (1990) and Pribram and McGuinness (1975), arose from the cognitive sciences and information-processing approaches, which deemphasized incentive response and emphasized global response readiness and attention.

As a result, one historical thread of theorizing about ADHD has drawn on temperament and learning theory (and, more recently, associated animal models of ADHD), thus emphasizing reward response (Sagvolden, Aase, Zeiner, & Berger, 1998; Sagvolden, et al., 2005). Another thread of ADHD theorizing has drawn on cognitive and information-processing theory and emphasizes impaired demand-response preparation generally (e.g., Sergeant et al., 1999). A detailed summation of those historical perspectives was provided in the second edition of this volume (Nigg, Hinshaw, & Huang-Pollack, 2006), so only key points are noted here.

To distinguish these two meanings of activation is important. The reward-based activation concept is related to dopaminergic reward-learning circuits, whereas the vigilance system under discussion in this section is related to noradrenergic projections. I consider activation as a demand-response function in the current section, and as reward and incentive responding in the section on impulsivity later.

Traditionally researchers in ADHD have been interested in a concept of sustained attention or functioning against time on task. Time-on-task effects, however, have never been persuasive as a major deficit in ADHD because ADHD-related task-performance problems tend to appear rather quickly when placed under cognitive load. Tucker and Williamson (1984) recast the time-on-task domain as *activation* with an emphasis on motor preparation rather than attention. When activation is viewed in this way, evidence is more supportive of an ADHD-related deficit. Dutch scientists using time-on-task and event rate data reported that children with ADHD show normalized performance at medium event rates but weaknesses at slow and fast event rates on CPT (van der Meere, Shalev, Borger, & Gross-Tsur, 1995) and go/no go tasks (Borger & van der Meere, 2000; van der Meere & Stemerdink, 1999), leading these investigators to favor an underactivation explanation of ADHD cognitive and performance deficits (Sergeant, et al., 1999; van der Meere, et al., 2010). In other words, varying the rate at which a computer presents stimuli can moderate and nearly normalize response accuracy for children with ADHD.

A meta-analysis of event rate effects on a go/no-go task confirms that ADHD response parameters are markedly influenced by the event rate (Metin, Roeyers, Wiersema, van der Meere, & Sonuga-Barke, 2012). That study showed that an ADHD deficit on the go/no-go task is not fully explained by event rate but is significantly moderated by it. ADHD slowing of reaction time was greater at slow event rates than at more activating fast event rates. Further evidence for a deficit in activation comes from the difficulty children with ADHD have in producing rapid motor responses over time (Carte, Nigg, & Hinshaw, 1996). In addition, some physiological data, in particular heart rate data, appear to be supportive (van der Meere, 2002).

Caveats to this argument entail failure of some activation predictions, versus arousal. For example, deficits on the CPT beta parameter (an index of response bias, that is, risky versus conservative) have not been confirmed in meta-analyses (Huang-Pollock et al., 2012; Karalunas, et al., 2012; Losier, et al., 1996). On balance, however, an activation dysfunction in ADHD remains an important possibility, with evidence of context-dependent functional deficits in children with ADHD requiring explanation.

Summary of Attention Section

Despite isolated neuroimaging data implicating brain regions in the ventral attention network, most evidence suggests that problems in a salience network or attentional capture process are not central to ADHD in aggregate. The picture may change when considering a subset of children who are sluggish and inattentive but it is too early to draw that conclusion. Instead, what appear as alerting or attentional capture problems appear to be better understood as problems not in type 1 attention, but in allocation of resources, via a problem in phasic arousal or, alternatively, tonic activation. Children with ADHD tend to have low arousal or low energy capacity to respond to tasks, reflected in signal detection and reaction time patterns as well as in physiological measures. Meantime,

type 2 attention is clearly affected in ADHD. The question is why those effect sizes remain modest: whether due to massive heterogeneity in ADHD children, to failure to use sufficiently difficult tasks that reach the top of the task hierarchy and demand full engagement of the executive networks in the brain, or to other reasons. I return to this point later when I consider future directions.

IMPULSE CONTROL: CONCEPTUAL FRAMEWORK AND KEY ADHD EFFECTS

Like attention, impulsivity is not unitary but involves multiple behavioral and neural systems, in addition to the interpersonal and incentive context in which the child is acting. When considering impulsivity measured by behavioral ratings of personality, for example, investigators find multiple dimensions.

Whiteside and Lynam (2001) conducted a factor analysis of numerous rating scale measures of related constructs (e.g., impulsivity, behavioral inhibition, sensation seeking) in adults. They identified four dimensions: (1) sensation seeking; (2) urgency (tendency to act rashly when distressed, also called by others negative urgency); (3) lack of planning; and (4) lack of perseverance (Whiteside & Lynam, 2003). Zapolski et al. (2010) confirmed a similar structure in children. These dimensions are not highly intercorrelated, consistent with other personality data that aspects of impulsivity are carried across different personality traits like extraversion (which includes a facet for sensation seeking), conscientiousness (facets for planning and persistence), and neuroticism. Thus, consideration of affective and nonaffective components of impulsivity and of the intersection with cognitive and stylistic tendencies in personality suggests a multifaceted construct.

In the experimental and laboratory measurement domain, then, it is not surprising that we see distinct approaches that are probably tapping different aspects of the everyday definition of impulsivity as a disposition to rash action. Reflecting this, two major frameworks or aspects of impulsivity have guided thinking in this area experimentally.

The first framework focuses on regulation of the impulse—how are impulses contained, stopped, or interrupted? Here, an impulsive action is seen as a hasty (stimulus-driven) action that was not adequately interrupted, resulting in doing what I did not want to do. The second framework focuses on decision making—how incentives are weighted, such that poor immediate rewards get chosen over superior but delayed rewards, with the result that I choose what I ultimately do not want as much (Ainslee, 2001). An impulsive action from this perspective is seen as one in which the ill-advised (that is, ultimately not desired) immediate option was preferred to the better (ultimately more desired), later option through a process of extreme *temporal discounting*. This second perspective intersects with the growing field of neuroeconomics.

Consider first the inhibition perspective. Here, within the child, I can simplify the descriptive options for a moment by considering again the deceptively simple question: How does a behavior (an impulse or a response that was about to be carried out) get stopped, interrupted, suppressed, or inhibited? Developmental studies suggest that either (1) more than one process is involved in controlling impulses in this way, or (2) an underlying control mechanism becomes able to interrupt different kinds of behavior at different points in development. For example, Dempster (1993) noted that the ability of children to suppress or inhibit motor movements develops earlier than the ability to suppress or inhibit word meanings in language use, although whether this is due to the differential rates at which motor and language skills develop or to distinct control operations coming online is uncertain.

Consider further that impulses can arise in at least two basic ways using our type 1 and type 2 process perspective. The type 1 action operates via an immediate incentive (reaction) that invites approach; type 2 action operates via memory of a long-term goal that comprises a series of next steps (strategic planning) and preidentified or learned steps. Correspondingly, impulses to action (motor or vocal response) are *controlled* by both top-down and bottom-up processes (Eisenberg et al., 2004; Nigg, 2001; Rothbart & Bates, 1998; Valiente et al., 2003). To achieve an important goal, one might overcome fear of a possible punishment (a new professor anxious about speaking in front of colleagues does so anyway to explain his work) exemplifying a top-down process. At the same time, anxiety might interrupt deliberate processes (the new professor forgets his next point due to the intrusion of a worry about how the talk is going), exemplifying a bottom-up process.

Affective processes thus can both trigger impulsive responding (negative urgency), or interrupt an impulse (anxious stopping of behavior). In the prior edition of this volume my colleagues and I provided a detailed description of bottom-up behavioral inhibition, derived from related lines of thought emanating from work by Jeffrey Gray and work by Jerome Kagan (Nigg, Hinshaw, & Huang-Pollock, 2006; Nigg, 2000b, 2001). Those related lines of work each suggest an important role for negative affect in both stimulating and interrupting impulsive behavior.

In this way, reward responding can also be seen as affectively driven source of impulse. From this perspective it is anchored in ascending dopaminergic systems in the brain, as also noted in the prior edition of this volume (Nigg, Hinshaw, & Huang-Pollock, 2006). Because those concepts are explained in detail in there, herein I focus on a different aspect of type 1 processing and impulsivity: temporal discounting of reward, which has dominated this literature in relation to ADHD and substance abuse recently and so is timely to review in this edition of the handbook.

Impulsivity and Type 1 Processes: Temporal Discounting of Reward and ADHD

One primary approach to studying impulsivity currently has been using the study of reward discounting—a research area which, while noted in economics since the nineteenth century and a focus of experimental study in psychology for over 40 years, has exploded exponentially, particularly in relation to psychopathology, in the decade since the prior publication of this volume. This approach, widely used in the substance abuse field to study decision making in relation to craving, has been surprisingly little utilized in attention-deficit disorders. This is despite the fact that ADHD confers elevated risk of future drug addiction. Therefore highlighting it can also serve to stimulate more work in that area.

The fundamental phenomenon here can be understood by asking whether you would prefer a modestly appealing option now or a more appealing option later, or whether you would endure an unappealing option now to reach an appealing option later. In a classic example (Rachlin & Jones, 2010), the alcoholic prefers being sober and healthy to being drunk and sick in the long run, but in the next 5 minutes he or she prefers to have a drink than not to have one. If the long-term pay-off always wins, he or she stays sober; if the short term one always wins, he or she is constantly drinking. In an experimental case, a neuroeconomist can ask whether you would prefer to have $10 now or $100 tomorrow. As with other impulse control disorders such as addiction or compulsive gambling (Bickel, Jarmolowicz, Mueller, Koffarnus, & Gatchalian, 2012), in the case of ADHD it is fairly straightforward to demonstrate a group effect of excess preference for smaller sooner over later bigger rewards (Antrop et al., 2006; Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001; Demurie, Roeyers, Baeyens, & Sonuga-Barke, 2012; Paloyelis, Asherson, Mehta, Faraone, & Kuntsi, 2010; Scheres, Tontsch, Thoeny, & Kaczkurkin, 2010; Wilson, Mitchell, Musser, Schmitt, & Nigg, 2011).

While the posing of the question experimentally implies that some reflection is involved, and while deliberate self-control clearly can override one's temporal preferences, the supposition in this theoretical approach is that these discounting computations are rather automatic as people make moment to moment choices. The symmetry in human and animal decision making paradigms, even in rodents and pigeons (noted below) supports this assumption of a type 1 process. Key questions concern how to best quantify discounting, how to use it to measure individual differences, how to define the phenotype so as to go after brain and gene correlates in development, and how to explain the phenomenon psychologically and biologically.

All of this has led to extensive new work on the discounting function, a function of considerable theoretical importance in ADHD (Sagvolden, et al., 1998). By progressively longer delays of the larger reward (how about in 2 days, 2 weeks, 2 months, 2 years?) the experimenter finds the *point of indifference* for that individual—how much time delay balances the value of the small and large payoff. This provides a precise quantification of the degree to which discounting occurs for that person. Of course, negative consequences (loss of reward) are also discounted—a punishment to occur in 10 years is not as concerning as one that will occur later today (think of how frequently people sign up for a balloon-payment mortgage). Discounting occurs not just over time, but also over probability or certainty of outcome, but it is not clear whether the same mechanism undergirds both kinds of discounting—an individual may discount more steeply for time than for probability or vice versa (Green & Myerson, 2013). This important complexity has not been much considered in work on ADHD.

In any event, the degree of preference for each reward (or outcome) over time can be captured by various mathematical functions, of which the most commonly supported is a now-characteristic hyperbolic function (Ainslee, 2001; Blackburn & El-Deredy, 2013):

$$V_d = A/1 + kd'$$

where V_d is the discounted present value of the future reward (e.g., $100 in a year is equal to $10 today), A is the reward amount, d is the delay period, and k is the discounting rate. This function is illustrated schematically in Figure 14.9 (Bickel, et al., 2012). Researchers typically solve for k, or else simply compute the area under the curve for the plotted function to compare different

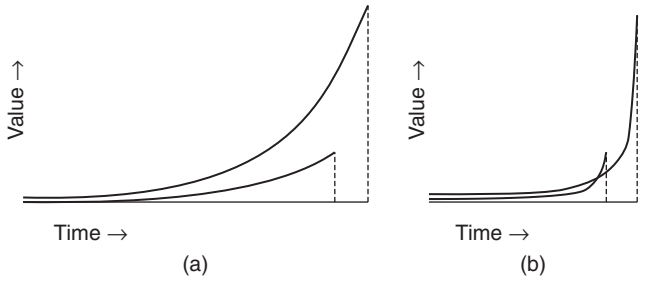

Figure 14.9 Temporal discounting hypothetical curve in addiction. This figure shows the predicted values of two reinforcers as a function of the delay until their receipt as predicted by the exponential model (left panel, A) and hyperbolic model (right pane, B). The height of the vertical lines represents the magnitude of subjective value on the future reward. *Source:* Reprinted with permission from W. K. Bickel, D. P. Jarmolowicz, E. T. Mueller, M. N. Koffarnus, & K. M. Gatchalian, (2012) Excessive discounting of delayed reinforcers as a trans-disease process contributing to addiction and other disease-related vulnerabilities: Emerging evidence, *Pharmacology & Therapeutics, 13*, page 289.

groups, as recommended by Madden & Bickel (2010) as well as Myerson, et al. (2001). The nuances of the difference between the *logical* exponential function and the *actual hyperbolic* function are intriguing with regard to the meaning of human cognition and how it handles uncertainty, but I bypass those here. However, note that accounting for differences in the slope function in clinical and normative samples is an important target in the field regardless of which shape is best fit to the data. A key advantage of the paradigm is the ability to translate it to animals, and one source of support for the conclusion of a hyperbolic discount function is that the same function appears in both animals (most commonly rats and pigeons) and humans.[4]

The neurobiology of discounting is relevant. When it comes to impulsivity, much of the classic impulsivity literature has emphasized the importance of serotonin systems on impulsive aggression and its relation to anxiety, mood, and impulsive behavior generally, but generally from the perspective of inhibitory control (next section), rather than discounting of reward (Apter, Plutchik, & van Praag, 1993; Coscina, 1997; Depue & Spoont, 1986). When it comes to reward discounting, emphasis has been placed on the role of dopamine functioning (Gianotti, Figner, Ebstein, & Knoch, 2012), and its importance in enhancing reward salience, particularly striatal-cortical dopamine projections. Important regions include the nucleus accumbens (ventral striatum) and medial and orbital-frontal regions of prefrontal cortex. An integrated understanding of the neurobiology of impulsivity will naturally integrate the role of both neurotransmitters along with norepinephrine, which also has important regulatory projections to PFC (Dalley, Mar, Economidou, & Robbins, 2008) as discussed earlier under the section on *capacity* and *arousal*.

The steepened slope of discounting function has been extensively studied in relation to drug addiction, but much less so in ADHD, despite a substantial literature in ADHD animal models and extensive theorizing on this gradient in relation to ADHD by leaders in the ADHD field (Sagvolden, et al., 2005).

Extensive reviews of simple two choice paradigms have concluded that ADHD is associated with some alteration in reward processing, typically preferring a small immediate reward to a delayed larger reward (Antrop, et al., 2006; Bitsakou, Psychogiou, Thompson, & Sonuga-Barke, 2009; Marco et al., 2009; Paloyelis, Asherson, & Kuntsi, 2009; Tripp & Alsop, 2001); for a review see (Luman, Oosterlaan, & Sergeant, 2005).

However, the slope of the discount function cannot be estimated in a simple two-choice procedure, leaving the findings open to alternative explanations such as aversion to delay. Only a few studies have examined ADHD using the insights from the discounting perspective. In part this is rarely studied because children's cognitive limitations make it more difficult to implement the experimental paradigms involved in choice discounting paradigms. However, with some caveats, they tend to show the expected alteration in discounting function in ADHD. Barkley, Edwards, Laneri, Fletcher, and Metevia (2001) compared adolescents (aged 12 to 19 years) with ADHD and comorbid oppositional defiant disorder (ODD) to controls. The ADHD group displayed steeper discounting of delayed hypothetical rewards of $100 but not $1,000 when delays were between 1 month and 10 years. Scheres, Lee, and Sumiya (2006; 2008) found an association in college students between steepness of the discounting gradient and symptoms of hyperactivity/impulsivity, but not inattention, when rewards were real, but not when they were hypothetical. Paloyelis and colleagues (2009) found that

[4]One caveat must be noted. Whereas a reward is a desired object that motivates approach, a reinforcer is an outcome contingent on behavior that increases the likelihood that the behavior will reoccur. Not all rewards function as reinforcers, and not all reinforcers are rewards. Strictly speaking, most animal studies examine reinforcers, while human studies usually examine rewards. However, the expectation is that the dysfunction of reinforcement processes, which result in steeper discounting gradients observed in experiential procedures used with animals, will be captured also using procedures assessing delay discounting in humans.

preference for immediate rewards using a single-delay task design was positively related to ratings of inattention in children (average 8.8 years old). Neither of those child studies examined individuals with an ADHD diagnosis, however.

Scheres and colleagues (2006) found no difference in delay discounting in children and adolescents with ADHD and matched controls using an experiential task with actual rewards up to $0.10 using very short delays (up to 30 seconds). However, in their next study (Scheres, et al., 2010), using three delayed reward amounts and delays up to one minute, again in a sample of 6–17-year-olds with and without ADHD, found steeper delay discounting among participants with ADHD.

Only one other study has examined subjective value across longer delays in ADHD or looked exclusively at preadolescent children with ADHD. In that study, Wilson et al. (2011) estimated discount function, compared children with ADHD and typically developing children aged 7–11 years on a hypothetical discounting choice task in which children were given a pairing of different short and long term hypothetical rewards and discounting curves were computed. Their results are shown in Figure 14.10, illustrating the classic fit of the hyperbolic function and showing the steeper discounting in ADHD. Using a subset of that sample, Cost-Dias et al. (2013) conducted functional connectivity using resting state MRI, and showed an association of the discounting function with increased connectivity from the nucleus accumbens to prefrontal cortex—a finding that fits well with conceptions

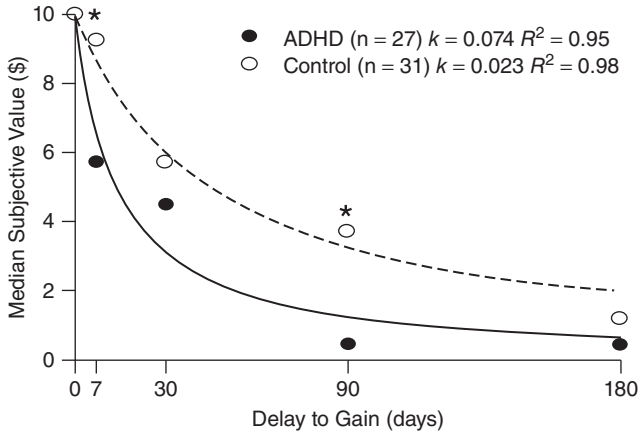

Figure 14.10 Temporal discounting curve in children with ADHD and typically developing control children. *Source:* Reprinted with permission from V. B. Wilson, S. H. Mitchell, E. D. Musser, C. F. Schmitt, & J. Nigg, (2011) Delay discounting of reward in ADHD: Application in young children, *Journal of Child Psychology and Psychiatry, 52*, page 260.

of the neurobiology of the dopamine circuits involved in reward-related decision making.

Similar behavioral findings were reported by Demurie et al. (2012) for a sample of 8–16-year-old children. Notably, they also distinguished children with ADHD from those with autism spectrum disorder, suggesting some specificity to ADHD. Thus, it appears that the field is beginning to consistently describe a group effect in ADHD, confirming a discounting function in this population similar to what is seen in substance addiction.

Still, more definitive work is needed. For one thing, the issue of domain generality of effects (money, versus other incentives) has barely begun to be investigated in ADHD (Demurie, Roeyers, Baeyens, & Sonuga-Barke, 2013). For another, the relation to other cognitive abilities, including IQ, needs further examination to understand the structure of cognition and decision making in ADHD. A proliferation of explanatory ideas related to ADHD deficit and reward function has not been matched by experimental studies that would differentiate different explanations for the phenomenon (Luman, Tripp, & Scheres, 2010).

Impulsivity and Type 2 Processes: Response Inhibition and ADHD

The second general control process is characterized by the involvement of strategic (i.e., deliberate, long-term) responses to events and their relation to long-term goals, closely connected to the now familiar construct of executive functions. This type of control can thus be termed executive or deliberate response suppression (referred to as executive inhibition in (Nigg, 2000b). It refers to the deliberate suppression of a response to achieve a later, internally represented goal (e.g., not scratching a mosquito bite so that it will heal faster; managing not to interrupt a long-winded colleague so as to fulfill a personal resolution to be more patient). Neurally, the specific suppression of a prepared or triggered motor response for strategic reasons (a hallmark of cognitive control) is related to a well-described brain network that includes the prefrontal cortex (in particular, orbitoprefrontal and right inferior frontal, especially inferior frontal gyrus (Aron, et al., 2003), basal ganglia (especially the caudate), and thalamus (Alexander, Crutcher, & DeLong, 1990; Middleton & Strick, 2002). It is modulated by frontal-cerebellar loops throughout development (Diamond, 2000; Middleton & Strick, 2001).

Convergence of approaches in describing the executive control system is apparent, given that deliberate or effortful

control of responding is emphasized in theories of both early cognitive development (Zelazo, et al., 2003) and early social-emotional development (Murray & Kochanska, 2002). However, these approaches have not yet been fully applied to the development of risk for ADHD. For example, surprisingly little research has considered *temperament antecedents* or *personality outcomes* in relation to ADHD (Nigg, Goldsmith, & Sachek, 2004; Olson, 2002; Sanson, Smart, Prior, & Oberklaid, 1993).

Yet the few studies to do so are quite consistent in suggesting that a broadly defined deliberate control domain (usually studied as *conscientiousness* in adults, or as *effortful control* in children) is associated with ADHD symptoms in preschool children (Goldsmith, Lemery, & Essex, 2004), school-age children (De Pauw & Mervielde, 2011; Martel, Goth-Owens, Martinez-Torteya, & Nigg, 2010; Martel, Nigg, & Lucas, 2008; Martel, Nikolas, Jernigan, Friderici, & Nigg, 2010), and adults (McKinney, Canu, & Schneider, 2013; Nigg, Blaskey, Huang-Pollock, & Rappley, 2002; Nigg et al., 2002; van Dijk, Lappenschaar, Kan, Verkes, & Buitelaar, 2012).

Once again, we must consider more than two basic processes when considering response inhibition. Several proposals for fractionating strategic response suppression or inhibition are extant. For example: (1) stopping a primary, intended response on the basis of new information; (2) suppressing a competing and never intended response; or (3) inhibiting a reflex response that may be construed as distinct or similar, depending on the conceptual framework (Bari & Robbins, 2013; Barkley, 1997; Friedman & Miyake, 2004; Miyake et al., 2000; Nigg, 2000a).

The most influential model of response suppression on research about ADHD entails the interrupting of a prepared response before it was executed. Functional connectivity studies (Duann, Ide, Luo, & Li, 2009), while not without controversy, are supported by animal studies that again seem to confirm that a neural network involving basal ganglia, thalamic nuclei, and right inferior frontal cortex is involved in this ability (Aron & Poldrack, 2005; Bari & Robbins, 2013) as depicted in Figure 14.11.

Many tasks are used to assess this ability, such as the oculomotor antisaccade task and the go/no-go task. The formal model, assessed by a task called the stop task, was developed by Logan and colleagues (1984) and extended to work on ADHD by Schachar, Logan, and Tannock (Schachar et al., 1995; Tannock, Schachar, Carr, Chajczyk, & Logan, 1989). This model is illustrated in Figure 14.12. It proposes that independent psychological and physiological processes are involved in triggering and executing a response (measured by go reaction time or

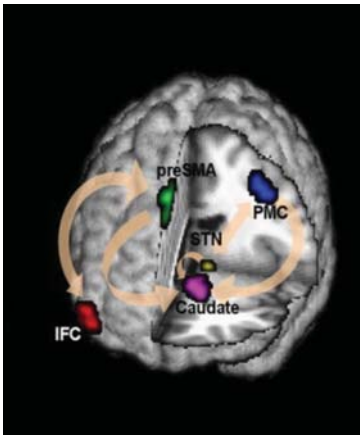

Figure 14.11 Brain model of response inhibition. Response inhibition has been mapped through a series of animal and human studies. The network now considered to be involved includes the subthalamic nucleus (STN), caudate, premotor cortex (PMC), presupplemental motor area, and inferior frontal cortex (IFC) and their interconnecting white matter tracts. See footnote 1. *Source:* Reprinted with permission from A. Bari & T. W. Robbins (2013) Inhibition and impulsivity: Behavioral and neural basis of response control, *Progress in Neurobiology, 108, 62*; and J. R. Duann, J. S. Ide, X. Luo, & C. S. Li, Functional connectivity delineates distinct roles of the inferior frontal cortex and presupplementary motor area in stop signal inhibition (2009) *Journal of Neuroscience, 29*, page 10176.

Go RT, depicted in the top process in the figure) versus interrupting or stopping that response (measured by stop signal reaction time or SSRT, in the second process in the figure). The two processes race; whether or not the action is executed depends on the relative speed of the two processes. The everyday paradigm is the check swing in baseball: the batter begins to swing at the pitch and then interrupts the swing as the pitch breaks wide of the plate. The interrupt process is initiated after the go process (Figure 14.12) and has to catch up to it to stop the response from going forward. The delay after the pitch is thrown and the swing is begun until the warning not to go (the pitch begins to break) is the stop signal delay or SSD in Figure 14.12. With enough warning, the triggered motor response can still be interrupted.

This stop task accordingly uses varied timing of warnings to evaluate how much time individuals need to interrupt a response they were about to make. It has performed well in simulation studies (Band, van der Molen, & Logan, 2003). The concepts underneath this model also have found considerable support. For example, animal neuroscience data suggests distinct brain regions are involved in executing versus withholding a response (Baxter, Bucci, Holland, & Gallagher, 1999; Chiba, Bucci,

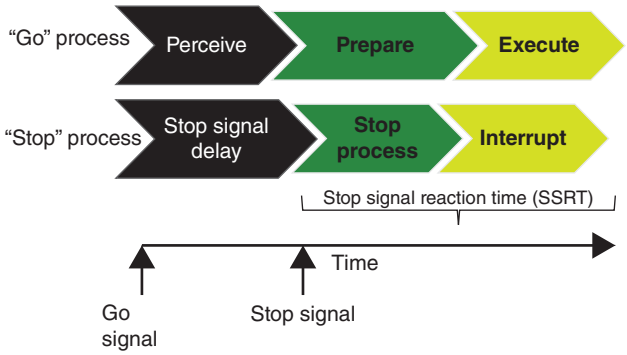

Figure 14.12 Race model of response inhibition. Two processes compete in this model. The go process launches when the go signal is perceived; the stop process launches when the stop signal is perceived. Depending on the timing of the stop signal and the speed of the two processes, the response will be executed or interrupted. SSRT = Go RT minus stop signal delay. The relative speed of the component processes is illustrative only and not to scale.

Holland, & Gallagher, 1995). Single electrode recording studies in nonhuman primates suggest that a specific inhibition activity operates centrally when stopping a response (Hanes, Patterson, & Schall, 1998; Hanes & Schall, 1995). The fundamental idea is that a disorder like ADHD, or any major impulse control disorder, is influenced by a too slow stop process or a very fast go process or both. Because it is already known that children with ADHD are unusually slow when executing fast actions, the primary hypothesis now is that they are even slower in their stop process. Accordingly in human children, efforts are made to measure the warning time needed so as to estimate the speed of the physiological stop signal. Dozens of studies in this vein suggest that children with ADHD have slower stop signal speed than typically developing children (Alderson et al., 2013; Lijffijt, Kenemans, Verbaten, & van Engeland, 2005; Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). Thus, this measure of response inhibition is among the most well established correlates of ADHD in the field.

However, one can question the mechanism behind that observation. This is in part due to other aspects of the data, and in part because of uncertainty about the meaning of the imputed stop signal reaction time under different data properties. The stopping process cannot be directly measured behaviorally, because nothing happens—the response does not occur. Instead it has to be inferred; for example in Figure 14.12, the warning delay is subtracted from average response time to estimate speed of stopping process. One problem is that because the stopping process is estimated, it has been unclear to what extent different methods of estimating will distort results due to reliance on assumptions about the distribution of responses (Verbruggen, Chambers, & Logan, 2013). This leads to the second issue, which is that the variability of the stop process cannot be estimated. In turn, psychometric inferences about the nature of the stop process are limited. Recent work suggests possible solutions to this problem (Matzke, Dolan, Logan, Brown, & Wagenmakers, 2012). Meantime, the race model of stopping is a viable way to model response interruption conceptually, but clinical application will require further work to evaluate psychometric properties of specific task implementations.

Indeed, neuroimaging studies using versions of stop and go/no-go tasks have been productive in clarifying the ADHD-related weakness in response inhibition. Rubia et al. (2013) also conducted a meta-analysis of response inhibition studies that used fMRI. The tasks they included were the stop task and go/no-go to index motor response inhibition, and Simon, Flanker and Stroop tasks to index interference inhibition (the latter is, arguably, as much a measure of attention as of inhibition). Those results are reproduced in part in Figure 14.13. They reveal altered activation in these tasks in children with ADHD, including effects in the insula, supplemental motor area, anterior

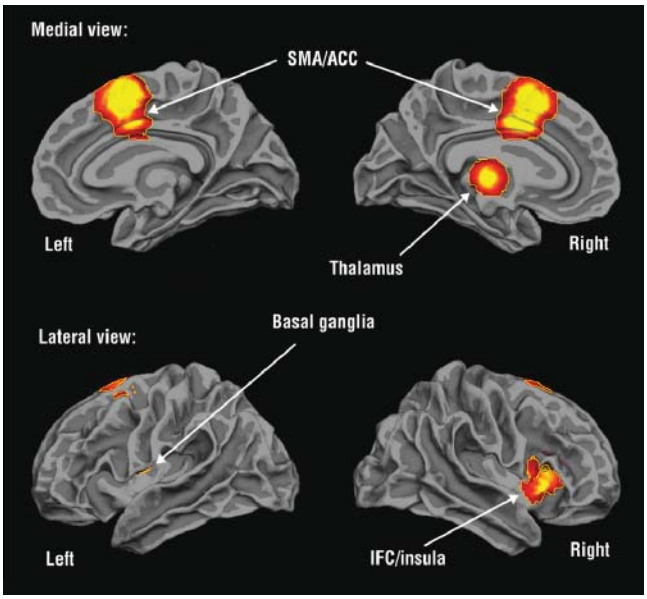

Figure 14.13 Altered brain activation during inhibition tasks in ADHD. Meta-analytic results. cingulate cortex, and thalamus. As noted earlier, the role of the thalamus in response suppression has been discussed for several years. Only recently, however, have imaging studies begun to highlight the thalamic component of the neural networks involved in type 2 processing in ADHD.

Impulse Control: Interim Conclusions and Additional Considerations

Neither response interruption nor temporal discounting mechanisms claim to provide a complete account of impulse control. Other relevant considerations are that impulsive ideas come from many sources; motor and language development affect level of control; personality attributes (e.g., optimism) modulate impulse regulation and discounting; and other modulating mechanisms could be identified.

Nonetheless, four salient interim conclusions stand out. First, fractionation of the impulsivity domain at the behavioral level in ADHD (e.g., using personality measures) has been largely lacking. This is important because much research relies on the *DSM* symptom domain of hyperactivity-impulsivity, but it includes only three impulsivity items that poorly capture the range of impulsivity in the literature. Second, reactive or anxiety-based response suppression (behavioral inhibition) does not appear to be central to ADHD, apart from its linkage to early-onset conduct disorder. Third, abnormal reward response, particularly related to temporal properties of reward, shows promise as a potential contributing causal mechanism in at least some cases of ADHD and to the hyperactive-impulsive behavioral symptom domain, suggesting that type 1 processes may be involved. Fourth, measures of response suppression or inhibition show consistent and moderate-size effects in children with ADHD, albeit clearest and most well-replicated in only a few measurement paradigms (e.g., stop signal task) that still receive some debate as to their properties. These response suppression measures are reflected in altered neural responding during these tasks, beginning to set the stage for increasingly elaborated cognitive-neuroscience models of ADHD. Clinical applications will require better integration of these models and resolution of measurement questions that remain for the most sophisticated laboratory measures.

Heterogeneity and Multiple Developmental Pathways: Recent Developments

Nosologists face a recurring dilemma—seek unity across apparently distinct conditions, or else seek differentiation within an apparently single condition. In the first approach, investigators may identify a common personality dimension of constraint or behavioral inhibition that cuts across ADHD, ODD, conduct problems, aggression, and substance abuse, helping to unify those disparate disorders under a single rubric (Krueger & Markon, 2006; Tackett et al., 2013). In the second approach, investigators identify more homogenous subgroups within a single disorder. For example, the field has seen progress with the differentiation of conduct disorder into childhood-onset persistent versus adolescent limited (Moffitt et al., 2008) as further refinements of this developmental taxonomy are emerging (Fairchild, van Goozen, Calder, & Goodyer, 2013). Both approaches are necessary in converging on a refined understanding of developmental psychopathology and developmental trajectories. The unifying approach has helped, for example, in clarifying the extent of shared genetic liability for many forms of psychopathology (Lahey, Van Hulle, Singh, Waldman, & Rathouz, 2011). The splitting approach, meanwhile, has been helpful in clarifying the etiology of conduct disorder and mental retardation and other diseases like cancer.

When it comes to ADHD, as noted at the outset of this chapter, it is helpful to recognize opportunities for lumping. Thus, it has been useful to recognize the overlap of hyperactivity-impulsivity with emotional dysregulation, with conduct disorders, and with substance abuse disorders. Likewise, it is useful to recognize the overlap of inattention-disorganization with learning problems, as well as with internalizing problems like anxiety.

At the same time, and as emphasized in this section, it can be helpful to recognize and parse the considerable heterogeneity within the ADHD population. This section considers how different fractionations of the ADHD domain can be accomplished that may shed light on distinct and perhaps more homogenous subgroups that may prove to have better validity in terms of neurobiology and clinical prediction than does the current ADHD definition.

Three approaches have been taken to parse ADHD. The first approach relies on clinical observation followed by empirical validation. For example, as noted earlier, a recurrent theme in the literature has been the possible existence of a group of children with inattention without hyperactivity, sometimes referred to as sluggish cognitive tempo. This chapter reviewed a handful of studies suggesting distinct psychological mechanisms in a refined inattentive group. Additional review of this domain is provided by Barkley (2014) and by accompanying articles in the same special issue of *Journal of Abnormal Child Psychology* (Becker, Marshall, & McBurnett, 2014).

A related clinical approach has focused on the subgroup of more aggressive or antisocial youth with ADHD. More recently, we pursued this idea using a refinement borrowed from recent work on conduct disorder, known as the *callous-unemotional* trait. In the conduct disorder realm, it seems that important differences in etiology, prognosis, and treatment response accrue to children who present as callous-unemotional (Frick, Ray, Thornton, & Kahn, 2014). This term designates a tendency to be indifferent to the needs and feelings of others, and to display a lack of empathy. It is reminiscent of adult psychopathy, but is not synonymous with psychopathy because children who are callous-unemotional, although at elevated risk of severe antisocial behavior, do not necessarily go on to be psychopathic as adults (Frick et al., 2014). The term nonetheless carries substantial risk of stigma when applied to children and therefore provokes considerable caution in applied settings. (For this reason, the *DSM-5* used the term with limited prosocial emotions.) In the case of children with conduct disorder, it is most relevant due to the potential of differential treatment response that can improve outcome for these children (Frick & Nigg, 2012; Frick et al., 2014).

Because emotional dysregulation as well as aggression commonly overlap with ADHD, this approach may also be fruitful in ADHD even when conduct disorder is not present, although for now we do not know whether it will be relevant to improved treatment tailoring for children with ADHD and so it is not being suggested that it should come into use in clinical practice for youth with ADHD. Even so, it may help us understand neurobiology in the research setting at this stage. To examine this, we (Musser et al., 2013) measured two cardiac parameters of emotional regulation. The first, the preejection period, is conceptually related to type 1 regulatory processing. The second, respiratory sinus arrhythmia, is an index of vagal tone and is conceptually related to type 2 regulatory processing (Beauchaine, Katkin, Strassberg, & Snarr, 2001). Children with ADHD without conduct disorder watched an emotionally evocative film, while cardiac measures were obtained. They were divided based on their surface phenotype (behaviors) into two groups. The first group was rated by both parents and teachers as beyond the 95th percentile (compared with national norms) in their lack of prosocial behaviors like empathy. They were designated as callous-unemotional and comprised about a third of the ADHD sample.

The results were striking and are reproduced in Figure 14.14. The left panel (A) shows results for the sympathetic or type 1 process. The two ADHD groups are on the opposite side of the typically developing children, with type 1 process of over-arousal characterizing the main group of ADHD children, while under-arousal characterizes the callous-unemotional group of ADHD. Differences are most striking in the presence of negative emotional stimuli, which tend to over-stimulate the ADHD youth but to which the callous-unemotional youth are relatively

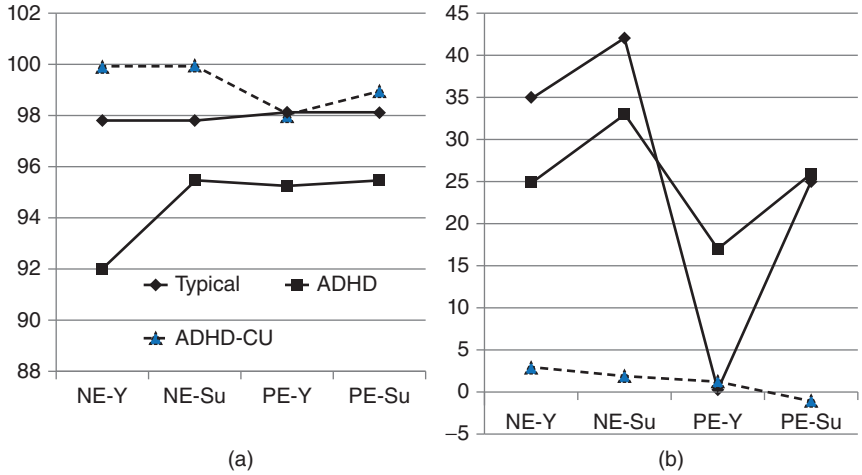

Figure 14.14 ADHD physiology and CU subgroup. Three groups are depicted: typically developing children (typical, $n = 128$), ADHD ($n = 54$), and ADHD with callous-unemotional features (ADHD-CU; $n = 21$). The x axis depicts four emotion conditions: (1) negative and (2) positive emotion (NE, PE); (3) emotional induction (Y); and (4) suppression (Su). Panel A: Preejection period on the y axis; higher value = lower sympathetic arousal. Panel B: Respiratory sinus arrhythmia (*100) difference from baseline (at 0) on y axis; higher value = greater regulatory engagement. *Source:* Adapted with permission from E. D. Musser, H. S. Galloway-Long, P. J. Frick, & J. Nigg (2013) Emotion regulation and heterogeneity in attention-deficit/hyperactivity disorder, *Journal of the American Academy Child and Adolescent Psychiatry, 52*(2), 169.

indifferent in terms of autonomic response. The right panel (B) shows results for respiratory sinus arrhythmia or type 2 process. Here the callous group showed a failure to engage regulatory processes at all, indicating they did not perceive an emotional challenge to be regulated. The ADHD group had a normal, but muted, regulatory response. What is helpful about data of this nature is that they reveal physiological differences within the ADHD population that are hidden when simply looking at all children with ADHD together, and, crucially, that do not appear when considering the *DSM-5* presentations.

A second fundamental approach is to use clustering techniques to regroup children with ADHD based on their configuration of ADHD symptoms. This approach has been used in several studies and is reviewed by Willcutt et al. (2012). In brief, it tends to replicate a set of several ADHD types that maps only partially onto the *DSM-5* presentations. Most striking is that these studies tend to support the existence of the hypothesized group with ADHD without hyperactivity, and suggest that the best cut point symptom-wise for that group is 2 or fewer symptoms of hyperactivity and 5 (or 6) or more symptoms of inattention. As reported earlier, Carr et al. (2010), Goth Owens et al. (2011), and Derefinko et al. (2008) used similar cut points to show somewhat distinct cognitive response patterns in that subgroup with ADHD.

A third approach also uses clustering algorithms, but instead of relying on ADHD symptoms tries to look at measures of mechanism that might be more closely related to neurobiology. To again borrow an example from our group, Fair et al. (2012) used a clustering technique to find subpopulations of children with ADHD with distinct profiles of neuropsychological measures. We identified four subpopulations that are depicted in Figure 14.15. It suggests that one ADHD group is impaired on type 2 processes represented by cognitive control, with poor performance on response inhibition, working memory, and memory span. A second group is impaired on a capacity process, here indexed by reaction time variability. A third group is impaired only on time estimation, an ability that depends on cerebellar-frontal connections. A fourth group also has a capacity problem, with deficits in signal detection. While more investigation will be needed to determine how the two capacity oriented groups differ, overall the model suggests that some forms of ADHD are characterized by breakdowns in type 2 processing, others in type 1 processing or resource capacity. More work will be needed to replicate this study, to integrate it with measures of reward discounting, and to determine whether the hypothesized brain differences proposed here in fact

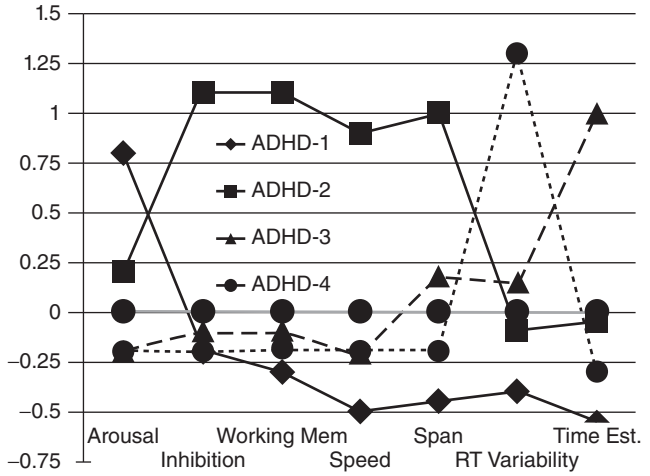

Figure 14.15 ADHD neuropsychological subtypes suggested by empirical clustering. Derived from graph theory analysis. Control group scaled to 0, all measures are in standard deviation units scaled on control group mean; high scores=poor performance. *Source:* Data from D. A. Fair, J. T. Nigg, S. Iyer, D. Bathula, K. L. Mills, N. U. Dosenbach, … M. P. Milham (2012) Distinct neural signatures detected for ADHD subtypes after controlling for micro-movements in resting state functional connectivity MRI data, *Frontiers in Systems in Neuroscience, 6*, 80.

emerge. For now this result suggests an approach that may be fruitful going forward.

Further progress was made extending this work forward by our team using measures of emotional regulation derived from temperament theory (Karalunas et al., 2014). We again used a clustering technique to divide up the ADHD population based on parent-rated measures of temperament from the Temperament in Middle Childhood Rating Scale, a version of Rothbart and colleagues' childhood behavior questionnaire (Rothbart, Ahadi, Hershey, & Fisher, 2001) designed for middle childhood. These parent ratings have several advantages: (1) they are similar to clinical ratings of symptoms, so they are easily extended into the clinic; (2) they overlap the clinical symptom domain while broadening it beyond ADHD; and (3) the dimensions (negative and positive emotion, emotion regulation) have ready linkages to neurobiological systems that are defined in animal work (Nigg, 2006b). These results were also quite heuristic, and are depicted in Figure 14.16. (The figure displays 7 of the 16 temperament scales used, for simplicity.) One group was labeled as *mild* ADHD because their emotional regulation was essentially the same as the normal control group. The second group was labeled as *surgent* because they were high in activity and positive emotion. The third group was labeled as *irritable* because they were high in anger and low in soothability, connoting

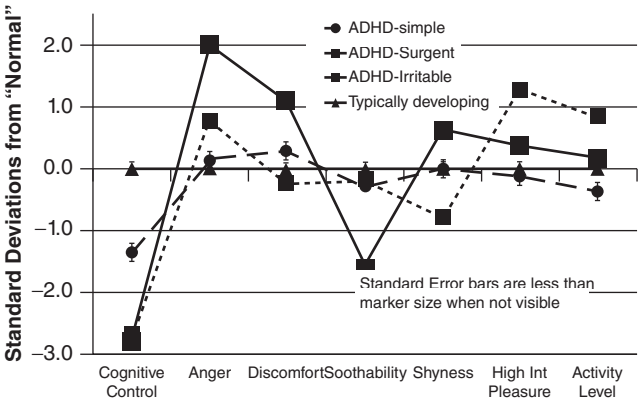

Figure 14.16 ADHD temperament types suggested by empirical clustering. Three temperament based subtypes of ADHD based on a graph theory analysis of maternal ratings. $N = 310$ ADHD, 180 typically developing. Control children scores are scaled to 0 on all scales; the y axis is standard deviation units scaled to the control group.

a tendency to extended anger outbursts and tantrums (Shaw et al., 2014). These children might be expected to exhibit negative urgency impulsivity as discussed earlier. While these groups are clinically recognizable, what was significant about this was study was the external validations conducted. Clustering techniques are no more than exploratory results or hypotheses, because any set of data can be clustered in an almost infinite number of ways. We therefore validated extensively.

First, we showed that the pattern reproduced in a random split of the sample, indicating results were not simply random. To confirm that, we perturbed the data using a variation of information algorithm. The results were robust to data perturbation, meaning that changing some data points to random data did not readily change the story. We next showed that when the same children were seen one year later and the clustering techinque repeated, the same three clusters appeared. Moreover, most of the children in the surgent and negative emotion groups remained in those groups. The mild ADHD group, however, was less stable.

Having done extensive internal validation, we then examined three kinds of external validators. First was the cardiac indicators mentioned in the callous-unemotional study by Musser et al. (2013). Here, we found that the surgent group had a dramaticaly different and unusual regulatory profile, tending to apparently release rather than exert regulation in the face of emotional stimuli, especially emotionally positive stimuli. Striking also was that the mild group had a normal physiological pattern. Second, on functional brain imaging, all three groups differed from each other and from the control group (although we only had imaging data on a small subset of the sample so that particular finding is somewhat preliminary). However, the irritable group had the most striking unique pattern, exhibiting underconnectivity from amygdala to insula, suggesting a breakdown in neural circuits that regulate negative emotions. Third, we examined clinical outcomes one year later. The negative emotion group had a 50% chance of incurring a new psychiatric diagnosis in the ensuing year, versus less than 20% for the other groups. The ability to predict this clinical outcome by this grouping was unmatched by other clincial methods including *DSM* presentations, comorbid picture, or callous-unemotional tratis. This configuration of types or subphenotypes therefore emerges as a superior clinical predictor to any existing symptom picture that might be obtained with children with ADHD. It suggests these subphenotypes as new targets for etiology research.

This last finding about clinical prediction points to the fourth, and perhaps most powerful (and as yet hardly attempted) approach to ADHD subclassification: longitudinal course. While it is know that children with ADHD differ in longitudinal course, little systematic work has formally mapped these trends statistically for predictive purposes. To illustrate this from a related field, we (Jester et al., 2008), conducted a longitudinal study of changes in attention and conduct problems from age 5–17 years as measured by teacher ratings, and related these to early onset drug and alcohol use (a major predictor of substance abuse problems later). We found that drug use was predicted in novel and important ways by the developmental trajectory of attention problems as opposed to the cross sectional number of those problems. At a neurobiological level, the NIMH intramural group several years ago initiated a longitudinal study of structural brain imaging (structural MRI looking at gray matter volumes). This work bore fruit since the last edition of the current book. It suggests that ADHD outcomes are related to trajectory of brain development and highlight the importance of cortical thickness as an endophenotype measure (Shaw, Lerch, et al., 2006; Shaw et al., 2013).

Summary of Heterogeneity

Both lumping and splitting approaches are important to clarify nosology. In the case of ADHD, it is likely that in addition to being related to other disorders, the current definition also encmopasses more than one biological group that is not mapped onto existing descriptive types or presentations. The several methods available suggest that work

toward an improved nosology is becoming tractable. Such work benefits from appeal to neurobiologically based measures of type 1 and type 2 regulation.

FUTURE DIRECTIONS AND CONCLUSIONS

The future is exciting for studies of ADHD, and my hope is that this chapter conveys some of the progress, possibilities, and excitement that characterize the field at present to both young and seasoned investigators. I consider key future directions, including some areas not covered in this review, and then conclusions.

With regard to the future, one theme of this review has been that the field continues to accumulate evidence not only of neurobiological correlates, but now of neurobiological heterogeneity in ADHD. This heterogeneity is on the cusp of being tractable. As this goes foreward, we may confirm that ADHD does contain within it subgroups that have distinct neurobiology with a stronger clinical signal than is available from existing clinical types. It therefore appears that, in time, the field should be able to improve on the current nosology for ADHD. The method of doing so, suggested by us and also by Lenzenweger (Lenzenweger, McLachlan, & Rubin, 2007) is illustrated in Karalunas et al. (2014) in the prior section.

This means that a core future direction is the further confirmation and further development of refined subphenotypes as targets for biological analysis. Clinical types, apparent from observational measures, need to go beyond ADHD symptom dimensions and examine core dimensions related to neurobiology, including clever use of measures of the subdomains of type 1 and type 2 attention and impulse regulation described herein but also, crucially, the domains usually thought of as involving emotion regulation (such as irritability, anger, and dysphoria), which are inseparable from ADHD due to the intricate interrelatedness of self-control, self-regulation, attention, arousal state, and emotion.

With that work going forward, what might it achieve? What might a future nosology look like? It is too early to tell, but by drawing upon some principles of this review one can speculate the following with regard to the nosology of clinical presentation. First, it will be helpful to differentiate children in regard to whether the primary problem is in (1) type 2 processing or in (2) type 1 processing or resource capacity. Second, it will be important to recognize that breakdowns in emotion regulation and in cognition need to both be considered in subdividing this population for clinical purposes and for etiological study.

Children with problems in type 2 processes may resemble the group seen by Fair et al. (2012) that has global problems in executive functioning, yet may not have marked problems in emotional regulation, corresponding to the mild group seen by Karalunas et al. (2014). Children with type 1 processing problems may be extremely impulsive, like both of the emotionally dysregulated groups seen by Karalunas et al. (2014). Those who are extremely irritable may have a problem with type 2 regulation of emotion, while those who are callous or exhuberant may have problems with either underarousal or with type 1 regulation of reward signals. Integrating these different possibilities will require extensive exploration, and probably will lead to modifications of this model.

However, in addition to neurobiology and nosology of child features, nosology of *context* is also needed. That work has scarcely begun. Thus, a second key future direction is to better characterize the contextual limitations and influences on neurobiology, and to identify when context is more important than neurobiology for purposes of nosology. For example, this review has had little to say about race, ethnicity, or culture (more discussion of race and culture in relation to ADHD is provided in Nigg & Barkley, 2014). Yet their influence on what is described herein may be far reaching. Aside from active work in Brazil and Oceania, with a small literature out of Israel and out of Puerto Rico, most of the scientific and clinical literature on ADHD has been from the northern hemisphere and from Western Europe or English-speaking parts of North America. This is rapidly changing as work scales up in China, Japan, Iran, Korea, Mexico, Argentina, and elsewhere. Meantime, in Europe and English speaking North America there has been a relative and substantial neglect of the real boundaries of ADHD neurobiology across race and culture (e.g., African-American and Latino-Latina youth in the United States). This raises the real risk of medical and psychological practice being misguided in those populations. Increasing foci on individualized and genetically informed medicine will mandate a remedy to this gap in knowledge. Across the world, emerging work in China, the Middle East, South America, Israel, and South Africa promise to help further clarify the boundaries of clinical practice and etiology, but programs in those nations need further development and cross talk with those established in the West. Meanwhile, work in the United States, Canada, and western Europe needs to more aggressively examine race, culture, and ethnicity, particularly as population mixes are rapidly changing on both continents due to immigration. This work is beginning and needs to markedly expand. It is notable that

environmental risk factors, emphasized herein, vary widely across these settings and this will be a critical source of trying to understand developmental epigenetics of ADHD.

Related to this point (because race and ethnicity are often correlated with economic position), recent work has revived interest in the influence of low SES in driving some proportion of cases of ADHD, likely via a range of risk factors that are concentrated and accumulate in disadvantaged population. Several approaches could be taken here, but one striking point is the potential convergence of some classes of ADHD with work on the role of systemic stress (e.g., allostatic load) in the emergence of psychopathology and problems in self-regulation.

A further contextual consideration was mentioned only in passing herein yet represents another future direction, and that is the rapid changes in children's socialization by social networking, internet, and other online media and how they may influence ADHD (Pea et al., 2012; Smith & Livingston, 2014s). This domain is having poorly understood effects on children's socialization that will require integration with other methodologies as we consider environmental effects.

Third, emanating more directly from the core material in this review, a major next direction for ADHD will be mapping G×E effects in detail. A shift toward mechanism is occurring. Success likely requires better understanding of epigenetic effects (via DNA methylation, histone methylation, chromatin remodeling, or other mechanisms). Progress will be slow at first, and will eventually join up with related work in other areas of psychiatry. Epigenetic studies require careful balancing of the limits of studies of peripheral tissue in disorders thought to originate in the brain, while also recognizing the profound potential for identifying new diagnostic biomarkers that are more powerful than genomic structure (DNA allele or genotype). For example, recent work illustrates in animals that lead exposure a known correlate of ADHD in humans; (Nigg, 2008) leads to overactivity in rats and this is mediated by altered histone methylation in the hippocampus (Luo et al., 2014; Nigg, Nikolas, Knottnerus, et al., 2010). We recently conducted the first methylome wide study of DNA methylation in children with ADHD, finding in a preliminary sense several signals of methylation related to brain development that may hold promise for future exploration (Wilmot et al., 2014). One can imagine that at some point in the not-too-distant future, we may be able to create active cross talk between animal studies and methylation markers identified in children with ADHD. At that point we can begin not only to conduct diagnostic tests for biological types based on blood markers but also to type based on the combination of genotype and developmental history. The full realization of this picture is still far off, but work on this vision is a major future direction for the field in ADHD given its status as the most common neurodevelopmental disorder in the nosology.

Epigenetic marks, however, are only the tip of the emerging iceberg for potential biomarker studies in ADHD and other neurodevelopmental conditions. The eventual picture will have to include analysis of high-dimensional data sets that integrate understanding from a systems biology perspective, including RNA expression, protein expression, and metabolite studies (Mason, Porter, & Smith, 2014). These approaches may benefit from newly emerging technologies, such as single molecule sequencing, as well as from the rapidly diminishing costs of genomic and molecular sequencing technologies. However, analytic algorithms to exploit these data still require considerable development for application to the complex phenotypes of neurodevelopmental disorder. Thus progress in this domain is likely to proceed in fits and starts for some time to come as methods come on line, are tried, and are refined.

Further, epigenetic studies raise the possibility of unifying work on early developmental risk factors such as environmental neurotoxicants and ADHD (Nigg, Nikolas, Knottnerus, et al., 2010) with genetics and other ADHD work, helping to resolve a kind of paradox in which one field works on environment and another on genes, without sufficient cross talk. Making this connection can open up more focused targets for prevention in vulnerable individuals. Additionally, epigenetic marks are potentially reversible even in post-mitotic tissue such as the brain (Szyf, 2010). While work on reversing behaviorally relevant methylation or demethylation is in its infancy, the potential for powerful new therapeutic agents is inescapable.

Fourth, as shown in the work reviewed here and by others, ADHD is heterogeneous with regard to outcome. A crucial future direction is to understand this. In part, this means identifying determinants of natural recovery or resilience in children with ADHD, especially in adolescence and adulthood (Cherkasova, Sulla, Dalena, Ponde, & Hechtman, 2013). These remain under-explored and potentially extremely important as clues to future directions (Cicchetti, 2013). The contemporary brain imaging literature that was summarized in this chapter is almost entirely confined to cross sectional studies. The only longitudinal studies to date have focused primarily on gray matter volumes or cortical thickness. Thus, a major future direction will be longitudinal studies of functional brain imaging in ADHD, using either resting state or task-based metrics to map functional neurobiology in vivo.

Finally, whereas this chapter outlines in detail the rich possibilities for capturing ADHD phenotype and subphenotype at multiple levels of analysis, genetic studies have as yet not taken much advantage of advances in brain imaging or neuropsychology. In part this is a logistical problem: genetic studies as conducted to date require massive samples (upward of 10,000) to get adequate power to see effects. Genome wide association studies using sample sizes of 25,000 to 40,000 ADHD cases and more are in preparation and will be appearing in genetic studies of ADHD around the time this volume appears in print. Conducting sufficient neuromimaging or even neuropsychological evaluation for such work is still in progress around the world and will take longer. Yet, pooled consortia are beginning to reach this point. The ENIGMA consortium has begun to examine GWAS data in relation to structural brain imaging metrics (Thompson et al., 2014) and this consortium is continuing to expand and improve the brain metrics it can examine via pooled analyses. Even on a smaller scale, however, it is possible to conduct statistically powerful work using gene pathways or prioritized gene sets in relation to novel and more contemporary brain network metrics (Mooney, Nigg, McWeeney, & Wilmot, 2014). Doing so should have the purpose not simply of correlating genes and brains, but of identifying biological subtypes of ADHD that can be cross-replicated in brain and gene (as illustrated in part by Karalunas et al., 2014).

It is worth pausing on this last point. It can be seen from the prior examples that different causal mechanisms may lead to the same ADHD phenotype or that distinct mechanisms may be associated with novel subgroups of ADHD that all have the disorder. These types of findings exemplify equifinality but also enrich our thinking about which children truly have a clinical disorder. Do children with a simple under-controlled presentation, but with normal sympathetic and parasympathetic physiology and benign clinical outcomes, have a clinical disorder? We can also imagine moving closer to personalized medicine: do children with an irritable presentation benefit from a distinct pharmacology or behavioral intervention at higher rates than other children with ADHD?

Many challenges suggest that realizing such hopes remains some distance off. For example, tracing the course of development and recognizing which developmental path a given child is on will take more work. To give an analogy, pediatricians routinely examine growth charts to locate the growth trajectory of a child patient. In subsequent years, they do not ask whether the child is tall or short for age, but rather whether she has diverged from the prior trajectory. In the same way, we can imagine mapping trajectories of change for ADHD that reflect routes for temperament types, neurocognitive types, or even brain profiles, and then asking in future assessments whether they remain on an improved, same, or worse trajectory compared with the prior picture.

A key challenge will be in actual clinical implementation. Current clinical practice remains accustomed to diagnostics reliant on simple algorithms and symptom lists. Combining of future data will likely require the field to abandon simple diagnostic algorithms that clinicians keep in their head (as is now done in *DSM-5*) and instead move to complex algorithms that use machine computations to assist with diagnosis. Clinicians of the future may rely instead on complex algorithms implemented in handheld computing devices, which become a vital tool of psychiatric and psychological assessment.

A final key research consideration will be extending these trajectories back to very early life. Nearly all clinical prediction work in ADHD, be it treatment outcome or brain imaging, goes no younger than 3–4 years of age. Yet it is quite likely that indicators of ADHD may be seen in early infancy or even before birth, if we know where to look (Auerbach et al., 2004; Sullivan et al., 2015). Such work on the early developmental origins of ADHD, of self-regulation, and of the early programming of response tendencies represents a major opportunity for the next generation of research. This approach is particularly compelling when we consider epigenetics, because the prenatal and early postnatal periods are likely to be of primary importance for epigenetic change and programming. The long term hope of preventing ADHD, so as to allow vulnerable youngsters to achieve their full potential without developmental handicap, will ultimately require understanding these early origins of the emergence of self-regulation.

Overall, progress in the last decade has shown several trends for this field. First, a gene × environment perspective is increasingly ascendant and lays the groundwork for imagining epigenetic models of neurodevelopmental conditions like ADHD. Identification of epigenetic mechanisms could, conceivably, bring a turning point in the coming century, but how soon this can be done for human behavior will depend on improved technologies that have yet to be invented, which would enable assessment of epigenetic change in the central nervous system in living humans. This in turn has revised interest in specifying the developmental environments associated with ADHD in conjunction with genetic analysis. Second, multiplicity of types and mechanisms within the ADHD population appear to exist and are increasingly recognized. Reaching some consensus on how they can be best characterized is

now a chief goal in the field as we begin to imagine moving toward personalized care for children within the ADHD rubric. Third, integrated multilevel analyses of ADHD, that take into account genes, environments, physiology, and brain function are increasingly becoming normative around the world. Seeing whether these rich assessments actually can enhance clinical outcomes will be the critical test of utility for this type of work in the coming generation.

In conclusion, self-control and self-regulation are of ubiquitous interest in regard to human adaptation and mental health. ADHD is a paradigmatic disorder that encompasses and exemplifies many of the developmental processes involved and how they may go awry. Use of a two-process perspective is useful in beginning to understand and unpack the complexity in this syndrome. Study in this area is in an exciting phase and opportunities abound for dramatic progress in the decades to come.

A BRIEF HISTORY

Children and adolescents who are uncooperative and angry and who steal, fight, destroy property, break the law, and attack others have always been a concern for adults. Antisocial behavior in youths is costly and unpleasant to parents, peers, and the community. Moreover, chronic antisocial behavior in childhood and adolescence is the major disruptor of healthy development and results in pain and suffering in adult relationships, patterns of incarceration, disturbed mental health, and difficulties in employment (Miller, 2004).

Research into antisocial behavior has long been an applied science, largely in response to these disruptions to youthful lives and the community. Experts who have studied and written about the nature of delinquent behavior are also those who are concerned with the design of rehabilitation services. Healy (1926) initially observed that delinquent youths were in frequent company with delinquent peers but hesitated to attribute causal status to peers. Inspired by the new psychodynamic perspective of the times, some researchers surmised that antisocial behavior in children was motivated primarily by internal conflicts and turmoil, mostly from troubled relationships with caregivers. Speculation about the influence of peers, however, shifted a bit when the effectiveness of various rehabilitative services for delinquent youths was evaluated (Healy & Bronner, 1936). In the context of a quasi-experimental design, Healy found less recidivism among youths in foster care treatment in Boston than among youths grouped in institutional care in Chicago. These findings suggested that warehousing youths with other troubled youths might actually exacerbate their problems. Although this was not a randomized trial, the finding portended future findings about the problems of peer influence in group care (Dodge, Dishion, & Lansford, 2006; Leve & Chamberlain, 2005).

Criminology

The field of criminology emerged from a confluence of psychological and sociological theories and methods. Accordant with the logical positivist philosophy of science (e.g., Popper, 1959), a plethora of longitudinal studies was conducted to determine which children become delinquent. The methods of these early longitudinal studies were intensive and often involved extensive home observations and carefully transcribed caseworker notes (e.g., Glueck & Glueck, 1950). These studies often took many

The work described in this chapter was supported by grants AA022071 from NIAAA and NIDA and DA07031 and DA016110 from NIDA, all awarded to the first author. We appreciate Cheryl Mikkola's support and attention to detail when editing this manuscript.

decades to code, tabulate, and analyze before their full scientific value was realized (Elder et al, 1986). For example, the findings from a longitudinal study with an embedded randomized prevention trial conducted prior to World War II did not yield findings until 30 years later (e.g., McCord, 1978). Fortunately the findings were well worth the wait. For example, the Cambridge–Sommerville youth study found that early harsh parenting (coded from home visitor ratings) was prognostic of later antisocial behavior and aggression. For the prevention trial, early-adolescence youths were carefully matched and then randomized to a 4- to 5-year intervention experiment that ended at about the time the United States entered the war. After 30 years of follow-up, much to the surprise of the scientific community, the youths in the intervention group had somewhat worse outcomes than did those in the control group. Four to five years of social work apparently had no effect or perhaps even had an iatrogenic effect.

Several patterns of findings emerged from the early criminological studies about predictors of delinquency, which investigators reviewed in the early 1980s. Meta-analysis of all the existing criminological longitudinal studies on the prediction of delinquency revealed that disorganized, harsh, and lenient family environments were the most prognostic of future delinquency (Loeber & Dishion, 1983). A close second in predictive power was the youths' own problem behavior in childhood, with teacher ratings being most prognostic, followed by parent ratings. The patterns of findings across the early criminological investigations were largely replicated in more recent longitudinal work on the prediction of crime, such as the Cambridge Youth Study (Farrington, 1985; West & Farrington, 1973). In general, paradoxical patterns of harsh and overly lenient parenting result in children arriving to school with problem behaviors, which in turn is prognostic of escalation to more serious forms of delinquent offending in adolescence and beyond. Not surprisingly, early onset of problem behavior was found to be associated with escalations to more serious and repeated offending in adulthood (Farrrington & Gallagher, 1986; Robins & Hill, 1963). Measures of children's cognitive abilities and genetic vulnerability were only modestly predictive of future delinquency (Loeber & Dishion, 1983).

Many of the early longitudinal studies on the etiology and prediction of delinquency did not measure peer environments. It was not until the 1950s that criminologists, such as James Short, began to speculate about the causal role of peers in the development and escalation of antisocial behavior (Short, 1957). Differential association theory motivated the study of group processes associated with gangs, in particular the Chicago "street corner" gang (Short & Strodbeck, 1965). These early studies of peer dynamics amplifying delinquent behavior were largely observational. However, at the same time, learning theory was dominating the study of behavior. The match between differential association theory and learning theory was natural and adopted by criminologists as an explanation for crime and delinquency (Burgess & Akers, 1966). Direct observations of group institutional settings verified that the rich reinforcement for deviant behavior provided by peers far outweighed the meager rewards for prosocial behavior provided by adults in the same setting (Buehler, Patterson, & Furniss, 1966). Further support for the unique contribution of peers to the development of delinquent behavior in criminology was found in larger community studies (Elliott, Ageton, & Canter, 1979; Jensen, 1972). Most theories of crime thereafter have conferred causal status on peer influence in general (Reiss, 1988), and on gangs in particular (Thornberry, 1998).

Child Psychiatry and Psychology

Until the late 1970s, child psychiatry and psychology were neophytes to the scientific study of antisocial behavior in children. Psychology brought two major contributions to the scientific study and understanding of antisocial behavior. The first was a developmental perspective, initially formulated as developmental lines (Freud, 1963). Psychiatric epidemiology was an emerging science with unique design features and methodologies. For example, the case control method of identifying youths at risk and conducting follow-up assessments with them and with the case controls became part of the scientific literature. For example, in the Robins and Hill (1963) study, it was suggested that the developmental patterns of early-onset and late-onset antisocial behavior had unique etiologies. The early- and late-onset developmental pathways to adult antisocial behavior later became an organizing principle in theories about the etiology of antisocial behavior (Moffit, 1993; Patterson, 1993).

Psychology's strong emphasis on measurement theory made a major contribution to the study of antisocial behavior. Advances in the science of psychological measurement were made largely as a function of the massive demands on psychologists to assist with the selection and deployment of young adults to World War II (Wiggins, 1973). The formal guidelines for testing individual differences in basic concepts as *traits* were developed, and the concept of a *construct* was born (Cronbach & Meehl, 1955). A methodological framework was articulated for statistically differentiating between variation in a measurement method and a personality trait construct (Campbell & Fiske, 1959). For example, one could explore whether

teacher and parent ratings of a child's antisocial behavior reflected a trait of the child or unique reporting biases of each adult. It turns out that indeed, when multiple measurement methods are used there is ample evidence that children's antisocial behavior reflects a trait of the child (Patterson, Reid, & Dishion, 1992).

Despite the scientific advancements in personality psychology, measurement, and developmental psychology, clinical psychology lagged with respect to scientific rigor. In the early formulations of clinical psychology, treatment was not its strongest suit, and there was very little flow of information between the field of criminology and the psychological treatment of antisocial behavior. In the beginning, treatments for antisocial behavior were exercises in armchair psychology, and theoretical models were applied loosely to the design of outpatient and residential treatment programs (e.g., Redl & Wineman, 1951, 1952). The prevailing view at the time, which is largely shared to this day, was that antisocial youths were best treated by pulling them out of the pathogenic family and peer environment and providing them with intensive residential treatment. Implied is that the more intensive treatment yields the most long-term effects on reducing future antisocial behavior.

Not surprisingly, after scientific scrutiny of intensive residential treatment, pessimism was in order. Although it was possible to create a residential environment in which youth problem behavior was dramatically reduced, therapeutic gains were lost when children were returned to their home and neighborhood environments (Redl & Wineman, 1952).

The experimental approach to studying and analyzing operant behavior formed the foundation of the behavioral revolution in psychological science (Skinner, 1938, 1955). Applied behavior analysis expertise was invaluable for improving the lives of children and adolescents with a variety of psychopathologies. The framework was applied to the design of group homes for delinquent youths in the form of the teaching-family model (Wolf et al., 1976). The model is both humane and sophisticated, with the laudable goal of deinstitutionalizing the treatment of antisocial youths. Unfortunately, careful evaluations of group homes that were using the teaching-family model revealed that they did not reduce antisocial behavior over and above other community group homes. However, compared with community treatment, the teaching-family model was superior for improving academic achievement (Weinrott, Jones, & Howard, 1982). It appeared, once again, that the gains that youths made in the carefully engineered group home facility did not generalize well when they were returned to the community.

A group of investigators began designing behaviorally oriented interventions for the family environment. Several clinical researchers applied operant theory to treat children's problem behavior, with considerable promise of success. First and foremost were Wesley Becker, Rex Forehand, Gerald Patterson, and Robert Wahler (O'Dell, 1974). Patterson's work was noteworthy in terms of the application of conditional probability analysis to understand the antecedents and consequences of specific antisocial acts, which led to the understanding that being mindful of the social interaction context in families provided clues to treatment and prevention (Patterson & Cobb, 1971, 1973). These early studies were process focused. It was particularly intriguing that after weeks of observation, a simple bug in the ear to the mother to change her "antecedent behaviors" led to dramatic reductions in children's aggressive behavior on a case-by-case level (Patterson & Moore, 1979). Studies such as these were critical for the early stages of theory development that integrated an understanding of social interaction dynamics of antisocial behavior with children's developmental trajectories and effective prevention and treatment (Patterson, 1982; Patterson & Reid, 1984; Patterson et al., 1992).

BUILDING MODELS OF ANTISOCIAL BEHAVIOR

Translational Framework

In the 1980s a new generation of longitudinal studies on the development of antisocial behavior emerged. Consistent with a developmental psychopathology framework (Cicchetti, 1990; Cicchetti & Toth, 2009), the studies were conducted with an eye toward designing more effective interventions. The concept of performance models became appealing to the scientific community and to the National Institutes of Health, and longitudinal studies were funded that included direct observations of family interactions that had been previously demonstrated to be sensitive to change in treatment (Patterson & Moore, 1979). The new scientific game was to account for variance in child and adolescent antisocial behavior. If directly observed family interaction accounted for unique and substantial variation in present and future antisocial behavior, those constructs would be promising as targets for prevention and treatment. Thus, an explicitly translational framework was adopted, which resulted in substantial improvements to prevention and treatment strategies.

At around the same time innovations in statistical procedures empowered causal modeling (Jöreskog & Sorbom, 1976). An explosion of longitudinal studies incorporated multiple indicator causal models of a variety of behavioral

issues and a method for directly comparing the fit of competing models (Bentler & Bonnett, 1980). The use of structural equation models provided an explicit means for the simultaneous analysis of both measurement and causal effects in longitudinal models. A seldom-cited breakthrough book by James Dwyer (1983) helped forge the link between measurement theory and causal modeling, showing that classic issues such as multi-trait and -method models could be operationalized and tested within the structural equation environment. Several researchers began to emphasize the value and importance of integrating multiple measurement methods in the analysis of various forms of problem behavior (Dishion & Loeber, 1985; Patterson & Bank, 1986; Patterson & Dishion, 1985). These mostly correlational models of family and peer factors associated with child and antisocial behavior were suggesting that both relationship environments were contributing substantial variance to the development of antisocial behavior. These early correlational pilot studies hypothesized causality but were hardly rigorous tests of mediation and moderation (e.g., MacKinnon & Fairchild, 2009).

Ecology

Urie Bronfenbrenner's (1989) conceptual framework for an ecological perspective on child development became particularly useful for systematic causal modeling. As discussed by Dwyer and several other methodologists interested in structural equation modeling, one of the key shortcomings of a statistical approach was the misspecification problem. Models in which key putative causal constructs are omitted are simply misspecified and the magnitudes of effects biased. Thus it became a central concern of researchers studying antisocial behavior to have a stronger argument for the environmentally and biologically oriented constructs included in a causal model (Dishion & Patterson, 1999). Thus, in two Dishion and Patterson reviews on the development of antisocial behavior, the literature was organized relative to the Bronfrenbrenner framework (Dishion, French, & Patterson, 1995; Dishion & Pattterson, 2006). These reviews reflected an emerging literature about the etiology and course of antisocial behavior that clearly indicated parenting, peer, and self-regulatory mediation and moderation in childhood and adolescence progressions of antisocial behavior. From this literature it was safe to conclude the most contextual stressors on children associated with higher antisocial behavior and crime rates, such as neighborhood and poverty, were mediated by the disruption of parenting and through effects on the self-organization of deviant peer clusters.

Without question, genetic-based vulnerabilities and resilience factors moderate the effect of environments on the development of antisocial behavior. It is likely, however, that behavior–genetic approaches to estimating sizes of shared environmental effects and of genetic effects are not accurate reflections of nature or nurture (Beauchaine & Hinshaw, 2008). One key factor to consider from a modeling perspective is the measurement method: parent reports tend to produce somewhat higher estimates of genetic effects than do direct observations of behavior (Bullock, Deater-Deckard, & Leve, 2006; Leve, Winebarger, Fagot, Reid, & Goldsmith, 1998). Regardless, there is considerable value in using twin designs to model estimates of genetic effects, with a particular effort to consider mediation and moderation (e.g., Lemery-Chalfant, 2010; Meier, Slutske, Heath, & Martin, 2011). Recent efforts to integrate adoption designs are noteworthy and suggest the cross-fostering conditions of key causal processes, such as family conflict. For example, Harold and colleagues used a twin and an adoptive design to examine the role of interparental conflict and found substantial evidence that the effects on early emergence of antisocial behavior were not simply passive correlations of shared genetic traits (Harold et al., 2013). The integration of multiple design frameworks is the future for research on the ecological conditions giving rise to antisocial behavior, as well as drug abuse, high-risk sexual behavior, and violence.

During the past 10 years research has moved rapidly toward direct measurement of genetic polymorphisms associated with development of a variety of human behavioral characteristics, including antisocial behavior (Rutter, 2006). Caspi and colleagues, for example, tested a model with a gene by environment interaction that accounted for adult violence in males. In this model, boys with the MAO-A single nucleotide polymorphism who also had been exposed to parental maltreatment in early childhood were the most likely to be violent adult offenders (Caspi et al., 2002). Cicchetti and colleagues, who also examined the impact of child maltreatment on the development of antisocial behavior, significantly extended this finding. Among youths with a history of maltreatment, three genetic polymorphisms (tryptophan hydroxylase, serotonin transporter, and MOA), amplified the impact of maltreatment on various indices of antisocial behavior in adolescence (Cicchetti, Rogosch & Thibodeu, 2012). The gene by environment interaction also seems to amplify the effects of parenting practices in early adolescence. For example, Dick and colleagues found that youths with

the GABRA2 polymorphism were more likely to develop externalizing problems in the context of low levels of parental monitoring (Dick et al., 2009). Thus, genetic vulnerability for antisocial behavior may come into play in that it amplifies somewhat different aspects of parenting effects in early childhood, middle childhood, and adolescence. Little research to date has examined the moderation of peer effects on various forms of antisocial behavior, a topic discussed in more detail later in this chapter.

Most investigators assume that genetic effects are transmitted to the development of antisocial behavior through identifiable traits, such as temperament. Temperamental traits are characteristics of the child that are observable and define basic action and reaction patterns to the environment and ecology. These endophenotypes have been hotly pursued in scientific research that is attempting to link genetic effects to social behaviors (Gottesman & Gould, 2003). As has been discussed previously, various indices of self-regulation in general and of effortful control in particular seem to be very promising as endophenotypes linking genes with antisocial behavior (Dishion & Patterson, 2006). The pioneering work of Rothbart and Posner (2006) is exemplary with respect to linking imaging of brain neurocircuitry to genetic constitution in research on attention and emotion regulation and the construct of effortful attention control. Remaining unclear is mapping of various temperament traits, such as effortful control, emotionality, and impulsivity, with respect to shared and unique features, but it does appear that the genetic regulation of dopamine receptors lies at the core of vulnerability to development of problem behavior (Beauchaine & Hinshaw, 2008).

As discussed by Leve and colleagues (2010), social mediation of genetic effects is likely to provide a deeper understanding of etiology. Although it is promising, we have yet to show that temperament mediates genetic effects on antisocial behavior, a problem originally identified by Rutter's (2006). Presumably, integration of solid environmental, neuroscience, and genetic research will lead to breakthroughs that trace development from gene, brain circuitry, and temperament, to antisocial behavior. Multilevel models such as these will likely enhance our collective capacity to improve the lives of susceptible children and families.

An ecological view of development assumes that biology and social experience are inextricably linked with the form and function of development. Of particular salience in children's development of antisocial behavior are the patterns of interaction within close relationships, such as families, friendships, and later romantic partners. In the past 10 years, however, considerable progress has been made in research on the relationship dynamics relevant to understanding and reducing antisocial behavior in children and families. Relationship dynamics is a pattern of interactions that cannot be accurately captured in a snapshot of children's lives; it requires measurement over specific periods of time. The history of research on development of antisocial behavior suggests that the study of relationship dynamics has been the most promising in terms of accounting for variance in antisocial behavior in childhood and adolescence (Dishion & Patterson, 2006). Interventions that target relationship dynamics tend to be more reliable with respect to improving children's lives (Weisz & Kazdin, 2010).

This review next focuses on progress made during the past 10 years with respect to (a) modeling the relationship dynamics and ecological conditions underlying the development and course of antisocial behavior, and (b) considering the successes and failures of randomized intervention trials designed to test underlying developmental models.

Micro and Macro Relationship Dynamics

While examining a child's ecology, one can parse the social environment into specific microsocial and macrosocial influences (Dishion & Patterson, 2006; Patterson, in press). Microsocial influences involve relatively immediate action and reaction patterns in which antisocial behavior is learned and amplified. In terms of the development of aggression, parent–child, sibling–child, and peer–child interactions are the most frequently studied relationships. These transactions occur in seconds, and the patterns are observable and reliably quantified in an hour of observation of a relationship.

Macrosocial dynamics evolve over longer periods of time and are often labeled and measured as global outcomes. For example, peer rejection, drift to deviant peers, and academic failure are examples of macro relationship dynamics relevant to the development and course of child antisocial behavior. Changes in network dynamics constitute perhaps the most rigorous definitions of relationship dynamics that are macro. For example, engaging with a gang network in a community can confer status, basic resources, and potential sexual partners (see Dishion, Ha, & Véronneau, 2012), which are functional outcomes that often unfold over the course of days, weeks, months, and years. This perspective is helpful when studying the development of antisocial behavior in children, in that one examines the child's movement from the family, to peers and teachers in school, to friendships and eventually to

an intimate partner, adult family relationships, and relationship networks in the community (e.g., military service, gangs, coworkers, extended family).

From an ecological perspective, when antisocial behavior evokes friendships and deviant peer cliques, the behavior pattern has shaped the social context and network of the individual. Thus, macrosocial effects in turn shape microsocial influences. Once a youth becomes a member of a gang, daily rates of reinforcement for deviant talk and behavior increase, and the payoffs for studying and prosocial relationship development diminish. The same synergistic link could be made between becoming isolated over time and the power of rumination and stress to generate depression. The more one becomes depressed and isolated, the more powerful one's own thoughts become in defining a course of action (e.g., Fyodor Dostoyevsky's *Crime and Punishment*).

This sort of macrosocial function is often of interest to evolutionary psychologists, particularly social adaptations that function to promote survival of both individual and collective gene pools (e.g., Belsky, Steinberg, & Draper, 1991; Ellis, Figueredo, Brumbach, & Schlomer, 2009). The evolutionary framework is helpful for suggesting foci that would otherwise be ignored in a purely psychological analysis. Behavior is shaped by consequences, but the consequences can be viewed from different temporal perspectives and in terms of different units of aggregation (Biglan, 2003). Behavior is also shaped by the momentary reactions of the audience and by the biologically driven need for procreation and group affiliation (Dishion & Patterson, 2006; Dishion et al., 2012).

When relationship niches are considered in the context of the life course, attention is given to the functional dynamics within (i.e., microsocial) and to the movement from one relationship to another (i.e., macrosocial). Several investigators have used the cascade metaphor to represent the development of antisocial behavior from early childhood through adolescence (Dodge, Greenberg, & Malone, 2008; Masten et al., 2005; Moilanen, Shaw, & Maxwell, 2010; Patterson et al., 1992). The key point of the cascade model (see Figure 15.1) is that each developmental stage has its adjustment outcomes and collateral effects that can be seen as products of the outcome. In early childhood, relatively normal challenges in emotion regulation and defiance of parents can lead to problems in school readiness, and lead to failure in academics and peer relationships. Even as early as age 5, marginalized children can associate and reinforce problem behavior, during childhood. Continued difficulties in school and growth of problem behavior predict movement into more serious deviant peer groups. Peer clustering for problem behavior

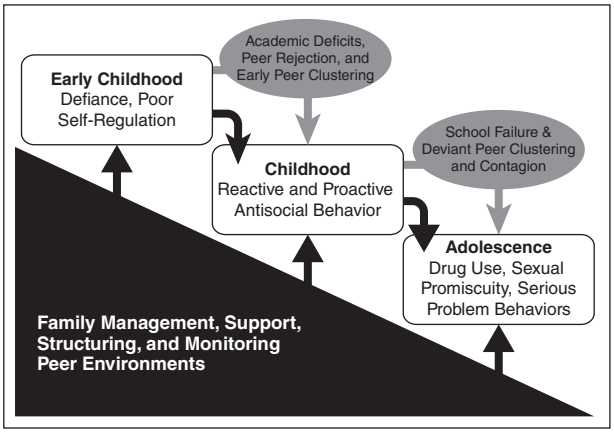

Figure 15.1 A developmental cascade model: parenting contributions and amplifying mechanisms.

is one of the strongest predictors of escalation to more serious antisocial, criminal, and drug use in adolescence. From a biosocial perspective, genetic and other biological characteristics (e.g., sex, puberty) of the child motivate developmental progressions and interact with microsocial and macrosocial dynamics to account for individual differences in various forms of antisocial behavior. We unpack the cascade model shown in Figure 15.1 in the sections that follow.

One of the core achievements in developmental psychopathology is the multilevel analysis of early childhood self-regulation with respect to the emergence of serious forms of antisocial behavior in young adulthood (Cicchetti & Toth, 2009). In this chapter, we focus on two underlying behavioral processes within which thoughts, feelings, and norms are associated with antisocial behavior and its growth over time. Coercion and contagion dynamics at each stage of development can account for variation in numerous forms of problem behavior, beginning with aggression and culminating in multiple forms of problem behavior in adolescence.

COERCION AND CONTAGION DYNAMICS

Coercion is a basic interpersonal dynamic by which individuals use aversive behavior to attain access to rewarding resources and to reduce unpleasant experiences. It can involve being aggressive or unpleasant, or it can play out as emotional manipulation. Although aggression and violence are certainly examples of more extreme forms of coercion, the vast majority of coercive exchanges go unnoticed by the participants. A young child's whining sets the stage for parents to attend to, and potentially reward,

the behavior, for example. However, most parents at some time reverse the pattern and work to teach the child to use language to make requests rather than rely on whining and crying (Patterson, 1982). The coercion process is inherently bidirectional in that it builds on response tendencies of both the child and the parent. The key to change often lies in parents' ability to regulate their emotional reaction to aversive child behavior rather than yell, withdraw, spoil, or hit, and to mindfully manage the child's behavior by using patience and by optimizing opportunities for their child to learn social skills. The link between understanding coercion and promoting family management becomes clear: The latter is the remedy for the former. Positive family management practices reduce the functional utility of coercive dynamics in the family.

Intensive research on the coercion dynamic began in the homes of children referred to outpatient clinics for aggressive behavior (Patterson, 1974). To isolate the underlying patterns that accounted for the coercion dynamic, Patterson and colleagues conducted a series of studies that looked at the conditional probability of a child's aggressive response to a parent's behavior. This series of detailed observational studies revealed the importance of stimulus control in the aggressive exchange (Patterson, 1976; Patterson & Cobb, 1973; Patterson & Moore, 1979). Although work on coercion theory was initially driven by intensive study of clinically aggressive children, the concepts were measured in epidemiologically defined community samples of youths and found to predict escalations in problem behavior from childhood through adolescence (for a review, see Dishion & Patterson, 2006). When the coercion model was then applied to the design of prevention studies, it was found that targeting coercive parenting practices prevented the escalations in problem behaviors one would expect among high-risk adolescents (Dishion, Patterson, & Kavanagh, 1992) and in families undergoing divorce and remarriage (for a review, see Forgatch & Patterson, 2010). These findings suggested that whatever the origins of coercive dynamics in families, interventions that reduce coercion help reduce antisocial and aggressive behavior in childhood and adolescence.

The peer contagion dynamic is of particular interest with regard to the amplification of children's aggression to other forms of problem behavior. Since the beginning of systematic research on antisocial and delinquent behavior, it was observed that peers are core to the problem, but the influence process was unclear (Dishion & Patterson, 2006). Study of the microsocial dynamic called *deviancy training* was begun (Dishion, Capaldi, Spracklen, & Li, 1995; Dishion, Spracklen, Andrews, & Patterson, 1996) by carefully observing the adolescent male friendships of a sample of 13- to 14-year-old boys in the Oregon Youth Study (Patterson et al., 1992). In these videotaped interactions, the boys' deviant talk and their affective reactions were coded in real time. To study the reinforcement of deviant values in verbal exchanges among peers, one must use an extension of the typical learning approach to studying aggressive behavior. Relational frame theory (Hayes & Hayes, 1992) clarified the mechanisms by which reinforcement of words is equivalent to reinforcement of behavior. A uniquely human capability that comes with language is that rewarding deviant talk is as powerful as rewarding the actual behavior.

The matching law was applied to evaluate the extent to which the boys were being selectively reinforced for deviant talk than for other, more normative topics (i.e., relative rate of reinforcement). In general, it was found that the amount of deviant talk in an adolescent friendship was directly proportionate to the friend's relative amount of positive affect in response to deviant versus normative talk (Dishion et al., 1996). Snyder and colleagues (2008) extended the concept of deviancy training to include young children mocking adult behavior, such as pretending to smoke cigarettes during playtime at school. In the studies by Snyder and colleagues, positive affect was also coded and revealed that some youths were mutually reinforcing deviant talk and that this dynamic contributed to later increases in antisocial behavior. The idea that peer contagion has a unique influence on future behavior of children and adolescents has been supported by studies of iatrogenic effects, which have indicated that random assignment to group interventions that aggregate high-risk children can potentially increase problem behavior, and that these increases are associated with deviancy training in the sessions (Dishion, McCord, & Poulin, 1999; Dodge et al., 2006).

Coercion and contagion often occur outside of participants' awareness. Coercion is more characteristic of established relationships in which members share a certain level of fate control, such as parent–child, sibling, and marital relationships. Contagion, on the other hand, is a concept typically applied to understanding how behaviors become disinhibited in the context of age-mates (Dishion & Tipsord, 2011). To study coercion and contagion as real-time behavioral dynamics, it is necessary to code interpersonal events as they unfold over time and to link interpersonal outcomes (ending conflict, mutual laughter) with the coercion and contagion dynamic over time. It is possible, however, to use global ratings of direct observation data to surmise the extent to which a

relationship interaction is characterized by either coercion or deviancy training.

EARLY CHILDHOOD: COERCION IN FAMILIES

Given the evidence that early-onset antisocial behavior is potentially the most problematic for the child and the community, it stands to reason that considerable work would have been done to examine early-childhood parent–child interactions and interventions. This developmental period is characterized by strong dependence on primary caregivers for nurturance, safety, and socialization (Ainsworth, 1989). This foundation is not to be underestimated; lack of it will set the stage for struggles in other periods of development of self-regulation (Rothbart, Ellis, Rueda, & Posner, 2003) and of correlated problem behaviors, such as oppositional behavior and aggression (Olson, Sameroff, Kerr, Lopez, & Wellman, 2005).

Patterson's theoretical framework of coercive family processes is relevant to understanding how the interaction of child characteristics and parenting practices prompts development of early problem behavior (Patterson, 1982; Patterson et al., 1992). Caregiver depression can be a powerful disruptor of positive parent practices when isolated mothers care for young children without adequate support (Wahler, 1980). Depression certainly disrupts positive parenting and the critical exchanges between a young child and his or her caregiver (Hops, Sherman, & Biglan, 1990). However, surprisingly little research has identified the effects of caregiver isolation and depression on actual parent–child coercion dynamics. A notable exception is the work of Shaw and colleagues. In longitudinal research, these investigators found that a tendency for the child to be bold in the face of a fearful stimulus, together with maternal depression at child age 2, were the best predictors of the early-onset trajectory (Shaw, Gilliom, Ingoldsby, & Nagin, 2003).

The study of coercion dynamics presents some difficulty because it requires the measurement of parent–child interaction as it unfolds in real time. With an observed microsocial data stream, one can examine how contingent events lead to escalation of the aversiveness of the interaction. Early on, use of Markov models of social interaction and computation of sequential analyses activated interest among scientists studying microsocial dynamics (Gottman & Roy, 1990), but these models became increasingly suspect, partly because of the base rate problem. Aversive events generally constitute a minority of social events, and the probability of a parent responding aversively contingent on a child's coercive behavior is about .5 of 10% of the interaction. Given the rarity of aversive exchanges, estimates of coercive interaction patterns were somewhat unreliable (Stoolmiller, 2001).

Snyder and colleagues (Snyder, Edwards, McGraw, Kilgore, & Holton, 1994) were the first to consider intensity and duration as critical parameters of escalating patterns of coercion. In an examination of 10 aggressive and 10 nonaggressive preschool children, parent–child interactions were studied for 10 hours. The researchers found that duration of conflict was the key to studying the progression of coercion. Using the Family Process Code, which captures real-time duration of parent–child interactive behavior (Dishion, Gardner, Patterson, Reid, & Thibodeaux, 1983), these researchers determined that parent–child interactions that involved aggressive children were characterized by longer durations of conflict, greater intensity of conflict, and a statistically reliable tendency for the children to be reinforced for their behavior during conflict.

The application of a dynamic systems framework (Granic & Hollenstein, 2003; Granic & Patterson, 2006) is helpful when studying coercive parent–child interactions, and more important, the mutual effects of positive and coercive family interactions. Within a dynamic systems framework, social interaction can be seen as a dyadic state space (Lewis, 1999) in which the microsocial exchange between the parent and child moves from one dyadic space to another (see Figure 15.2). To capture these microsocial dynamics, it is critical to code behavior for all participants in real time and identify duration and emotional valence of all behaviors. As shown in Figure 15.2, the parent (PC) and child (TC) moved from one dyadic state (e.g., mutually positive or neutral, or dyadic positive engagement) to dyadic coercive (e.g., mutual directives, negative talk). These dyadic states are thought to be theoretically meaningful because both members of the dyad are responding in kind. In our work on direct observations of young children from age 2 through 5, we have studied dyadic positive engagement and dyadic coerce, which are summarized in Figure 15.2.

Recently, Smith and colleagues tested the coercion model longitudinally in an ethnically diverse sample of 730 toddlers followed to age 7.5 (Smith, Dishion, Shaw, & Wilson, 2013). Dyadic coercion between the parent and child was measured using duration coding and was found to increase from age 2 through age 5, suggesting that coercion dynamics emerge in early childhood and are not in place at age 2. Key to the coercion model is children's noncompliance (Patterson, 1982). Children's noncompliance was

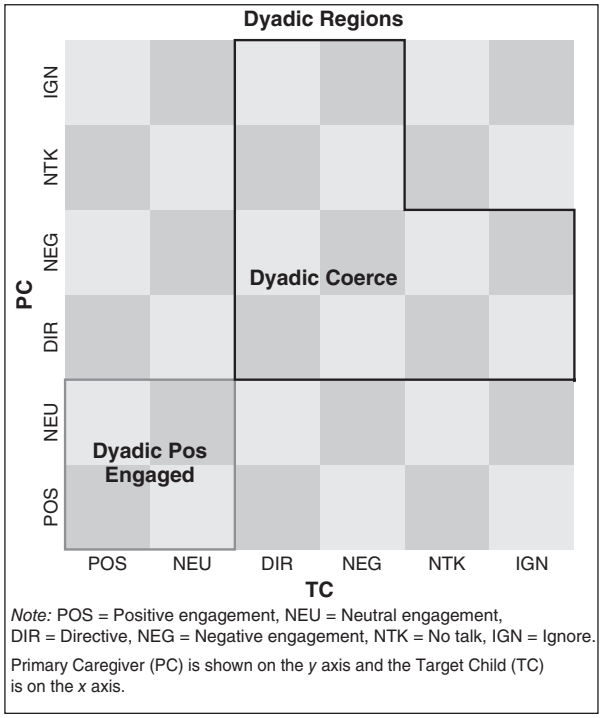

Figure 15.2 A state space grid summarizing parent–child interaction in early childhood. *Source:* Adapted from Hollenstein, T. (2013).

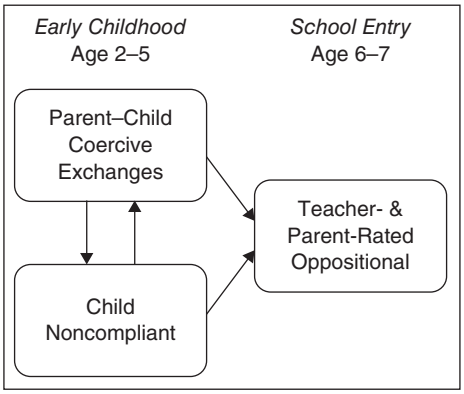

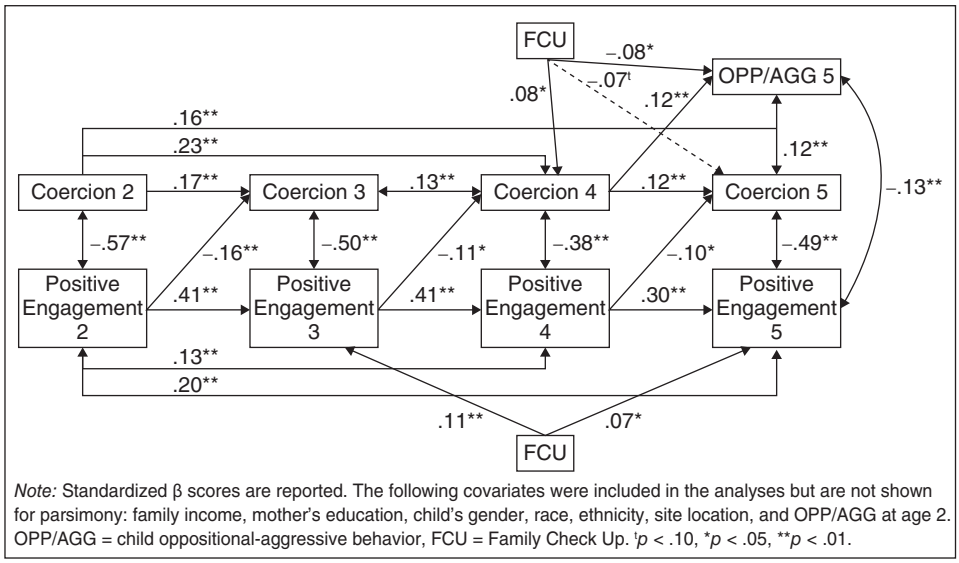

Figure 15.3 Early development of oppositional and aggressive behavior.

rated by coders who watched the videotaped parent–child interaction sessions; mothers rated their child's problem behavior (aggression and oppositional behavior) at age 2, 3, and 5; and teachers rated the child at age 7.5. Findings from the model are summarized in Figure 15.3.

The model summarized in Figure 15.3 was used to systematically test the evocative effects of child noncompliance on parent–child coercion, as well as the reverse. It was hypothesized that these dynamic interaction patterns would be prognostic of growth in oppositional behavior in the home from age 2 to 5 and of teachers' rating of oppositional behavior in first or second grade. It is important to note that teacher perceptions of problem behavior in the first two grades of elementary school are highly predictive of more serious problem behavior in adolescence and adulthood (Loeber & Dishion, 1983; Robins & Hill, 1966). As shown in Figure 15.3, the effects of the unfolding coercion cycle were decidedly bidirectional. It appears that coercion dynamics at age 2 and 3 feed future noncompliance and oppositional behavior problems perceived by parents. However, the reverse is also true: Children's noncompliance and oppositional behavior at age 3 predicts later coercive parent–child interactions. It is especially noteworthy that increases in parents' ratings of oppositional child behavior, the average level of noncompliance during the 4-year period, and coercive parent–child interactions predict teacher ratings of oppositional behavior problems. The model fit the data well, and 22% of the variance in teacher ratings was accounted for by the developmental dynamics underlying family coercion in early childhood.

Of interest to developmental and prevention scientists is the extent to which parent–child positive interactions from age 2 through 5 reduced growth in family coercion. Coercive interactions, albeit risky, occur only a small percentage of the time (estimated 5%). The vast majority of parent–child interactions are either neutral or positive. It is within these positive and neutral exchanges with caregivers that the majority of the socialization takes place. Sitnick and colleagues used a cross-lagged, autoregressive model to examine the mutual effects of dyadic positive engagement and dyad coercive interactions at age 2, 3, 4, and 5, as shown in Figure 15.4 (Sitnick et al., under review). These patterns of mutual positive and coercive interactions were related longitudinally to the child's problem behavior at age 5, controlling for previous levels. As shown in Figure 15.4, it was found that positive parent–child engagement tended to reduce levels of coercive family interaction over time. However, consistent with the Smith et al. (2013) findings, the coercive interaction dynamic was most prognostic of children's problem behavior at age 5. It is noteworthy that randomization to the Family Check-Up, a brief parenting intervention that emphasizes periodic contact with children and families (Dishion & Stormshak, 2007), resulted in improved levels of positive engagement at age 3 and reduced levels of coercive interaction at age 5.

Sitnick et al. (under review) examined the duration of microsocial positive engagement and coercion for the dyad at child ages 2, 3, 4 and 5 years. These analyses do not address change in the momentary dynamics of parent

Note: Standardized β scores are reported. The following covariates were included in the analyses but are not shown for parsimony: family income, mother's education, child's gender, race, ethnicity, site location, and OPP/AGG at age 2. OPP/AGG = child oppositional-aggressive behavior, FCU = Family Check Up. $^{t}p < .10$, $^{*}p < .05$, $^{**}p < .01$.

Waller, . . . M. Wilson, *Parenting and the family check-up: Development and changes in observed parentchild interaction following early childhood intervention,* under review.

and child interactions. Systematically testing hypotheses on changing dynamics has long been a methodological challenge for researchers interested in social interaction patterns. Sequence was the core concept of a social interaction pattern. Much of the early work on coercion theory tested key hypotheses that a coercive event was contingent on an antecedent or was increased by a consequence, such as avoidance or escape. Analyses of contingency were fraught with methodological problems. For example, to analyze the conditional probability that a child's negative behavior is contingent on a mother's threats, it is necessary to examine the reactions to only 5% of the child's overall behavior in an observation session. Thus, 95% percent of the data on the child is tossed out in the analysis of sequences that involve reactions to child's negative behavior. The *z* scores derived from sequential analyses such as these were weak because of challenges in estimation of low base rate events (see Dishion & Granic, 2004; Gottman & Roy, 1990). In the past 5 years methodologists have applied a multilevel framework to improve the statistical estimation of dynamic events in social interaction (Dagne, Howe, Brown, & Muthén, 2002; Stoolmiller & Snyder, 2006). The multilevel framework promotes the estimation of latent constructs at the microsocial level. The most promising of these strategies is multilevel survival modeling, which takes into consideration the analysis of duration of events of interest. To oversimplify, the ability to systematically test hypotheses regarding the duration of specific interaction events increases the robustness of the estimators, because far more data are brought into estimates of dynamic events.

For example, Kim et al. (in preparation) were interested in the dynamic patterns of parent–child dyads illustrated in the state space grid shown in Figure 15.2. From a dynamic systems perspective, parent–child dyads who are not engaged in the coercion process are likely to show two dynamic patterns. The first is that if a dyad goes into the dyadic coercive state, they are likely to leave very quickly. Families who are not caught up in conflict avoid extended negative exchanges. Similarly, parent–child dyads engaged in positive and secure relationships are likely to return to dyadic positive engagement if they leave (see Figure 15.5). The statistical reliability of individual differences in these

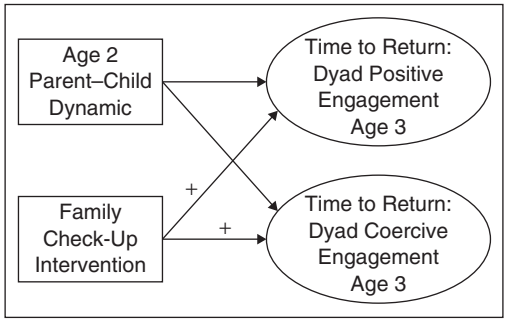

Figure 15.5 A multilevel analysis of intervention effects on family microsocial dynamics in early childhood. *Source:* Adapted from H. Kim, T. Dishion, J. Tein, C. Winter, D. Shaw, & M. Wilson, *Changing the microsocial dynamics of families: The family check-up in early childhood*, in preparation.

two dynamic patterns is estimated by using multilevel survival models. Kim et al. were particularly interested in whether randomization to the Family Check-Up (FCU; Dishion & Stromshak, 2007) intervention influenced these two microsocial dynamics from age 2 to 3. It was found that families in the intervention group were quicker to leave dyadic coercive states and also more rapidly returned to dyadic positive engagement, compared with control families. Thus brief feedback about parenting apparently changed parents' motivation and leadership to improve the positive exchanges and to reduce the duration of conflict.

These analyses suggest that the glass is half full for research on the coercion model in early childhood. The emerging coercion dynamic between children and caregivers is observable, predicts growth in noncompliance, and predicts that caregivers and teachers will perceive the youth to be problematic. The interaction process can be studied in real time, and the dynamics can be improved with a brief, strengths-based family intervention. Consistent with a developmental psychopathology framework (Cicchetti & Toth, 2009), broad constructs, such as conflict and attachment, can be translated to real-time dynamic relationship events (Granic & Patterson, 2006) that involve an analysis of the duration of interpersonal behaviors. From a microsocial view, attachment and coercion are not opposing theories, but rather are interrelated dynamic patterns in relationships. However, the effect sizes on coercive interaction dynamics are relatively small. Additional analyses of the factors related to change in parent–child coercion in early childhood revealed that these dynamics were most responsive in the FCU when therapists provided videotaped feedback to caregivers that showed their interaction dynamics (Smith et al., 2013). Given that coercive interactions are relatively low base rate and are often on "automatic pilot," more structure may be needed at the front end to motivate change with the FCU and follow-up services to change those overlearned interactions (Forgatch & Patterson, 2010).

Data such as these, however, provide considerable support for the hypothesis that how the parent reacts to their child's behavior can allay the development of early behavior problems and aggression. Of course, many randomized studies that targeted parenting practices have revealed consistent effects on reduction of aggression in early childhood; most noteworthy are the findings of Webster-Stratton and colleagues (Webster-Stratton & Reid, 2010). Recent studies have found that randomized assignment to the FCU resulted in improved child behavior and increased positive parenting (Dishion et al., 2008; Shaw, Dishion, Supplee, Gardner, & Arnds, 2006). In the Dishion et al., 2008, study, changes in parents' use of positive behavior support, observed during videotaped parent–child interactions, mediated the covariation between the intervention and reductions in child problem behavior from ages 2 to 4. Moreover, significant reductions were noted in teachers' ratings of oppositional defiance at age 7.5. In one study, the FCU, which was designed for use in public health or public school settings, was provided to families enrolled in the Women, Infants, and Children (WIC) program in three geographically distinct communities (urban, suburban, rural). Results revealed that the number of FCU interventions that a family completed increased the effect sizes on parent ratings of oppositional behavior and teacher ratings of problem behavior at age 7 (Dishion et al., 2014). Taken together, the findings suggest that parenting is indeed modifiable, and the benefits to children are pronounced and long-lasting.

MIDDLE CHILDHOOD: COERCION AND CONTAGION

Relevant to the cascade model (Figure 15.1), it is proposed that problem behavior in early childhood is prognostic of growth in new forms of such behaviors in childhood, including lying, stealing, and other covert behaviors. In the 1980s the field was concerned with potential specialization in children's antisocial behavior. Patterson's (1982) early work on coercion theory attempted to identify the unique family interaction profiles and treatment needs of children referred for stealing, distinct from those of children referred for aggression. This distinction was carried forward in an important review of the literature by Loeber and Schmaling (1985), in which the terms *overt* and *covert* antisocial behavior were coined. Several interesting studies compared the correlates of these two forms of antisocial behavior. It may be surprising that overt and covert antisocial behaviors have unique effects on children's lives, despite the fact that the two factors were correlated at about .8 in a community sample (Patterson et al., 1992). Loeber and Stouthamer-Loeber (1998) later clarified that involvement in both covert and overt antisocial behavior (mixed, early-onset) posed the greatest risk for more serious forms of violence and aggression in adolescence. These findings and conclusions were confirmed and extended in a comprehensive approach to longitudinal modeling that combined six data sets (Broidy et al., 2003). All six identified a group characterized by chronic antisocial behavior from childhood to early adolescence. In most youths, as Tremblay would hypothesize, aggression tended

to decrease over time (Tremblay, 2000). However, for the chronic group, the level of physical aggression remained stable. Interestingly, only for children in the urban sample, physical aggression actually increased from childhood to early adolescence, suggesting a contextual effect for the communities the youths resided in.

It has become increasingly clear that neighborhoods and communities have an influence on the peer group, which is readily observable in the context of neighborhoods and playgrounds. Coercion on the playground and deviant peer influence are observable in the first grade in the public school environment. It is interesting, however, that what is learned on the playground at school is only loosely associated with what the child has learned in the family. Examination of coercive dynamics with parents and those with peers on the playground has indicated a correlation of .19 between the two settings (Dishion, Duncan, Eddy, Fagot, & Fetrow, 1994). Thus it seems that interactions with peers potentially provide a relatively independent influence on the development and growth of antisocial behavior in childhood.

Research by Snyder and colleagues has provided insights about the role of peers in the growth of covert and overt antisocial behavior during childhood. These researchers developed a protocol that enabled the measurement of deviancy training among 5-year-olds in the school context (Snyder et al., 2005; Snyder et al., 2010). They found that deviancy training and coercion could be identified in peer interactions on the kindergarten playground. Moreover, as would be expected, coercive exchanges were associated with growth in overt forms of antisocial behavior in the ensuing year. That is, children who engaged with peers in a coercive manner were actually seen as more aggressive even by their parents, suggesting for the first time that there may be a carryover from peers to the family early in development. It previously had been assumed that the general direction of influence was from the family to peers (Patterson et al., 1992). Snyder and colleagues also found that deviancy training led to growth in covert antisocial behavior during the ensuing year, as seen by parents and by teachers. Covert and overt antisocial behaviors have been associated with a general tendency to engage in antisocial behavior at ages 7 and 8 (Snyder et al., 2008).

Figure 15.6 summarizes findings from the Snyder group (Snyder et al., 2010) regarding the general influence of deviancy training in kindergarten on subsequent development of antisocial behavior by age 9, based on youth report. Note that observed children's deviant talk in kindergarten independently predicted growth of antisocial behavior, controlling for the same behavior at age 5. These findings suggest that organization and structure of informal play settings in public elementary schools are key to learning antisocial behavior patterns that are prognostic of later aggression and violence.

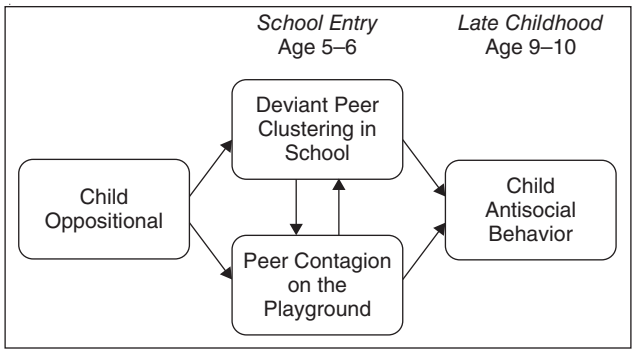

Figure 15.6 Peers and the emergence of covert antisocial behavior in middle childhood.

Several prevention trials have indicated that with relative ease, the public school environment can be modified to reduce ambient levels of peer aggression and antisocial behavior. For example, when teachers use the Good Behavior Game in classroom settings, levels of aggression drop at a group level; in addition, individual children who experience this intervention are less likely to become antisocial and violent (Kellam, Reid, & Balster, 2008; Petras et al., 2008). It is interesting to note that a relatively brief and focused contextual intervention in the first grade can have such a dramatic effect on growth of serious forms of antisocial and violent behavior in adolescence. As shown in Figure 15.1, relatively small improvements in microsocial interaction patterns can alter the child's adaptation in school and among peers, which in turn potentiates large reductions in risk over time.

Given the collateral effects of childhood antisocial behavior on several developmental outcomes, it is important to consider the evidence that it is malleable. Some intervention venues show success in reducing children's antisocial behavior. The first is to motivate and support caregiving behavior management and supervision. The vast majority of the research on parent management training, which has focused on conduct problems in middle childhood, has shown that supporting parenting practices reduces antisocial behavior (e.g., Kazdin, 2010). Especially noteworthy are the findings described by Forgatch and Patterson (2010), which showed effects endure for up to 9 years following intervention. Models of mediation have also revealed that improved parenting practices mediated long-term improvements in children's behavior that endured through adolescence, as documented by reduced

court-documented arrest rates. The second promising intervention venue is to work directly with the child, to motivate and support children's prosocial coping (Kazdin, 2010; Lochman, Boxmeyer, Powell, Barry, & Pardini, 2010). Both Kazdin's and Lochman's work provide empirical support for the idea that building youth skill in using prosocial strategies for resolving conflict and handling stress can reduce antisocial behavior.

ADOLESCENT PROBLEM BEHAVIOR

Peers and Sexual Selection

In a cascade developmental model, aggressive and antisocial behavior have collateral effects on normative peer relationships and academic achievement. Dodge and Coie's early studies inspired an entire era of research on peer rejection, and the covariation between aggressive behavior and peer rejection is well established. The aggressive child is quickly rejected by normative peers (Coie & Kupersmidt, 1983; Dodge, 1983). In my dissertation work, a general model was developed and tested that revealed that family interaction dynamics were prognostic of antisocial behavior and poor academic achievement, and both outcomes were prognostic of peer rejection (Dishion, 1990). Patterson tested the dual failure model, which added a depression overlay to concerns about the antisocial child, in that academic failure and peer rejection were found to be associated with depressed mood (Patterson & Stoolmiller, 1991).

Most relevant to the development of aggression and violence is the tendency to self-organize into deviant peer groups. In longitudinal research on the Oregon Youth Study sample, academic skill deficits, peer rejection, antisocial behavior, and poor parental monitoring combined to predict affiliation with deviant peers in early adolescence (Dishion, Patterson, Stoolmiller, & Skinner, 1991). Stoolmiller's (1990) work clarified that involvement with deviant peers was in part motivated by the child's behavior; in what was conceptualized as wandering, antisocial boys actually pulled themselves away from parental supervision and actively shopped for unsupervised settings and activities. This research prompted investigators to think of deviant peer affiliation as fitting the dynamic systems idea of self-organization. The biological and social changes associated with adolescence motivate youths to self-organize into groups, a process often studied intensively by social network researchers.

An evolutionary framework is critical to understanding what function is served when antisocial children self-organize into deviant peer clusters, beginning on the school playground in childhood and spreading to the community in adolescence and beyond. The vast majority of the research that seeks to understand the evolutionary function of social behavior in children emphasizes the role of harsh rearing environments in early childhood in adolescent pubertal development and adjustment (e.g., Belsky et al., 2010; Ellis et al., 2009). Primate studies, however, suggest that an overemphasis on the familial context and individual outcomes misses a critical aspect of the ecology of both normative and problematic development: the socializing influence of peers. Among primate adolescents approaching puberty, social interactions in the peer group define the process leading to status and dominance, both critical in later mate selection. In particular, among male rhesus macaques, puberty brings a demand to leave the matriarchal familial group and to form temporary adolescent peer groups. The timing of the departure depends on the social status of the mother, with low social status adolescents leaving earlier and higher social status adolescents leaving later. Thus social status of the mother confers risk to the offspring. An evolutionary-based correction factor for this disadvantage is adaptation to and survival in the all-male peer group. Thus males who survive the adolescent peer group phase enter a new troop, where status is renegotiated in the context of the dominant adult males in the new group. Presumably, status and dominance in the all-male peer group provides critical training for managing dominant males in the new troop. Thus the peer group functions to ensure survival of the fittest for the species, not the individual.

The peer group has often been posited to be critical for healthy social and emotional development (Piaget, 1965; Sullivan, 1953). Hartup and Moore (1990) brought to light the hypothesis that peers may be most influential when it comes to socializing problem behavior. As discussed earlier in this chapter, the contribution of peers to criminology was well accepted and acknowledged. Thinking about the role of peers in development from an evolutionary perspective, however, may bring new insights into previously unsolvable problems. One such problem was the age crime curve, in that across societies and cultures, youths tend to increase rule breaking, but the problem behavior decreases in young adulthood and is coincident with establishing new families (Gottfredson & Hirschi, 1990; Hirschi & Hindelang, 1983).

Two simultaneous trends co-occur during puberty that are particularly relevant to amplification of problem behavior during adolescence. This early-adolescence process, termed *premature autonomy,* involves pulling away from parental monitoring and influence at the same time

as seeking unsupervised time with peers (Dishion, Nelson, & Bullock, 2003). Youths whose parents disengage at the same time as they associate with other youths who promote deviancy are most likely to escalate in problem behavior from early adolescence to young adulthood.

Life history framework is a model of development that integrates environmental disruption with an evolutionary perspective on development (Ellis et al., 2009). Belsky et al. (1991) initially used the life history framework to understand individual differences in child and adolescent social and emotional adjustment and emphasized female development, puberty, and early sexual promiscuity. The concept is that stressful early child-rearing environments, especially those characterized by harshness and unpredictability (e.g., social disadvantage, marital instability, family conflict), evoke fast life history strategies, which are characterized by early menarche, early sexual involvement, and early and frequent childbearing and low-investment parenting. In contrast, safe, secure, and predictable child-rearing environments (e.g., adequate socioeconomic resources, marital stability, supportive parent–child relationships) promote slow life history strategies characterized by later onset sexual behavior, later puberty, enduring monogamous relationships, fewer and later offspring, and high-investment parenting strategies.

Introduction of the life history framework to developmental psychology opened the door to novel hypotheses regarding the links between childhood experiences, tempo of pubertal development, and concomitant reproductive strategies (see Belsky, Steinberg, Houts, Halpern-Felsher, & NICHD Early Child Care Research Network US, 1991; Ellis et al., 2009). The life history framework was recently applied to a longitudinal sample of females followed from early childhood through adolescence. In support of life history theory, the researchers found that maternal harshness at age 5 predicted the child's early menarche, which in turn predicted sexual risk taking and other problem behaviors, such as substance use (Belsky et al., 2010; see also James, Ellis, Schlomer, & Garber, 2012). The model fit the data for females, but a model for males has not yet been tested.

A significant omission from the life history framework is the function of peer clustering in early to middle adolescence with regard to regulating reproductive strategies. As described earlier, children and adolescents tend to self-organize into peer groups based on similarities of attitudes, behavior, and circumstances, and those interpersonal dynamics of peer contagion tend to amplify various forms of problem behavior (Dishion & Tipsord, 2011). Most important for a life history perspective, deviant peer clustering has been found to consistently be the strongest predictor of early and promiscuous sexual activity in adolescence, over and above pubertal maturation of males or females (Capaldi, Crosby, & Stoolmiller, 1996; French & Dishion, 2003). High peer group status is important in several primate species (de Waal, 2006). Primate studies demonstrate that peers not only serve a repair function for maternal deprivation (Suomi & Ripp, 1983), but also as a socialization nexus between early maternal rearing and adolescent mate selection and production of offspring (Kohler & Gumerman, 2000; Sameroff & Suomi, 1996).

Pellegrini and colleagues completed a creative longitudinal study that followed 138 early-adolescence males and females during their first 2 years of public middle school (Pellegrini & Long, 2003). Of interest were the peer dynamics among males and females that defined the basis for dating popularity in early adolescence. In their analysis the researchers included observable behaviors, such as poking play during unstructured school hours, as well as peer nominations of relational aggression, dominance, and dating popularity. The study found that for girls, high levels of relational aggression accompanied increases in dating popularity, whereas for boys, high levels of dominance accompanied increases in dating popularity. Consistent with sexual selection theory (e.g., Trivers, 1972), these results suggest that intrasexual competition was played out by gender-specific forms of problem behavior, which in turn increased the likelihood of sexual relationships in early adolescence.

If self-organization into peer groups is critical to sexual selection, a developmental history of marginal peer relationships and attenuated family ties may be particularly salient as an ecology that promotes the formation of deviant peer groups. Youths with a history of marginalization in school by teachers and peers, with attenuated family ties, and with low socioeconomic status would most likely self-organize into groups. These groups would naturally support adult-like behaviors that are correlated with mate selection and sexual activity in adulthood.

Dishion and colleagues used longitudinal data to examine whether the peer-enhanced life history perspective accounted for differences in deviant peer clustering in early adolescence, which in turn predicted both sexual activity and timing and number of children (Dishion et al., 2012). The model shown in Figure 15.7 was tested on a multiethnic sample of males and females followed from age 11 through age 24. In general, the model fit the data well, and there were no differences in fit for males and females or for European American or African American adolescents. As predicted, a history of peer and teacher rejection in middle school, along with attenuated family ties (low monitoring, involvement, positive parenting)

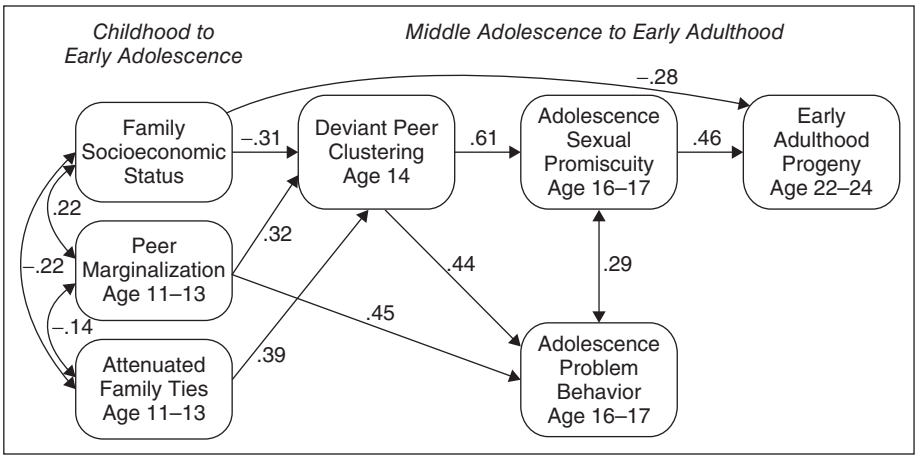

Figure 15.7 Life history perspective on peer influence in adolescence.

combined to predict self-organization into gangs by age 14. Deviant peer clustering at age 14 predicted sexual promiscuity by age 16–17, which in turn predicted the number of children by young adulthood. Of interest to the life history perspective was that deviant peer clustering predicted later sexual promiscuity ($\beta = .61$) more than did problem behavior ($\beta = .41$) by age 16.

These findings support the theory that the child's ecology and developmental history predict motivation to self-organize into groups and that such groups could be seen as functional to procreation. Consistent with the fast life history pathway, having more children more quickly may even the playing field from an overall fitness coefficient. Although the dynamic shown in Figure 15.7 is primarily social, it is hypothesized that future research will suggest that the changes are epigenetic. A relatively underemphasized dimension of environmental threat for human and nonhuman primates is exclusion, marginalization, and rejection (de Waal, 2009). Evidence suggests that threats of rejection, even during simple lab tasks, elicit strong reactions of emotional distress, as evidenced by amygdala activation (Eisenberger, Lieberman, & Williams, 2003). Therefore, a sense of isolation, exclusion, and social disadvantage may elicit mutual interest in forming subgroups among youths with similar circumstances.

Early adolescence may be a particularly critical period for concerns of social inclusion and exclusion. Physiological changes in the developing brain during adolescence suggest the importance of peers. The primacy of the peer group in adolescence is supported by a shift in the physiological substrate and in cortical processing that affects the salience and experience of social rewards (Spear, 2010). Several patterns of neuroanatomical response indicate increased processing of social reward during adolescence (Dahl, 2004; Fareri, Martin, & Delgado, 2008; Spear, 2000), which suggests an enhanced desire and potential for peer group affiliation. The consequences of peer marginalization and attenuated family ties, therefore, may be particularly salient motivations for the formation of deviant peer clusters.

It is likely that the model tested in Figure 15.7 is most salient for youths with an early-onset developmental trajectory of antisocial and problem behavior. As described in early- versus late-onset models, early-onset youths may actually gain status vis-à-vis their problem behavior in the peer group, with late starters following suit by imitation and deviancy training (Moffitt, 1993). One of the challenges of a developmental model of problem behavior is to account for the covariation between deviant peer networks and various forms of problem behavior in adolescence. As summarized in Figure 15.8, the adolescent peer group is associated with escalations in drug use, violence, and sexual activity.

There is a fork in the developmental pathway for adolescent peer influence. One path leads to increases in

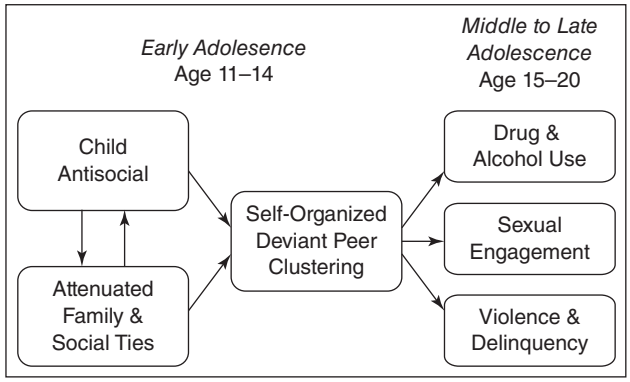

Figure 15.8 Self-organized peer groups and adolescent problem behavior.

the seriousness of aggression and to violence. In early adolescence, aggression can become a salient strategy for friendship selection and social status (Logis, Rodkin et al, 2013; Rulison et al., 2013). The formation of gangs in early adolescence creates a peer context in some ecologies that promotes aggressive responses to provocation and rejection. The second developmental pathway leads to adolescent substance use. Relatively well-adjusted adolescents may initiate alcohol and other drug use as a strategy for developing a peer group context that is highly rewarding and autonomous from parents (see Light et al, 2013). Indeed, growth in popularity over time is associated with growth in alcohol use (Osgood et al., 2013). A careful examination of the nature and quality of the friendships and the microsocial interactions therein provides clues about the processes by which these two pathways lead to dramatic differences in developmental outcomes by young adulthood.

Peers and Substance Use

It is likely the shift in sensitivity to social rewards in puberty renders youths vulnerable to both marginalization and influence in the context of friendships (Steinberg et al., 2006). One of the most effective strategies for expanding one's social network is to share alcohol and drug use (ADU). Legal drugs, such as tobacco and alcohol, are easy venues for early adolescents to mutually explore and engage in adult-like, rewarding activities. An especially vulnerable time for young adolescents is the hours after school, when youths have ample opportunity to smoke or drink in settings without adults (Friedman, Lichtenstein, & Biglan, 1985). The number of hours unsupervised with peers is the best predictor of escalations in tobacco, alcohol, and marijuana use between ages 12 and 15 (Dishion, Bullock, & Kiesner, 2008). Youths self-organize into informal groups and gatherings to explore the rewarding properties of substances and social connection, and they collude to avoid detection and adult sanctions (Dishion & Bullock, 2002; Stoolmiller, 1990). Pulling away from adult supervision to engage in rewarding social and sexual activities during puberty is surely an ancient human primate practice that is unlikely to change.

Unfortunately, use of substances by age 15 is highly prognostic of developing alcohol and drug dependence by young adulthood (Anthony, 1991; Robins & Pryzbeck, 1985). Early-onset and persistent substance use can undermine achievement of adult milestones and healthy adult adaptation (Kandel, Davies, Karus, & Yamaguchi, 1986; Yamaguchi & Kandel, 1985). A critical question for developmental and intervention theory is whether some youths are more vulnerable genetically to moving from adolescent exploratory use to addiction. Although the evidence is clear for a genetic liability (see Grigorenko & Dozier, 2013), it remains unclear whether it is specific to addiction or to impulsive behavior in general (Beauchaine & Hinshaw, 2008; Dick et al., 2009; Kalivas & Volkow, 2005). Evidence does suggest that the progression to ADU dependence from early-adolescence problem behavior indicates unique dynamics within the peer group.

Research on early pathways leading to substance use supports the cascading developmental model summarized in Figure 15.1, with antisocial problem behavior preceding the onset of smoking, alcohol, and marijuana use (Dishion, Capaldi, & Yoeger, 1999; G. M. Smith & Fogg, 1979). A substantial body of research has established the importance of neighborhood environments for child and family development (Leventhal & Brooks-Gunn, 2000; Shonkoff & Phillips, 2002), particularly for youth problem behavior and specifically for youths living in high-risk, low-income neighborhoods characterized by disadvantage and residential instability (Coley, Morris, & Hernandez, 2004; Hawkins, Van Horn, & Arthur, 2003), low collective efficacy (Sampson, Raudenbush, & Earls, 1997), and presence of deviant peers and adults (Ingoldsby, Shaw, Winslow, Schonberg, & Gilliom, 2006). ADU is not confined to youths in disadvantaged settings or youths of minority status, however. Several studies have identified European American youths as having the most pervasive ADU, and youths in families with high socioeconomic status are often quite vulnerable to high levels of ADU (Luthar & Barkin, 2012).

Ecological conditions and genetic vulnerability to develop ADU problems appear to be moderated by parenting practices, such as monitoring and contact and engagement with drug-using peers. Shaw et al. (2004) reported that deviant peer clustering attenuated the effects of parental monitoring and limit setting on youth problem behavior in the highest risk, low-income urban neighborhoods. Already-classic work by Dick and colleagues (2009) found that increased risk for a variety of problem behaviors in adolescence, including substance use, is associated with the GABRA2 polymorphism. However, those youths with genetic liability who were monitored well by parents showed no vulnerability toward engaging in these problem behaviors. Systematic prevention research by Brody and colleagues (2009) revealed that random assignment to a family-centered prevention program reduced the effects of genetic liability for adolescent substance use.

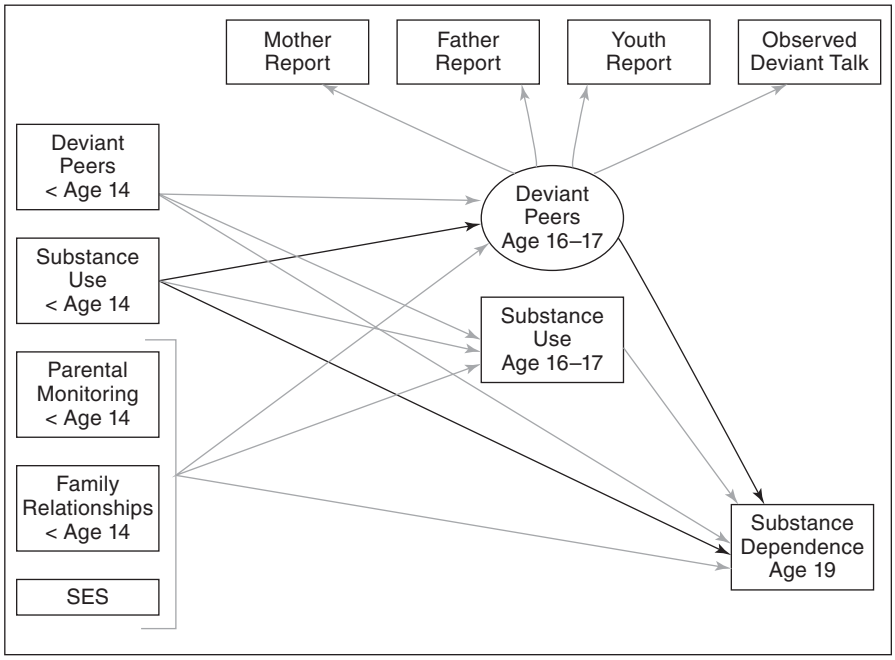

Figure 15.9 Self-organized peer groups and progressions to adolescent ADU dependence. *Source:* Adapted from M. J. Van Ryzin & T. J. Dishion, Adolescent deviant peer clustering as an amplifying mechanism underlying the progression from early substance use to dependence, *Journal of Child Psychology and Psychiatry,* 2014, pp 667.

My colleagues and I have intensively studied the contribution of the peer network and friendship dynamics on the progression from ADU in early adolescence to ADU dependence by early adulthood. In a sample of 998 ethnically diverse youth (males and females), we examined the progression from early-adolescence use to dependence by age 19 (Van Ryzin & Dishion, 2012). As found in previous studies, European American males were the most likely to initially use tobacco, alcohol, and marijuana and not surprisingly, progress to dependence by age 19. We were interested in the role played by deviant peer clustering in the progression from early use to dependence by age 19 (Figure 15.9). By studying the progression of tobacco, alcohol, and marijuana use separately, we examined the dynamics of drug-using friendships in the progression to dependence, controlling for early use and parental monitoring. The construct measuring deviant peer clustering at age 16–17 was defined by parent, youth, and teacher report and by direct observations of the youth and friend's deviant talk (Dishion, Capaldi, et al., 1995).

The results of these three longitudinal models are summarized in Table 15.1. For each substance, we found early use to be a robust predictor of progression to dependence by age 19. However, in addition to the effects of early use, deviant peer clustering was by far the strongest predictor. Thus becoming addicted to tobacco, alcohol, and marijuana as a youth is strongly associated with the company

TABLE 15.1 Peer Clustering on ADU as a Mediator for Progressing to Late-Adolescence Dependence

Predictors	Nicotine dependence	Alcohol dependence	Marijuana dependence	Deviant peer affiliation (ages 16–17)
Deviant peer affiliation (ages 16–17)	11.71[1]	14.68[2]	11.80[1]	—
Substance use (ages 16–17)	1.14[1]	1.14[1]	1.15[1]	—
Early tobacco use	1.19	1.46	.98	.25[3](.06)
Early alcohol use	.93	.48	.97	.05(.05)
Early marijuana use	.97	.61	1.11	.14(.07)
Early parental monitoring	1.01	1.37	1.35	−.07[2](.03)
Early family relations	1.39	.98	1.35	−.03(.03)
Early deviant peer affiliation	.70	.55	.70	.08[3](.02)
Socioeconomic status	1.27	.59	1.35	.02(.03)

one keeps. In previous research, it was found that the covariation between use of tobacco, alcohol, and marijuana and friendship selection and influence was bidirectional. Early use predicted the selection of friends on the basis of conversations about drug use and deviant behavior. In turn, selecting a friend who engages in these discussions uniquely predicts escalation in the use pattern (Dishion & Owen, 2002).

One can think of friendship selection and influence as a process of joining. Finding common ground and mutual interests is one way to connect with a potential friend. Thus, for a smoker, pulling out a cigarette and smoking together could be seen as joining around tobacco use. Undoubtedly many friendships are established this way, around the use of a specific substance, and some may progress to be satisfying relationships that include other interests and activities besides substance use. Relationship dynamics that account for socialization and influence are of special interest to the peer relationship field (see Bukowski, Pizzamiglio, Newcomb, & Hoza, 1996; Hartup, 1996). The quality of the friendship would seem to enhance the power of the friendship to influence youths toward ADU. However, youths more prone to ADU are perhaps less likely to have high-quality friendships, because of underlying antisocial behavior. Thus, friendship quality might be a sign of positive adaptation and potentially an indicator of less risk for ADU progression.

One of the problems in measuring friendship quality is that global reports may be biased with respect to the youth's need for a friend. Those who are more desperate for a friend may be more disposed toward endorsing any friendship as desirable. To avoid this difficulty, Piehler carefully observed the friendship dynamics of the Project Alliance sample ($N = 998$), who were videotaped while interacting with their close friends at age 16–17 (Piehler & Dishion, 2014). He coded their ability to coregulate during the course of their 40-minute videotaped interaction task, which included their ability to take turns talking, to mutually reference each other's discussion topics, facilitate the discussion with eye contact and head nodding, and to remain attentive to the discussion. Coders were highly reliable in coding coregulation and duration of deviant talk.

Dyadic coregulation was found to moderate the covariation between observed deviant talk and progression in drug use from age 16 to 19. However, the nature of the moderation was opposite of what had been expected (Figure 15.10). Stronger covariation was found between deviant talk and later drug use in the friendships that were highly coregulated. Friendships that were less coregulated tended to be less likely to progress toward more serious use by age 19. The basic conclusions are summarized in Figure 15.11. Youths in friendships that are coregulated and that include talk about ADU are the most influential

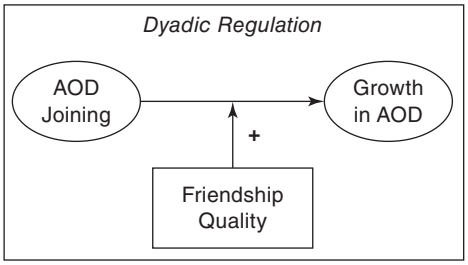

Figure 15.10 Adolescent friendship influence on the ADU progression.

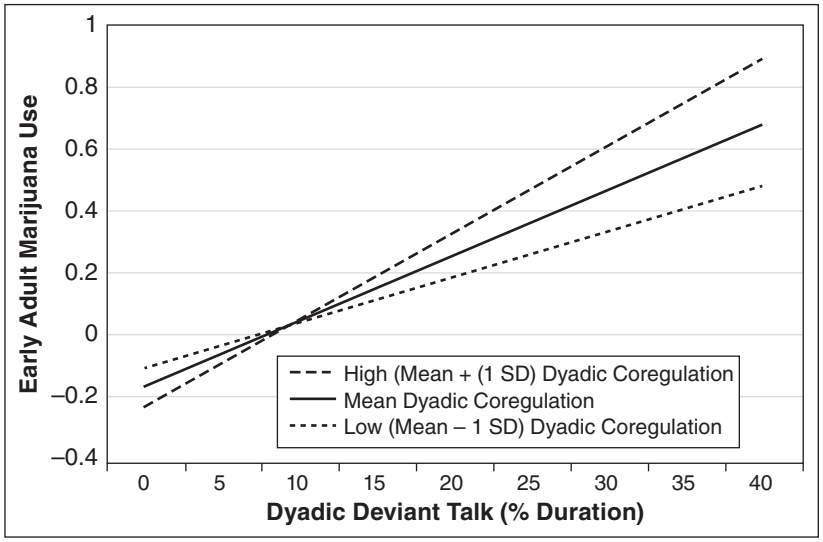

Figure 15.11 Dyadic coregulation as a moderator for friendship influence progressions in substance use.

for progression of ADU. These findings square with earlier research (Dishion, Nelson, & Bullock, 2004) on the moderation of deviancy training at ages 13–14 on later antisocial behavior (ages 23–24). Friendships that were dynamically more organized and engaged in deviant talk were more prognostic of escalations in problem behavior through young adulthood.

Piehler followed up on these findings to better understand the link between individual vulnerability and friendship influence. When the youths were young adults (ages 22 and 23), their ADU and dependence were again assessed (Piehler, Véronneau, & Dishion, 2012). These models included a multiagent construct of effortful control, also measured at ages 16–17, along with a construct measuring friendship drug use at the same age and prior levels of drug use. In these models, it was again hypothesized that high levels of effortful control would moderate the influence of friends on ADU progression. However, no such interaction was found. Prior substance use, friendship influence, and effortful control all predicted progression from ADU to problematic use in early adulthood, with effortful control predicting less use.

These findings suggest that an individualistic model of adolescent ADU progression is likely to be incomplete and insufficient for guiding prevention. Research on the etiology and progression of ADU has clarified that the developmental and interpersonal dynamics of adolescence ADU are very different from the dynamics of aggression and violence. ADU is a strategy for expanding one's social friendships and engaging peers in the context of rewarding activities. Although early antisocial behavior and aggression are prognostic of early-adolescence initiation, it is clear that ADU behaviors are about reward: pharmacological, social, and sexual. Future research will clarify if ADU actually provides the antisocial adolescent with a venue for learning social skills that were underdeveloped in childhood. ADU in adolescence, however, presents the significant challenge of self-regulation of reward. As we have seen, the inability to regulate the rewarding properties of ADU leads to dependence and addiction in early adulthood.

Coercive Joining and Violence

One of the most perplexing problems for criminology is predicting movement from being a troublesome child to becoming a violent offender. The vast majority of research about this transition suggests simply that early-onset youths with high rates of antisocial behavior are those who progress to violence in late adolescence and young adulthood (Capaldi & Patterson, 1996; Farrington, 1991; Loeber & Farrington, 1998; Monahan, 1978). However, most early-onset antisocial youths do not progress to being violent offenders. Quite the opposite, there is a general downward trend in aggressive behavior from childhood through adolescence, except for those youths living in a high-risk urban setting (Broidy et al., 2003).

There is some evidence that escalation from antisocial tendencies to violent offending involves peer group macro- and microsocial processes. At the macro level, self-organization into gangs provides ample support for violent behavior. Systematic longitudinal research on gangs has revealed surges in violent and other forms of problem behavior during the time youths identify and associate with gangs (Thornberry, 1998). In early research on deviancy training, it was found that longer durations of deviant talk and discussions of violence in 30-minute videotaped interactions uniquely predicted later arrests for violent offending (Dishion, Eddy, Haas, & Spracklen, 1997).

Another approach to longitudinal data is to model trajectories of peer groups and map onto those groups longitudinal changes in antisocial behavior. When Lacourse and colleagues used this strategy, they found that the youths who increased their violent behavior were those who were in the chronically deviant peer group from childhood through adolescence (Lacourse, Nagin, Tremblay, Vitaro, & Claes, 2003). These data suggest that the passage from troublesome to dangerous is by and large not a solitary endeavor and that some peer groups cocreate violence.

The cascading developmental process has been tested in several longitudinal studies and found to be prognostic of adolescent violence (Dishion, Véronneau, & Myers, 2010; Dodge et al., 2008). As described previously, marginalized youth with attenuated family ties are more likely to self-organize into gangs, which in turn, support aggressive and violent acts. Given the consequences, it is essential to know which youths are more vulnerable to gang membership. As one might expect, gangs are more prevalent in specific communities. From a historical perspective, poor and disorganized communities with pockets of marginalized individuals tend to have high rates of crime and gang structures (Sampson & Laub, 1994). For example, Sampson & Laub (1994) reported that in early nineteenth century Boston, Irish immigrants were more likely to be involved in crime and gang activity.

The friendship dynamics that define the deviant peer group determine in part what becomes socialized in the group. When my colleagues and I first intensively studied friendship dynamics, we focused on a sample of mostly European American boys from a suburban community. We

were surprised to find very little negativity or aggression in the friendship interactions (Dishion, Andrews, & Crosby, 1995). Only a handful of the 204 boys participated in coercive exchanges with friends during an observation task. Consequently, we focused primarily on the role of positive reinforcement (i.e., laughter) in supporting deviant talk (i.e., deviancy training). However, when we later analyzed friendship interactions among an urban sample of youths, the picture changed. Significantly more than a handful of friendships were characterized by a mutually aggressive posture and overt efforts to exert and maintain dominance over one another. It did not take a rocket scientist to see a connection to gang involvement, in that many of the youths in the friendship interactions were dressed in gang attire and used gang-like mannerisms. We became interested in the idea that specific social interaction patterns presented a coercive stance to the social world that amplified a youth's tendency to become violent in late adolescence to early adulthood. That is, they would become dangerous people.

We came to term the process we had been witnessing *coercive joining*; that is, a friendship of two individuals is organized in terms of coercing others primarily and each other secondarily. When coercion is the organizing theme, the individual who is more likely to escalate in aversiveness or dangerousness (e.g., physical aggression, assault) is the one who has the most influence. Moreover, the dyad is made stronger by joining in coercion; that is, they coerce others and take pride and enjoyment in treating others abusively or with aggression. As is often documented in the gang literature, the ability to be fearless and highly aggressive is directly linked to status in the group (Raine, 2002). Being able to regulate emotion during a dangerous fight and to assault your opponent is valued by the peer group. Recent research on the macrodynamics of adolescent aggression has revealed that status in the peer network is a driving mechanism for the maintenance and amplification of aggression in early adolescence. For example, in urban New York City, changes in social status within the peer network are associated with carrying weapons (Dijkstra et al., 2010).

We were interested in studying the microsocial dynamics within adolescent friendships that might map onto network findings about the role of status. Is it possible that adolescents who are prone to escalating violence actually select and socialize one another to be more violent? In our multiethnic sample of 998 adolescents, we found that indeed, high levels of observed coercive joining uniquely predicted movement from antisocial behavior to violence by early adulthood (Dishion & Van Ryzin, 2011). Violence was defined by multiple indicators, including violent arrests, self-reports of carrying weapons, mother and father report, and self-reported aggression. Observed coercive joining was measured in 40 minutes of videotaped friendship interaction and included youths' efforts to dominant one another, talk that promoted the abuse of others, and profanity. Observed coercive joining accounted for substantial unique variance in later violence more than did antisocial behavior measured at the same time.

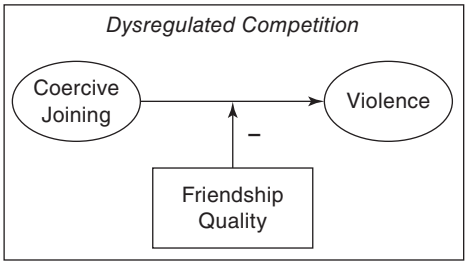

Figure 15.12 Adolescent friendship influence on violence progression.

We were next interested in whether the quality of the friendship moderated the influence of coercive joining on later violence. We suspected that poor-quality friendships were actually prognostic of socialization of violence in friendships (Figure 15.12). If such friendships are motivated by status in the peer network, then they are a sign and symptom of a friendship of convenience. A friendship of convenience is one that is easily available by means of proximity, such as the same neighborhood. In previous research on another sample, it was found that early starters were more likely to select friends from the same neighborhood (Dishion, Andrews, et al., 1995). To examine their friendship quality, each youth was asked to report about their satisfaction with the friendship, pleasant activities they shared, and the extent to which they agreed about basic friendship issues. In a model that included antisocial behavior at ages 16–17 and coercive joining and friendship quality that predicted serious violence by ages 22–23, all three predictors were statistically reliable. As one might expect, an interaction effect was found between friendship quality and coercive joining, and youths with the lowest friendship quality and the highest levels of coercive joining were the most violent 5 years later. Coercion in friendships undermines the relationship and socializes youths to become increasingly dangerous.

Youths with a long history of behavioral difficulties and marginalization are likely to have also accumulated traumatic experiences that disrupt emotional regulation and that can potentially amplify aggression in the face of conflict. Research by Gorman-Smith and Tolan (1998) suggests that trauma in violent communities begets violence.

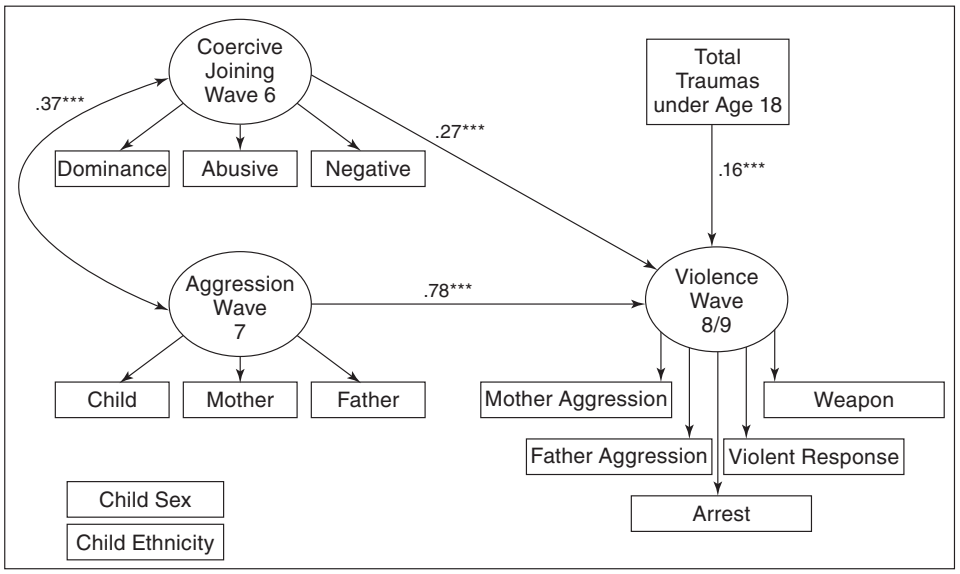

Figure 15.13 Unique contributions of trauma to adolescent violence. *Source:* Adapted from Dishion & Zerr, in preparation.

When the youths were age 18–19, they were queried about their retrospective history of traumatic experiences, including exposure to violence in the community and betrayal by a significant other (Freyd, 1996). The total self-reports of trauma indeed accounted for unique variation in later violent offending, controlling for coercive joining in the friendship and aggression at age 17 (see Figure 15.13). Interestingly, when traumatic experiences were divided between betrayal and community violence, the number of traumatic experiences that involved an interpersonal betrayal accounted for variation in later violence. Such traumas include sexual abuse by trusted others and other abusive experiences by family members.

Involvement in coercive dynamics with friends and continued aggression is best understood by looking at the family–peer ecology. It has been hypothesized that youths who were observed in coercive interactions with family members in early adolescence would most likely be those who engaged coercively in the peer group, which in turn would predict amplification to violence by adulthood. The coercion model suggests that coercive interaction patterns in families provide the basic training for youths to feel comfortable establishing coercive friendships (Figure 15.14). This hypothesis was tested with a subset of the sample described earlier, who were preselected to also complete family observation tasks when they were young adolescents (Van Ryzin & Dishion, 2012). Coercive interactions within the family were prognostic of later coercive joining in friendships, which in turn predicted violence in young adulthood, controlling for previous levels of antisocial behavior and even observed deviancy training with friends at ages 16–17. The covariation between observed coercion in the family at ages 12–13 and acting out dangerous behaviors 10 years later was mediated by coercive joining with friends at age 16.

Yet another question about the development of violence requires more research: To what extent is violence reinforcing? Systematic research revealed that when young children countered aggression on the playground with more intense aggression, the behavior was reinforced and led to more aggression later (e.g., Patterson, Littman, & Bricker, 1967). For some youths, dangerous threats or acts are reinforcing at an individual and group level. For example, in some contexts, an attack on a victim that leads to death or submission can positively affect the status of the offender in a violent community. The person most willing to face potential danger to self in the process of harming others is revered as dangerous or bad. Such a process can be realized only when the ambient level of violence is high, such as in a gang or in the context of war (Patterson, 2012). Ellis and colleagues (Ellis et al., 2012) similarly point out that in bullying behavior in early adolescence, the bully gains status. The entry card is risking one's own safety to inflict harm on others.

If violence is understood as individually reinforcing with respect to social status, current interventions designed to reduce antisocial behavior at younger ages may have only limited effectiveness. In Project Alliance 1, 999 11-year-olds were individually randomized to either middle school as usual or middle school with the offer

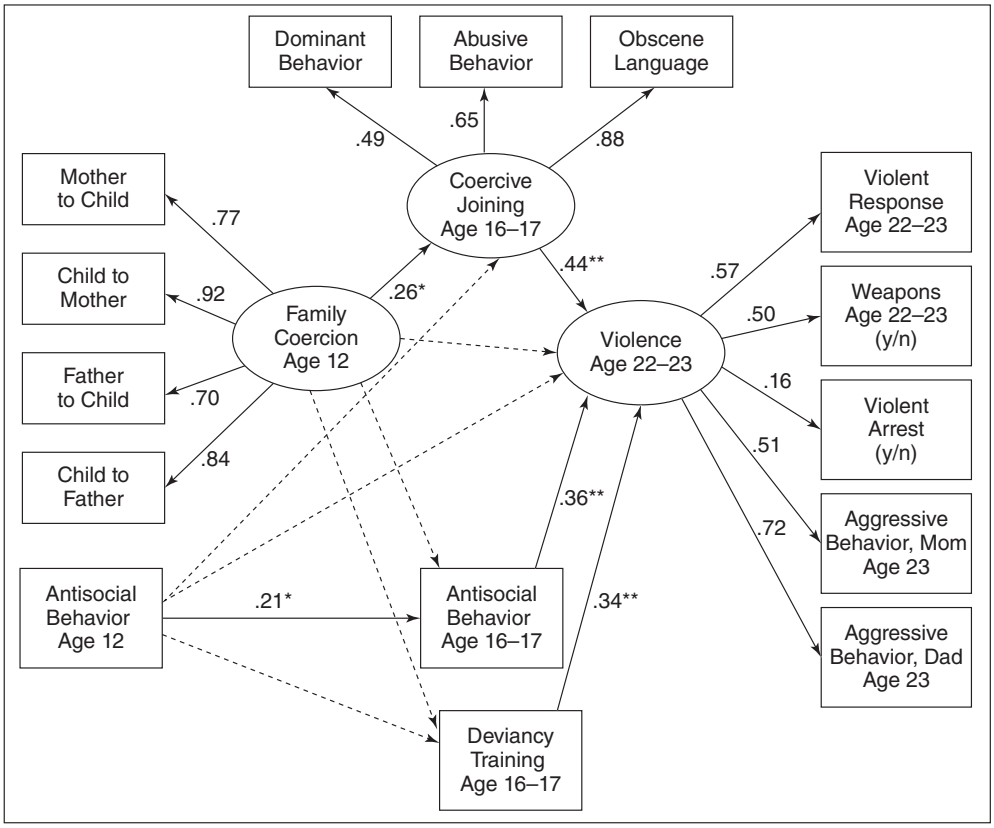

Figure 15.14 From family to peers: microsocial coercion in the development of violence.

of an FCU. Of the families assigned to the intervention group, 25% agreed to engage in the FCU. Using intention-to-treat analyses, we found that participation in the FCU was associated with reduced substance use (Dishion, Kavanagh, Schneiger, Nelson, & Kaufman, 2002), and for high-risk youths, changes in substance use were associated with improved parental monitoring practices (Dishion, Nelson, & Kavanagh, 2003). Our research team later found that antisocial behavior by age 18 was reduced for those in the intervention group, an outcome that was partially mediated by long-term reductions in parent–adolescent conflict (Van Ryzin & Dishion, 2012). Using mixture modeling longitudinal data analysis, it was found that randomization to the FCU reduced serious forms of antisocial behavior, including arrests (Connell, Dishion, Yasui, & Kavanagh, 2007). The intervention, on the other hand, did not prevent serious violence.

It is generally the case that randomized intervention studies provide only limited evidence that adolescent violence can be reduced through intensive, family-centered interventions (Henggeler & Schaeffer, 2010). Adolescent involvement in gangs seems particularly intractable. Malcolm Klein, whose career focused on understanding and intervening with adolescent delinquent gangs, concluded that the best approach is to prevent gangs from forming rather than try to reduce gang influence after they have formed (Klein, 2006).

SUMMARY AND FUTURE DIRECTIONS

Decades of research in development and psychopathology are providing an empirical account of how some children move from minor problems in self-regulation and problem behavior to more serious problem behaviors, such as ADU, high-risk sexual behavior, illegal behavior, and violence. One of the most surprising outcomes of the past decade of research on antisocial behavior is the lack of gender differences in the etiology of problem behavior (Miller, Loeber, & Hipwell, 2009; Odgers et al., 2012). In our developmental and intervention models in early childhood, my colleagues and I have found that intervention effects and key environmental factors are at play for both males and females. Moreover, we have not found major differences in the structure of risk factors across African American, European American, and Latino families to

date, despite the resource and health inequities observed (Trentacosta & Shaw, 2009). The major gender difference is that more males are identified as early-onset persistent in their antisocial behavior (Odger et al, 2012), which is consistent with the fact that more males are referred to clinical services and come into contact with juvenile courts than do females. There is some evidence from behavior genetic research that heritability of antisocial behavior is somewhat higher in males than in females (Meier et al., 2011), and this accounts for the high levels of stability often seen in male aggression (Olweus, 1983).

Clearly, there are deep gender differences with respect to male and female social networks, the role of romantic relationships and sexuality, and the need to drop out of the deviance process because of pregnancy and childbirth. Of interest is the finding that academic failure and peer rejection predict gang membership for boys and for girls. However, ratings of being liked were predictive of gang membership only for boys, suggesting that social status of potential gang members is high among males in early adolescence. One problem with research on gender differences with regard to various forms of problem behavior is that the environmental constructs measured are often rather crude, in that they often define global parenting and peer constructs by means of youth or parent report. Direct observation of male and female behavior within contexts that pull for gender differences might yield more promising results. The naturalistic observation research by Pellegrini and Long (2003) is one example, in that the predating play within the context of unstructured time in public schools yielded rather striking gender differences specific to sexual selection theory.

Dishion and Patterson (2006) reviewed the emerging literature about self-regulation in general and effortful control (Rothbart, 2012) in particular accounting for the etiology of problem behavior in childhood and adolescence. Conceptually, difficulties in self-regulation and effortful control seem to be obvious candidates for explaining the timing and course of antisocial and other problem behaviors. Moreover, several evidence-based interventions that specifically target children's self-regulation show moderate effect sizes (e.g., Kazdin, 2010; Lochman et al., 2010). A handful of studies in the last review (Dishion & Patterson, 2006) indicated that child and adolescent self-regulation could moderate the impact of pathogenic environments on later outcomes, thus empirically defining the critical construct of resilience (Luthar, 1991; Masten & Coatsworth, 1998; Zautra, 2009). The moderation framework is in agreement with the differential susceptibility hypothesis, which proposes that vulnerable children are more responsive to positive environments and reactive to pathogenic environments (Belsky & Pluess, 2009). The differential susceptibility hypothesis, therefore, is an optimistic stance that does seem to fit with some of the data. For example, several prevention scientists are finding that interventions that effectively change the environment seem to have the most pronounced effects on those youths who are at highest risk initially (Bierman et al., 2010; Connell et al., 2007; Dishion et al., 2008; Forgatch & Patterson, 2010).

There continue to be problems, however, in the constructs of dysregulation, self-regulation, or emotion-related self-regulation that require attention in future research. Aside from the conceptual overlap with problem behavior, the measure of these constructs must be further refined along the lines suggested by Beauchaine, Hinshaw, and Gatzke-Kopp (2008), with particular focus on vulnerability to reward and on the dopamine system. Much of the work on self-regulation occurs in a motivational vacuum, with low levels of reward in laboratory settings assessments of attention control. Typically, in laboratory assessments of self-regulation of children and adolescents, frustration and rewards are studied that are out of the context of close relationships with caregivers and peers. Very low correlations have been found between the key evoked response potential (ERP) indices of self-regulation and behavioral measures of self-regulation. Most surprising has been the lack of correlation between parent and youth report of effortful control or executive functioning on either ERP or behavior measures of self-regulation in laboratory settings (Felver, Dishion, & Racer, in preparation). However, under conditions of fMRI anterior cingulate activity has been detected in response to Posner's attention network task (ANT), and chronic adolescent drug users showed more activation than did controls (Abullaev, Posner, Nunnally, & Dishion, 2010). Moreover, when adolescents were placed in a driving task scenario in which peer attention was manipulated, in general they were shown to engage in higher risk driving behavior (Peake, Dishion, Stormshak, Moore, & Pfeifer, 2013).

Thus there is considerable evidence that individual differences in self-regulation in children and adolescents are prognostic of various forms of problem behavior at both developmental phases. Seriously needed is a multilevel program of research that addresses the challenges of measurement problems and the lack of convergence of key indicators of self-regulation measured at the level of global ratings, electrophysiology, and neuroimaging, and at the behavioral level. From this work one may expect that the child's challenges in managing behavior under

conditions of reward will emerge as a key vulnerability factor. Identifying the relative magnitude of genetic and environmental effects at various ages and developmental periods will be especially helpful for the design of effective prevention strategies that apply to an array of public health outcomes, from violence to drug abuse.

Linking Theory to Intervention

The study of antisocial behavior in children and adolescents is often a very applied effort. The applied focus of this area of research is centered on the need to develop improved interventions that address the multiple needs of these vulnerable and potentially dangerous children and adolescents. A simple perusal of evidence-based literature reveals several intervention strategies for antisocial behavior that are effective in childhood (Webster-Stratton & Reid, 2010; Zisser & Eyberg, 2010), middle childhood (Forgatch & Patterson, 2010; Kazdin, 2010; Sanders & Murphy-Brennan, 2010), and adolescence (Henggeler & Schaeffer, 2010; Liddle, 2010; Smith & Chamberlain, 2010; Waldron & Brody, 2010). Thus, the applied program of research has been quite successful.

A summary of the effective strategies suggests that two components are especially important to successful interventions: (1) support to caregivers with respect to motivation and to behavior management skills; and (2) support to youths for developing self-regulatory skills associated with antisocial behavior. In the past 10 years considerable progress has been made in applying the principles of evidence-based intervention to changing entire communities. For example, Forgatch and colleagues collaborated with researchers in Norway and successfully implemented PMTO, and found that generations of therapists were able to achieve the same effects as those of the program developers (Ogden et al., 2012). There is also evidence that principles of behavior change can be applied to entire communities to reduce the prevalence of problem behavior. For example, the pioneering work of Hawkins and colleagues randomly assigned communities to a support system called Communities That Care and found significant effects on children's antisocial behavior (Hawkins, Catalano, & Kuklinski, 2012). Other researchers have shown that a universal approach to promoting evidence-based parenting practices can reduce the incidence of child abuse in communities (Shapiro, Prinz, & Sanders, 2010). Science points the way to reduce the incidence and prevalence of these problem behaviors at the community level, but it is troubling to note that willingness to allocate the necessary resources and training to accomplish this goal seems limited.

Unfortunately, publishing successful interventions and neglecting null or negative findings is the rule rather than the exception. Given the state of funding for intensive longitudinal studies, it becomes possible to selectively ignore measures that are not sensitive to change while attending to others that show intervention effects. At times comparing those variables that show effects with those that do not can provide insights about the complexity of the developmental phenomenon being targeted (Eddy, Dishion, & Stoolmiller, 1998). Other times, we may surmise that measures that do not show intervention effects are simply poor measurements (see Meehl, 1978, for an extended discussion).

The cascade model shown in Figure 15.1 that is supported by several longitudinal studies has implications for intervention theory with respect to the timing and type of intervention needed to improve the lives of children and adolescents with antisocial behavior. I suggest that our intervention science is half full, in that we have shown we can reduce many forms of antisocial and problem behavior at various stages of development. However, we have been less successful in showing that we can return youths to adaptive functioning in other areas that are essential for normative development and well-being. Figure 15.15 provides a summary of the two sides of the developmental cascade. When focusing on problem development, we see

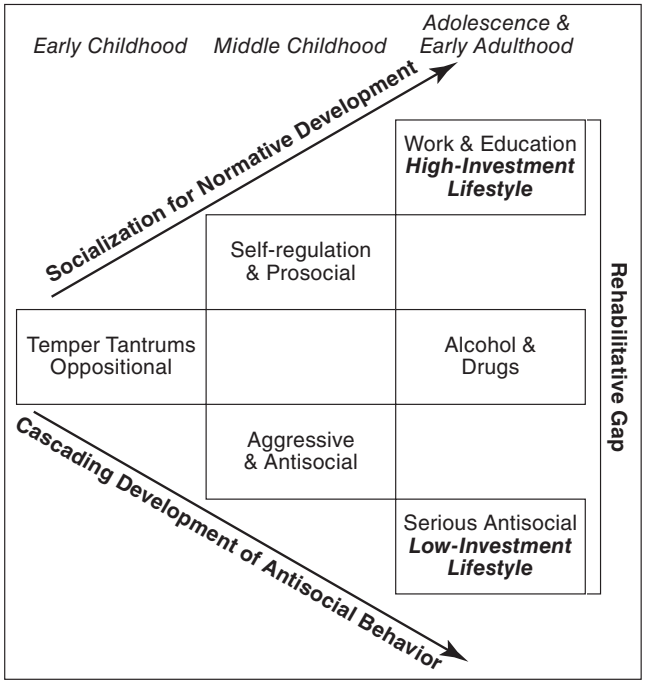

Figure 15.15 Normative and antisocial development and young adult rehabilitation.

that children can cascade into increasingly problematic behavior patterns and environments entrenched with support for deviance. However, on the positive side, caregivers are able to support the development of self-regulation and prosocial behavior from childhood through adolescence. The development of this complex array of abilities enables many, and indeed, most, to walk the same high-risk settings and not engage in the problem behavior or drug use they see around them. There is no temptation, because the behaviors are so clearly a distraction from more important and salient long-term goals. Without doubt, time of onset of the problem behavior affects both positive and negative child adjustment outcomes. Thus adolescence-onset youths more likely have a modicum of self-regulation, especially in specific domains in which they have had practice and support (e.g., finishing homework assignments, working quietly and focusing, taking turns in social interaction). Understanding that development of self-regulation is generally improving and problem behavior is decreasing allows us to rethink the intervention needs of early- versus late-onset adolescents.

Interventions designed to treat adolescents with a long history of problem behavior, including ADU, may require provision of more intensive support for inhibiting the behavior and for successful prosocial engagement and development of self-regulation skills (Figure 15.15). The disparity between prosocial and problem behavior may be referred to as a *rehabilitative gap*. In many ways models such as the teaching-family model are on the right track in that they are used to reduce problem behavior in the treatment home and improve academic skills. The shortcoming is that these improvements may not be maintained if the youths are returned to an environment that is replete with opportunities for problem behavior. We may have underestimated the needs of these vulnerable youths and the plasticity of their behavior in response to positive and negative social environments. In contrast, youths with a relatively positive developmental history who become drug involved in adolescence may require less in the way of support for prosocial development and more attention to the immediate self-regulatory demands associated with ADU. Identifying the optimal intervention strategy that meets the specific needs of children and adolescents is the cornerstone of the FCU's adaptive and tailored approach (Dishion & Kavanagh, 2003; Dishion & Stormshak, 2007). However, for youths who initiate antisocial behavior early, this approach has been less successful in terms of prevention and treatment; for example, my research group found it to be ineffective for reducing arrests and violence (Connell, Klostermann, & Dishion, 2012; Van Ryzin & Dishion, 2012). On the other hand, for adolescents who initiated delinquent behavior late, the number of court contacts was reduced. As shown in the model in Figure 15.14, highest risk youths might be better served in an adaptive, tailored framework that assesses both caregiver parenting and youth prosocial development and self-regulation, after which interventions target those specific needs.

At this juncture, two comments and one suggestion for future directions must be made. First, ample evidence for a developmental cascade process seems to account for amplification of deviance over time (Dishion et al., 2010; Dodge et al., 2008). Doubtless, some violent offenders act alone and are not directly supported by a peer group. Although many school shootings, for example, have elements of group support and contention as a preamble to violence, many individual violent and aggressive acts appear to be an outcome of individual rumination that has no clear history in the individual aside from acquisition of a weapon and ammunition. Data suggest that if interventions addressed and reduced the developmental processes described in this chapter, then a significant level of violence in many communities could be curtailed and even prevented.

Second, some interventions are not yet effectively addressing the peer group dynamics seemingly left to run amuck in urban communities immobilized by poverty, joblessness, and marginalization of some of our fellow citizens (Sampsom & Laub, 1994). A historical perspective confirms that problems of gangs and gang violence are not isolated to a specific group of people defined by culture, religion, or race. The process of marginalization is an ever-shifting target that changes across eras and geographic boundaries. Self-organization into peer groups that promote violence is adaptive behavior, and as we know, extremely difficult to change once it is in place (Klein, 2006). This unique vantage point on the problem of peer group influence clarifies the role of status and hierarchy in generating problem behaviors. As has been discussed in this chapter, the need for status may breed some forms of aggression, and interventions that target aggression and bullying may either ignore this dynamic or inadvertently exacerbate youths' tendency to bully for status. At a developmental level, we need to address the process early, which likely begins with bullying and aggression as it unfolds in public school and in some neighborhood settings. Recent efforts to prevent bullying have come down to adults being reminded that it is unacceptable for youths to be unsafe and victimized in schools and public settings (Olweus, 1993). Effective prevention programs mobilize adults to

nurture, safeguard, and teach skills to youths to reduce bullying and aggression.

As is clear from the vast majority of the work described in this chapter, researchers' focus to date has been on the dark side of family and peer relationships. Normative and prosocial family development and peer relationships ordinarily do not get the attention of prevention and intervention researchers. However, all children have the potential to be either a kind person or violent. Would an effort to promote prosocial behavior, compassion, empathy, and self-regulation add significantly to the impressive array of interventions now available to reduce the dark side of family and peer relationships? Without doubt, the kinds of friendships and romantic relationships that emerge from a developmental history of antisocial behavior and violence are not happy and satisfying, and as such, provide very little reinforcement for kindness and compassion. A focus on health promotion may in fact have a unique bearing on the developmental cascade toward violence, and therefore is decidedly worthy of future research.

This is an exciting time for the behavioral sciences as the findings from unique methodologies converge on an increasingly clear picture of developmental trajectories leading to various forms of problem behavior in children and adolescents, as well as comorbidities. We are able to map the microsocial patterns that give rise to these outcomes and understand how such patterns influence the macrolevel dynamics associated with establishing peer networks and shopping for rewarding settings and opportunities that potentiate further maladaptation. At this juncture we must continue the mapping process of linking changes in neural circuitry with these micro and macrolevel changes, in the context of interventions designed to prevent and treat problem behavior.

INTRODUCTION

The mythological figure Narcissus was a handsome, self-absorbed, and vain young man who passionately fell in love with his own reflection in the water. Although some degree of self-love may be healthy from time to time, Narcissus' self-love was obsessive. He ultimately pined away by the waterside, unable to let go of the reflection of himself that he loved so passionately. What Narcissus did not know at the time is that his personality would attract attention long after his death. Over the past century, psychologists and psychiatrists have had a vested interest in narcissism—the personality type, named after Narcissus, which is marked by a sense of grandiosity, and a strong need to get attention and admiration from others. In recent years, psychologists and psychiatrists have become increasingly interested in narcissism in youth. Considerable progress has been made in understanding how narcissism manifests in childhood and adolescence, how narcissism may emerge and develop over time, and how narcissism impacts youths' lives.

Narcissism lies at the intersection of normal and abnormal development: Typically developing youth gradually differ from one another in how narcissistic they are, and at the same time, higher levels of narcissism often (but not always) interfere with healthy psychological development. As such, our understanding of youth narcissism is likely to benefit from a developmental psychopathology approach: an integrative, interdisciplinary approach that seeks to elucidate both normal and abnormal narcissistic

Sander Thomaes, School of Psychology, University of Southampton, and Department of Psychology, Utrecht University; Eddie Brummelman, Department of Psychology, Utrecht University.
The writing of this chapter was co-supported by The Netherlands Organization for Scientific Research (Grant 431–09–022).

development over the life course. We hope that this chapter will encourage more developmental psychopathologists interested in personality and self-development to join the collaborative study of youth narcissism.

The goal of this chapter is to provide an integrative review of current knowledge of narcissism in children and adolescents. Despite the recent growth of interest in youth narcissism, one factor that hampers scientific progress is a lack of integration between disciplines, especially between developmental, social-personality, and clinical disciplines. Developmental and social-personality psychologists have typically conceptualized narcissism as a normal trait, an individual difference variable that is normally distributed in the general population. Clinical psychologists and psychiatrists, on the other hand, have often focused on narcissistic pathology, including the diagnostic category of narcissistic personality disorder (NPD). Because these different research approaches have remained largely separated thus far, little is known about how (if at all) the nature and development of trait narcissism and narcissistic pathology are different from one another. Most experts believe that the difference is dimensional, and that narcissistic pathology is an extreme manifestation of trait narcissism that is associated with more substantial impairment. This same assumption underlies the current chapter, but we note at the outset that more needs to be learned about how trait narcissism and narcissistic pathology are different. This chapter aims to integrate knowledge from different disciplines into a comprehensive understanding of youth narcissism, addressing both its normal and its pathological manifestations.

We begin by discussing historical conceptions of narcissism. Although the term narcissism was coined by the end of the nineteenth century, philosophers have been discussing the topic of self-love for ages. What these writings teach us is that grandiose and entitled self-views have been a source of intellectual curiosity and concern throughout history. We then consider the manifestations of trait narcissism and narcissistic pathology. Narcissism has both grandiose manifestations (such as inflated feelings of superiority and entitlement) and more vulnerable manifestations (such as sensitivity to negative interpersonal evaluation). Although there is a common core of narcissistic characteristics that presumably can be found in narcissistic individuals of all ages, some narcissistic characteristics appear to be more typical in youth than in adults. Next, we address common questions and concerns regarding the assessment of youth narcissism. Narcissistic traits in youth are best measured using self-report instruments, and at least two psychometrically sound self-report instruments are now available to measure trait narcissism in older children and adolescents. We also discuss key theoretical models of narcissism, stemming from the social-personality and clinical literature. These models help understand how seemingly paradoxical narcissistic characteristics are interrelated, and why narcissistic maladjustment often persists over time. We then address the etiology and development of narcissism, focusing on when and why narcissism may emerge. We cast narcissism as a derailment of normal self-development, and propose a diathesis–stress model for the developmental origins of narcissism. Next, we discuss clinical and applied issues, such as why clinicians may or may not want to diagnose NPD in youth, how narcissistic pathology is different from closely related forms of pathology, and how we can intervene with narcissism and its consequences. Finally, we address three key controversies that surround the topic of youth narcissism—whether or not narcissism has been on the rise over the past decades, whether or not narcissism is partially adaptive, and whether or not narcissists hold deep-seated feelings of insecurity and inferiority. Thus, this chapter comprehensively reviews current knowledge of youth narcissism, and calls into attention the many exciting opportunities to further uncover the developmental psychopathology of narcissism.

HISTORY OF NARCISSISM

The myth of Narcissus can be traced back to the Thracians (a group of Indo-European tribes living in the fifth and fourth century BC; Wieseler, 1856), and entered into Western literature through Ovid's poems. Narcissus was born to the nymph Liriope. From his birth on, Narcissus was admired for his beauty. When a prophet was asked whether Narcissus would live to ripe old age, he answered: "Unless he knows himself." Narcissus grew up surrounded by people who admired his beauty, but at the same time, he turned down the overtures of those who admired him. Eventually, the pain Narcissus had caused to others was punished by goddess Nemesis, who condemned him into unrequited love—"So may he love himself, and not get what he loves!" One day, Narcissus lay down by a pool and caught a glimpse of himself in the water. Paralyzed by the beauty of his own image, Narcissus failed to eat and sleep, and slowly pined away at the waterside. He turned into a flower with white leaves and a saffron center, bowing down to the water.

The concept of Narcissism has had many different definitions and connotations since it was introduced

in the psychological literature. We first describe what philosophers and other thinkers wrote about self-love and narcissism. Then, we describe the multiple meanings that narcissism has had in psychology, and we outline two lessons that the history of narcissism has taught us.

Self-Love in Philosophy

The topic of self-love has fascinated philosophers from ancient times onward, long before narcissism was studied by psychologists. Schools of thought differed in how they defined self-love. Broadly, there have been three philosophical definitions of self-love—self-love as self-enhancement, self-love as self-preservation, and self-love as self-maximization.

Self-Love as Self-Enhancement

Conventional wisdom often refers to self-love as the tendency to place much worth on oneself as a person, while being blind to one's failures or inadequacies. This conceptualization of self-love already appears in ancient philosophy. Several pre-Christian Greek philosophers considered such self-love to be a universal human trait. For example, Plato (trans. 2008) believed that "men are not in the habit of dwelling upon the dark side of their own lives. . . . They are very kind and very blind to their own faults; the rhetoric of self-love is always pleading with them on their own behalf" (p. 40). Although some degree of self-love was considered universal, philosophers recognized that there are individual differences in self-love as well. For example, in his book *The Characters*, Theophrastus (a student of Aristotle) described 30 moral types, including the boastful man: "The Boastful Man will stand in the market at the Piraeus and tell foreigners that he has a good deal of money invested at sea; . . . and while he is exaggerating this beyond all proportion he will send his slave to the bank, although there is [not even a single] drachma in his account" (Theophrastus, 2004, p. 131).

Much like narcissists, the boastful man exaggerates his talents and achievements and tries to instill upon others an overly positive image of himself. Later philosophers have proposed that self-love may give rise to defensiveness and hostility. For example, French philosopher Pascal (1829) noted: "But to what a state is man reduced! He cannot prevent this object of love from being full of defects and miseries" (p. 71). "This state of disappointment," Pascal argued, "generates in [man] the most wretched and criminal passion that can be imagined: he conceives a deadly hatred against the truth which reproves him, and convinces him of his faults" (p. 71). Similarly, La Rochefoucauld (1658/1851) believed that "[self-love] makes men idolize themselves, and would make them tyrants over others if fortune were to give them the means" (p. 1).

Self-Love as Self-Preservation

Stoics, such as Chrysippus, referred to self-love as a universal tendency of humans to secure their own survival. Self-love was seen as an innate tendency to promote self-preservation. As Diogenes Laertius (trans. 1853) summarized the Stoic view, "[We] must assert that nature has bound the animal to itself by the greatest unanimity and affection; for by that means it repels all that is injurious, and attracts all that is akin to it and desirable" (p. 290). Among later philosophers, Voltaire (1764/1856) similarly believed that "self-love is the instrument of our preservation; it resembles the provision for the perpetuity of mankind" (p. 297).

Self-Love as Self-Maximization

Another philosophical tradition considered self-love a tendency to maximize oneself, either by striving for noble qualities (e.g., seeking to do noble deeds), or by striving for hedonism (e.g., seeking bodily pleasures).

Aristotle (trans. 1984) distinguished between self-love of "good" and "wicked" people (p. 1847, 1919). Good people's self-love is expressed when they assign to themselves noble qualities, and try to act in accordance with these qualities. By doing noble deeds, good people benefit not only others but themselves as well, such as through the interpersonal approval that noble deeds yield. Such self-love also underlies true friendship, Aristotle argued: because people tend to experience friends as part of the self, good people love their friends as they love themselves (p. 1843). In contrast, wicked people's self-love is expressed when they "assign to themselves the greater share of wealth, honours, and bodily pleasures" (p. 1847). According to Aristotle, wicked people are greedy and excessively focused on gratifying their own needs, while disregarding the needs of others.

French philosopher Rousseau (1762/1979) also proposed two forms of self-love, *amour de soi* and *amour-propre*. He proposed that children are born into a state of *amour de soi*, or healthy self-love. "A child's first sentiment is to love himself; and the second, which derives from the first, is to love those who come near him" (p. 213). Throughout development, however, children's healthy self-love is corrupted by society, and may give rise to *amour-propre,* which is a "relative sentiment, artificial and born in society, which inclines each individual to have a greater esteem for himself than for anyone else,

inspires in men all the harm they do to one another" (Rousseau, 1755/1993, p. 91). *Amour-propre* leads children to compare themselves with others, to place excessive value on themselves, to expect admiration from others, and to feel entitled—in fact, what Rousseau labeled *amour-propre* shares much similarity to what we define as narcissism today.

Similarly, English philosopher Joseph Butler distinguished between *cool self-love* and *sensual self-love*. Cool self-love refers to a desire for obtaining happiness, and thus motivates behaviors that promote happiness. Much like Aristotle and Rousseau, Butler (1726/1828, p. 27) argued that self-love and benevolence are "so perfectly coincident . . . that we can scarce promote one without the other." In his view, "self-love is one chief security of our right behaviour towards society" (p. 27). Similarly, Voltaire argued that people should embrace rather than reject their self-love, because "it is love of self that encourages love of others, it is through our mutual needs that we are useful to the human race" (as cited in Hulliung, 2001, p. 63). In contrast, sensual self-love refers to a desire for obtaining sensual pleasure, such as obtaining pride, power, and bodily pleasures.

Summary

The topic of self-love has been of focal interest to philosophers for a long time. Strikingly, ancient philosophers already distinguished between healthy and unhealthy forms of self-love, foretelling, in a sense, current empirically based attempts to distinguish healthy and unhealthy forms of favorable self-regard (e.g., Thomaes, Brummelman, Reijntjes, & Bushman, 2013). Some forms of self-love were assumed to foster self-preservation, compassion, and the ability to form close relationships. Other forms of self-love were assumed to foster entitlement, egoism, greed, and a need for admiration. It is the latter form of self-love that most closely resembles our current conceptions of what narcissism entails.

Narcissism as Sexual Disorder

Although philosophers had discussed the topic of self-love for centuries, it was not until the end of the nineteenth century that the term narcissism was introduced to psychology. British physician and sexologist Havelock Ellis (1898) was the first to use the mythical figure Narcissus to describe psychological phenomena. In his clinical practice, he encountered people who—much like Narcissus—found much pleasure, even erotic pleasure, in gazing at themselves in the mirror. He considered these people Narcissus-like. One of his Narcissus-like patients was a 28-year-old woman:

> She is a handsome woman, of very large and fine proportions. . . . She has an intense admiration for her own person, especially her limbs; she is never so happy as when alone and naked in her own bedroom, and, so far as possible, she cultivates nakedness. She knows by heart the various measurements of her body, is proud of the fact that they are strictly in accordance with the canons of proportion, and she laughs proudly at the thought that her thigh is larger than many a woman's waist. (Ellis, 1927/2007, pp. 188–189).

Yet, Ellis did not coin the term *narcissism*. German psychiatrist Näcke (1899) wrote a summary of Ellis's work and first used the term narcissism (*Narcismus*) to refer to the sexual condition in which people view their own body as a sexual object.

Narcissism as Developmental Phase

In the early twentieth century, psychoanalysts further elaborated upon the concept of narcissism. During this period, narcissism gradually became detached from its initial meaning as sexual disorder. Psychoanalysts such as Sadger (1908), Freud (1910), and Rank (1912) proposed that narcissism—which they defined as love for the self—is a normative developmental phase, which children pass through for healthy development. Consistent with the idea of narcissism as normative phase, Freud highlighted several narcissistic traits of young children—including their overly positive self-views, their egocentrism, their illusions of power, and their belief in the magic powers of their thoughts and wishes.

In his paper *On Narcissism*, Freud (1914/1957) proposed that narcissism reflects libido invested in the self, which comes at the cost of libido invested in others. Thus, controversially, Freud suggested that the more people love themselves, the less they love others. Freud also argued that children are born in a state of *primary narcissism*, in which their libido is still entirely directed toward the self, not toward others. In normal development, he argued, children proceed from self-love to other-love and gradually come to direct their libido toward others. Even though Freud thought of narcissism as a developmental phase that children normally leave behind, he also believed that some relics of early narcissism remain apparent throughout life. For example, he noted that "if we look at the attitude of affectionate parents toward their children, we have to recognize that it is a revival and reproduction of their own narcissism, which they have long since abandoned" (Freud, 1914/1957, pp. 90–91).

Thus, early psychoanalysts considered narcissism a normative developmental phase in early childhood. This view has never been empirically confirmed, however, and so it has disappeared from current conceptualizations of narcissism. Later theorizing paved the way for the current view of narcissism as a personality trait rather than a sexual disorder or developmental phase.

Narcissism as Personality Trait

Adult Narcissism

Jones (1913/1951) was the first to describe narcissism as a personality trait. He identified the so-called *God Complex*, a term he used to describe the unconscious fantasy that some people may hold of identifying themselves with God. "The main foundation of the complex," Jones believed, "is to be discovered in a colossal *narcissism*" (p. 247). According to Jones, people with the God Complex are self-effacing, aloof, inaccessible, and unsocial. They are not shy or inhibited, but rather feel superior to other people and therefore feel the need to disengage from them. They fantasize about having power over others, and believe they are omniscient.

Sometime later, Wälder (1925) wrote that people with narcissistic personalities feel superior to others and are self-focused, preoccupied with admiration, and in lack of empathy. Subsequently, Freud (1931/1961) wrote a paper on so-called libidinal types, which he described as normally distributed basic personality traits, which included the narcissistic type:

> The subject's main interest is directed to self-preservation; he is independent and not open to intimidation. His ego has a large amount of aggressiveness at its disposal, which also manifests itself in readiness for activity. . . . People belonging to this type impress others as being 'personalities'; they are especially suited to act as a support for others, to take on the role of leaders and to give a fresh stimulus to cultural development or to damage the established state of affairs. (P. 218).

Wilhelm Reich (1933/1972) proposed in his book *Character Analysis* the phallic-narcissistic character. According to Reich, phallic-narcissistic individuals feel superior to others, and are overly confident, arrogant, haughty, and provocative or even sadistic in their relationships. Reich described these individuals' tendency to lash out aggressively when their egos are threatened. "If their vanity is offended, they react with cold disdain, marked ill-humor, or downright aggression" (p. 218). Reich believed that phallic-narcissism, perhaps unsurprisingly given the term, originates from "an identification between the ego as a whole and the phallus" (p. 219).

An important contribution was made by Horney (1939), who distinguished narcissism from self-esteem. In her view, narcissism represents *unrealistic* self-inflation (i.e., valuing oneself for characteristics and values that one does not possess in reality), whereas self-esteem represents *realistic* self-evaluation (i.e., valuing oneself for characteristics and values that one does possess). Thus, whereas other theorists believed that the difference between narcissism and self-esteem was only quantitative (i.e., with narcissism representing extremely high self-esteem), Horney believed that narcissism and self-esteem were qualitatively different.

Additionally, Horney disagreed with the popular idea in her time that narcissists simply love themselves too much. Instead, she believed that narcissism is "an expression not of self-love but of alienation from the self" (Horney, 1939, p. 99–100). According to Horney, narcissists feel that to be accepted by others, they must be as others expect them to be. That is, their self-evaluations are overly contingent upon others' approval. "[The narcissistic child] is bad or stupid when others think he is bad or stupid, intelligent when others order him to be intelligent, a genius when others consider him one" (Horney, 1939, p. 92). Horney believed that narcissistic children attempt to escape painful feelings of self-alienation by conceiving of themselves as superior beings. Yet this thin veneer of self-love may easily give way to feelings of worthlessness when narcissists fail to obtain approval from others.

The notion that narcissism might be a defense against vulnerability inspired the thinking of subsequent theorists. For example, Annie Reich (1960) suggested that narcissists are unable to regulate their self-esteem in healthy ways, and often experience strong self-esteem fluctuations. She noted that narcissists' self-esteem can quickly rise to a sense of grandiosity and then fall deeply into self-despise. To defend themselves against negative self-feelings, narcissists retreat from others and turn their attention inwards, where the world is a better place: "It is not so. I am not helpless, bleeding, destroyed. On the contrary, I am bigger and better than anyone else. I am the greatest, the most grandiose" (Reich, 1960, p. 220).

Much like early psychoanalysts, Kohut (1971) cast narcissism as a normative developmental phase. He argued that children are born in a state of primary narcissism, which is then disturbed by inevitable shortcomings in parental care. In response, children establish two core aspects of the self: the so-called *grandiose self* and the *idealized parent image*. Under optimal developmental conditions, the grandiose self and the idealized parent image

become integrated into adult personality. The grandiose self comes to underlie individuals' ambitions, enjoyment, and self-esteem, and the idealized parent image comes to underlie individuals' ideals. However, so Kohut argued, if children experience trauma (e.g., when their parents are insensitive to their needs), the grandiose self and the idealized parent image may keep their original form and may lead to pathological narcissism. Thus, Kohut thought that pathological narcissism arises from developmental arrest, and is only quantitatively different from normal narcissism.

In contrast, Kernberg (1975) believed that pathological narcissism is qualitatively different from normal narcissism. In his view, normal narcissism arises from libidinal investment in self-representations that can be both positive and negative, and allow for realistic self-evaluation. By contrast, pathological narcissism arises from libidinal investment in self- and object-representations that can only be positive. In pathological narcissism, negative representations are repressed, dissociated, and projected onto the external world—giving rise to narcissists' negative views of others.

The works of Kohut and Kernberg on pathological narcissism have been influential in shaping our current understanding of NPD. In 1980, NPD was first introduced into the *Diagnostic and Statistical Manual of Mental Disorders,* 3rd ed. (*DSM-III*; American Psychiatric Association, 1980). It was included mainly because clinicians often identified narcissism in their patients but had no common ground for its diagnosis (Gunderson, Ronningstam, & Smith, 1995).

Taken together, multiple theorists and clinicians, especially psychoanalysts, have made contributions to the early understanding of narcissism as a form of personality. They described the intra- and interpersonal manifestations of adult narcissism, distinguished it from self-esteem, tried to understand its developmental roots, and identified healthy as well as unhealthy forms of narcissism—themes that are still of primary interest to empirical researchers today.

Youth Narcissism

From the 1980s, clinicians became increasingly interested in youth narcissism, and started studying narcissism in children and adolescents (for early examples, see Miller, 1981; Ornstein, 1981; Rinsley, 1980). These authors sought to answer questions regarding the diagnosis, treatment, and developmental origins of narcissistic pathology.

Rinsley (1980) and Bleiberg (1984) offered a developmental approach to diagnosing pathological narcissism in children. They argued that pathological narcissism results from children's failure to accomplish important self-developmental tasks. For example, Bleiberg (1984) argued that narcissistic children have often failed to achieve an autonomous identity, to relinquish feelings of omnipotence, to develop a sense of self-esteem that is independent of others' evaluations, to develop a resilient ego to cope with the stresses of life, or to internalize moral standards.

Kernberg (1989) described the characteristics of narcissism in childhood, and addressed how normal narcissism might differ from pathological narcissism. She argued that it is normative for young children to have grandiose fantasies, try to control their parents, try to be at the center of attention, and take pride in their accomplishments. What distinguishes children with pathological narcissism, she argued, is that these children use their grandiose fantasies to maintain emotional equilibrium, have a strong need to be admired by everyone, have unrealistic expectations of others, take pride in their accomplishments only to the extent that they capture others' attention, and are unable to show genuine love for others.

Bleiberg (1994) also discussed what may distinguish narcissistic development from more typical development. He proposed that *narcissistic vulnerability*—feelings of shame that arise from a discrepancy between one's ideal self and actual self—is central to both normal and pathological development, and is especially prominent during adolescence. According to Bleiberg, narcissistic vulnerability "provides one of the fundamental engines of growth throughout life" (p. 37) by motivating people to reach their ideals. In normative development, children do not experience extreme narcissistic vulnerability, because they have ideals that can realistically be met. What distinguishes narcissistic development, he argued, is that children have ideals that cannot realistically be met, as evident from narcissists' tendency to hold unrealistically positive, inflated self-views.

In summary, over the past 3 decades, clinical interest in youth narcissism has resulted in theoretical contributions to our understanding of its manifestations, developmental roots, and developmental consequences. Clinicians were the first to recognize that narcissism can be observed in children and adolescents.

Empirical Research on Narcissism

Until the 1980s, virtually all literature on narcissism was based on clinical observation rather than empirical data. The inclusion of NPD in the *DSM* in 1980 changed this trend, and encouraged empirical researchers to develop self-report instruments to measure narcissism in both

general population and clinical samples of adults. In 1979, Raskin and Hall (1979) developed the Narcissistic Personality Inventory (NPI), a self-report instrument that aimed to measure NPD traits as an index of subclinical narcissism (see Raskin & Terry, 1988, for the final version of the NPI). The NPI rapidly became the standard measure of trait narcissism, and sparked a strong increase in research on narcissism in adults. Empirically oriented clinical and social-personality psychologists started exploring the structure and correlates of narcissism, and how narcissism impacts psychological adjustment and interpersonal behavior. More recently, developmental psychologists started exploring the development, manifestations, and origins of narcissism in youth.

Conclusion

The concepts of self-love and narcissism have been studied for centuries. The history of narcissism teaches two important lessons. The first lesson is that research and practice benefit from a clear and strict definition of narcissism. Up to today, it is not unusual for researchers and practitioners to equate narcissism with traits such as self-esteem, egoism, and egocentrism—concepts that are clearly distinct from narcissism. The second lesson is that, while narcissism was already of interest to ancient philosophers, empirical research interest in narcissism has steeply increased over the past three decades. The development of standardized self-report measures to assess narcissism in adults (and, more recently, youth) was key to this development. Yet, there might be another factor that has accounted for increased interest in narcissism as well. Perhaps it is no coincidence that interest in narcissism rose over the exact same time period that Western society itself became more individualized, self-focused and, according to some, narcissistic (for a discussion, see *Controversies* section). Psychologists do not live in a social vacuum; they are influenced by the salient societal phenomena of their time.

NARCISSISM AND ITS MANIFESTATIONS

Most laypersons have at least some notion of what narcissism involves. When asked to describe a prototypical narcissist, they will often describe individuals who think remarkably highly of themselves, who seem to be constantly on the lookout to draw attention to themselves, who feel entitled to special privileges or exceptional treatment, who feel superior to others even when there is no obvious reason to do so, or who are arrogant and feel disdain for other people. Such depictions are correct: they all describe common features of narcissism. Yet these depictions do not tell the whole story: There is more about narcissism than common belief suggests. Indeed, narcissistic individuals also attach great importance to what others think of them, are emotionally sensitive to even the slightest of criticisms, feel easily rejected or ridiculed by others, quickly lose their feelings of grandeur, and feel ashamed or enraged as readily as they feel proud or enchanted. If anything, narcissists are individuals full of paradoxes.

Many of the aforementioned traits and behavioral dispositions can be found in adults as well as in youth. Indeed, most laypersons will be able to think of (older) children or adolescents they know who seem to hold inflated self-views, seek to place attention on themselves, and show haughty interpersonal attitudes. In this section, we first review current knowledge of the manifestations of trait narcissism and narcissistic pathology as derived from research involving adults. Next, we review emerging knowledge of how narcissism is manifest in children and adolescents.

Manifestations of Narcissism in Adults

Clinicians and researchers typically agree that the phenotypic manifestations of narcissism converge into two broad dimensions. These dimensions have received different labels, such as *thick-skinned* versus *thin-skinned*, *egotistical* versus *dissociative*, *oblivious* versus *hypervigilant*, *exhibitionistic* versus *closet*, and *grandiose* versus *vulnerable* narcissism (see Cain, Pincus, & Ansell, 2008, for an overview). It is the latter label of grandiose versus vulnerable narcissism that is now most commonly used (Dickinson & Pincus, 2003). We will use this same terminology in the present chapter as well.

Diagnostic Approaches

The *DSM-IV* (American Psychiatric Association, 2000) includes NPD as a personality disorder to be diagnosed using the following criteria: (1) grandiose sense of self-importance; (2) fantasies of unlimited success; (3) feelings of being special and unique; (4) requiring excessive admiration; (5) harboring a sense of entitlement; (6) being interpersonally exploitative; (7) lacking empathy; (8) being envious often; and (9) showing arrogant, haughty behaviors. As one may notice, these criteria mainly emphasize the grandiose, self-assured aspects of narcissism. Yet, in an accompanying paragraph, it is argued that "vulnerability in self-esteem makes individuals with NPD very sensitive to 'injury' from criticism or defeat. Although they

may not show it outwardly, criticism may haunt these individuals and may leave them feeling humiliated, degraded, hollow, and empty" (American Psychiatric Association, 2000, p. 715). Thus, according to conventional diagnostic guidelines, narcissistic pathology involves both grandiose and vulnerable traits.

Clinical Observations and Empirical Research

The differential manifestations of narcissistic pathology are acknowledged in clinical observations and empirical research as well (e.g., Akhtar & Thomson, 1982; Fossati et al., 2005; Ronningstam, 2009). For example, in reviewing clinicians' accounts of the manifestations of narcissistic pathology, Ronningstam (2009, p. 113) distinguished between what she called arrogant (i.e., grandiose) and inhibited, shame-ridden, and hypersensitive (i.e., vulnerable) manifestations:

> Outstanding for the arrogant type is the more striking predominant presentation, with openly featured expressions of self-serving and enhancing behaviors and attitudes in their more active and deliberate interactions with others. This is in contrast to the inhibited, shame-ridden, and hypersensitive shy type, whose low tolerance for attention from others and hypervigilant readiness for criticism or failure makes him/her more socially passive, tuned in, and interpersonally awaiting. Nevertheless, under a modest surface, the shy narcissistic individual is equally preoccupied with self-enhancing fantasies and strivings and hyperreactive to oversights or unfulfilled expectations from others.

Extending clinical observation, one empirical study (Russ, Shedler, Bradley, & Westen, 2008) asked a large random sample of psychiatrists and clinical psychologists to provide detailed descriptions of the patients they treated using a standardized protocol. The researchers used Q-factor analysis (a statistical technique that groups together individuals with similar traits) to be able to identify subtypes of NPD patients. Two substantial groups of patients emerged from this analysis: one group that the authors labeled grandiose/malignant (i.e., grandiose narcissists), and another group that they labeled fragile (i.e., vulnerable narcissists). Both groups of patients showed some similar traits—traits that might be viewed as the common core of NPD: Both groups of patients were described as having an exaggerated sense of self-importance, and holding an adversarial interpersonal orientation (i.e., they were prone to being hostile and critical of others). Still, there were several important differences in how NPD was manifest in the two groups. Grandiose narcissists were described by their therapists as holding a tendency to feel entitled and privileged, to manipulate others and seek power, and to lack empathy. Moreover, they were said to frequently get into power struggles, and to hold long-lasting grudges. By contrast, vulnerable narcissists were characterized by their therapists as being prone to experience negative affect (e.g., depressed or anxious affect, envy), to ruminate over negative events, and to be unable to maintain close relationships. Thus, this study provided empirical evidence that narcissistic pathology can take different forms.

Social-Personality Research

Social-personality research has mainly focused on trait narcissism, and also found compelling evidence for the distinction between grandiose and vulnerable manifestations of narcissism.

In an initial study, a principal-component analysis was conducted on a number of trait narcissism scales derived from the Minnesota Multiphasic Personality Inventory, which was completed by a community sample of adult participants (Wink, 1991). This analysis yielded two orthogonal factors, labeled grandiosity–exhibitionism (i.e., grandiose narcissism) and vulnerability–sensitivity (i.e., vulnerable narcissism). Although the two factors shared a common core of grandiose beliefs and disregard for the needs of other people, they were marked by distinct patterns of psychological and interpersonal adjustment. Grandiose narcissism was associated with self- and observer-ratings of extraversion, exhibitionism, self-assurance, and aggression; vulnerable narcissism was associated with introversion, anxiety, and defensiveness.

In another study (Rose, 2002), participants completed measures designed to assess subclinical traits of grandiose narcissism and vulnerable narcissism. Grandiose narcissism was positively associated with self-esteem, happiness, and life satisfaction. Conversely, vulnerable narcissism was negatively associated with these indices of well-being. Importantly, the links between narcissism and well-being were mediated by self-esteem, such that grandiose narcissists had higher well-being because they held high self-esteem, and vulnerable narcissists had lower well-being because they held lower self-esteem.

In a more recent study (Miller et al., 2011), participants completed a number of standard measures of trait narcissism, as well as measures of personality, interpersonal behavior, and psychopathology. The two factors that emerged from factor analysis were labeled grandiose and vulnerable narcissism. Both forms of narcissism were characterized by a disagreeable, antagonistic, and entitled interpersonal orientation. Yet grandiose narcissism

was associated more strongly with the Big Five trait of extraversion, and vulnerable narcissism was associated more strongly with the Big Five trait of neuroticism. Another major difference emerged in how both forms of narcissism were associated with cognitive-emotional schemas about interpersonal relationships. Whereas grandiose narcissism was not associated with attachment difficulties, vulnerable narcissism was associated with both anxious and avoidant attachment styles, suggestive of a fearful interpersonal orientation (involving fear for the loss of intimate relationships, and independence strivings at the cost of developing emotional closeness). Finally, grandiose and vulnerable narcissism differed in their associations with psychopathology. Vulnerable narcissism was linked to symptoms of internalizing pathology (depression and anxiety), as well as to symptoms of somatization, obsessive-compulsiveness, paranoia, and borderline and schizotypical personality. Grandiose narcissism was less clearly linked to symptoms of psychopathology, but did show robust links to antisocial traits.

Together, social-personality research on trait narcissism has used multiple research methods and measures of narcissism to find converging evidence that grandiose and vulnerable narcissism are distinctive manifestations of narcissism.

Two Cautionary Notes

In light of this evidence, it is tempting to think of narcissistic individuals as being either grandiose narcissists or vulnerable narcissists. In fact, in our own work, we have used such nomenclature as well (e.g., Thomaes, Bushman, Stegge, & Olthof, 2008). Although for clarity purposes it seems acceptable to cast grandiose and vulnerable narcissism as personality traits or subtypes that characterize certain individuals more than others, there is now emerging consensus that the different manifestations of narcissism are best conceptualized as *states* that oscillate or co-occur within the same individual (Pincus & Lukowitsky, 2010). Thus, at some times narcissistic individuals may be in a grandiose state, whereas at other times these same individuals may be in a more vulnerable state. In fact, such grandiose and vulnerable narcissistic states may alternate rapidly, such as when a narcissist feels on top of the world after being praised but feels like sinking into the ground after being criticized. To be sure, some narcissistic individuals may be more prone to exhibit grandiose characteristics, and others to exhibit vulnerable characteristics, but the notion that there are two types of narcissists is not entirely accurate.

Also note that the terms *overt narcissism* and *covert narcissism* are sometimes used as seemingly synonymous with *grandiose narcissism* and *vulnerable narcissism*, respectively. We agree with Pincus and Lukowitsky (2010), however, that it is best to use consistent terminology, and to refer to grandiose and vulnerable narcissism when describing the different phenotypes of narcissism. The terms overt and covert narcissism can be used to describe how these phenotypes are *expressed*. Some narcissistic characteristics are evident in observable behavior, such as narcissistic aggression, haughty interpersonal attitudes, or expressions of distress that follow from threatening events. These characteristics may be labeled overt narcissism. Other narcissistic characteristics are less observable patterns of cognition or emotion, such as fantasies of grandeur and superiority, or feelings of shame and humiliation that are held in check. These characteristics may be labeled covert narcissism. According to Pincus and Lukowitsky (2010), both grandiose and vulnerable narcissism can have overt and covert manifestations. Thus, overt and covert narcissism simply refer to how narcissistic phenotypes are expressed—they do not refer to narcissistic phenotypes themselves.

Manifestation of Narcissism in Children and Adolescents

There are various developmental factors (e.g., cognitive and emotional maturation, changes in age- and stage-relevant tasks) that are likely to influence how narcissism manifests among individuals of different ages.

In the following section, we will describe the main characteristics of narcissism in youth as evident from clinical observations and empirical data, focusing on those narcissistic characteristics that appear more typical in youth than in adults. In doing so, we follow the distinction between grandiose and vulnerable manifestations of narcissism.

Grandiose Narcissism: Clinical Observations

Phenotypic descriptions of grandiose narcissism from the clinical child and adolescent literature show considerable overlap with those from the clinical adult literature. In particular, feelings of superiority and entitlement, haughty and manipulative behaviors, and lack of genuine empathic concern for others have been described as core features of grandiose narcissism among youth, as much as they have been described as core features of grandiose narcissism among adults (e.g., Bleiberg, 1984; Kernberg et al., 2000). A few characteristics, however, stand out as typical manifestations of grandiose narcissism in children and adolescents.

First, grandiose fantasy has been described in clinical writings as one important means by which narcissistic

youth try to create and uphold their grandiose self-views, more than narcissistic adults do (Bardenstein, 2009; Bleiberg, 1984). Some common themes that narcissistic youth fantasize about are becoming wealthy, powerful, and physically attractive, or being capable of exceptional sports performances—or any other theme that allows them to feel they stand out from others. To be sure, especially in the early school years, it is not uncommon for typically developing children to engage in grandiose fantasy. What makes grandiose fantasy narcissistic is its age inappropriateness, its intensity, and the extent to which it interferes with children's daily functioning. For example, clinical observation suggests that grandiose fantasies tend to become less frequent from middle childhood in typically developing children, but not so in narcissistic children (Bleiberg, 1984). Some authors (Kernberg et al., 2000) have also argued that narcissistic fantasy differs from typical fantasy in the extent to which children believe that their fantasies reflect reality. Indeed, some narcissistic children do not just *fantasize* about being a superhero; they may actually believe they are a superhero. Such reality distortions may occur in children who suffer from more severe narcissistic pathology. Reality distortion by no means is a defining feature of narcissism: Many narcissistic children rationally understand that they are not superheroes, and may even realize that their personal traits or skills are not exceptional. Yet they cling to their grandiose fantasy because this makes them feel good about themselves.

Second, so-called false self-behavior (Harter, 2006, 2012) is a trait that is particularly salient among narcissistic youth, perhaps especially narcissistic adolescents (Bleiberg, 1984). False self-behavior refers to public acts that are discrepant with how one actually thinks or feels. Adolescents often feel that they are not acting in line with their true feelings, or that they behave in ways that someone else wants them to be (Harter 2006, 2012). In typically developing adolescents, false self-behavior often emerges as a form of role experimentation or in response to peer pressure. However, in narcissistic adolescents, false self-behavior is believed to result from a failure to develop an autonomous identity (Bleiberg, 1984) and from the intense desire to make positive impressions on peers. Because narcissistic adolescents may lack an authentic sense of who they are, and because they are highly motivated to obtain approval from peers, peer norms and expectations, rather than true feelings, may have a disproportionate impact on their behavior.

Third, age-inappropriate attitudes of self-sufficiency and self-reliance have also been described as typical for narcissistic youth (Bardenstein et al., 2000; Bleiberg, 1984). From a young age, many narcissistic children present themselves as not needing anyone, and being well able to take care of themselves. The common interpretation is that narcissists carefully avoid presenting themselves as in need of affiliation (even if the need for affiliation would be entirely age-appropriate), in an attempt to make themselves look independent or invulnerable. According to Kohut (1971), perhaps due to earlier experiences with parental coldness or abandonment, many narcissistic children lack trust that other people will support or care for them. To be able to cope with that painful belief, they may take a defensive interpersonal stance that communicates their self-reliance. Ironically, such a self-reliant interpersonal stance may cause even further detachment from others, potentially creating a downward spiral over time: Narcissists' detached interpersonal style might cause them to experience decreased interpersonal support, which may confirm them in the belief that other people are unlikely to support them, which subsequently cultivates their detached interpersonal style and ultimately may lead narcissists to become alienated from others. Illustratively, Bardenstein (2009) describes a young narcissistic client who noted that he had 1000 friends, but could not name anyone who knew him well or whom he trusted.

Grandiose Narcissism: Empirical Evidence

Empirical evidence on grandiose narcissism suggests considerable developmental consistency in the manifestations of narcissism. For example, research has shown that narcissistic children, much like older narcissistic individuals, tend to feel superior to others (Thomaes, Stegge, et al., 2008), and to hold more agentic than communal social goals (i.e., they are invested with establishing dominance and gaining respect from others, rather than with establishing close relationships; Thomaes, Stegge, et al., 2008).

One study examined adolescents' behavior on social networking sites, and found evidence suggesting that narcissistic adolescents are relatively concerned about making favorable impressions on others (Ong et al., 2011). In particular, narcissistic adolescents rated the pictures they posted on their Facebook profiles as more physically attractive, more fashionable, more glamorous, and more cool than less narcissistic participants did. Moreover, narcissistic participants updated their status on Facebook more frequently than less narcissistic participants, suggesting that they are eager to present to others what's on their minds. Importantly, these findings held even after controlling for extraversion, a personality trait that is associated with narcissism and also has strong impact on self-presentation.

Narcissistic youth are also prone to behave aggressively. In our own work, we have found that narcissistic children and adolescents can be particularly aggressive when they are faced with ego threatening experiences, such as when they are humiliated or ridiculed, criticised, or experience failure (Thomaes, Brummelman, Reijntjes, et al., 2013; Thomaes, Bushman, Orobio de Castro, Cohen, & Denissen, 2009; Thomaes, Stegge, Olthof, Bushman, & Nezlek, 2011). In one experimental study (Thomaes, Bushman, et al., 2008), participants (aged 10–13 years) first completed a measure of narcissistic traits and then played a competitive game with an unknown virtual opponent. The game was rigged so that participants lost. In the ego threat condition, participants were told their opponent was really bad on the task and that they should easily win. After losing, they saw their own name at the bottom of a ranking list on a bogus web page. In the control condition, they were told nothing about their opponent and did not see any rankings. Next, participants could blast their opponent with loud noise through headphones (a validated laboratory measure of aggression). Narcissists were more aggressive than others, but only when faced with ego threat. In fact, most aggressive were narcissists who had also reported very high self-esteem; narcissists who reported lower levels of self-esteem (potentially reflective of more vulnerable narcissism) were not more aggressive than other children. When triggered by ego threatening experiences, aggression is a manifestation of grandiose narcissism, in that it reflects an attempt to turn the tables and protect one's favorable self-image by restoring interpersonal dominance relations.

In addition to experimental findings, findings from survey research have consistently shown links between narcissism and predispositions to engage in physical, verbal, and relational aggression (i.e., excluding others, spreading rumors; Ang & Raine, 2009; Fossati, Borroni, Eisenberg, & Maffei, 2010; Golmaryami & Barry, 2010; Thomaes et al., 2009), aggression on the Internet (Ang, Ong, Lim, & Lim, 2010), and more broadly defined disruptive, antisocial, or delinquent behaviors (including stealing and lying; Barry, Frick, & Killian, 2003; Barry, Grafeman, Adler, & Pickard, 2007; Ha, Petersen, & Sharp, 2008). These findings were obtained in children and adolescents from both community and at risk samples, using different operationalizations of conduct problems, which attests to the robustness of the link between narcissism and conduct problems. Moreover, longitudinal research has found that narcissism also promotes the stability of aggressive behavior, such that aggressive young adolescents are more likely to remain aggressive over a 1-year period to the extent that they are more narcissistic (Bukowski, Schwartzman, Santo, Bagwell, & Adams, 2009).

Thus, there is rather comprehensive evidence for grandiose manifestations of narcissism among children and adolescents. The available literature, both clinical writings and empirical research, converges in suggesting that the grandiose manifestations of youth narcissism are in important ways similar to those in adults. Still, some manifestations are more salient in children and adolescents than they are at later age, including grandiose fantasy, false self-behavior, and age-inappropriate attitudes of self-sufficiency and self-reliance.

Vulnerable Narcissism: Clinical Observations

Phenotypic descriptions of vulnerable narcissism from the clinical child and adolescent literature show substantial overlap with those from the adult literature as well. Youth with narcissistic pathology are described to be hypersensitive to insults or criticisms, to feel unworthy when they fail to obtain admiration from others, to suffer from intense, recurrent feelings of shame and humiliation, and to be vulnerable to develop symptoms of anxiety and depression. A few characteristics stand out from clinical writings as early manifestations of vulnerable narcissism, manifestations that are less common or salient in adults.

Envy has been described as a manifestation of vulnerable narcissism that is relatively salient in children and, perhaps, adolescents. Narcissistic youth need reassurance that they are special, and accordingly, they tend to be hypervigilant to cues that other people get the attention and respect that they themselves seek to get (Bardenstein, 2009; Kernberg et al., 2000). They often avoid being a spectator of other people's accomplishments, deny that other people have exceptional skills, lead attention of audiences away from other people and direct it towards themselves, or express distress or resentment over other people's successes and opportunities. It is not uncommon for narcissistic children to be hostile to those who they see as attracting the attention that they themselves deserve to get. Narcissists tend to experience their quest for external validation as a zero-sum game, such that when other people gain attention or admiration, they believe this comes at the cost of their own chances to validate their grandiose egos: When other people stand out, narcissists feel unable to stand out themselves. Accordingly, envy can be considered a manifestation of vulnerable narcissism in that it is rooted in emotions of anxiety or distress over not being able to have one's grandiosity needs fulfilled. To be sure, adult narcissists are prone to experiencing envy as well, but they

may be better able to regulate their envy or to express it in more subtle ways.

Another salient manifestation of vulnerable narcissism in youth, especially adolescents, is the emotion of shame. Shame is the painful feeling associated with appearing worthless or inferior in the eyes of other people. Narcissistic youth are prone to experiencing shame for several reasons; they hold high standards for themselves (they want to radiate an image of perfection), and they are highly concerned about what other people might think of them. Consequently, when narcissists believe that others might see imperfections in them, they experience intense feelings of shame (Beren, 1988; Bleiberg, 1984). Normative developments in adolescence (e.g., increased self-consciousness, increased perceived importance of peer evaluation) already make shame a more common and painful emotion among typically developing adolescents. This normative development is magnified, however, among narcissistic adolescents, causing them to experience shame as particularly aversive. Importantly, precisely because shame is so painful, narcissists may sometimes try to repress or trump shame by less self-threatening forms of negative emotion, especially anger (Thomaes et al., 2011). Such an emotional state of shame-based anger has been called humiliated fury (Lewis, 1971).

Vulnerable Narcissism: Empirical Evidence

Empirical research has identified some manifestations of vulnerable narcissism in children and adolescents. First, correlational research found that narcissistic children are not only prone to experiencing positive affect, but to experiencing negative affect as well (Thomaes, Stegge, et al., 2008). If anything, narcissistic youth show emotional extremity, with episodes of positive affect (e.g., pride, euphoria) being interspersed with episodes of more negative affect (e.g., shame, dysphoria) relatively frequently. In one experiment, we found that public failure on an easy task causes children high in narcissistic traits to experience relatively intense feelings of shame, presumably because such failure threatens narcissists' grandiose self-image (Thomaes et al., 2011). Another experiment, conducted in a sample of adolescents, found that blatant positive feedback (participants were told, "You did much better than other people your age—great job!" following a general knowledge quiz) can sometimes cause vulnerable narcissists to feel shame, perhaps because they do not believe that such positive feedback is genuine (Malkin, Barry, & Zeigler-Hill, 2011; note that even in nonnarcissists, positive feedback is sometimes experienced as debilitating or discouraging (Brummelman, Thomaes, Orobio de Castro, Overbeek, & Bushman, 2014; Kamins & Dweck, 1999; Meyer, 1992). Thus, although more research is needed to identify situational triggers and boundary conditions, it is clear that narcissistic youth are prone to experience emotional extremity.

Similarly, we have found empirical evidence for the view that narcissists' self-esteem is vulnerable, and that they are prone to lose self-esteem following ego threatening events. In an experimental study (Thomaes et al., 2010), participants (aged 8–12 years) first completed a measure of narcissistic traits and then competed in an online popularity game, in which the least liked person was voted out of the group by a panel of peer judges. Participants first completed a personal profile (e.g., "How do you describe yourself?"). Next, participants in the social threat condition received negative feedback on their personal profile (they were announced as least likeable), whereas participants in the control condition received neutral feedback (an opponent was announced as least likeable). Both before and after the game, participants completed a measure of state self-esteem (e.g., I am satisfied with myself right now). Although most children lost some level of self-esteem following negative feedback, this effect was considerably stronger among narcissistic children: Narcissists tend to feel good about themselves, but they lose worth quickly in the face of negative social experiences.

Other empirical research has shown that narcissistic children and adolescents are prone to experience anxiety. Initial research found that narcissists are prone to experience symptoms of social anxiety, especially fear of negative evaluation (Thomaes, Stegge, et al., 2008). Thus, narcissistic youth are not only observed by clinicians to be socially anxious, they actually acknowledge and report being socially anxious as well. Other research has suggested that the anxiety problems of narcissistic youth may not be limited to social anxiety alone. Research among both children and adolescents has found narcissism, and especially its more maladaptive facets, to be associated with a rather broad set of internalizing problems, including symptoms of fear, worry, and depression (Barry & Malkin, 2010; Washburn, McMahon, King, Reinecke, & Silver, 2004). The exact pattern of links between narcissism and internalizing problems is rather complicated, however, with other facets of narcissism showing no or even negative associations with internalizing problems (Barry & Malkin, 2010).

Recent research sought to provide further clarification (Nelemans et al., 2015). A large community sample of schoolchildren (aged 8 to 14) completed measures of narcissism and self-esteem, as well as anxiety (i.e., symptoms

of social anxiety, generalized anxiety, separation anxiety, and panic) and depression. Using a latent class analysis it was possible to distinguish empirically between groups of children who were high in both narcissism and self-esteem (this group was labeled grandiose narcissism) and those who were high in narcissism but lower in self-esteem (this group was labeled vulnerable narcissism). Compared with other groups, children in the vulnerable narcissism group experienced elevated levels of overall anxiety and depression, whereas children in the grandiose narcissism group experienced lower levels of overall anxiety and depression. This pattern sustained longitudinally, such that vulnerable narcissism (but not grandiose narcissism) predicted increased overall anxiety and depression problems 1 year later. Thus, these results suggest that narcissistic children's level of self-esteem foretells how much they are at risk to suffer from anxiety and depression symptoms.

In summary, clinical writings and empirical research suggest that vulnerable manifestations of narcissism are, to a considerable extent, similar among youth and adults. Yet some manifestations may be especially salient in children and adolescents, including the predisposition to experience envy, shame, worthlessness, anxiety, and depression.

ASSESSMENT OF NARCISSISM IN CHILDREN AND ADOLESCENTS

Up until the early years of this century, empirical research on narcissism in children and adolescents was virtually nonexistent. The study of narcissism in youth was patented by clinicians who described the manifestations, consequences, progress, and treatment of narcissistic problems in their young patients. This status quo changed when the first standardized measures of trait narcissism became available that were specifically developed for children and adolescents (Barry et al., 2003; Frick, Bodin, & Barry, 2000). The availability of these measures has made it easier for researchers to study narcissism in youth. In this section, we discuss some common questions and concerns regarding the assessment of narcissism in youth, and review available measures.

Questions and Concerns

A number of questions and concerns are occasionally raised regarding the assessment of narcissism in youth, and we address them here.

1. *Do children who hold narcissistic traits actually report narcissistic traits?* One may perhaps suspect that scores on measures of youth narcissism will be strongly positively skewed, possibly because youth who hold narcissistic traits may not acknowledge or self-endorse their narcissistic traits; they might be concerned about the negative impression they would make on others by self-endorsing such traits (we anticipated this possibility when we started doing research on narcissism). Such suspicion seems unwarranted, however. Youth narcissism is a normally distributed trait, as has been found across different measures, across respondents of different ages (i.e., aged 8–18 years), and across samples of different types (e.g., community samples of typically developing youth and clinical samples of incarcerated youth; Barry & Wallace, 2010). Also, youth narcissism is unrelated to standard measures of social desirability, suggesting that social desirability or impression management concerns do not typically keep children and adolescents from reporting narcissistic traits (Thomaes, Stegge, et al., 2008).
2. *Is it ethical to assess narcissism in youth?* Two ethical concerns are sometimes raised regarding the assessment of youth narcissism in scientific research. First, it is argued that because aspects of narcissism may be relatively normative or age-appropriate in some stages of development, researchers assessing youth narcissism run the risk of problematizing patterns of thought, feeling, and behavior that are actually quite transient and innocuous. Second, it is argued that because the term narcissism has the connotation of being a stable, ingrained personality structure that is hard to overcome, researchers should use a different term.

   Although these concerns are understandable, we do not believe that simply refraining from assessing narcissism or using different terminology would be good solutions. First, it is true that aspects of narcissism are more age-appropriate in some stages of development than in others. For example, self-consciousness and egocentrism are aspects of narcissism that show normative developmental increases with the onset of adolescence. However, the same holds for other personality traits—in fact, it is the rule rather than the exception that there are stages in development when what appear as manifestations of maladjustment actually are age-appropriate phenomena. We believe that narcissism should be studied both in stages when it is more and less age-appropriate, as this may provide important insight into when levels of narcissism become atypical given an individual's age.

   Similarly, it is true that while relatively little is known on how stable narcissistic traits are in youth, the term

narcissism may inadvertently communicate that it is an ingrained, highly stable trait. Still, we do not believe that a change of terminology is recommendable. First, it would isolate research on youth narcissism from research on adult narcissism. Second, it would involve the risk of introducing confusion regarding the exact psychological phenomenon that the new label would cover, and how it would be similar to or different from the former label. Third, the change in terminology might not even bring about the intended change: New terminology to describe negative psychological phenomena may sound neutral when first introduced, but may easily gain the same connotations as its predecessor when it becomes more commonly used.

3. *Do we really need a measure of narcissism specifically developed for youth?* This question is occasionally asked, perhaps mainly by social-personality and clinical psychologists. The argument is that the field might be better off with a single measure of trait narcissism that would function as a gold standard. We agree that such a gold standard would facilitate the interpretation and generalization of findings across development, from childhood into adulthood. Also, if a gold standard were available, it would be easier to examine the developmental stability of narcissism, especially its mean level stability.

   Measures of youth narcissism are needed, however. First, and most prosaically, the wording of standard adult measures of narcissism is too complicated to be used with youth. For example, not all 8-year-olds will be able to understand such items as, "I like having authority over other people" (included in the NPI). Second, adult measures of narcissism often require relatively complex self-reflective skills—skills that are too complex for many children and adolescents. For example, not all children will be able to understand the statement that "It is hard for me to feel good about myself unless I know other people like me" (taken from the Pathological Narcissism Inventory). Third, as discussed in the *Manifestations* section, some key narcissistic characteristics manifest themselves differently in different stages of development: Developmental psychologists studying narcissism are hunting a moving target. For example, the items "People always seem to recognize my authority" (included in the NPI) and "I am a great example for other kids to follow" (included in the Childhood Narcissism Scale) likely tap a similar underlying narcissistic cognition (i.e., self-perceived authority), but the latter item is more age-appropriate and thus more meaningful for children. Thus, although a gold standard measure of narcissism would be ideal for pragmatic reasons, it is neither feasible nor desirable. The field benefits most from age-appropriate measures of narcissism.

4. *Does the assessment of youth narcissism add to the assessment of self-esteem?* At first blush, it may seem reasonable to assume that narcissism and self-esteem are strongly correlated, perhaps to such an extent that any variance they do not share is of trivial importance. Yet, although narcissists hold grandiose self-views and feel superior to others, they are not necessarily satisfied with the person they are. Indeed, correlations between youth narcissism and self-esteem are typically small, with *r*s often ranging between .0 and .30 (Barry & Ansel, 2011; Thomaes, Stegge, et al., 2008). Moreover, narcissism and self-esteem tend to have different correlates, supporting the notion that in many ways narcissism is the less adaptive cousin of high self-esteem (e.g., Barry et al., 2007; Thomaes et al., 2013). Also note that narcissism and self-esteem sometimes interact at predicting important outcomes, including the outcomes of aggressive behavior and symptoms of depression and anxiety, presumably reflecting the different consequences of grandiose (high narcissism and high self-esteem) versus more vulnerable (high narcissism and lower self-esteem) manifestations of narcissism (for a review, see Thomaes, Brummelman, Reijntjes, et al., 2013). Thus, the assessment of narcissism adds to the assessment of self-esteem.

Self-Report Measures of Narcissism for Children and Adolescents

Narcissism is a form of self-evaluation, so self-report is the method of choice to assess youth narcissism. It is only by means of self-report that key narcissistic characteristics, such as grandiose self-views, or the sense of entitlement and superiority, can be directly assessed.

Unsurprisingly, then, the standard measures of adult narcissism are self-report questionnaires. The NPI (Raskin & Hall, 1979; Raskin & Terry, 1988), in particular, has become the standard for the assessment of trait narcissism in adults in the social-personality and clinical literature. A more recent, promising measure of narcissism in adults is the Pathological Narcissism Inventory (PNI; Pincus et al., 2009). This measure was developed in response to the concern, voiced by some experts, that the NPI may assess relatively adaptive manifestations of narcissism. The PNI is developed with the goal of assessing more maladaptive manifestations, and it assesses both narcissistic grandiosity and narcissistic vulnerability.

To assess narcissism in youth using self-report there are two main measures: the Childhood Narcissism Scale (Thomaes, Stegge, et al., 2008) and the Narcissistic Personality Inventory for Children (NPIC; Barry et al., 2003). These measures are similar in that they aim to measure narcissistic traits in the general child and adolescent population (i.e., in children about age 8 and older), and that they have been well validated in multiple cultures. The main difference between the measures is their breadth of measurement and their length. No single measure of youth narcissism is preferable over the other—rather, both measures can be used for different purposes.

Childhood Narcissism Scale

The Childhood Narcissism Scale (Thomaes, Stegge, et al., 2008) is a short (i.e., 10-item) yet comprehensive measure of individual differences in trait narcissism. It can be used in community samples of children and adolescents aged 8 years and older. Sample items include, "I am a great example for other kids to follow," and "I love showing all the things I can do." Items are rated along a 4-point scale ranging from 0 (not at all true) to 3 (completely true).

A principal components analysis, parallel analysis, and confirmatory factor analysis conducted in representative community samples of Dutch children (aged 8–13) found that the CNS has a one-dimensional factor structure. The original Dutch version of the CNS has been translated and cross-validated in a community sample of children from the United States (aged 10–14 years). A confirmatory factor analysis found again that a one-dimensional structure underlies the CNS. Internal consistency of the CNS is good (with alphas typically ranging between .75 and .90), and 2- and 6-month test-retest reliability estimates of .76 and .69 have been found, respectively. Research on the psychological and interpersonal correlates of the CNS suggests that CNS-measured childhood narcissism fits in a largely similar nomological network as adult narcissism. The CNS is related to self-appraised superiority but virtually unrelated to self-esteem (i.e., individuals high in CNS-measured narcissism tend to feel superior to others, but are not particularly satisfied with themselves). Moreover, the CNS is associated with self-esteem contingency (i.e., the tendency to base one's worth as a person on approval from others), agentic but not communal social goals (i.e., the motivation to dominate social interactions and gain admiration, but not to establish close relationships), emotional extremity (the tendency to experience both positive and negative emotions frequently and intensely), other dark-triad personality traits (i.e., psychopathic and Machiavellianist personality traits), aggression, conduct problems, and reduced empathic concern (Barry & Wallace, 2010; Thomaes, Stegge, et al., 2008; Van Baardewijk et al., 2008).

Narcissistic Personality Inventory for Children

The NPIC (Barry et al., 2003) is a 40-item measure of individual differences in narcissistic traits. It is a downward extension of the NPI: Items closely mirror those from the original NPI, but some are adapted to make them more developmentally appropriate (for example, the original NPI item, "Modesty doesn't become me," has been changed to, "I like to show off the things that I do well"). The NPIC has been used in both community and clinical samples of older children and adolescents. Respondents first select one statement from a pair of statements (e.g., "I would rather be a leader" vs. "I don't care if I'm a leader or not"; and "I really like to be the center of attention" vs. "I'm not comfortable being the center of attention"), and then indicate whether the selected statement is sort of true or really true for them.

Whereas the CNS is primarily meant to assess narcissism as a single construct, the NPIC assesses narcissism as a multifaceted construct. Specifically, the NPIC can be used to distinguish between what has been labeled as adaptive and maladaptive narcissism. The Adaptive Narcissism subscale comprises 14 items that tap feelings of self-sufficiency and authority. The Maladaptive Narcissism subscale comprises 18 items that tap exhibitionism, exploitativeness, and entitlement (Barry, Frick, Adler, & Grafeman, 2007; Barry & Ansel, 2011). Although both subscales are relatively strongly correlated (with *r*'s typically ranging between .50 and .60), they have different correlates. Adaptive narcissism is associated with social skills, the quality of one's social relationships, and self-esteem; whereas maladaptive narcissism is associated with callous-unemotional traits, hyperactivity/impulsivity, conduct problems, delinquency, and reduced self-reliance (Barry & Ansel, 2011; Barry, et al., 2007; Barry & Wallace, 2010).

There has been some debate on what adaptive narcissism exactly means. Some have argued that the traits presumed to constitute adaptive narcissism, traits such as self-confidence, self-reliance, and self-perceived authority, often yield social rewards in present-day Western society and may be considered adaptive (Barry & Ansel, 2011). Others have argued that the traits that constitute adaptive narcissism represent nothing else than self-confidence—a trait that is associated with narcissism but is not inherent to it (Brown, Budzek, & Tamborski, 2009). These latter authors argued that it is important to distinguish

narcissism itself (which is essentially maladaptive) from the more adaptive, self-secure traits that are associated with it.

Additional Measures of Narcissism for Children and Adolescents

Antisocial Process Screening Device

The Antisocial Process Screening Device (APSD; Frick & Hare, 2001), a measure of psychopathic traits in youth, contains a 7-item Narcissism subscale. Some aspects of psychopathy, in particular the sense of grandiosity, are indicative of narcissism, and the APSD measures overt behaviors that reflect grandiosity. Sample items include, "Brags about accomplishments, abilities, or possessions," and "Thinks she/he is better or more important than other people." Items are rated along a 3-point scale ranging from 0 (not at all true) to 2 (definitely true). The APSD was originally developed as a parent- and teacher-report measure, but a self-report version was developed later (e.g., Vitacco, Rogers, & Neumann, 2003). APSD self-reported narcissism (sometimes labeled psychopathy-linked narcissism) is associated with both proactive and reactive aggression (even after controlling for the other psychopathy dimensions of callous-unemotional traits and impulsivity), delinquency and conduct problems, number of police contacts, but also with elevated levels of fear, worry, and depression (Barry & Malkin, 2010; Barry, Thompson, et al., 2007; Barry & Wallace, 2010; Munoz & Frick, 2007).

What is the utility of the APSD narcissism subscale for the assessment of narcissism in youth? The APSD has some practical benefits: It is short, and in some research settings it is advantageous that parent-, teacher-, and self-report equivalents are available. Moreover, the APSD is a preferred measure when researchers are specifically interested in assessing grandiosity features insofar as they relate to psychopathic traits. Yet if researchers are interested in narcissism per se, the APSD is not recommended. It assesses narcissistic behaviors, but not narcissistic cognitions and feelings (e.g., grandiose self-evaluations, feelings of entitlement) that are at the core of narcissism.

Observed Narcissism

Observational measures of narcissism are sometimes used, especially in analyses of existing longitudinal data sets that include observational measures of personality. For example, a set of 10 items from the California Adult Q-set (CAQ; Block, 1978), scored by a team of psychologists and advanced psychology students, has been taken to index narcissism in adolescent participants (Carlson & Gjerde, 2009). The items were selected based on their relatively strong correlations to the NPI as found in other research (Raskin & Terry, 1988), and includes such items as, "Genuinely submissive, accepts dominance comfortably" (reversed), and "Unaware of self-concern, feels satisfied with self." Observational measures can be useful to index narcissism in analyses of existing longitudinal data; they may allow researchers to explore the long-term stability or developmental precursors of narcissism (which is precisely what Carlson and Gjerde did). They may also be useful to measure early, rudimentary manifestations of narcissism or its precursors before they can be measured using self-report. Yet, observational measures are not ideal measures of narcissism in that, again, they only tap outward expressions of narcissism, not the internal narcissistic cognitions and feelings that are at the core of narcissism.

THEORIES OF NARCISSISM

Narcissists are individuals full of paradoxes. They feel superior to others but also crave others' admiration. They appear self-confident but are also easily threatened by criticism. They are charming but also insensitive to other people's needs. What personality constellation or psychological process may underlie these seemingly paradoxical traits? Over the years, several psychological theories of narcissism have been proposed in an attempt to answer this question. We will describe the most influential theories here.

Dynamic Self-Regulatory Processing Model

The dynamic self-regulatory processing model of narcissism (Morf & Rhodewalt, 2001) is the most influential model of narcissism to date. This model is based upon the assumption that people, narcissists and nonnarcissists alike, are universally invested with creating and maintaining desired self-views (sometimes called ideal selves). To that end, people employ a variety of inter- and intrapersonal self-regulatory strategies. According to the model, narcissists have the ultimate goal of building and maintaining a grandiose self. They want to feel superior, important, and influential, and they employ social, cognitive, and affective self-regulatory strategies to achieve this goal. Yet, narcissists achieve their goal only fleetingly, because their grandiose self-views are virtually impossible to maintain: In everyday life, narcissists, like anyone else, cannot avoid encountering information that falsifies their grandiose self-views, such as failure, criticism,

or rejection. Because narcissists' self-views are ultimately vulnerable, they need constant external validation, such as praise and admiration, to create, maintain, or rebuild their grandiose self. Thus, narcissists are in a chronic state of self-under-construction (Morf & Rhodewalt, 2001): They continuously employ a variety of inter- and intrapersonal strategies to create and maintain the grandiose self they so strongly desire.

On the *interpersonal level*, narcissists try to instil favorable impressions on others, and try to mold their social interactions such that they will receive others' attention and admiration. For example, they constantly try to be at the center of attention, to garner others' admiration, and to prove they are superior to others: Narcissists are more concerned with getting ahead than with getting along. On the *intrapersonal level,* narcissists seek to validate their grandiose self-views, such as by taking excessive credit for successes, by dismissing negative outcomes, by overestimating their competencies and accomplishments, and by reconstructing past experiences in self-flattering ways. Thus, narcissists are highly inventive in finding ways to build and buttress their grandiose self-views.

Ironically, however, narcissists' relentless attempts to gain external validation may ultimately prove self-defeating. Their attempts to garner attention, praise, and admiration may eventually backfire, and repel the very people on which they are dependent for approval. On first encounter, narcissists typically appear charming, confident, and easygoing. Eventually, however, the more adversarial narcissistic self may surface when narcissists manipulate others, act in arrogant ways, have trouble empathizing with others, and deal in selfish ways with conflicts of interest. Once others notice narcissists' adversarial interpersonal orientation, they may no longer serve as the source of external validation that narcissists need. This dynamic has been considered the ultimate *narcissistic paradox* (Morf & Rhodewalt, 2001): In seeking others' approval, narcissists tend to destroy the very relationships on which they are dependent. Much like Narcissus—who reached out for his own image in the water, touched it, and thereby made it disappear—narcissists' strategies to build grandiose self-views may be counterproductive and eventually undermine the grandiose self they are trying to create.

Discussion

The self-regulatory processing model has contributed to our understanding of narcissism in important ways. It was the first model to illuminate not only narcissists' stable traits and characteristics, but also the moment-to-moment self-regulatory strategies by which narcissists seek to achieve desired self-views. In doing so, the self-regulatory processing model bridges trait- and process-based approaches to personality (Morf & Rhodewalt, 2001). According to the model, narcissists' stable characteristics are rooted in the predictability of the momentary strategies they employ to build the grandiose self. A major contribution of the model is that it outlines how social, cognitive, and affective processes interact to create and maintain the grandiose self.

Importantly, key aspects of the model have been confirmed by research in children and adolescents. For example, recent research shows that narcissistic children easily lose self-esteem, that they desire admiration, and that they employ a variety of intra- and interpersonal regulatory strategies to create and maintain their desired self-views. The model is not without limitations, however. One caveat is that one of the model's key postulates—that narcissists have a vulnerable self—has received mixed theoretical and empirical support. Experts disagree about whether narcissists have a vulnerable self in the first place, and among those who do believe that narcissists might have a vulnerable self, there is disagreement about the nature of such vulnerability.

Taken together, the self-regulatory processing model is comprehensive, provides unique insight into the nature of narcissism, and has received considerable empirical support in child and adolescent samples. The nature of narcissistic vulnerability, however, needs further clarification.

Addiction Model

The addiction model of narcissism (Baumeister & Vohs, 2001) draws a direct parallel between narcissists' addiction to being admired and more familiar addictions (e.g., drug addictions). In this view, narcissism may not be a personality trait in the strict sense, but a chronic pattern of urges and behaviors that shares striking similarity to the urges and behaviors that characterize addiction. Addiction refers to a condition in which people need a stimulus (e.g., cocaine, alcohol, gambling) to avoid physical or psychological withdrawal symptoms (American Psychiatric Association, 1994). In seeking short-term gratification of their needs, addicted people risk long-term costs, such as to their interpersonal relationships. Similarly, in their seeking for admiration from others, narcissists may inadvertently destroy the very relationships on which they are dependent for obtaining admiration (Baumeister & Vohs, 2001). And much like addicts experience highs and lows, narcissistic individuals do not hold stable inflated self-views but

experience periods of self-view highs that feel very good, interspersed by periods of self-view lows that feel very bad (Thomaes et al., 2010; Thomaes, Stegge, et al., 2008).

More to the point, narcissism may share three hallmarks of addiction—cravings, withdrawal, and tolerance. *Cravings* refer to an intense longing for a desirable stimulus. Narcissists crave to be admired by others, and they use many different strategies to reach this goal, even strategies that harm other people. As such, narcissists' strategies to get their admiration fix are not unlike other addicts' strategies to get their fix. *Tolerance* refers to a decrease in the effects of a drug, so that increasing dosage is needed to yield similar effects. Similarly, narcissists never seem to be satisfied with a given level of admiration; even when they have received the admiration they strived for, they typically want even more admiration from more sources on more occasions. *Withdrawal* refers to the distress that ensues when administration of a drug is withheld. Similarly, when narcissists fail to elicit admiration from others, their self-esteem drops and they tend to become angry, hostile, or aggressive—not unlike addicts who are denied their fix.

Additional similarities between narcissism and addiction lie within the interpersonal domain. The state in which narcissists become shortsighted and preoccupied with garnering others' admiration has been labeled *narcissistic myopia* (Baumeister & Vohs, 2001). In such a state, narcissists may see others primarily as a means to obtain admiration, and they disregard others' needs and concerns. Also, when narcissists have received from the relationship what they desire, namely admiration, they often move on to another potential source of admiration (e.g., a new friend or partner). Narcissists may thus neglect depleted sources of admiration. Together, these adversarial interpersonal processes may cause narcissists to repel others and, consequently, to lose others' appreciation and admiration.

Discussion

The addiction model has originally been proposed as a conceptual addition to the self-regulatory processing model of narcissism (Morf & Rhodewalt, 2001). Unsurprisingly, then, it shares several strengths with this model—it sheds light on not only narcissists' traits, but also their moment-to-moment self-regulatory strategies. Despite this overlap, the addiction model has several unique features. First, it emphasizes that the core of narcissism is motivational: Narcissists do not primarily differ from nonnarcissists in *how they see themselves*, but in *what they strive for*. Second, the model might provide novel insight into the origins, nature, and consequences of narcissism. For example, it has been suggested that narcissism might have similar developmental pathways and neurobiological determinants as other forms of addiction (Thomaes, Brummelman, Reijntjes, et al., 2013). If so, then effective treatment of narcissistic maladjustment might benefit from building upon effective treatments of more typical forms of addiction. These and other predictions may inform prevention and intervention efforts to curtail narcissistic development.

The addiction model of narcissism has conceptual power and charm. Unfortunately, however, it has never been tested directly, neither in adults nor in youth. An important task for future research will be to test the model, and to determine whether the parallel between narcissism and addiction is more than just a useful metaphor.

Big-Five Model

Personality can be cast in terms of the five basic dimensions of Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism—collectively labeled the Big Five (e.g., Costa & McCrae, 1997). Paulhus (2001) has proposed a minimalist model of narcissism, which represents narcissism in terms of two Big Five personality dimensions: Agreeableness and Extraversion. Specifically, narcissists may be viewed as disagreeable extraverts. Disagreeable individuals tend to be interpersonally distrusting, egocentric, noncompliant, arrogant, and tough-minded. Extravert individuals are generally warm, gregarious, assertive, active, excitement seeking, and prone to experience positive emotion. Thus, disagreeableness and extraversion may jointly account for narcissists' antagonistic, noncommunal, agentic, energetic, and reward-focused traits.

Discussion

The strength of the Big Five model of narcissism lies in its parsimonious account of narcissism and its relying upon a long-standing line of theory and research on the structure of personality. The model does have its downsides, though. First, and importantly, it is unlikely to explain the full range of narcissistic traits. For example, it is unclear how joint disagreeable and extraverted traits may explain why narcissists hold unrealistically positive, inflated self-views. Similarly, joint disagreeable and extraverted traits do not explain narcissists' sensitivity to ego threatening experiences. Another downside is that the Big Five model does not further understanding of the intra- or interpersonal strategies that characterize narcissism. Direct evidence for the validity of Big Five model of narcissism in youth is still lacking. Future research should examine the extent to

which youth narcissism can be understood from the Big Five model, and what narcissistic traits can and cannot be explained from this model.

Psychoanalytic Models

In the early stages of theorizing about narcissism, psychoanalytic models were relatively influential. In particular, the object-relations model (proposed by O. F. Kernberg) and self-psychology model (proposed by Kohut) provided frameworks from which psychologists tried to understand narcissism. Both models are briefly described here.

Object-Relations Model

Object-relations theory assumes that people have two fundamental drives—libido and aggression. In addition, it assumes that people hold self-representations (i.e., internal images of themselves) as well as object-representations (i.e., internal images of important others). These representations contain good or positively valenced aspects (caused by libido) as well as bad or negatively valenced aspects (caused by aggression).

According to Kernberg (1975), narcissism comes in different forms depending on how people integrate positive and negative self- and object-representations. *Normal narcissism* arises, he thought, when people integrate both positive and negative aspects into their self- and object-representations. As such, normal narcissism is a normative process, and allows people to evaluate themselves and others realistically. By contrast, *pathological narcissism* arises when people integrate only positive aspects into their self- and object-representations, and project bad self- and object-representations onto others. Thus, pathological narcissism involves unrealistically positive, grandiose views of the self yet highly negative views of others. Because pathological narcissists devalue others, they cannot develop self-esteem that is based on approval from others, Kernberg argued; instead, narcissists need constant admiration to feel good about themselves.

Self-Psychology Model

According to the self-psychology model (Kohut, 1971), children are born in a state of self-love called primary narcissism. Primary narcissism was thought to be a manifestation of the fundamental human motive or instinct to survive. According to the model, children initially hold highly positive views of both themselves (i.e., the grandiose self) and their parents (i.e., the idealized parent image). Under optimal developmental conditions, the grandiose self gradually matures, and comes to form the root of people's ambitions and self-esteem. Similarly, the idealized parent image gradually becomes internalized into a superego—moral standards and values that influence the ideals that people come to hold. Yet, as Kohut argued, if children experience trauma (e.g., when their parents are insufficiently sensitive to their needs), the grandiose self and the idealized parent image may keep their infantile form, and ultimately give rise to pathological narcissism. Thus, the self-psychology model assumes that pathological narcissism arises from developmental arrest. Narcissists may relive their unfulfilled interpersonal needs and developmental tasks in their later interpersonal relationships. For example, in friendships or romantic relationships, they may constantly seek others' acceptance and recognition, in an attempt to affirm their grandiose self.

Discussion

Although the importance of psychoanalytic models of narcissism to contemporary empirical research has been relatively limited, some postulates of these models have been influential. First, psychoanalytic models emphasized that narcissists have distorted views of themselves and others. Empirical research suggests that distorted self- and other-views might be a central component of narcissism (Andersen, Miranda, & Edwards, 2001; Morf & Rhodewalt, 2001). Second, psychoanalytic models made the important distinction between narcissism and self-esteem, which is consistent with current conceptualizations and research findings. Third, psychoanalytic models were the first to illuminate the wide-ranging cognitive strategies that narcissists employ in the face of setbacks to maintain their positive self-views. Empirical research has confirmed that narcissists frequently employ such strategies as denial, rationalization, and externalization of blame (Morf & Rhodewalt, 2001). Fourth, psychoanalytic models adopted a developmental perspective on narcissism, while other theories more or less assumed, either implicitly or explicitly, that the nature of narcissism remains similar over the course of development. Psychoanalytic models attempted to understand narcissism from a life-course perspective, in which early disruptions in self-development might lead to narcissistic pathology in adulthood—an assumption that is influential up until today.

Conclusion and Future Directions

Given its paradoxical nature, narcissism poses an intriguing challenge to theorists: How to understand its seemingly incongruous constellation of traits from a single psychological perspective? From the early days of psychology, several

models have been proposed to explain the nature of narcissism, models that have yielded important and sometimes counter-intuitive insights. What is lacking from the most influential models of narcissism, however, is a developmental perspective. This is unfortunate for two main reasons. First, both the manifestations of narcissism and its underlying processes may change over the course of development. Second, a developmental perspective is needed to illuminate the mechanisms that link developmental antecedents (e.g., dysfunctional socialization experiences, temperamental diathesis) to later narcissism (Olson & Dweck, 2008). Knowledge of these mechanisms will facilitate prevention and interventions efforts to curtail narcissistic development at an early age.

DEVELOPMENT AND ETIOLOGY OF NARCISSISM

The earliest experiences of Narcissus, as recorded by Ovid, were timed when he "had just reached his sixteenth birthday, and could be thought of as either a boy or a man (Ovid, trans. 2010, p. 76)." *When* and *why* did Narcissus become the self-absorbed, self-loving person he was? Or, in more psychological terms, how did Narcissus' personality emerge and develop over time, and what environmental and constitutional factors contributed to its development? We do not know yet. Similarly, we know relatively little about the factors that lead children to develop narcissistic traits.

There has been relatively little research into the development and etiology of narcissism, yet theoretical models exist and empirical evidence is beginning to emerge. We will first describe the development of narcissism as a derailment of normal self-development. Then, we will discuss the two most influential theories of the socialization of narcissism—social learning theory and psychoanalytic theory. Then, we will discuss empirical evidence for these theories, and explain how research has been hampered by methodological challenges. Finally, we will propose an integrative, diathesis–stress framework in which narcissism can be understood as arising from temperament × environment interactions.

When Does Narcissism Emerge?

Developmental psychology has had a longstanding fascination with the self, a fascination that has yielded detailed knowledge on normal self-development. We propose that narcissism can be seen as a derailment of normal self-development (Thomaes, Brummelman, Reijntjes, et al., 2013; Thomaes, Bushman, Orobio de Castro, & Stegge, 2009), and so knowledge of normal self-development may provide important insights into the development of narcissism.

Narcissistic and Nonnarcissistic Selves

When trying to understand narcissism from a normal self-developmental perspective, the first question one needs to ask is how narcissists' selves exactly differ from nonnarcissists' selves. One critical difference is that narcissists have an unusually strong need for self-esteem. To be sure, the tendency to pursue and be concerned about self-esteem is universal (e.g., Sedikides, Gaertner, & Vevea, 2005). People generally desire to feel worthy and valuable, and to be viewed by others in favorable ways. In that sense, narcissists and nonnarcissists differ in the degree to which they pursue self-esteem. For example, whereas nonnarcissists' pursue self-esteem only in naturally occurring situations that leave room for it (e.g., when they can accomplish something worthwhile), narcissists continuously seek and create situations in which they can enhance their self-esteem (Morf & Rhodewalt, 2001). Similarly, whereas positive illusions and a tendency to avoid negative feedback are common among nonnarcissists, such self-regulatory strategies are potentiated among narcissists, who greatly overestimate their competencies and relative standing to others, and who routinely deny or discredit negative feedback or lash out aggressively when receiving negative feedback (Bushman & Baumeister, 1998; Morf & Rhodewalt, 2001; Thomaes, Bushman, et al., 2008).

Besides differences in degree, however, there may also be some qualitative differences in the ways narcissists pursue self-esteem. Whereas nonnarcissists are typically invested in establishing social connections, narcissists are typically invested in establishing social dominance to be able to feel good about themselves (Campbell, Rudich, & Sedikides, 2002; Thomaes, Stegge, et al., 2008). Narcissists are rarely interested in creating warm and intimate social bonds. Instead, they want to stand out from the crowd, and their attempts to establish superiority often come at the expense of others. Thus, we propose that narcissism can be seen as an extreme expression of the universal human need for self-esteem. This need is expressed both more intensely and sometimes qualitatively differently in narcissists when compared with nonnarcissists.

Normal Self-Development and its Implications for the Emergence of Narcissism

Obviously, the mere understanding of how narcissists' and nonnarcissists' selves may differ from one another does

not tell us *when* narcissism may first emerge in development. Normal self-development may provide insight into this question. From about age 2 or 3, children start to show rudimentary signs that they can evaluate attributes of themselves (Harter, 2006, 2012). These evaluations typically focus on observable and salient behaviors or abilities (e.g., "I can count"). Later in early and middle childhood, children learn to evaluate an increasing number of self-attributes. However, these evaluations remain qualitatively different from those of older children in that they tend to be unrealistically positive (young children are not well able to distinguish their ideal competencies from their actual competencies, or to compare their own competencies with those of others) and domain specific (young children are not well able to aggregate self-evaluations across different domains). Young children also have limited abilities to consciously and intentionally reflect on themselves. Thus, they cannot yet form self-esteem as defined by a conscious, global evaluation of one's worth as a person (Harter, 2006, 2012).

From around age 8, children have acquired cognitive capacities that have important ramifications for how they view themselves. First and foremost, from this age, developmental increases in self-reflection and abstract reasoning allow children to make global evaluations of themselves as a person and to form self-esteem (e.g., "I like myself as a person"; Harter, 2006, 2012). Individual differences in self-esteem now rapidly emerge, with a majority of children thinking positively about themselves and a minority thinking less positively about themselves (note that relatively few children start to think negatively about themselves in an absolute sense; Thomaes, Brummelman, Bushman, Reijntjes, & Orobio de Castro, 2014). Furthermore, in late childhood, children have acquired the capacities to evaluate themselves from the perspective of others (Harter, 2006, 2012), and to incorporate social comparison information into their self-evaluations (e.g., "I am quite good at soccer: better than most of my peers, but not as good as Daniel"). Perhaps as a result, children this age have generally outgrown the unrealistically positive self-views that are normative for younger children (Marsh, Craven, & Debus, 1998). Importantly, from age 8 up into adolescence, children also become increasingly motivated to create and maintain favorable self-views and to avoid unfavorable self-views. This emergent need for esteem, or self-esteem motivation, is manifest in a number of important ways. First, older children and adolescents become increasingly self-conscious and concerned about how they are viewed by others (Elkind, 1967; Harter, 2006, 2012). Second, they more easily experience such emotions as shame and humiliation, emotions that are intimately linked to the maintenance of self-esteem (Reimer, 1996). Third, they increasingly use impression management strategies (e.g., acting cool) to try to influence the opinions that others hold of them (Harter, 2006, 2012).

There are several things that the normal development of self-esteem and the motivations that surround it may tell us about the development of narcissism. First, if narcissism essentially is an extreme form of self-esteem motivation, then its first observable manifestations are unlikely to emerge before about age 8 (although the early developmental processes leading to narcissism may well operate before this age). Indeed, it is difficult to see how children could possibly be overly invested in pursuing self-esteem before they formed a conscious, global evaluation of themselves. Second, also from about age 8, children have learned to evaluate themselves from the perspective of others (Harter, 2006, 2012), a skill that likely underlies narcissists' cravings to be valued or admired by others. Third, at this same age, children have typically outgrown the unrealistically positive, inflated self-views that are normative for younger children, which makes the inflated self-views that are characteristic of narcissism nonnormative from this age.

To be sure, narcissism likely has its developmental origins in individual traits and experiences that are present from the earliest stages of life (as we will argue hereafter). However, based on what we know about normal self-development, we propose that narcissism (1) does not become manifest before about age 8, and (2) will often become manifest after a derailment of normal self-development.

Initial research findings support the notion that narcissism is manifest and measurable beginning at about age 8. Personality questionnaires administered to community and clinic samples of older children and adolescents have yielded robust and replicable clusters of traits characteristic of narcissism (Frick, Bodin, & Barry, 2000). Our own work has found good internal consistency and test–retest reliability estimates for self-reported narcissism in children aged 8 and older (Thomaes, Stegge et al., 2008). Moreover, narcissism has many similar manifestations in childhood and adolescence as it has in adulthood. Future research is needed to validate the claims that narcissism cannot be meaningfully identified before about age 8, and that narcissism often becomes manifest after a derailment of normal self-developmental processes.

Developmental Change in Narcissism

One other critical question is how narcissism changes over the course of development. Traditional views on

personality would hold that narcissism should be relatively stable over the life course, both in terms of the level or intensity of its manifestations (which refers to the concept of mean-level stability), and in terms of individual differences (which refers to the concept of rank-order stability). Accordingly, the *DSM-IV* defines disorders of personality, diagnosed in adulthood, as pervasive and inflexible (American Psychiatric Association, 2000). Most current views, however, cast personality as more dynamic, and recognize that environmental influences (e.g., parenting experiences, life events, societal changes) may have a substantial impact on changes in personality over time (e.g., Caspi & Shiner, 2006). Unfortunately, whether and how narcissism changes over time is one of the most understudied questions in this field of research. Important questions such as (1) how population levels of narcissism differ from one developmental period to the other; (2) whether narcissism is best viewed as a transitory or as a lifelong or recurrent phenomenon; and (3) whether early emerging narcissistic traits increase the likelihood that children will develop narcissistic pathology in adulthood are largely unanswered today. On a more positive note, now that adequate measures of youth narcissism have become available over the past decade, the study of long-term change in narcissism has become much easier than it was in the past. In the following, we review the empirical evidence that does exist on the mean-level and rank-order stability of narcissism. Note that this evidence exclusively concerns trait narcissism; evidence on the stability of pathological manifestations of narcissism or NPD, is virtually nonexistent.

Both psychological theory and lay conceptions suggest that narcissism is more common in some developmental stages than in others. In particular, adolescence is often believed to be a narcissistic developmental period. Indeed, most high school or university teachers can provide anecdotes on the self-absorbed or entitled behavior of some of their students. One teacher of English at an institution for higher learning in the United States found the following note, written by a student who was unhappy with the way his course was organized: "I showed up to class today but no one was there. Where was class?!?! You need to make announcement when you are changing the location of class!!! No one likes to have to dig your syllabus out every day or check their email for your last minute changes. I DID show up today and you have to count my paper as ON TIME. Please email me with an explanation" (retrieved from http://www.passiveaggressivenotes.com).

Consistent with lay conceptions and anecdotal evidence, psychological theorists have described adolescence as a period of narcissistic vulnerability (Bleiberg, 1994). Several normative developments that occur in adolescence (e.g., developmental increases in self-focus and concern over one's public image) may become manifest in traits and behaviors that, at least on the surface, seem narcissistic. Similarly, it has been argued that separation-individuation processes, by which adolescents navigate between seeking connectedness and separation from their parents, are similar to the narcissistic interpersonal dynamic of seeking independence and validation from others at the same time (Hill & Roberts, 2011). Finally, adolescents often construct so-called personal fables (Elkind, 1967): illusions of invulnerability (the belief that one cannot be harmed or injured), omnipotence (the belief that one has special authority or influence), or personal uniqueness (the belief that one has unique traits, and cannot be understood by other people), which share surface features with narcissistic illusionary beliefs.

The long-term longitudinal research that is needed to provide adequate answers on how narcissism changes over time—research that runs from middle childhood into old age—is lacking. Cross-sectional research involving adolescents and older participants does exist, however. The outcomes of this research are consistent with the view that levels of narcissism typically are high in adolescence and then decrease over time. A large study including adolescents and adults from around the world found a steep linear decrease in narcissism from adolescence into older age. The difference in narcissism between the youngest participants (i.e., midadolescents) and the oldest participants in the study (i.e., who were older than 50) was nearly a full standard deviation (Foster, Campbell, & Twenge, 2003). In another study (Roberts, Edmonds, & Grijalva, 2010), introductory psychology students were found to be considerably more narcissistic than their parents who, in turn, were more narcissistic than the students' grandparents. The mean difference in narcissism between students and their grandparents was even more than a standard deviation.

In addition, one longitudinal study (Carlson & Gjerde, 2009) zoomed in on the developmental stages of adolescence and emerging adulthood, and examined how mean levels of observed narcissism (a narcissism measure was derived from the California Adult Q-set; Block, 1978) changed between ages 14 and 23 years. This study found that observed narcissism increased significantly from middle adolescence into late adolescence, and then followed a downward trend from late adolescence into emerging adulthood. This suggests that trait manifestations of narcissism may reach a normative peak in late adolescence and decrease from then on.

The putative trend for narcissism to be relatively high in adolescence and decline later has been interpreted in terms of the social investment model of personality trait development (Hill & Roberts, 2011). According to this model, changes in personality traits over time can be understood as normative developmental adaptations that allow individuals to take up age-appropriate roles. In adolescence, individuals need to develop an autonomous identity and set important personal goals with long-term relevance (such as deciding on a career to pursue; Collins & Steinberg, 2006). These developmental tasks might be facilitated when individuals adopt a rather narrow self-focus, characteristic of narcissism. From early adulthood onward, however, individuals typically commit themselves to such roles as being a husband, a father, and a colleague: roles that require them to take up a more communal, collectively responsible orientation, and to become less self-focused and narcissistic. Accordingly, from the perspective of the social investment model, narcissism is relatively high in adolescence because a self-focused, independent orientation might help individuals to form an autonomous identity. Narcissism then becomes considerably lower in adulthood because an other-focused, interdependent orientation might help individuals to take responsibility for their family, work, or community.

Importantly, the developmental trend of narcissism is different from that of self-esteem. Self-esteem typically is relatively high during childhood, drops sharply during adolescence, and then gradually increases throughout adulthood (Robins & Trzesniewski, 2005). Thus, adolescence might be a time when narcissism reaches its developmental high and self-esteem reaches its developmental low. Note that the combination of high narcissism and lower self-esteem reflects vulnerable narcissism, and so it may be no surprise that a number of hallmark features of vulnerable narcissism, including self-consciousness, social hypervigilance, and proneness to experiencing negative self-feelings, are more common during adolescence than during other developmental phases. Future research will need to examine whether it is specifically vulnerable narcissism—more than grandiose narcissism—that is high in adolescence.

A related, important set of questions concerns the rank-order stability, or stability of individual differences in narcissism (or its rudimentary manifestations) over the life course. Is it possible to identify early emerging individual differences in temperament that are linked to later narcissistic development? And when individuals are relatively high in narcissistic traits at one point in childhood or adolescence, then how likely are they to develop more ingrained narcissistic personalities later in life? Initial empirical evidence is beginning to emerge, and we will review that evidence here.

Personality theory and research has suggested that the earliest antecedents of personality traits and disorders can often be traced back to early childhood (American Psychiatric Association, 2000; Caspi & Shiner, 2006). Of course, this does not mean that personality already takes its mature, crystallized form in early childhood. It does imply, however, that it may be viable to try to identify broad temperamental traits at this age, traits that may lay the groundwork from which later personality structures, such as narcissism, emanate.

Following this reasoning, one longitudinal study used data from the Block and Block longitudinal project (Block & Block, 1980) to try to predict narcissistic traits in adolescence and emergent adulthood (ages 14, 18, and 23) from preschool personality attributes (Carlson & Gjerde, 2009). One strength of this study lies in the rigorous way personality was observed. At the preschool age, participants (N = 103, ages 3 and 4, recruited from nursery schools) were described by trained nursery school teachers using the California Child Q-set (CCQ, Block & Block, 1980), a Q-sort procedure consisting of a variety of statements about children's personality, cognitive, and social characteristics. Based on a priori expectations, five scales were derived from the CCQ that were anticipated to predict narcissistic traits in adolescence and emergent adulthood: (1) Interpersonal Antagonism (e.g., is aggressive; is considerate and thoughtful of other children [reversed]); (2) Center of Attention (e.g., tries to be the center of attention; is shy and reserved, makes social contacts slowly [reversed]); (3) Activity (e.g., is physically active; is vital, energetic, and lively); (4) Histrionic Tendencies (e.g., is emotionally labile; tends to exaggerate mishaps); and (5) Undercontrol of Impulse (e.g., is unable to delay gratification, cannot wait for satisfactions; overreacts to minor frustrations, is easily irritated and/or angered).

Years later, when participants were 14, 18, and 23, they were again described using a similar, age-appropriate Q-sort procedure, the California Adult Q-set (CAQ; Block, 1978), this time by advanced psychology students who did not know the participants before, but who intensively interviewed and observed them. From the Q-sort procedure, a narcissism measure was derived containing items known to correlate highly with the NPI (e.g., unaware of self-concern, feels satisfied with self; behaves in an assertive manner; and expresses hostile feelings directly). Importantly, the five preschool personality predictors were

significantly correlated with observed narcissism 10 to 20 years later.

A later study provided a conceptual replication (Cramer, 2011), and relied on the same dataset and preschool personality antecedents to predict narcissism at age 23 as indexed by a different set of CAQ items. In particular, this study distinguished between CAQ items reflecting what the authors labeled maladaptive narcissism (e.g., pushes and tries to stretch limits and rules; is self-indulgent; tends to "spoil" or pamper him or herself) and healthy narcissism (e.g., values own independence and autonomy; sets high personal goals; and is ambitious). It was found that the preschool attributes (i.e., antagonism, center of attention, activity, histrionic tendencies, and under control of impulse) specifically predicted maladaptive narcissism, but not its more adaptive counterpart.

Extending studies on the stability of observed narcissism, another study has provided insight into the stability of reported narcissism, in this case narcissism as a dimension of trait psychopathy (Frick, Kimonis, Dandreaux, & Farell, 2003). Narcissism is one dimension of psychopathy (callous-unemotional traits and impulsivity are the other psychopathy dimensions), and standard measures of youth psychopathy have a narcissism subscale. The Antisocial Personality Screening Device (Frick & Hare, 2001), a self-, parent-, and teacher-report measure that contains such items as "Thinks he/she is more important than others" and "Brags about abilities" was used in this study.

Participants were children and young adolescents (third to seventh grade) at the start of the study. Their parents rated their narcissistic traits annually for four years. Stability estimates for narcissism were quite high, with an intra-class correlation coefficient of .92 across all time points. Thus, a substantial amount of variance in parent-reported narcissism was consistent over time. Participants themselves also rated their narcissism at later time points. Although cross-informant (i.e., from parent-report to self-report) stability was considerably lower than within-informant stability, it still indicated that a substantial amount of variance in narcissism was consistent over time, with an intraclass correlation coefficient of .65 across time points. As the authors note, these stability estimates are somewhat higher than those typically found for child and adolescent personality measures.

Together, these results provide tentative empirical evidence to suggest that individual differences in narcissism may be quite stable over time—with preschool temperamental traits predicting individual differences in narcissism up into young adulthood, and parent- and self-reported narcissism being at least as stable as other forms of personality in late childhood and adolescence. Still, the research that has been done to date has limitations. First, the measures of narcissism that were used are unlikely to tap the full range of narcissistic characteristics. Both the Carlson and Gjerde study and the Cramer study relied on observational measures of narcissism. Observational measures are adequate to tap outward and observable narcissistic characteristics (manifest in behaviors or emotional expressions), but not internal narcissistic characteristics (thoughts and feelings). Similarly, the Frick et al. study focused on psychopathy-linked narcissism. Psychopathy-linked narcissism is distinct from normal subclinical narcissism in that it does not entail internal and vulnerable narcissistic manifestations. Thus, replication using standard, more comprehensive measures of narcissism is needed. Second, what is missing is longitudinal research that continuously follows up on narcissistic development from early age up into adulthood. Such research would allow researchers to answer to what extent youth who develop narcissistic traits are likely to remain narcissistic in adulthood, or even meet the criteria for NPD diagnosis. As the evidence stands, we cannot answer this important question conclusively.

Why Does Narcissism Emerge?

We have addressed the question of *when* narcissism may emerge, and now turn to *why* narcissism may emerge. The two most influential theories of the etiology of narcissism—social learning theory and psychoanalytic theory—emphasize that dysfunctional socialization experiences during childhood impact the emergence and development of narcissism.

Social Learning Theory

According to social learning theory (Millon, 1969), children acquire their self-views by observing and internalizing the way they are seen and treated by their parents. Specifically, social learning theory holds that parents cultivate narcissism in their children by overvaluing them—thinking that their children are more special and more entitled than other children are, and treating them accordingly. Our recent research shows that parents who overvalue consider their child to be superior to others, overclaim their child's knowledge, perceive their child as more gifted than actual IQ scores justify, want their child to stand out from others, and frequently praise their child in real-life settings (Brummelman, Thomaes, Nelemans, Orobio de Castro, & Bushman, 2014). Millon (1969) noted that parents of a future narcissist often see and treat their child as "God's

gift to man" (p. 263). Such socialization experiences might eventually lead children to internalize inflated, narcissistic views of themselves as extraordinary beings entitled to special treatment, admiration, and subservience from others (i.e., my wish is your command).

Millon (1969) also proposed that children who develop narcissistic traits often occupy a central position within the family, most notably the position of an only child (or, in certain cultures, the first male child). In line with the notion of the only child being spoiled, Millon believed that children with an only child status are often of special value to their parents and often are not subjected to the same restrictions and responsibilities as most other children. Consequently, Millon thought, only children may be more likely than other children to develop narcissistic traits.

Psychoanalytic Theory

Psychoanalytic theory holds that narcissists' inflated self-views are compensations for early deprivations in the parent-child bond. According to this perspective, narcissism develops in response to parents lacking warmth (e.g., being cold and unresponsive). Psychoanalytic theorists believe that narcissistic children have turned to themselves to obtain the warmth and approval they failed to receive from their parents. The theorists disagree, however, about the exact mechanisms through which such cold upbringing leads to narcissism. The disagreement between Kohut and Kernberg is of particular importance. Kohut (1971) argued that it is normative for infants to have an overly positive, grandiose self. This grandiose self needs to be mirrored by parents: Parents need to be sensitive and responsive to the child's unique experiences. When they do, children gradually develop more mature, realistic self-views. When they do not, children's self-views remain inflated, which might eventuate in later narcissism. In this view, narcissism represents an arrest of normal self-development.
